Tension-type headaches are common in children. They are typically frontal, and the pain is described as a pressing tightness; it is nonthrobbing in character and is not typically accompanied by nausea or vomiting. Simple analgesics, including acetaminophen and ibuprofen, are usually the most effective pharmacologic intervention. Biofeedback, cognitive behavioral therapy, and relaxation techniques may be useful nonpharmacologic interventions in children with recurrent tension-type headaches (Sieberg, Huguet, von Baeyer, et al, 2012).

MIGRAINE HEADACHE

Migraine headaches occur in children as well as adults. Migraine headaches can have their onset in very young children, including infants, although this is uncommon. The onset tends to be earlier in boys than girls (7.2 vs. 10.9 years), until puberty (approximately 12 years of age) when girls have a twofold increase in migraines than boys (Eiland and Hunt, 2010).

The exact pathophysiology of migraines continues to be researched. It is postulated that migraine headaches have a genetic and multifactorial etiology. However, no consistent genetic etiology for migraines has been established, except for familial hemiplegic migraine (International Headache Society, 2013). Previously, it was thought that migraine headaches were caused by dilatation of cerebral blood vessels. However, this is no longer thought to be correct. There is much attention on the specific vulnerability factors of the individual that leads to neuron dysfunction and the generation of the acute attack.

Revisions in the classification of migraine headaches introduced some new terms and eliminated, renamed, or reclassified others. Migraine headaches are now classified as migraine without aura and migraine with aura; the latter category includes the following subtypes: auras and prodrome, familial hemiplegic migraine, sporadic hemiplegic migraine, and basilar-type migraine (Box 32-14) (International Headache Society, 2013).

The headaches are paroxysmal. The symptoms of migraine headaches vary depending on age. Typical symptoms include nausea, vomiting, and abdominal pain, which are relieved by sleep. Toddlers may be seen with episodic pallor, decreased activity, and vomiting. The onset of a migraine headache in a young child is typically in the afternoon and may be bifrontal, temporal, and bilateral or unilateral. When compared to adults, migraine headaches in children are shorter in duration, lasting only 1 hour as compared to the 4-hour average for adults (Eiland and Hunt, 2010). A family history of migraine is elicited in 70% of children with migraine; 5% of all children who have migraines experience a headache before age 15 years. Migraine headaches are managed with general measures (e.g., education, a headache diary to identify and eliminate precipitating factors, and documented response to treatment), abortive treatment, and prophylactic treatment. At the onset of the headache, the child should rest or sleep in a quiet, dark room when feasible. Migraine therapy, if administered early in the course of the headache, may provide rapid relief. Acetaminophen or ibuprofen is often effective if given early.

BOX 32-14 MIGRAINE PATTERNS

Migraine with Aura

Aura may be: visual (most common); hemiparethetic (tingling and numbness of lips, lower face; second most common); hemiparetic; hemiplegic; or aphasic

Aura duration less than 1 hour and completely resolves. Followed by throbbing, unilateral or bilateral headache coupled with nausea, vomiting, photophobia, and phonophobia.

Migraine Without Aura

Prodrome that consists of pallor, alteration in personality, or change in appetite or thirst

Unilateral or bilateral headache coupled with nausea and/or vomiting, photophobia, and phonophobia

Pulsating quality

Moderate or severe pain intensity

Sporadic Hemiplegic Migraine

Migraine with aura

Motor weakness

No first- or second-degree relative who also has migraine with aura and motor weakness

Basilar-Type Migraine

Recurrent attacks

Headache typically occipital

Symptoms may include dysarthria, vertigo, diplopia, vomiting, and altered consciousness

DRUG ALERT

Triptans

Triptans are serotonin agonists and are effective in the abortive treatment of migraines. Triptans are commonly used for migraine treatment among adults but currently in the United States, almotriptan is the only approved triptan medication for use among adolescents ages 12 to 17 years (Eiland and Hunt, 2010). Sumatriptan nasal spray is commonly used for migraine treatment among children in Europe and the United Kingdom; however, it has not been approved for use in children in the United States (Eiland and Hunt, 2010). For children who experience frequent or refractory migraines, prophylactic medications such as tricyclic antidepressants, antiepileptic medications, or antiserotonergic medications may be considered (Eiland and Hunt, 2010).

The outlook for a child with migraine is good, but the child and parents should be informed that predisposition to the headaches may be lifelong. Severe headaches can adversely affect the child's routine activities of daily living, including family relations and school.

THE CHILD WITH CEREBRAL MALFORMATION

HYDROCEPHALUS

Hydrocephalus is not a single disease entity but rather a group of conditions, resulting from disturbances in the dynamics of cerebral circulation and CSF, which may be caused by various conditions. The advent of MRI and CT scanning has provided valuable information about the pathophysiology of hydrocephalus. The causes of hydrocephalus are diverse and include either congenital (e.g., myelomeningocele, intrauterine viral infection [cytomegalovirus, toxoplasmosis], aqueduct stenosis) or acquired conditions such as intraventricular hemorrhage, tumor, CSF infection, or head injury (Kinsman and Johnston, 2011).

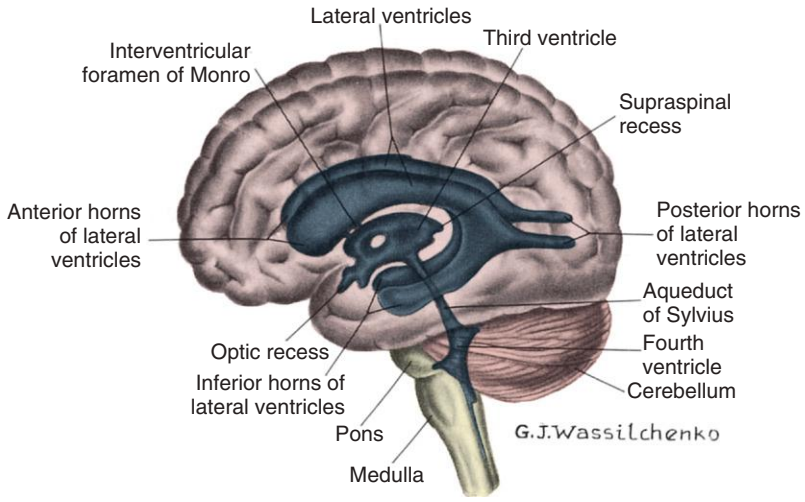

FIG. 32-11 Cerebral ventricular system. (From Thompson JM, McFarland G, Hirsch JE, et al: *Mosby's clinical nursing,* ed 5, St. Louis, 2002, Mosby.)

Pathophysiology

To appreciate the condition, an understanding of the dynamics of CSF and the relationship between the various structures that make up the ventricular and subarachnoid spaces is necessary (Fig. 32-11). The two mechanisms by which CSF is formed are secretion by the choroid plexuses and lymphatic-like drainage by the extracellular fluid of the brain. CSF circulates throughout the ventricular system and is then absorbed within the subarachnoid spaces by a mechanism that is not entirely clear.

Ventricular Circulation

The fluid flows from the lateral ventricles through the foramen of Monro to the third ventricle, where it combines with fluid secreted into the third ventricle. From there CSF flows through the aqueduct of Sylvius into the fourth ventricle, where more fluid is formed; it then leaves the fourth ventricle by way of the lateral foramen of Luschka and the midline foramen of Magendie and flows into the cisterna magna. From there CSF flows to the cerebral and cerebellar subarachnoid spaces, where it is absorbed. A large portion is absorbed through the arachnoid villi, but the sinuses, veins, brain substance, and dura also participate in absorption.

Mechanisms of CSF Fluid Imbalance

The causes of hydrocephalus vary, but the result is either (1) impaired absorption of CSF fluid within the subarachnoid space, obliteration of the subarachnoid cisterns, or malfunction of the arachnoid villi (nonobstructive or communicating hydrocephalus), or (2) obstruction to the flow of CSF through the ventricular system (obstructive or noncommunicating hydrocephalus) (Kinsman and Johnston, 2011). The terms *communicating* and *noncommunicating hydrocephalus* traditionally referred to obstructive and nonobstructive types of hydrocephalus when pneumoencephalography was used to establish the diagnosis. Because other diagnostic methods are now used, the terms may be used only as a reference point in the diagnosis. Hydrocephalus can also be classified according to the cause as either congenital or acquired hydrocephalus. Rarely, a tumor of the choroid plexus causes increased CSF secretion. Any imbalance of secretion and absorption causes an increased accumulation of CSF in the ventricles, which become dilated (**ventriculomegaly**) and compress the brain substance against the surrounding rigid bony cranium. When this occurs before fusion of the cranial sutures, it causes enlargement of the skull, as well as dilation of the ventricles. In children under 10 to 12 years of age, previously closed suture lines, especially the sagittal suture, may become diastatic, or opened. The cranial sutures do not permanently fuse until approximately the age of 12 years or later.

Most cases of hydrocephalus are a result of developmental malformations. Although the defect usually is apparent in early infancy, it may become evident at any time from the prenatal period to late childhood or early adulthood. Other causes include neoplasms, CNS infections (e.g., meningitis, encephalitis), and trauma (e.g., shaken baby syndrome). An obstruction to the normal flow can occur at any point in the CSF pathway to produce increased pressure and dilation of the pathways proximal to the site of obstruction. Table 32-8 describes the most frequent sites of obstruction and the consequences.

Developmental defects (e.g., Chiari malformation [see following discussion], aqueduct stenosis, aqueduct gliosis, and atresia of the foramina of Luschka and Magendie [Dandy-Walker malformation]) account for most cases of hydrocephalus from birth to 2 years of age. Dandy-Walker malformation involves a cystic expansion of the fourth ventricle, partial or complete absence of the cerebellar vermis, and subsequent obstruction of CSF flow, resulting in hydrocephalus (Spennato, Mirone, Nastro, et al, 2011). Hydrocephalus is so often associated with myelomeningocele that all such infants should be observed for its development. In the remainder of cases there is a history of intrauterine infection (e.g., toxoplasmosis, cytomegalovirus), hemorrhage (e.g., posthemorrhagic hydrocephalus in preterm infants), and neonatal meningoencephalitis (bacterial or viral). In older children hydrocephalus is most often a result of intracranial masses (e.g., vascular anomalies, cysts, tumors), preexisting developmental defects, intracranial infections, trauma, or hemorrhage.

TABLE 32-8 SITES AND TYPES OF HYDROCEPHALUS

SITE	TYPE	CAUSES AND COMMENTS
Aqueduct of Sylvius—Accounts for 33% of hydrocephalus	Stenosis or atresia	Congenital (X-linked recessive in small number) Insidious onset of symptoms from birth to adulthood
	Gliosis	Postinflammatory, usually secondary to perinatal infection or hemorrhage Prenatal maternal infection (toxoplasmosis)
	Obstructive	Tumors of 3rd ventricle or midbrain Ependymitis from maternal toxoplasmosis Congenital aneurysm of Galen vein
	Posthemorrhagic	Blood from intraventricular hemorrhage in germinal matrix; most common type of hydrocephalus in preterm infants
4th ventricle or subarachnoid pathway—Intraventricular hemorrhage, postinflammatory conditions, or tumors	Posthemorrhagic	Blood from intraventricular hemorrhage in germinal matrix; most common type of hydrocephalus in preterm infants
4th ventricle and foramen magnum—Accounts for 50% of all hydrocephalus	Type I Chiari malformation	Accounts for 28% to 40% of 4th ventricle obstructions Neural tube defect with herniation of medulla through foramen magnum; may be asymptomatic in childhood; similar to type II, but milder
	Type II Chiari malformation	More severe defect; downward displacement of brainstem, 4th ventricle, and lower parts of cerebellum through foramen magnum with fixed attachment of spinal cord at site of myelomeningocele
	Type III Chiari malformation (absence or occlusion of ventricles)	High cervical or occipitocervical myelomeningocele with cervical herniation through body defect Congenital (Dandy-Walker syndrome) caused by obstruction of foramina of Luschka and Magendie Tumors of posterior fossa (e.g., medulloblastoma) causing pressure on surrounding tissues to produce obstruction Less often—Subdural hematoma, bacterial or granulomatous meningitis
Arachnoid villi and cisterna magna—Obstruction by thick arachnoid membrane or meninges	Meningitis	Bacterial or granulomatous Acute phase—Clumping of purulent fluid in drainage channels Chronic phase—Organization of blood and exudate that results in fibrosis of subarachnoid spaces
	Prenatal maternal infections	Toxoplasmosis, cytomegalic inclusion disease, mumps
	• Meningeal malignancy	Secondary to leukemia or lymphoma
	• Arachnoid cyst	Located in basal cistern or (uncommon) over cerebral cortex
	• Tuberculosis, fungal or parasitic infection	More common in children ages 2-10 yr old

Chiari Malformations

A Chiari malformation is a brain defect involving posterior fossa contents. Table 32-8 describes the major types. The type II Chiari malformation, seen almost exclusively with myelomeningocele, is characterized by herniation of a small cerebellum, medulla, pons, and fourth ventricle into the cervical spinal canal through an enlarged foramen magnum. The resulting obstruction of CSF flow causes the hydrocephalus.

Clinical Manifestations

The three factors that influence the clinical picture in hydrocephalus are the acuity of onset, timing of onset, and associated structural malformations. In infancy, before closure of the cranial sutures, head enlargement (increasing **occipitofrontal circumference [OFC]**) is the predominant sign, whereas in older infants and children the lesions responsible for hydrocephalus produce other neurologic signs through pressure on adjacent structures.

Infancy

In infants with hydrocephalus, the head grows at an abnormal rate, although the first signs may be bulging fontanels with or without head enlargement (Fig. 32-12). The anterior fontanel is tense, often bulging, and nonpulsatile. Scalp veins are dilated and markedly so when the infant cries. With the increase in intracranial volume, the bones of the skull become thin and the sutures become palpably separated to produce the cracked-pot sound (Macewen sign) on percussion of the skull. In severe cases there may be frontal protrusion, or **frontal bossing**, with depressed eyes, and the eyes may be rotated downward, producing a **setting-sun sign**, in which the sclera may be visible above the iris. Pupils are sluggish, with unequal response to light.

The infant is irritable and lethargic, feeds poorly, and may display changes in level of consciousness, opisthotonos (often extreme), and lower extremity spasticity. The infant cries when picked up or rocked and quiets when allowed to lie still. Early infantile reflexes may persist, and normally expected responses

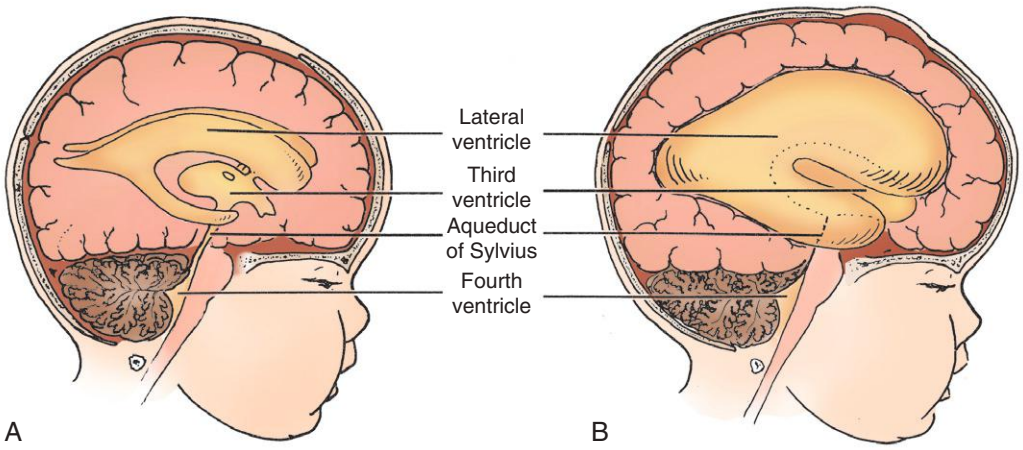

FIG. 32-12 Hydrocephalus: a block in flow of cerebrospinal fluid. **A,** Patent cerebrospinal fluid circulation. **B,** Enlarged lateral and third ventricles caused by obstruction of circulation—stenosis of aqueduct of Sylvius.

may not appear, indicating failure in the development of normal cortical inhibition.

Infants with Chiari malformation may exhibit behaviors that reflect cranial nerve dysfunction as a result of brainstem compression, including swallowing difficulties, stridor, apnea, aspiration, respiratory difficulties, and arm weakness.

The preterm infant with posthemorrhagic hydrocephalus may not exhibit any clinical signs and symptoms other than a gradual increase in head circumference. Alternatively, the nurse may note subtle seizure activity and alternating levels of consciousness. Ventricular size can be assessed by ultrasonography or CT scanning in preterm infants at high risk for intraventricular hemorrhage.

If hydrocephalus is allowed to progress, development of lower brainstem functions is disrupted, as manifested by difficulty in sucking and feeding and a shrill, brief, high-pitched cry. Eventually the skull becomes enlarged, and the cortex is destroyed. If the hydrocephalus is rapidly progressive, the infant may display emesis, somnolence, seizures, and cardiopulmonary distress.

Childhood

The signs and symptoms in early to late childhood are caused by increased ICP, and specific manifestations are related to the focal lesion. Most commonly resulting from posterior fossa neoplasms and aqueduct stenosis, the clinical manifestations are primarily those associated with space-occupying lesions (i.e., headache on awakening with improvement following emesis, papilledema, strabismus, and extrapyramidal tract signs such as ataxia [see Chapter 31]). As with infants, the child is irritable, lethargic, apathetic, confused, and often incoherent. In one of the congenital defects with later onset (by age 3 months), the Dandy-Walker syndrome, characteristic manifestations are a bulging occiput, nystagmus, ataxia, and cranial nerve palsies.

Manifestations of Chiari malformation in children over 3 years of age are related to spinal cord dysfunction rather than brainstem compression as observed in infants. Scoliosis proximal to the level of the myelomeningocele (usually associated with Chiari malformation) and development of upper extremity spasticity, which may progress to weakness and atrophy, are common. Cranial nerve deficits are rare.

Diagnostic Evaluation

Antenatal diagnosis of hydrocephalus is possible with fetal ultrasonography as early as 14 to 15 weeks of gestation. Delivery is not currently recommended until fetal lung maturity has been achieved.

In infancy the diagnosis of hydrocephalus is based on head circumference that crosses one or more percentile lines on the head measurement chart within a period of 2 to 4 weeks and on associated neurologic signs that are progressive. However, other diagnostic studies are needed to localize the site of CSF obstruction. Routine daily head circumference measurements are carried out in infants with myelomeningocele, hemorrhage, or intrauterine viral or CNS infections. In evaluation of a preterm infant, specially adapted head circumference charts are consulted to distinguish abnormal head growth from rapid but normal head growth.

The primary diagnostic tools for detecting hydrocephalus in older infants and children are CT and MRI (Fig. 32-13). Mild sedation is usually required because the child must remain absolutely still for an accurate picture. Diagnostic evaluation of children who have symptoms of hydrocephalus after infancy is similar to that employed in those with a suspected intracranial tumor. In the neonate, echoencephalography is useful in comparing the ratio of lateral ventricle to cortex. Sometimes isotope ventriculograms are used to assess the flow and patency of existing shunts and to evaluate the size of the ventricles.

Problems in differential diagnosis are related to the child whose head circumference is greater than the 95th percentile but whose head growth parallels the normal growth curve. It is sometimes valuable to measure the parental OFC to detect a possible normal familial characteristic (benign familial

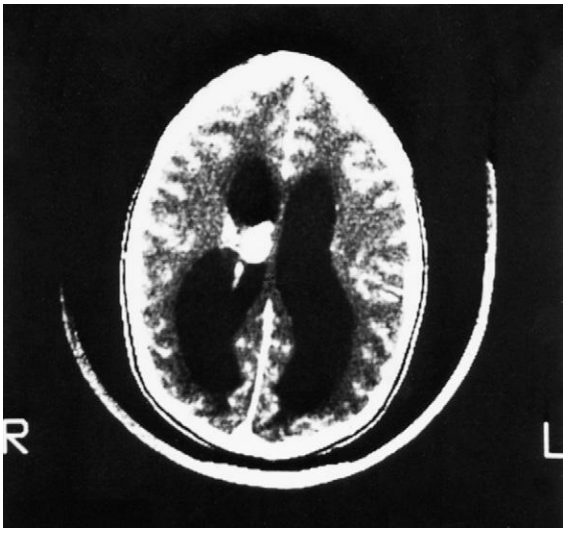

FIG. 32-13 Computed tomography scan reveals enlarged ventricles of child with hydrocephalus.

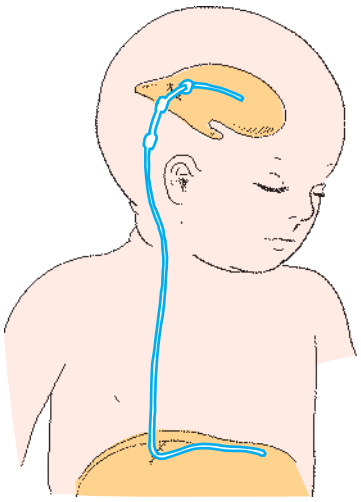

FIG. 32-14 Ventriculoperitoneal shunt. Catheter is threaded beneath skin.

megalencephaly). (See Table 32-2 for diagnostic tests for neurologic evaluation.)

Therapeutic Management

The treatment of hydrocephalus is directed toward relief of ventricular pressure, treatment of the cause of the ventriculomegaly, treatment of associated complications, and management of problems related to the effect of the disorder on psychomotor development. The treatment is, with few exceptions, surgical.

Medical therapy has been largely disappointing and inadequate. Many newborn infants with progressive cranial enlargement secondary to intracranial hemorrhage demonstrate spontaneous stabilization and resolution. Serial lumbar punctures and medications have been used with varying success but are recommended only until the preterm infant is stable enough to tolerate major surgery. The administration of acetazolamide and isosorbide or furosemide is somewhat beneficial in decreasing the production of CSF in selected cases of slowly progressive disease. The medication reduces the ICP until spontaneous arrest of hydrocephalus takes place or as a temporary measure when surgery is contraindicated.

Surgical Treatment

Improved neurosurgical techniques have established surgical treatment as the therapy of choice in almost all cases of hydrocephalus. This is accomplished by direct removal of an obstruction, such as resection of a neoplasm, cyst, or hematoma, or, in rare instances of fluid overproduction, by choroid plexus extirpation (plexectomy or electric coagulation). However, most children require a shunt procedure that provides primary drainage of the CSF from the ventricles to an extracranial compartment, usually the peritoneum.

Most shunt systems consist of a ventricular catheter, a flush pump, a unidirectional flow valve, and a distal catheter. All are radiopaque for easy visualization after placement, and all are tested for accuracy before insertion. A reservoir is frequently added to allow direct access to the ventricular system for administration of medications and removal of fluid. In all models the valves are designed to open at a predetermined intraventricular pressure and close when the pressure falls below that level, thus preventing backflow of fluid. Most shunts now in use have differential pressure and adjustable programmable valves with capability for changing the pressures with an external magnet, thus avoiding additional surgery.

The standard procedure for many years has been the **ventriculoperitoneal (VP) shunt**, especially in neonates and young infants (Fig. 32-14). There is greater allowance for excess tubing, which minimizes the number of revisions needed as the child grows. Since it requires repeated lengthening, the ventriculoatrial (VA) shunt (ventricle to right atrium) is reserved for older children who have attained most of their somatic growth and children with abdominal pathologic conditions. The VA shunt is contraindicated in children with cardiopulmonary disease or elevated CSF protein.

Although placement of ventricular shunts (into the amniotic sac) in utero for ventricular enlargement is possible, results have not been as promising as shunting soon after birth (Kandasamy, Jenkinson, and Mallucci, 2011).

The initial shunt is placed when indicated on the basis of individual assessment. The timing of revisions varies widely. In most instances revisions are performed when physical signs indicate shunt malfunction (i.e., signs of elevated ICP). Sometimes revisions are planned for specific times during development. The initial success rate is relatively high. However, shunts are associated with complications that interfere with continued shunt function or that threaten the child's life.

Endoscopic third ventriculostomy (ETV) is a procedure that has potential for allowing greater independence from VA or VP shunting in children with obstructive hydrocephalus. In this procedure a small opening is made in the floor of the third ventricle, allowing CSF to flow freely through the previously blocked ventricle. The procedure is indicated for children with hydrocephalus secondary to congenital aqueductal stenosis,

RESEARCH FOCUS

Endoscopic Ventriculostomy Success Based on Age

There is conflicting evidence about the success rate of ETV among young infants. Some studies have reported poor results of ETV among infants less than 2 months of age (Drake, 2007; Gallo, Szathmari, De Biasi, et al, 2010); others report success with ETV in infants as young as 1 month of age (Faggin, Bernardo, Stieg, et al, 2009; Sufianov, Sufianova, and Iakimov, 2010).

third ventricular tumor, Dandy-Walker malformation, intraventricular hematoma, myelomeningocele, and craniosynostosis and is not indicated for children with posthemorrhagic, postinfective hydrocephalus (Agarwal, Namdev, Pande, et al, 2012). Success of ETV in children is good, but reports vary among young infants (see Research Focus box). Close clinical and radiologic assessment must be performed in children undergoing ETV, especially in the first year when postoperative failures most commonly occur. The incidence of complications ranges from 2% to 15% (Agarwal, Namdev, Pande, et al, 2012). Immediate complications include CSF leak, hemorrhage, and meningitis, while long-term complications can include developed of diabetes insipidus, precocious puberty, and weight gain (Agarwal, Namdev, Pande, et al, 2012).

Complications

The major complications of VP shunts are infection and malfunction. All shunts are subject to mechanical difficulties, such as kinking, plugging, or separation and migration of tubing. Malfunction is most often caused by mechanical obstruction either within the ventricles from particulate matter (tissue or exudate) or at the distal end from thrombosis or displacement as a result of growth. Functional obstruction of a shunt's antisiphon device remains a common complication. Shunt malfunctions are reported to be 14% within the first month and 50% at 1 year (Sivaganesan, Krishnamurthy, Sahni, et al, 2012). The child with a shunt obstruction often is seen in an emergency visit with clinical manifestations of increased ICP, such as nausea, vomiting, irritability, and a bulging fontanel, that is frequently accompanied by worsening neurologic status.

The most serious complication, shunt infection, can occur at any time, but the period of greatest risk is within the first 6 months after placement (Sivaganesan, Krishnamurthy, Sahni, et al, 2012). Shunt infection rates are reported to be approximately 8% to 10% (Sivaganesan, Krishnamurthy, Sahni, et al, 2012). The infection may be a result of intercurrent infections at the time of shunt placement. Infections include sepsis, bacterial endocarditis, wound infection, shunt nephritis, meningitis, and ventriculitis. Brain abscess associated with colonic perforation and infection with a gram-negative enteric organism suggests an ascending shunt infection in a child who has a VP shunt. Meningitis and ventriculitis are of greatest concern because any complicating CNS infection is a significant predictor of subnormal intellectual outcome. Infection is treated with antibiotics administered intravenously or intrathecally for a minimum of 7 to 10 days. The use of perioperative antibiotic prophylaxis or antibiotic-impregnated shunts has significantly decreased shunt infection rates among all age ranges of patients and all types of shunts (Wong, Ziewacz, Ho, et al, 2012). A persistent infection may require removal of the shunt until the infection is controlled, and an external ventricular drainage (EVD), or external ventriculostomy, is used until CSF is sterile. EVD allows removal of CSF from a tube placed in the child's ventricle that flows by gravity into a collection device.

The primary reasons for inserting an EVD include unstable status, increased ICP that is difficult to stabilize, or infection from an existing VP shunt. The EVD may drain CSF intermittently or continuously according to need. The EVD is a closed system made up of transparent pliable tubing, a collection bag, and, at times, a drip chamber between the tubing and the collection bag. The EVD is placed at the level of the child's external auditory meatus with the head at a 20- to 30-degree elevation, depending on physician preference. Elevating the EVD above this level decreases the flow of CSF, and placing the device below the level of the external meatus increases the flow. Ambulation or sitting up in bed or a chair usually requires that the tubing be clamped to prevent imbalance in CSF drainage. In addition, the EVD is a closed sterile system and should be handled as such in relation to emptying the device or changing the scalp dressing. Accurate and frequent documentation of the incision site; amount, color, and consistency of drainage into the device; and the child's vital and neurologic signs are an important part of the nursing care.

Another serious shunt-related complication is subdural hematoma caused by too-rapid reduction of ICP and, in some cases, tentorial herniation as a result of imbalance in CSF drainage. These complications can be averted by careful assessment of ICP before insertion of the shunt and use of correct valvular pressure. Other complications that may occur include peritonitis, abdominal abscesses, perforation of abdominal organs by catheter or trocar (at the time of insertion), fistulas, hernias, and ileus. Children often need shunt lengthening as body growth occurs. This procedure usually involves replacing the distal catheter below the valve during the toddler period and again before the growth acceleration of puberty.

Prognosis

The prognosis of children with treated hydrocephalus depends largely on the cause of the dilated ventricles before shunt placement and the amount of irreversible brain damage before shunting (Kinsman and Johnston, 2011). For example, malignant tumors have a high mortality rate regardless of other complicating factors.

Survivors have a high incidence of subnormal intellectual capacity, and a large majority have major physical and disabling neurologic handicaps such as ataxia; poor fine motor, visual-motor, and spatial skills; and visual or hearing deficits (Kulkarni, 2010). Some children demonstrate aggressive or delinquent behavior, such as oppositional and acting-out behaviors, and attention-deficit hyperactivity disorder, and have lower perceptions of self-competency (Kulkarni, 2010).

Surgically treated hydrocephalus in patients with little or no evidence of irreversible brain damage has a survival rate of

about 80%, with most deaths occurring within the first year of treatment (Paulsen, Lundar, and Lindegaard, 2010). Those with poor outcomes included children shunted for posthemorrhagic hydrocephalus or meningitis. Most children who require shunting must depend on the shunt for the remainder of their life.

Nursing Care Management

The infant with suspected or confirmed hydrocephalus is observed carefully for signs of increasing ventricular size and increasing ICP. In infants the head is measured daily at the point of largest measurement—the OFC. (See Chapter 4 for technique.) To avoid the likelihood of wide discrepancies, the point at which the measurements are taken is indicated on the head with a marking pen. Fontanels and suture lines are palpated for size, signs of bulging, tenseness, and separation. Irritability, lethargy, seizure activity, and altered vital signs and feeding behavior may indicate an advancing pathologic condition.

In older children, who are usually admitted to the hospital for elective or emergency shunt revision, the most valuable indicators of increasing ICP are an alteration in the child's level of consciousness, complaint of headache, and changes in interaction with the environment. Changes are identified by observing and comparing present behavior with customary behavior, sleep patterns, developmental capabilities, and habits obtained through a detailed history and a baseline assessment. This baseline information serves as a guide for postoperative assessment and evaluation of shunt function.

The nurse is responsible for preparing the child for diagnostic tests such as MRI or a CT scan and for assisting with procedures such as a ventricular tap, which is often performed to relieve excessive pressure and to obtain CSF during the preoperative period. Sedation is required because the child must remain absolutely still during diagnostic testing. A variety of drugs are available for sedation. (See Chapter 23 for preparing children for procedures.) If surgery is anticipated, IV infusions should not be placed in a scalp vein.

Postoperative Care

In addition to routine postoperative care and observation, the infant or child is positioned carefully on the unoperated side to prevent pressure on the shunt valve. The child remains flat to help avert complications resulting from too-rapid reduction of intracranial fluid. The surgeon indicates the position to be maintained and the extent of activity allowed.

The nurse continues observation for signs of increased ICP, which indicate obstruction of the shunt. Neurologic assessment includes pupil dilation (pressure causes compression or stretching of the oculomotor nerve, producing dilation on the same side as the pressure) and blood pressure (hypoxia to the brainstem causes variability in these vital signs). The nurse also observes for abdominal distention because CSF may cause peritonitis or a postoperative ileus as a complication of distal catheter placement.

Because infection is the greatest hazard of the postoperative period, nurses are continually on the alert for the usual manifestations of CSF infection, including elevated temperature, poor feeding, vomiting, decreased responsiveness, and seizure activity. There may be signs of local inflammation at the operative sites and along the shunt tract. Antibiotics are administered by the IV route as ordered, and the nurse may also need to assist with intraventricular instillation. Inspect the incision site for leakage, and test any suspected drainage for glucose, an indication of CSF.

Family Support

Specific needs and concerns of parents during periods of hospitalization are related to the reason for the child's hospitalization (e.g., shunt revision, infection, diagnosis) and the diagnostic and surgical procedures to which the child must be subjected. Parents may have little understanding of anatomy; therefore, they need further explanation and reinforcement of information that was given to them by the physician and neurosurgeon, including information about what to expect. They are especially frightened of any procedure that involves the brain, and the fear of disability or brain damage is real and pervasive. Nurses can calm their anxiety with explanations of the rationale underlying the various nursing and medical activities such as positioning or testing and by simply being available and willing to listen to their concerns.

To prepare for the child's discharge and home care, instruct the parents on how to recognize signs that indicate shunt malfunction or infection. Active children may have injuries, such as a fall, that can damage the shunt, and the tubing may pull out of the distal insertion site or become disconnected during normal growth. Contact sports should be avoided, but swimming or tennis is appropriate. A helmet may be worn to protect the head in case of a fall or injury when outside play is vigorous. It is also important for the nurse to encourage families to enroll infants and toddlers with hydrocephalus into an early childhood development program. Depending on the degree of initial damage and the underlying cause, many children have normal intellectual development.

The management of hydrocephalus in a child is a demanding task for both the family and health professionals, and helping the family cope with the child's difficulties is an important nursing responsibility. Children with hydrocephalus have lifelong special health care needs. The nurse can provide optimum primary health care, including advice on immunizations, treatments for common infectious conditions, or child care and school precautions. The overall aim is to establish realistic goals and an appropriate educational program that will assist the child in achieving the maximum potential. Families can be referred to community agencies for support and guidance. The National Hydrocephalus Foundation (NHF)* and the Hydrocephalus Association† in the United States and the Spina Bifida & Hydrocephalus Association of Canada†† provide informa-

tion on the condition for families; the NHF also assists interested groups in establishing local organizations.

Anticipatory guidance will prepare parents for possible problems and help them avoid being overprotective of the child. Few restrictions need be placed on the child's activities (mainly contact sports), and the child is encouraged to live as would any other youngster of the same age and abilities. Parents need support and encouragement in coping with the child and problems the child may encounter in relationships with peers and others. Reactions of other children when the child has a noticeably enlarged head or requires special restrictions are stressful for both the child and the parents. (See Chapter 19 for problems and coping with a child with a disability.)

NCLEX REVIEW QUESTIONS

1. You are the nurse assigned to care for a child with a basilar skull fracture. Your most important nursing observation is change in level of consciousness. You will be highly alert for:
   - **A.** Alterations in vital signs that often appear before alterations in consciousness or focal neurologic signs
   - **B.** Bleeding from the ear, which is indicative of an anterior basal skull fracture
   - **C.** Seizures that are relatively uncommon in children at the time of head injury
   - **D.** Changes in posturing, such as any signs of extension or flexion posturing, unusual response to stimuli, and random versus purposeful movement
2. As the nurse assigned to a child diagnosed with bacterial meningitis, you know that:
   - **A.** The child will not need to be placed in isolation because antibiotics have been started
   - **B.** Enteric precautions will remain in place for up to 48 hours
   - **C.** Respiratory isolation will remain in place for 24 hours after antibiotics are started
   - **D.** Due to headache, the child will want the head of the bed elevated with two pillows
3. You are working with a pediatric nurse who has just transferred to the pediatric clinic. You are role-playing phone triage related to a child with a head injury. You ascertain that the nurse needs more teaching based on what response?
   - **A.** "After initial physical exam, if there was no loss of consciousness with the head injury, the child can be observed at home."
   - **B.** "If there is a language barrier, written instructions can be given, followed by discharge."
   - **C.** "Another physical exam should take place in 1 or 2 days."
   - **D.** "Parents should call the doctor if their child has any of these signs: blurred vision, walking unsteadily, or is hard to awaken."
4. You are caring for a child with hydrocephalus who is postoperative from a shunt revision. Which assessment finding is your priority for increased intercranial pressure?
   - **A.** Nausea and refusal to eat postoperatively
   - **B.** Complaint of a headache
   - **C.** Irritability and wanting to sleep
   - **D.** Decrease in heart rate over the last hour
5. You are working with a family that brought their child into the pediatric clinic. The mother describes what may be a type of seizure. What subjective data will help you determine the type? Select all that apply.
   - **A.** The presence or absence of an aura
   - **B.** If the child appeared disoriented after the seizure
   - **C.** Presence of vomiting after the seizure
   - **D.** The duration of the seizure
   - **E.** If the seizure was related to certain foods or occurred after a certain activity

Correct Answer

1. D
2. C
3. B
4. D
5. A, B, D

THE ENDOCRINE SYSTEM

The endocrine system controls and regulates metabolism; this includes energy production, growth, fluid and electrolyte balance, response to stress, and sexual reproduction (Baxter and Ribeiro, 2004). This system has three components: (1) the cell, which sends a chemical message using a hormone; (2) the target cells, or organs, which receive the chemical message; and (3) the environment through which the chemical is transported (e.g., blood, lymph, extracellular fluids) from the site of synthesis to the sites of cellular action.

The endocrine glands, which are distributed throughout the body, are listed in Box 33-1; also listed are several additional structures sometimes considered endocrine glands, although they are not usually included.

HORMONES

A **hormone** is a complex chemical substance produced and secreted into body fluids by a cell or group of cells that exerts a physiologic controlling effect on other cells (Kliegman, Stanton, St. Geme, et al, 2011). Local hormones create their effect near the point of secretion. For example, secretin, a digestive hormone made by cells lining the duodenum, stimulates the pancreas. General hormones are released by endocrine glands into the bloodstream, where they are carried to responsive tissues (Fig. 33-1). Some of these hormones (such as thyroid hormone [TH] and growth hormone [GH]) affect most cells of the body, whereas others (such as the tropic hormones) produce their effects on specific tissues, called **target tissues**. These responsive, or target, tissues may be another endocrine gland, an organ, or tissue (Baxter and Ribeiro, 2004). For example, pituitary hormones stimulate the adrenal glands and the thyroid gland to secrete adrenocorticotropic hormone (ACTH) and thyroid-stimulating hormone (TSH), respectively.

Control of Hormone Secretion

Regulation of hormonal secretion is often based on negative feedback. As a rule, endocrine glands have a tendency to oversecrete particular hormones. However, once the hormone's physiologic effect has been achieved, this information is transmitted to the producing gland, either directly or indirectly, to inhibit further secretion. If the gland undersecretes, the inhibition is stopped, and the gland increases production of the hormone again. As a result, the hormone is secreted according to the amount needed. This is the primary function of the tropic hormones.

BOX 33-1 ENDOCRINE GLANDS

Pituitary gland (hypophysis cerebri)—A pea-sized gland that lies within a deep bony depression at the base of the cranium (the sella turcica) and is attached to the hypothalamus on the undersurface of the brain by a slender infundibulum, or pituitary stalk

Thyroid gland—Two large lateral lobes and a connecting portion, the isthmus, situated on the anterior aspect of the neck just below the larynx

Parathyroid glands—Four or five (more or less) small round bodies attached to the posterior surfaces of the lateral lobes of the thyroid gland

Adrenal glands—Pyramid-shaped glands situated atop the kidneys, fitting like caps over these organs

Ovaries—Glands located in the female pelvis on each side of the uterus at the fimbriated end of the fallopian tubes

Testes—Oval-shaped glands situated within the male scrotum

Islets of Langerhans—Small clusters of endocrine cells within the pancreas situated between the acinar or exocrine-secreting portions of the gland

Structures Sometimes Considered Endocrine Glands

Pineal body (epiphysis cerebri)—A gland located in the cranial cavity behind the midbrain and third ventricle, the functions of which are largely speculative

Thymus—A gland situated behind the sternum and below the thyroid gland; plays an important role in immunity but only during fetal life and early childhood

Gastrointestinal glands—Mucosal lining of the gastrointestinal tract containing cells that produce hormones that play important roles in controlling and coordinating secretory and motor activities of digestion

Placenta—A body that secretes ovarian hormones and chorionic gonadotropin during gestation; only a temporary endocrine gland

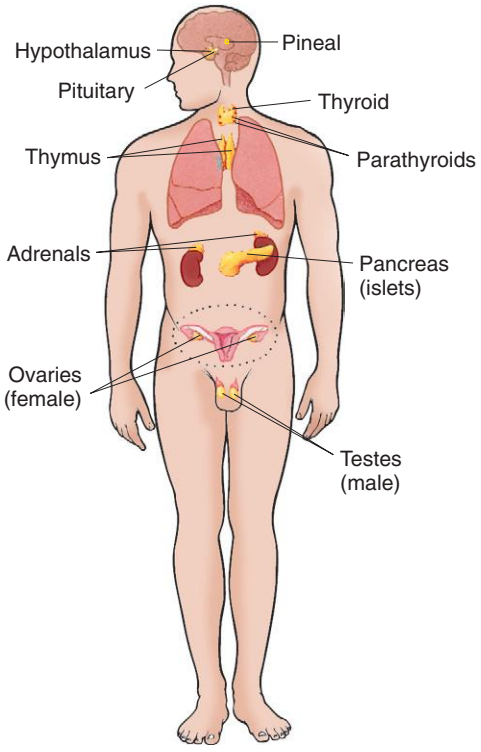

FIG. 33-1 Location of the endocrine glands and structures sometimes considered endocrine glands. (From Thibodeau GA, Patton KT: *Structure and function of the body*, ed 13, St. Louis, 2008, Mosby.)

The anterior pituitary gland, located below the hypothalamus, is often referred to as the master gland. It is primarily responsible for stimulation and inhibition of tropic hormones. Tropic (which literally means "turning") hormones secreted by the anterior pituitary regulate the secretion of hormones from various target organs (Fig. 33-2). As blood concentrations of the target hormones reach normal levels, a negative message is sent to the anterior pituitary to inhibit release of the tropic hormone. For example, TSH responds to low levels of circulating TH. As blood levels of TH reach normal concentrations, a negative feedback message is sent to the anterior pituitary, resulting in diminished release of TSH.

The pituitary gland is controlled by either hormonal or neuronal signals from the hypothalamus. Two types of substances are secreted from the hypothalamus: (1) releasing hormones and (2) inhibitory hormones. Both are secreted within the hypothalamus and transported by way of the pituitary portal system to the anterior pituitary, where they stimulate the secretion of tropic hormones. An example of this is the secretion of corticotropin-releasing factor (CRF) by the hypothalamus. CRF stimulates the pituitary to secrete ACTH. In this instance the anterior pituitary is the target of the hypothalamus. ACTH then stimulates the adrenals to secrete glucocorticoids, which have multiple target sites throughout the body. Pituitary hormones that lack feedback control from the product of a target tissue (e.g., GH, prolactin, and melanocyte-stimulating hormone) require hypothalamic inhibitors and stimulators for their control.

Not all hormones depend on other hormones for their release. For example, insulin is secreted in response to blood glucose concentrations. Other glandular hormones that are not under the control of the pituitary gland are glucagon, parathyroid hormone (parathormone, PTH), antidiuretic hormone (ADH), and aldosterone.

NEUROENDOCRINE INTERRELATIONSHIPS

Two regulatory systems maintain hemostasis: the endocrine and the autonomic nervous systems (collectively known as the neuroendocrine system) (Baxter and Ribeiro, 2004). The autonomic nervous system consists of the sympathetic and parasympathetic systems that control nonvoluntary functions—specifically that of smooth muscle, myocardium, and glands. The parasympathetic system primarily regulates the digestive processes, whereas the sympathetic system functions to maintain homeostasis during times of stress.

The higher autonomic centers, located in the hypothalamus and limbic system, help control the functioning of both autonomic systems. Both sympathetic and parasympathetic nerve fibers secrete neurotransmitting substances: acetylcholine, released by cholinergic fibers, and norepinephrine, released by adrenergic fibers. Release of norepinephrine into the plasma produces the same effects as secretion of this substance by the adrenal medulla. Thus the interrelatedness between the two systems is demonstrated.

The neuroendocrine system acts by synthesizing and releasing various chemical substances that regulate body functions. Information is carried by means of neural impulses in the

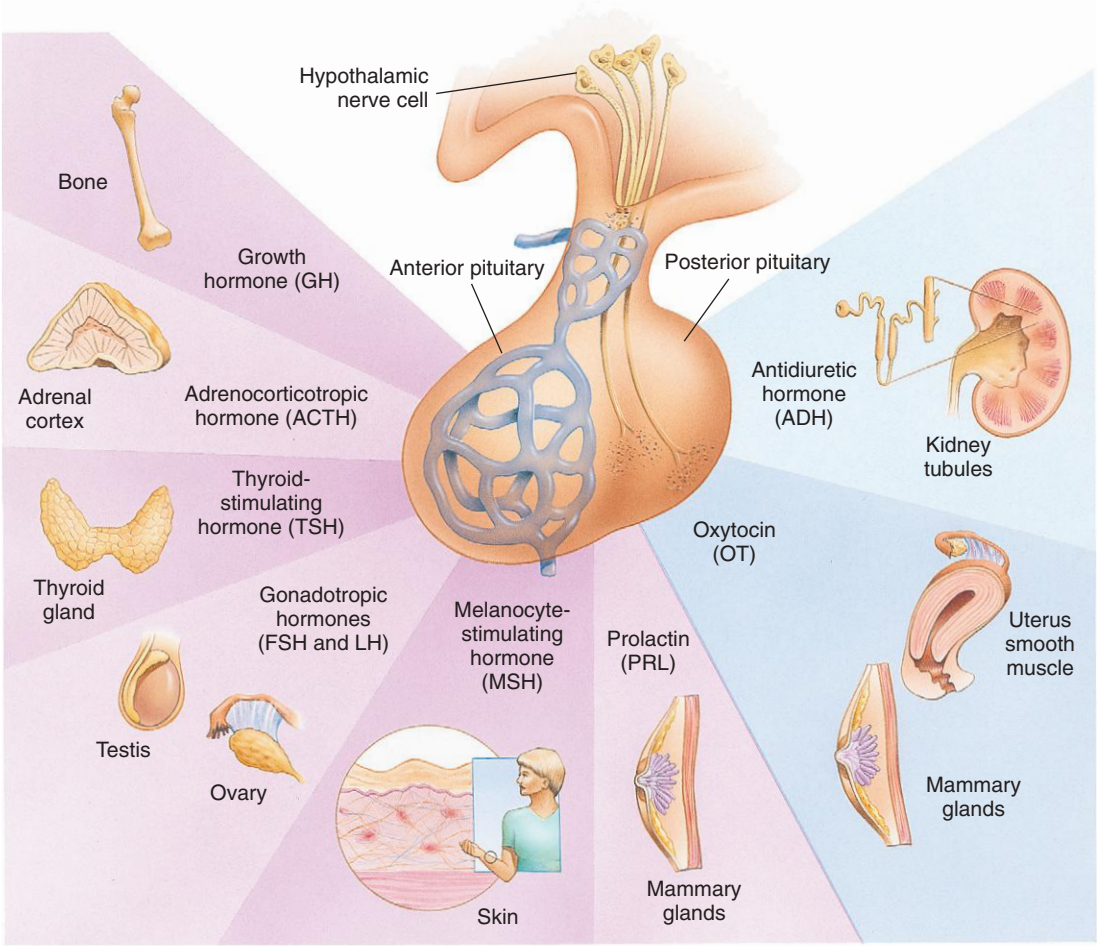

FIG. 33-2 Principal anterior and posterior pituitary hormones and their target organs. (From Thibodeau GA, Patton KT: *Structure and function of the body*, ed 13, St. Louis, 2008, Mosby.)

autonomic system and by the blood in the endocrine system. In general, neural responses are more rapid and localized, while endocrine responses are more lasting and widespread. The two systems function synergistically because neural impulses transmitted to the central nervous system (CNS) stimulate the hypothalamus to manufacture and release several releasing or inhibiting factors.

Because of the interdependent relationship of these glands, a malfunction in one gland produces effects elsewhere. Endocrine dysfunction may result from an intrinsic defect in the target gland or from a diminished or elevated level of tropic hormones. Endocrine problems occur when there is hypofunction or hyperfunction of the glands. Primary hypofunction is usually associated with a more profound deficiency of the target gland hormone because little or no hormone is secreted. In secondary dysfunction the target glands secrete some of their hormones but in smaller amounts and less rapidly.

DISORDERS OF PITUITARY FUNCTION

The pituitary gland is divided into two lobes: the anterior pituitary (adenohypophysis) and the posterior pituitary (neurohypophysis). It is regulated by hormones secreted from the hypothalamus. The anterior pituitary is responsible for secreting growth hormone (GH), thyroid-stimulating hormone (TSH), adrenocorticotrophic hormone (ACTH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin. The posterior pituitary secretes antidiuretic hormone (ADH) and oxytocin (Sathyapalan and Dixit, 2012).

Deficiencies of the anterior pituitary hormones may be due to organic defects or have an idiopathic etiology. Clinical manifestations depend on the hormones involved and the age of the patient. If the tropic hormones are involved, the resulting disorder reflects the altered stimulus of the target gland. For example, if TSH is deficient, then the thyroid gland does not secrete thyroid hormone (TH) as well and the child displays clinical signs of hypothyroidism.

An overproduction of the anterior pituitary hormones can result in gigantism (caused by excess GH production during childhood), hyperthyroidism, hypercortisolism (Cushing syndrome), and precocious puberty from excessive gonadotropins (LH and FSH). Overproduction may be caused by hyperplasia of the pituitary cells—which may eventually progress to a tumor (adenoma)—or a primary hypothalamic defect that results in an excess of the hormone's releasing factor. Although the initial clinical manifestations are a result of pituitary

oversecretion, eventually pituitary insufficiency occurs, and the signs of panhypopituitarism become evident. **Panhypopituitarism** is often defined clinically as the loss of all anterior pituitary hormones, leaving only posterior pituitary function intact (Toogood and Stewart, 2008).

! NURSING ALERT

Children with panhypopituitarism should wear medical identification, such as a bracelet.

HYPOPITUITARISM

Hypopituitarism is the diminished secretion of one or more pituitary hormones. The consequences of the condition depend on the degree of dysfunction. It often leads to:

- Gonadotropin deficiency (decrease in LH or FSH), where children show absence or regression of secondary sexual characteristics
- GH deficiency, in which children display stunted somatic growth
- TSH deficiency, which produces hypothyroidism
- Corticotropin deficiency, which results in manifestations of adrenal hypofunction

Hypopituitarism can result from any of the conditions listed in Box 33-2. The most common organic cause of pituitary undersecretion is a tumor in the pituitary or hypothalamic region, especially the craniopharyngiomas. These tumors usually invade the anterior and posterior pituitary lobes and the hypothalamus, causing panhypopituitarism (Box 33-3). The child may experience decreased growth velocity for some time before developing any symptoms or signs of increased intracranial pressure, local compression, or the destructive effects of the tumor. Other causes of panhypopituitarism include encephalitis, radiation to the head or neck, traumatic brain injury, and congenital hypoplasia of the hypothalamic area (Darzy, 2009; Hanberg, 2005; Rose and Auble 2012; Sathyapalan and Dixit, 2012).

Congenital hypopituitarism can be seen in newborn infants and can run in families, suggesting a genetic cause (Alatzoglou and Dattani, 2010). Neonates may have symptoms of hypoglycemia and seizure activity (Toogood and Stewart, 2008). A child with combined GH deficiency and hypothyroidism should be screened for congenital pituitary defects and genetic mutations (Pine-Twaddell, Romero, and Radovick, 2013).

Idiopathic hypopituitarism, or idiopathic pituitary growth failure, is usually related to GH deficiency, which inhibits somatic growth in all cells of the body (Miller and Zimmerman, 2004). Although most children with hypopituitarism are normal at birth, many show growth patterns that progressively deviate from the normal growth rate, often beginning in infancy. The chief complaint is often short stature. Of those who seek help, boys outnumber girls three to one. Idiopathic hypopituitarism can be associated with deficiencies of other pituitary hormones, such as TSH and ACTH; thus it is theorized that the disorder is probably secondary to hypothalamic deficiency.

Isolated GH deficiency without other associated pituitary hormone deficiencies or a known organic cause is also seen in

BOX 33-2 CAUSES OF HYPOPITUITARISM

- Aplasia or hypoplasia
- Developmental defects
- Idiopathic—Sporadic; genetic
- Destructive lesions
- Trauma—Perinatal; child abuse; basal skull fracture
- Irradiation—Central nervous system, eye, middle ear
- Autoimmune hypophysitis
- Surgery—Removal of pharyngeal pituitary, ablation of craniopharyngioma or other tumor
- Vascular—Aneurysm, infarct
- Functional deficiency
- Psychosocial dwarfism
- Anorexia nervosa

BOX 33-3 CLINICAL MANIFESTATIONS OF PANHYPOPITUITARISM

Growth Hormone
Short stature but proportional height and weight
Delayed epiphyseal closure
Stunted bone age proportional to height
Premature aging common in later life
Increased insulin sensitivity

Thyroid-Stimulating Hormone
Short stature with infantile proportions
Dry, coarse skin; yellow discoloration, pallor
Cold intolerance
Constipation
Somnolence
Bradycardia
Dyspnea on exertion
Delayed dentition, loss of teeth

Gonadotropins
Absence of sexual maturation or loss of secondary sexual characteristics
Atrophy of genitalia, prostate gland, breasts
Amenorrhea without menopausal symptoms
Decreased spermatogenesis

Adrenocorticotropic Hormone
Severe anorexia, weight loss
Hypoglycemia
Hypotension
Hyponatremia, hyperkalemia
Adrenal apoplexy, especially in response to stress
Circulatory collapse

Antidiuretic Hormone
Polyuria
Polydipsia
Dehydration

Melanocyte-Stimulating Hormone
Decreased pigmentation

children (Stanley, 2012). **Growth failure** is defined as an absolute height of less than –2 SD for age, or a linear growth velocity consistently less than –1 SD for age. When this occurs without the presence of hypothyroidism, systemic disease, or malnutrition, then an abnormality of the GH–insulin-like growth factor (IGF) axis should be considered (Richmond and Rogol, 2008).

Not all children with short stature have GH deficiency. In most instances the cause of short stature is considered idiopathic. Idiopathic short stature (ISS) is defined as a condition in which the height of an individual is more than 2 standard deviations below the mean height for his or her age, sex, and population group, without evidence of systemic, endocrine, nutritional, or chromosomal abnormalities (Cohen, Rogol, Deal, et al, 2008). Children with ISS fall into one of three groups: those with familial short stature, those with constitutional delay of growth and puberty, and those with a yet unidentified cause of short stature (Cohen, Rogol, Deal, et al, 2008). Familial short stature refers to healthy children who have ancestors with adult height in the lower percentiles and whose height during childhood is appropriate for genetic background (Fig. 33-3). Constitutional delay of growth and puberty refers to individuals with delayed linear growth and delayed skeletal and sexual maturation for age (Halac and Zimmerman, 2004; Miller and Zimmerman, 2004). GH therapy in children with ISS continues to be debated frequently by pediatric endocrinologists.

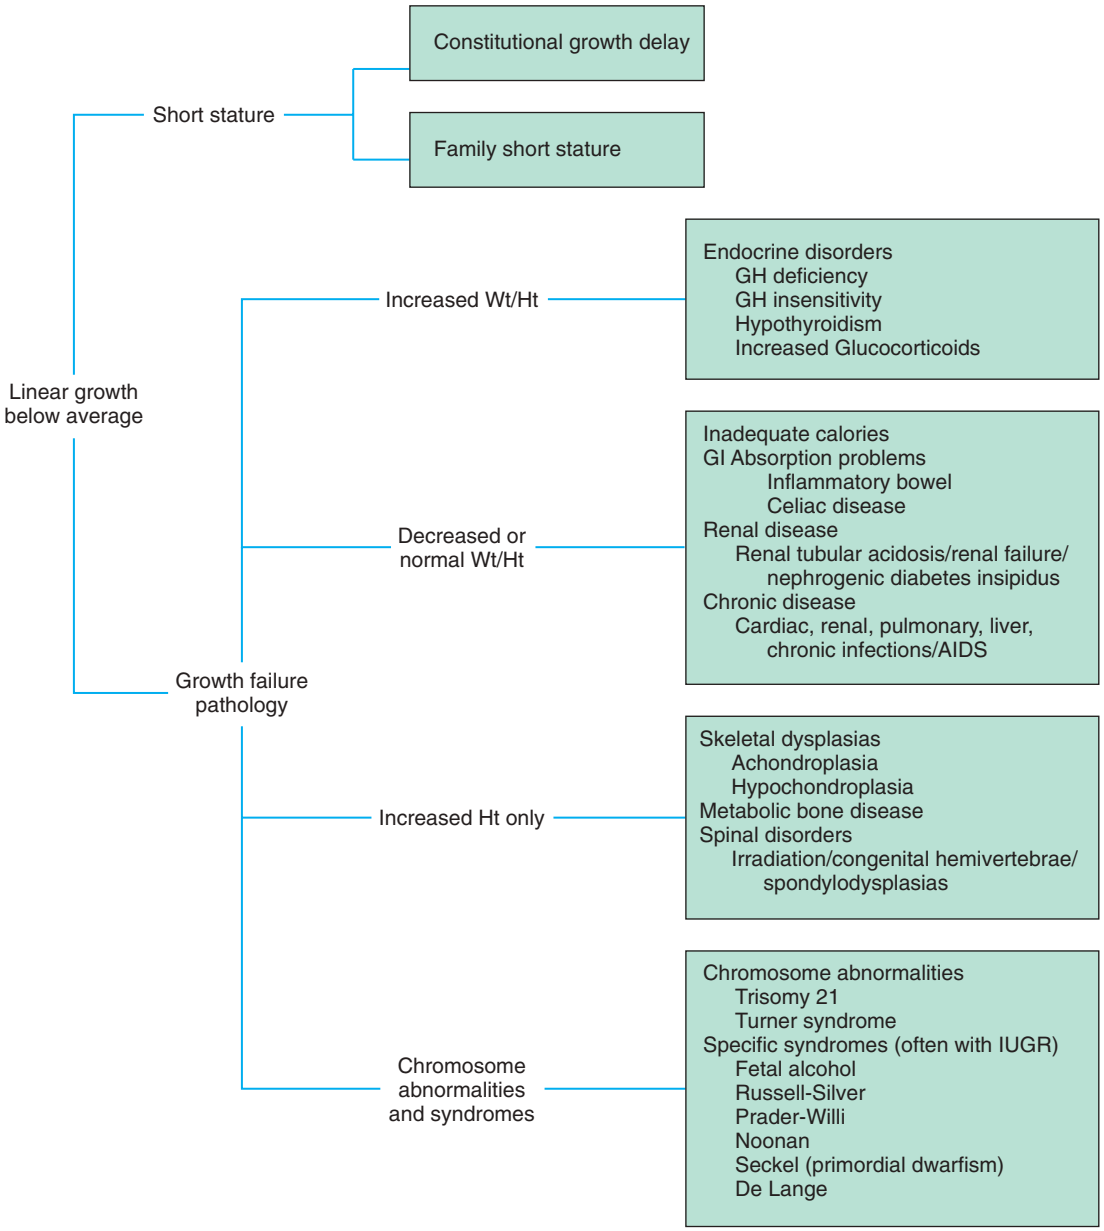

FIG. 33-3 Causes of short stature. *AIDS,* Acquired immunodeficiency syndrome; *GI,* gastrointestinal; *GH,* growth hormone; *IUGR,* intrauterine growth restriction; *Wt/Ht,* weight-to-height ratio. (From Vogiatzi MG, Copeland KC: The short child, *Pediatr Rev* 19(3):92-99, 1998.)

Clinical Manifestations

Children with GH deficiency often grow normally during the first year and then follow a slowed growth curve that is below the 3rd percentile. In children with a partial GH deficiency, the growth retardation is less marked than in children with complete GH deficiency. Height may be stunted more than weight because, with good nutrition, these children can become overweight or even obese. Their well-nourished appearance is an important diagnostic clue to differentiation from other disorders such as failure to thrive. Skeletal proportions are normal for the age, but these children appear younger than their chronologic age. Later in life, premature aging is common. Bone age is delayed but is closely related to height age; the degree of growth delay depends on the duration and extent of the hormonal deficiency. Because of the underdeveloped jaw, teeth may be overcrowded and malpositioned.

Children with isolated GH deficiency have normal intelligence. However, emotional problems are not uncommon, especially as they near puberty, when their smallness becomes increasingly apparent in comparison with their peers. Height discrepancy has been significantly correlated with emotional adjustment problems and may be a valuable predictor of the extent to which GH-delayed children will experience difficulty with anxiety, social skills, and positive self-esteem (Sandberg, Kranzler, Bukowski, et al, 1999).

Diagnostic Evaluation

Only a small number of children with delayed growth or short stature have hypopituitary dysfunction. Diagnostic evaluation is aimed at isolating organic causes, which, in addition to GH deficiency, may include brain tumor, hypothyroidism, oversecretion of cortisol, gonadal aplasia, chronic illness, nutritional inadequacy, Russell-Silver dwarfism, or hypochondroplasia.

A complete diagnostic evaluation should include a family history, a history of the child's growth patterns and previous health status, a physical examination, and a psychosocial evaluation. Specific radiographic imaging, including MRI, endocrine studies and genetic testing, may also be warranted (Stanley, 2012).

Family History

A family history is of utmost importance in relating short stature to genetic background. The midparental height is an important prognosticator of the child's ultimate adult height. Normal adult height should fall within 5 cm (2 inches) of midparental height (Miller and Zimmerman, 2004). Children with constitutional delays frequently are the products of parents who experienced similar slow growth patterns and delayed sexual maturation. A small percentage of those with hypopituitarism demonstrate an autosomal recessive inheritance pattern. Height and weight of siblings should be compared with the child's growth patterns at comparable age periods.

Child's History

The child's history should include a thorough prenatal history to rule out maternal disorders that may have influenced growth, such as malnutrition. Compare birth height and weight with gestational age. Children with hypopituitarism are usually of normal size and normal gestational age at birth.

Investigate the child's health history for evidence of chronic illness that may have influenced growth patterns, although a chronic illness, such as congenital heart disease, malabsorptive disorders, severe anemia, or neurologic impairments, usually is identified long before the growth problem becomes a concern. Signs and symptoms suggesting a tumor, such as visual disturbances, headache, and signs of increasing intracranial pressure, are important. With lesions involving the hypothalamus, the history may also reveal somnolence, thermodysregulation, epilepsy, and polyphagia, resulting in obesity. Because a craniopharyngioma can affect the secretion of any of the pituitary hormones, assessment for hypothyroidism, hypoadrenalism, and hypoaldosteronism should also be included.

Whenever possible, evaluate the child's growth patterns since birth, especially growth velocity, and compare them with standard measurements. The age of onset of short stature provides a significant diagnostic clue. When the clinician evaluates the results of plotting height and weight, upward or downward changes in height velocity in children older than 3 years may indicate a growth abnormality (Halac and Zimmerman, 2004).

Physical Examination

Accurate measurement of height (using a calibrated stadiometer) and weight and comparison with standard growth charts are essential (Box 33-4). Multiple height measures reflect a more accurate assessment of abnormal growth patterns (Hall, 2000). Other measurements may include crown-to-pubis and pubis-to-heel length to compare body proportions. Sexual

BOX 33-4 EVALUATING THE GROWTH CURVE

Make sure measurements are reliable—Accurately obtain and plot height and weight measurements.

Determine absolute height—The child's absolute height bears some relationship to the likelihood of a pathologic condition. However, the majority of children who have a height below the lowest percentile (either 3rd or 5th percentile on the height curve) do not have a pathologic growth problem.

Document height velocity—The most important aspect of a growth evaluation is evaluating a child's height over time, or height velocity. Accurate determination of height velocity requires at least 4 and preferably 6 months of observation. A deceleration in height velocity (crossing several percentiles) between 3 and 12 or 13 years of age indicates a pathologic condition until proven otherwise.

Assess the weight-to-height ratio—Evaluation of the weight-to-height ratio has some diagnostic value in ascertaining the cause of growth retardation in a short child.

Estimate target height—The height of a child can be judged inappropriately short only in the context of his or her genetic potential. Determine the target height of the child with the formula: [Father's height (cm) + Mother's height (cm) + 13]/2 for boys or [Father's height (cm) + Mother's height (cm) – 13]/2 for girls. Most children achieve an adult stature within approximately 10 cm (4 inches) of the target height.

BOX 33-5 EVALUATING BONE AGE FOR GROWTH DISORDERS

Bone age is a method of assessing skeletal maturity by comparing the appearance of representative epiphyseal centers obtained on x-ray examination with age-appropriate published standards. Most conditions that cause poor linear growth also cause a delay in skeletal maturation and a stunted bone age. Observation of even a profoundly delayed bone age is never diagnostic or even indicative of a specific diagnosis. A delayed bone age merely indicates that the associated short stature is to some extent "partially reversible," since linear growth will continue until epiphyseal fusion is complete. In comparison, a bone age that is not delayed in a short child is of much greater concern and may, in fact, be of some diagnostic value under certain circumstances.

development should be assessed and compared with age-appropriate development. Observation of general appearance yields valuable clues, especially signs of premature aging and infantile facial features. Funduscopic examination and testing for visual acuity are important to detect evidence of ocular damage from a tumor.

Radiographic Surveys

A skeletal survey in children less than 3 years of age and radiographic examination of the hand-wrist for centers of ossification (bone age) (Box 33-5) in older children are important in evaluating growth. Epiphyseal maturation is delayed in GH deficiency but consistent with height. This is in contrast with gonadal dysplasia, such as Turner syndrome, in which bone age is near normal. A skull series may help identify abnormalities such as an abnormally small sella turcica where the pituitary is located. Magnetic resonance imaging (MRI), computed tomography (CT), radionuclear scans, or carotid angiograms may be needed to establish diagnosis and localization of brain lesions (Stanhope, 2004).

Endocrine Studies

Definitive diagnosis of GH deficiency is based on absent or subnormal reserves of pituitary GH. Measuring a single GH level is inaccurate due to the pulsatile secretion of this hormone (Richmond and Rogol, 2008). GH levels are normally so low in children that differentiation from abnormal concentrations is unreliable. Measuring serum IGF-I and IGF binding protein 3 (IGFBP3) levels may assist in the decision to pursue further testing for GH deficiency. It is recommended that GH stimulation tests be reserved for children with low serum IGF-I and IGFBP3 levels and poor growth who do not have other endocrine or nonendocrine causes for short stature (Hokken-Koelega, 2011). However, although the IGF-1 test is useful in detecting severe GH insensitivity, it may not be accurate in detecting less severe cases of idiopathic short stature (Cohen, Rogol, Deal, et al, 2008; Hokken-Koelga, 2011).

GH stimulation, or provocative testing, involves the use of pharmacologics to provoke the release of GH either directly or indirectly. Provocative testing involves the use of neuromodulators such as levodopa or agents such as clonidine, arginine, insulin, propranolol, or glucagon, followed by the measurement GH blood levels (Kliegman, Stanton, St. Geme, et al, 2011; Richmond and Rogol, 2008; Stanley, 2012). The GH stimulation test of choice is currently country dependent (Cohen, Rogol, Deal, et al, 2008). Studies have shown that traditional GH stimulation test results can be less reliable than previously accepted (Stanley, 2012). Currently, findings in a child of poor linear growth, delayed bone age, and peak levels of GH at less than 10 ng/ml in two stimulation tests are consistent with GH deficiency (Kliegman, Stanton, St. Geme, et al, 2011). New reference standards that decrease the lower limit of normal GH levels have been proposed (Cohen, Rogol, Deal, et al, 2008).

Therapeutic Management

Treatment of GH deficiency caused by organic lesions is directed toward correction of the underlying disease process (e.g., surgical removal or irradiation of a tumor). The treatment of GH deficiency is replacement of GH. For more than 20 years cadaver-derived human growth hormone (HGH) was used successfully to enhance linear growth in short children. In 1985 the U.S. Food and Drug Administration stopped use of the hormone in response to reported deaths resulting from Creutzfeldt-Jakob disease (CJD) in three former HGH recipients. Patients have been identified who both received HGH and became infected with CJD, a rare and fatal neurodegenerative condition iatrogenically transmitted through human tissue (Wetterau and Cohen, 2000). Donation of organs or tissues from HGH recipients for transplantation should be prohibited because of the inability to test for infection with CJD. Blood banks do not accept donations from former HGH recipients. Biosynthetic GH prepared by recombinant deoxyribonucleic acid (DNA) technology (and without the risk of CJD) is now used exclusively (Miller and Zimmerman, 2004).

In the United States the recommended dosage range of recombinant GH is 0.037 to 0.18 mg/kg/week, divided into six or seven daily subcutaneous doses (Cohen, Rogol, Deal, et al, 2008; Kliegman, Stanton, St. Geme, et al, 2011). Growth velocity increases in the first year of treatment and is often above the 95th percentile. With each consecutive year of treatment, growth rates decline (Kliegman, Stanton, St. Geme, et al, 2011). A meta-analysis of the GH literature concluded that, although GH may improve growth velocity in children, individuals who receive treatment remain shorter than their peers (Bryant, Baxter, Cave, et al, 2007). For children to achieve their genetic growth potential, early diagnosis of and intervention for growth disorders are essential (Leschek, Rose, Yanovski, et al, 2004).

The child, family, and health care team make the decision jointly to stop GH therapy. Growth rates of less than 1 inch/year and a bone age of more than 14 years in girls and more than 16 years in boys are often used as criteria to stop GH therapy (Kliegman, Stanton, St. Geme, et al, 2011). Children with other hormone deficiencies require replacement therapy to correct the specific disorders. This may involve administration of thyroid extract, cortisone, testosterone, or estrogens and progesterone. The sex hormones are usually begun during adolescence to promote normal sexual maturation.

Nursing Care Management

The principal nursing consideration is identifying children with growth problems. Although the majority of growth problems are not a result of organic causes, any delay in normal growth and sexual development poses special emotional adjustments for these children.

The nurse may be a key person in helping establish a diagnosis. For example, if serial height and weight records are not available, the nurse can question parents about the child's growth compared with that of siblings, peers, or relatives. Investigating clothing sizes is often helpful in determining growth at different ages.

QUALITY PATIENT OUTCOMES

Growth Hormone Deficiency

- Early recognition of growth problems
- Accurate diagnosis of GH deficiency
- GH effective in stimulating growth
- Child and family able to cope with diagnosis and treatment

Because the behavioral or physical changes that suggest a tumor are insidious, they are frequently overlooked. It is important to correlate the onset of any positive findings with the initial evidence of growth retardation. For example, visual problems and headaches are not uncommon in school-age children and can coincidentally occur after a growth problem is recognized. In fact, headache may represent the emotional trauma caused by short stature rather than be a symptom of a tumor. Pursue this line of questioning cautiously to avoid alarming parents unduly about the possibility of a brain tumor.

Part of a nurse's role in helping establish a diagnosis is assisting with diagnostic tests. Preparation of the child and family is especially important if a number of tests are being performed and the child requires particular attention during growth hormone stimulation testing. Blood samples are usually taken every 30 minutes for a 3-hour period. Children also have difficulty overcoming hypoglycemia generated by tests with insulin, so they should be carefully observed for signs of hypoglycemia. Those receiving glucagon are at risk of nausea and vomiting. Patients receiving clonidine require close blood pressure monitoring. Nursing administration of intravenous (IV) fluids may be required if hypotension is detected. The use of arginine is often well tolerated by children, but it may cause hypoglycemia in some infants and toddlers. Therefore, close monitoring for hypoglycemia is necessary.

Child and Family Support

If an organic cause of the problem has been confirmed, the parents and child need an opportunity to express their thoughts and feelings. Frequently a growth problem that was present since birth is missed until adolescence, at which time the child's difference in body development becomes dramatically evident in comparison with peers. Family members may feel anger and resentment toward members of the health staff for not detecting the problem sooner. Parents may experience guilt for not seeking medical attention earlier, especially if the child has been miserable from the ridicule and criticism of peers. Appropriate emotional support from the nurse can include an affirmation of each person's justified feelings, such as anger or guilt, and emphasis on the treatment plan and prospects for improvement in the future.

DRUG ALERT

Growth Hormone

GH is most effective when it is administered at bedtime. Physiologic release is more normally stimulated as a result of pituitary release of GH during the first 45 to 90 minutes after the onset of sleep.

Even when hormone replacement is successful, these children attain their eventual adult height at a slower rate than their peers; therefore, they need assistance in setting realistic expectations regarding improvement. Psychologic counseling may be considered for children diagnosed with idiopathic short stature whether done in conjunction with GH therapy or treatment instead (Cohen, Rogol, Deal, et al, 2008). Both sexes need guidance toward appropriate vocational goals. Because these children appear younger than their chronologic age, others frequently relate to them in infantile or childish ways. Children having school problems need special counseling. Parents and teachers benefit from guidance directed toward setting realistic expectations for the child based on age and abilities. For example, in the home such children should have the same age-appropriate responsibilities as their siblings. As they approach adolescence, encourage them to participate in group activities with peers. If abilities and strengths are emphasized rather than physical size, such children are more likely to develop a positive self-image.

Professionals and families may find research, education, support, and advocacy from the Human Growth Foundation.* Treatment is expensive—up to $20,000 to $30,000 per year, depending on the dosage (Lee, Davis, Clark, et al, 2006; Radetti, Buzi, Paganini, et al, 2003). Usually the cost is partially covered by insurance if the child has a documented deficiency, and some pharmaceutical companies offer copay assistance.

PITUITARY HYPERFUNCTION

Excess GH before closure of the epiphyseal shafts results in proportional overgrowth of the long bones until the individual reaches a height of 2.4 m (8 feet) or more. Vertical growth is accompanied by rapid and increased development of muscles and viscera. Weight is increased but is usually in proportion to height. Proportional enlargement of head circumference also occurs and may result in delayed closure of the fontanels in young children. Children with a pituitary-secreting tumor may also demonstrate signs of increasing intracranial pressure, especially headache.

*997 Glen Cove Ave., Suite 5, Glen Head, NY 11545; 800-451-6434; e-mail: hgf1@hgfound.org; **www.hgfound.org**.

If oversecretion of GH occurs after epiphyseal closure, growth is in the transverse direction, producing a condition known as **acromegaly**. Typical facial features include:

- Overgrowth of the head, lips, nose, tongue, jaw, and paranasal and mastoid sinuses
- Separation and malocclusion of the teeth in the enlarged jaw
- Disproportion of the face to the cerebral division of the skull
- Increased facial hair; thickened, deeply creased skin
- Increased tendency toward hyperglycemia and diabetes mellitus (DM)

Excessive secretion of GH by a pituitary adenoma causes most cases of acromegaly. Acromegaly can develop slowly, with patients being diagnosed as much as 10 years after their symptoms first appear. Left untreated, these patients have a higher mortality rate due to potential cardiovascular, metabolic, and pulmonary complications (Katznelson, 2007; Natchtigall, Delgado, Swearingen, et al, 2008).

Diagnostic Evaluation

Diagnosis is based on a history of excessive growth during childhood and evidence of increased levels of GH. MRI may reveal a tumor in an enlarged sella turcica, normal bone age, enlargement of bones (such as the paranasal sinuses), and evidence of joint changes. Endocrine studies to confirm excess of other hormones, specifically thyroid, cortisol, and sex hormones, should also be included in the differential diagnosis.

Therapeutic Management

If a lesion is present, surgical treatment by cryosurgery or hypophysectomy is performed to remove the tumor when possible. Transsphenoid surgery (TSS) is the most common surgical treatment for pituitary adenoma. External radiation (XRT) or radioactive implants may be used to destroy GH-secreting tissue. Medical therapy using drugs that can suppress GH may be used in conjunction with TSS and/or XRT to treat this disease (Natchtigall, Delgado, Swearingen, et al, 2008). Depending on the extent of surgical excision and degree of pituitary insufficiency, hormone replacement with thyroid extract, cortisone, and sex hormones may be necessary.

Nursing Care Management

The primary nursing consideration is early identification of children with excessive growth rates. Although medical treatment of acromegaly will not reduce a patient's height, it will prevent further excess growth. The earlier treatment is initiated, the greater the chances of attaining a normal adult height. Nurses in ambulatory settings who are frequently involved in growth screening should refer children who demonstrate excessive linear growth for a medical evaluation. They should also observe for signs of a tumor, especially headache, and evidence of concurrent hormonal excesses, particularly the gonadotropins, which cause sexual precocity.

Children with excessive growth rates require as much emotional support as those with short stature. However, girls may suffer from the effects of excessive height much more than boys. Like boys, some girls may find their height to be an asset when pursuing sports such as basketball. Children and their parents need an opportunity to express their thoughts. A compassionate nurse can be supportive to these children, especially before adolescence when they are larger than their peers. The nurse can emphasize to a tall girl that as boys grow older, they become taller and she will not always be looking down at them.

PRECOCIOUS PUBERTY

Manifestations of sexual development before age 9 years in boys or age 8 years in girls have traditionally been considered precocious development, and these children were recommended for further evaluation (Carel and Leger, 2008; Kaplowitz, 2009), but guidelines on this have been debated (see Research Focus box).

Normally the hypothalamic-releasing factors stimulate secretion of the gonadotropic hormone from the anterior pituitary at the time of puberty. In the male, interstitial cell–stimulating hormone stimulates Leydig cells of the testes to secrete testosterone. In the female follicle-stimulating hormone and luteinizing hormone stimulate the ovarian follicles to secrete estrogens. This sequence of events is known as the **hypothalamic-pituitary-gonadal axis**. If for some reason the cycle undergoes premature activation, the child displays evidence of advanced or precocious puberty. Sex hormones affect bone growth, and premature exposure may cause short stature. Box 33-6 lists the causes of precocious puberty.

Isosexual precocious puberty is more common among girls than boys. Approximately 50% of children with precocious puberty have central precocious puberty (CPP), in which pubertal development is activated by the hypothalamic gonadotropin-releasing hormone (GnRH). This produces early maturation and development of the gonads, with secretion of sex hormones, development of secondary sexual characteristics, and sometimes production of mature sperm and ova (Lee, 1999; Root, 2000). CPP occurs more frequently in girls and is usually idiopathic, with 95% demonstrating no causative factor (Carel and Leger, 2008; Greiner and Kerrigan, 2006; Nebesio and Eugster, 2007; Root 2000). A CNS insult or structural abnormality occurs in more than 90% of boys with CPP (Carel and Leger, 2008).

RESEARCH FOCUS

Precocious Puberty

Concern that the onset of puberty may be occurring earlier has been raised and debated over the past 15 years (Carel and Leger, 2008). Based on several studies, authors have recommended only the evaluation of Caucasian girls younger than 7 years of age, or African-American girls younger than 6 years of age, who show signs of puberty (Biro, Huang, Crawford, et al, 2006; Kaplowitz and Oberfield, 1999). Earlier puberty in girls is now thought to be directly related to obesity, and newer data suggest that the timing of puberty has not changed for children who are not overweight (Walvoord, 2010). Some data suggested that boys may be beginning maturation earlier as well (Herman-Giddens, 2006). However, no change in the guidelines for evaluation of precocious puberty in boys is recommended (Walvood, 2010).

BOX 33-6 PRECOCIOUS PUBERTY

Central Precocious Puberty

Is known as idiopathic, with or without hypothalamic hamartoma

Secondary

- Congenital anomalies
- Postinflammatory—Encephalitis, meningitis, abscess, granulomatous disease
- Radiotherapy
- Trauma
- Neoplasms

After effective treatment of long-standing pseudoisosexual precocity

Peripheral Precocious Puberty

Familial male-limited precocious puberty

Albright syndrome

Gonadal or extragonadal tumors

Adrenal

- Congenital adrenal hyperplasia
- Adenoma, carcinoma
- Glucocorticoid resistance

Exogenous sex hormones

Primary hypothyroidism

Incomplete Precocious Puberty

Premature thelarche

Premature menarche

Premature pubarche or adrenarche

Peripheral precocious puberty (PPP) refers to early puberty resulting from hormone stimulation other than the hypothalamic GnRH–stimulated pituitary gonadotropin release. Clinical findings normally associated with puberty may be seen as variations in normal sexual development (Greiner and Kerrigan, 2006). They appear without other signs of puberty and are probably caused by unusual end-organ sensitivity to prepubertal levels of estrogen or androgen. Included are premature thelarche (development of breasts in prepubertal girls), premature pubarche (premature adrenarche, early development of sexual hair), and premature menarche (isolated menses without other evidence of sexual development).

Therapeutic Management

Children with evidence of precocious puberty should be evaluated by a pediatric endocrinologist. In every case, an MRI of the brain should be performed to assess for hypothalamic brain tumor (Carel and Leger, 2008). When there is no organic cause for CPP, patients will be monitored closely for growth. In 50% of cases, precocious pubertal development regresses or stops advancing without any treatment. CPP can be managed with monthly injections of a synthetic analog of luteinizing hormone–releasing hormone, which decreases the pituitary secretion of LH and FSH (Carel and Leger, 2008). A slow-release formulation of leuprolide acetate (Lupron Depot) is given in a dosage of 0.2 to 0.3 mg/kg intramuscularly q 4 wk. A longer-lasting preparation may be given intramuscularly every 3 months and has also been successful in the treatment of CPP in a majority of patients. Although expensive, the GnRH analog (GnRHa) histrelin has been formulated as a subdermal implant and may be beneficial for some patients who would like to avoid injections (Kaplowitz, 2009).

After initiation of treatment, breast development regresses or does not advance, and growth returns to normal rates, enhancing predicted height. Treatment is discontinued at a chronologically appropriate time, allowing pubertal changes to resume. Despite the early sexual development, maturation of the gonads and the appearance of secondary sexual characteristics proceed in the usual order. The most difficult time for the child is usually the school years before adolescence. After puberty, physical differences from peers are no longer present. Some patients, however, do not attain adult targeted height during therapy. Researchers have taken different approaches to address this issue, proposing the use of GH and, more recently, conducting trials of a nonaromatizable anabolic steroid to improved adult height (Carel and Leger, 2008; Kaplowitz, 2009).

Nursing Care Management

Psychologic support and guidance of the child and family are the most important aspects of management. Parents and children need anticipatory guidance, support and information resources, and reassurance (Greiner and Kerrigan, 2006). GnRH agonists are associated with side effects such as headache and hot flashes, as well as decreased bone mineral density (Carel and Leger, 2008). Nurses are essential in providing medical education to the patient and family. Dress and activities for the physically precocious child should be appropriate to the chronologic age. Sexual interest is not usually advanced beyond the child's chronologic age, and parents need to understand that the child's mental age is congruent with the chronologic age.

Although the child's sexual behavior may be appropriate for the chronologic age, the nurse should emphasize to parents that the child may be fertile. Usually no form of contraception is necessary unless the child is sexually active. In this situation proper counseling is important because hormonal forms of birth control, such as estrogen pills, prematurely initiate epiphyseal closure, resulting in stunted linear growth.

DIABETES INSIPIDUS

The principal disorder of posterior pituitary hypofunction is diabetes insipidus (DI). Also known as neurogenic DI, central diabetes insipidus results from the undersecretion of antidiuretic hormone (ADH), also known as vasopressin. This disease results in the production of large volumes of urine (polyuria) that leads to a state of uncontrolled diuresis (Makaryus and McFarlane, 2006; Di Iorgi, Napoli, Allegri, et al, 2012). Central DI is not to be confused with nephrogenic DI, a rare hereditary disorder affecting primarily males and caused by unresponsiveness of the renal tubules to the hormone. (See Chapter 25.)

Neurogenic DI may result from a number of different causes. Primary causes are familial or idiopathic. More than 55 genetic mutations have been identified, which result in a deficiency of vasopressin and cause familial central DI (Di Igori, Napoli, Allegri, et al, 2012). Secondary causes include trauma (accidental or surgical), tumors, granulomatous disease, Langerhans cell

histiocytosis (LCH), autoimmune disease, infections (meningitis or encephalitis), cranial malformations, and vascular anomalies (aneurysm). Certain drugs, such as alcohol or phenytoin (diphenylhydantoin), can cause a transient polyuria. DI may be an early sign of an evolving cerebral process (De Buyst, Massa, Christophe, et al, 2007; Di Igori, Napoli, Allegri, et al, 2012).

Clinical Manifestations

The cardinal signs of DI are polyuria and polydipsia. In the older child, signs can include excessive urination accompanied by insatiable thirst so intense that the child does little more than go to the toilet and drink fluids (Cheetham and Baylis, 2002). Frequently the first sign is enuresis. In the infant the initial symptom is irritability that is relieved with feedings of water but not milk. The infant is also prone to severe dehydration, electrolyte imbalance, hyperthermia, azotemia, and potential circulatory collapse. Other symptoms such as vomiting, constipation, fever, irritability, sleep issues, failure to thrive, and growth problems may be seen.

Dehydration is usually not a serious problem in older children, who are able to drink larger quantities of water. However, any period of unconsciousness, such as after trauma or anesthesia, may be life threatening because the voluntary demand for fluid is absent. During such instances careful monitoring of urine volumes, blood concentration, and IV fluid replacement is essential to prevent dehydration.

! NURSING ALERT

The child with DI complicated by congenital absence of the thirst center must be encouraged to drink sufficient quantities of liquid to prevent electrolyte imbalance.

Diagnostic Evaluation

The simplest test used to diagnose this condition is the water deprivation test, which restricts oral fluids and observes changes in urine volume and concentration. Normally, reducing fluids results in concentrated urine and diminished volume. In DI, fluid restriction has little or no effect on urine formation but causes weight loss from dehydration. Accurate results from this procedure require strict monitoring of fluid intake and urinary output, measurement of urine concentration (specific gravity or osmolality), and frequent weight checks. A weight loss between 3% and 5% indicates significant dehydration and requires termination of the fluid restriction.

! NURSING ALERT

Small children require close observation during fluid deprivation to prevent them from drinking, even from toilet bowls, flower vases, or other unlikely sources of fluid.

If this test is positive, the child should be given a test dose of injected aqueous vasopressin (Pitressin), which should alleviate the polyuria and polydipsia. Unresponsiveness to exogenous vasopressin usually indicates nephrogenic DI. A rise by more than 50% in urine osmolality after vasopressin administration indicates central DI (Carr and Gill, 2007).

An important diagnostic consideration is differentiating DI from other causes of polyuria and polydipsia, especially diabetes mellitis. MRI to look for secondary causes of central DI such as a tumor or central brain anomaly is essential (Di Iorgi, Napoli, Allegri, et al, 2012). Often kidney function tests, urine osmolality tests, blood electrolyte levels, and specific endocrine studies are sent to isolate associated problems (Carr and Gill, 2007). In rare instances a psychologic consultation may be warranted to confirm the possibility of compulsive water drinking related to psychogenic causes.

Therapeutic Management

The usual treatment is hormone replacement using DDAVP, which is a synthetic analog of the endogenous hormone arginine vasopressin (AVP). DDAVP can be given orally, intranasally, or parenterally. The intranasal and oral forms of DDAVP are most commonly used in children. Oral DDAVP has few complications and is easier to give, which likely increases compliance (Di Iorgi, Napoli, Allegri, et al, 2012).

DRUG ALERT

Vasopressin

To be effective, vasopressin must be thoroughly mixed in the oil by being held under warm running water for 10 to 15 minutes and shaken vigorously before being drawn into the syringe. If this is not done, the oil may be injected minus the ADH. Small brown particles, which indicate drug dispersion, must be seen in the suspension.

Previous formulations of vasopression have essentially been replaced by the use of desmopressin acetate (DDAVP). DDAVP is a long-acting analog of arginine vasopressin. It is often administered intranasally by way of a flexible tube to achieve adequate control. The child's response pattern is variable, with duration ranging from 6 to 24 hours (Makaryus and McFarlane, 2006; Verbalis, 2003). It is usually administered twice daily—at bedtime to allow the child to sleep through the night and in the morning to allow fewer interruptions in the school day. Some "breakthrough" urination is allowed during the evening hours as a precaution against overmedication. The signs of overmedication are similar to manifestations associated with the syndrome of inappropriate ADH (SIADH). (See the next section.)

Nursing Care Management

The initial objective is identification of the disorder. Because an early sign may be sudden enuresis in a child who is toilet trained, excessive thirst with bed-wetting is an indication for further investigation. Another clue is persistent irritability and crying in an infant that is relieved only by bottle-feedings of water. After head trauma or certain neurosurgical procedures, the development of DI can be anticipated; therefore, closely monitor these patients.

QUALITY PATIENT OUTCOMES

Diabetes Insipidus

- Early recognition of signs and symptoms of DI
- Differentiation of DI from other causes of polyuria and polydipsia (e.g., DM)
- Effective hormone replacement

Assessment includes measurement of body weight, serum electrolytes, blood urea nitrogen, hematocrit, and urine specific gravity taken before surgery and every other day after the procedure. Fluid intake and output should be carefully measured and recorded. Alert patients are able to adjust intake to urine losses, but unconscious or very young patients require closer fluid observation. In children who are not toilet trained, collection of urine specimens may require application of a urine-collecting device.

After confirmation of the diagnosis, parents need a thorough explanation regarding the condition, with specific clarification that DI is a different condition from DM. They must realize that treatment is lifelong. If children are to receive DDAVP, ideally two caregivers should learn the correct procedure for preparation and administration of the drug. Once children are old enough, encourage them to assume full responsibility for their care.

For emergency purposes, these children should wear medical alert identification. School personnel need to be aware of the problem so they can grant children unrestricted use of the lavatory. Failure to permit this may result in embarrassing accidents that often result in a child's unwillingness to attend school. Medication may need to be kept at school depending on dosing schedules.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

Oversecretion of the posterior pituitary antidiuretic hormone (ADH) causes the disorder known as syndrome of inappropriate antidiuretic hormone (SIADH). This disorder occurs with increased frequency in a variety of conditions that disrupt central nervous system function such as infection, tumor, or surgery. It can also be the side effect of a variety of medications. SIADH is the most common cause of hyponatremia in the pediatric population (Ranadive and Rosenthal, 2009; Rivkees, 2008).

Excess ADH causes free water to be reabsorbed from the kidneys. As increased free water circulates, serum osmolality goes down, and urine osmolality inappropriately increases. Clinical signs of SIADH are directly related to fluid retention and hyponatremia. When cells in the brain are exposed to too much water as opposed to sodium, swelling occurs (Rivkees, 2008). When serum sodium levels are diminished to 120 mEq/L, affected children may display anorexia, nausea, vomiting, stomach cramps, irritability, and personality changes. With progressive hyponatremia, more serious neurologic signs, such as stupor and seizures, may occur.

Fluid restriction is the immediate management of choice. Subsequent management depends on the cause and severity. Fluids may be restricted in anticipation of SIADH development postoperatively. Some children may be treated with oral sodium replacement. Severe SIADH may require hypertonic saline infusion that is only given in the hospital setting under close supervision (Ranadive and Rosenthal, 2009).

Nursing Care Management

The recognition of SIADH symptoms is the primary nursing goal. Close attention to measurements of intake and output, weight, and monitoring for the development of neurologic symptoms is essential, especially in patients at risk in the intensive care setting.

QUALITY PATIENT OUTCOMES

Syndrome of Inappropriate Antidiuretic Hormone

- Early recognition of signs and symptoms of SIADH
- Fluid overload prevented
- Seizures prevented

! NURSING ALERT

Nausea, vomiting, and malaise may precede the onset of more severe stages such as disorientation, confusion, coma, and seizures (Majzoub and Muglia, 2003).

Seizure precautions are implemented in children at high risk for SIADH. The child and family need education and support regarding the rationale for fluid restrictions. The rare child with chronic SIADH is placed on long-term ADH-antagonizing medication. The patient and family will need instruction regarding medication administration.

DISORDERS OF THYROID FUNCTION

The thyroid gland secretes two types of hormones: thyroid hormone (TH) and calcitonin. TH is made up of the hormones thyroxine (T_4) and triiodothyronine (T_3). The anterior pituitary hormone TSH controls the secretion of TH. Thyroid-stimulating hormone (TSH) is regulated by the hypothalamic hormone thyrotropin-releasing factor (TRF) as a negative feedback response. Hypothyroidism or hyperthyroidism may result from a defect in the thyroid or from a disturbance in the secretion of TSH or TRF. Because the functions of T_3 and T_4 are qualitatively the same, the term *thyroid hormone* (TH) is used throughout the discussion (Box 33-7).

The synthesis of TH depends on available sources of dietary iodine and tyrosine. The thyroid is the only endocrine gland capable of storing excess amounts of hormones for release. During circulation T_4 and T_3 are bound to carrier proteins (thyroxine-binding globulin). They must be unbound before they are able to exert their metabolic effect.

The main physiologic action of TH is to regulate metabolism and control the processes of growth and tissue differentiation,

BOX 33-7 PHYSIOLOGIC EFFECTS OF THYROID HORMONE

- Regulates metabolic rate of all cells; protein, fat, and carbohydrate catabolism; and nitrogen excretion
- Regulates body heat production and heat-dissipating mechanisms
- Regulates protein synthesis and catabolism, amino acid incorporation into protein, and transcription of messenger ribonucleic acid
- Increases gluconeogenesis and peripheral utilization of glucose
- Maintains appetite and secretion of gastrointestinal substances
- Maintains calcium mobilization
- Stimulates cholesterol synthesis and hepatic mechanisms that remove cholesterol from the circulation; stimulates lipid turnover and free fatty acid release
- Regulates hepatic conversion of carotene to vitamin A
- Maintains growth hormone secretion, skeletal maturation, and tissue differentiation
- Is necessary for muscle tone and vigor and normal skin constituents
- Maintains cardiac rate, force, and output
- Affects respiratory rate, depth of oxygen utilization, and carbon dioxide formation
- Affects central nervous system development and cerebration during first 2 to 3 years
- Affects milk production during lactation and menstrual cycle fertility
- Maintains sensitivity to insulin and insulin degradation
- Affects red cell production
- Affects cortisol secretion, probably by directly affecting the adrenal glands and by increasing adrenocorticotropic hormone secretion

as outlined in Box 33-7. Unlike GH, TH is involved in many more diverse activities that influence the growth and development of body tissues. Therefore, a deficiency of TH exerts a more profound effect on growth than that seen in GH deficiency.

Calcitonin helps maintain blood calcium levels by decreasing the calcium concentration. It inhibits skeletal demineralization and promotes calcium deposition in the bone. This effect is the opposite of parathyroid hormone (PTH).

JUVENILE HYPOTHYROIDISM

Hypothyroidism is one of the most common endocrine problems of childhood. It may be either congenital (see Chapter 8) or acquired and represents a deficiency in secretion of TH (Foley, 2001). Hypothyroidism from dietary insufficiency of iodine is now rare in the United States, since iodized salt is a readily available source of the nutrient.

Beyond infancy, a number of defects may cause primary hypothyroidism. For example, a congenital hypoplastic thyroid gland may provide sufficient amounts of TH during the first year or two but be inadequate when rapid body growth increases demands on the gland. A partial or complete thyroidectomy for cancer or thyrotoxicosis can leave insufficient thyroid tissue to furnish hormones for body requirements. Radiotherapy for Hodgkin disease or other malignancies may lead to hypothyroidism (Hudson, Krasin, Metzger, et al, 2011). Infectious processes may cause hypothyroidism. It can also occur when dietary iodine is deficient.

Low levels of circulating thyroid hormones and raised levels of TSH at birth characterize congenital hypothyroidism. If left untreated, congenital hypothyroidism causes mental retardation. Improvements in newborn screening have led to earlier detection and prevention of cognitive dysfunction (American Academy of Pediatrics, Rose, Section on Endocrinology and Committee on Genetics of the American Thyroid Association, et al, 2006; Nebesio, McKenna, Nabhan, et al, 2010).

Thyromegaly (enlarged thyroid gland) and growth deceleration are seen in children with hypothyroidism. Growth and development are less impaired when hypothyroidism is acquired at a later age. Because brain growth is nearly complete by 2 to 3 years of age, intellectual disability and neurologic sequelae are not associated with juvenile hypothyroidism. Clinical manifestations may include dry skin, puffiness around the eyes, sparse hair, constipation, sleepiness, lethargy, and mental decline. Growth failure, delayed puberty, and excessive weight gain can also be seen.

Therapy is TH replacement, the same as for hypothyroidism in the infant. In children with severe symptoms, the restoration thyroid function is achieved more gradually with administration of increasing amounts of L-thyroxine over a period of 4 to 8 weeks. This is done to avoid symptoms of hyperthyroidism. Researchers have found that children treated early continue to have mild delays in reading, comprehension, and arithmetic but should catch up over time (Rovet and Ehrlich, 2000). Adolescents may demonstrate problems with memory, attention, and visuospatial processing.

Nursing Care Management

The importance of early recognition of congenital hypothyroidism in the infant is discussed in Chapter 8. Growth deceleration in a child whose growth has previously been normal should alert the observer to the possibility of hypothyroidism. Treatment is daily oral TH replacement. The importance of daily compliance and the need for periodic monitoring of serum thyroid levels should be stressed to patients and their families.

GOITER

A goiter is an enlargement or hypertrophy of the thyroid gland. It may occur with deficient (hypothyroid), excessive (hyperthyroid), or normal (euthyroid) TH secretion. It can be congenital or acquired. Congenital disease usually occurs as a result of maternal administration of antithyroid drugs or iodides during pregnancy. Acquired disease can result from increased secretion of pituitary TSH in response to decreased circulating levels of TH or from infiltrative neoplastic or inflammatory processes. In areas where dietary iodine (essential for TH production) is deficient, goiter can be endemic.

Enlargement of the thyroid gland may be mild and noticeable only when there is an increased demand for TH (e.g., during periods of rapid growth). Where iodine deficiency is severe, a large percentage of the population display goiters. Enlargement of the thyroid at birth can be sufficient to cause severe respiratory distress. Sporadic goiter is usually caused by

lymphocytic thyroiditis, and intrinsic biochemical defects in synthesis of the hormones are associated with goiters. TH replacement is necessary to treat the hypothyroidism and reverse the TSH effect on the gland.

Nursing Care Management

Large goiters are identified by their obvious appearance. Smaller nodules may be evident only on palpation. Nurses in ambulatory settings need to be aware of the possibility of goiters and report such findings. Benign enlargement of the thyroid gland may occur during adolescence and should not be confused with pathologic states. Nodules are rarely caused by a cancerous tumor but always require evaluation. Include questions regarding exposure to radiation in the assessment.

! NURSING ALERT

If an infant is born with a goiter, immediately begin precautions for emergency ventilation, such as having supplemental oxygen and a tracheostomy set nearby. Hyperextension of the neck often facilitates breathing.

Immediate surgery to remove part of the gland may be lifesaving in infants born with a goiter. When thyroid replacement is necessary, parents have the same needs regarding its administration as discussed for the parents of children who have hypothyroidism. (See Chapter 8.)

LYMPHOCYTIC THYROIDITIS

Lymphocytic thyroiditis (Hashimoto disease, juvenile autoimmune thyroiditis) is the most common cause of thyroid disease in children and adolescents and accounts for the largest percentage of juvenile hypothyroidism (Szymborska and Staroszczyk, 2000). It accounts for many of the enlarged thyroid glands formerly designated as thyroid hyperplasia of adolescence or adolescent goiter. Although lymphocytic thyroiditis can occur during the first 3 years of life, it occurs more frequently after age 6, with peak incidence occurring during adolescence. The presence of a goiter and elevated thyroglobulin antibody with progressive increase in both thyroid peroxidase antibody and TSH may be predictive factors for future development of hypothyroidism (Radetti, Gottardi, Bona, et al, 2006).

Pathophysiology

There is a strong genetic predisposition to the development of lymphocytic thyroiditis. In families this disease is closely related to other thyroid disorders (e.g., Graves disease, idiopathic hypothyroidism, idiopathic myxedema) and autoimmune disorders (e.g., pernicious anemia, Addison disease, type 1 DM, and hypoparathyroidism).

Thyroid cell damage and death are autoimmune mediated by T cells and cytokines. Lymphocytes infiltrate the thyroid gland and cause inflammation. Eventually, thyroid cells are replaced with fibrous tissue. Several antithyroid antibodies have been recognized in patients with thyroiditis. The identification of genes involved in this disease has led to improved diagnostic testing and may lead to new treatments in the future (Brown, 2009).

Clinical Manifestations

Enlargement of the thyroid gland is often noted during routine examination. Parents may notice it when the youngster swallows. In most children the entire gland is enlarged symmetrically (but may be asymmetric) and is firm, freely movable, and nontender. There may signs of moderate tracheal compression (sense of fullness, hoarseness, and dysphagia). However, it is extremely rare for a nontoxic diffuse goiter to enlarge enough to cause tracheal compression. Most children are euthyroid, but some display symptoms of hypothyroidism. Others have signs suggestive of hyperthyroidism, such as nervousness, irritability, tachycardia, increased sweating, or hyperactivity.

Diagnostic Evaluation

Thyroid function tests are usually normal, although TSH levels may be slightly or moderately elevated. With progressive disease the T_4 decreases, followed by a decrease in T_3 levels and an increase in TSH. A variety of abnormalities in radioactive iodine uptake may be noted. The majority of children have serum antibody titers to thyroid antigens, but fewer children have a positive red blood cell hemagglutination test result. When both tests are used, almost all children with thyroid autoimmunity are detected. However, levels in children are lower than in adults; therefore, repeated measurements may be needed in doubtful cases, since titers may increase later in the disease.

Therapeutic Management

In many cases the goiter is transient and asymptomatic and regresses spontaneously within a year or two. Therapy of a nontoxic diffuse goiter is usually simple, uncomplicated, and effective. Oral administration of TH decreases the size of the gland significantly and provides the feedback needed to suppress TSH stimulation, and the hyperplastic thyroid gland gradually regresses in size. Surgery is contraindicated in this disorder. Evaluate untreated patients periodically.

Nursing Care Management

Nursing care consists of identifying the youngster with thyroid enlargement, reassuring the child that the condition is probably only temporary, and reinforcing instructions for thyroid therapy.

HYPERTHYROIDISM

Graves disease (GD) is the most common cause of hyperthyroidism in children. This disease runs in families and is autoimmune. Most cases of GD in children occur in adolescence, with a peak incidence at 12 to 14 years of age. Transient GD may be present at birth in children of thyrotoxic mothers. The incidence is higher in girls than in boys (Leger and Carel, 2013).

The hyperthyroidism of GD is caused by the generation of autoantibodies to the TSH receptor. This leads to excess secretion of TH. Currently, there is no cure for GD. Choice of treatment continues to be debated among pediatric endocrinologists due to the risk of side effects associated with each option (Leger and Carel, 2013).

Clinical Manifestations

Signs and symptoms of hyperthyroidism develop gradually, with an interval between onset and diagnosis of approximately 6 to 12 months. Clinical features include irritability, hyperactivity, short attention span, tremors, insomnia, and emotional lability. Gradual weight loss despite a voracious appetite occurs in half the cases. Linear growth and bone age are usually accelerated. Muscle weakness often occurs. Hyperactivity of the gastrointestinal tract may cause vomiting and frequent stooling. Cardiac manifestations can include rapid pulse at rest, widened pulse pressure, systolic murmur, and cardiomegaly. Dyspnea may occur during slight exertion, such as climbing stairs. The skin is warm, flushed, and moist. Heat intolerance may be severe and is accompanied by diaphoresis. The hair is unusually fine and unable to hold a wave.

Exophthalmos (protruding eyeballs), observed in many children, is accompanied by a wide-eyed staring expression, increased blinking, lid lag, lack of convergence, and absence of wrinkling of the forehead when looking upward. If exophthalmos progresses, the eyelid may not completely cover the cornea. Visual disturbances may include blurred vision and loss of visual acuity. Eye disease associated with hyperthyroidism can develop before or after the clinical diagnosis.

Diagnostic Evaluation

The diagnosis of GD is established on the basis of increased levels of T_4 and T_3. TSH is suppressed to unmeasurable levels. Other tests are rarely indicated.

Therapeutic Management

Therapy for hyperthyroidism is controversial, but the end goal is the same: to decrease circulating TH. The three available treatments for children are antithyroid drugs, subtotal thyroidectomy, and ablation with radioiodine (^{131}I iodide, RAI) (Leger and Carel, 2013; Rivkees and Cornelius, 2003; Streetman and Khanderia, 2004). Each therapy has advantages and disadvantages.

When affected children exhibit signs and symptoms of hyperthyroidism (e.g., increased weight loss, pulse pressure, and blood pressure), their activity should be limited to schoolwork only. Vigorous exercise is restricted until thyroid levels are decreased to normal or near-normal values. The American Thyroid Association* has an extensive website with information relation to prevention, treatment, and cure of thyroid disease.

Drug Therapy

Antithyroid drug (ATD) therapy with carbimazole, methimazole or propylthiouracil interfere with the biosynthesis of TH. Most centers use this as first-line treatment for hyperthyroidism. Generally, some improvement is noted within the first 2 weeks, with evidence of decreased nervousness, less fatigue, increased strength, a lowered pulse, and weight gain. In many children an initial treatment course of 1 to 2 years is followed by a complete remission of the disorder. Others require 2 to 4 years before remission is achieved (Leger and Carel, 2013).

ATD disadvantages include drug reactions (e.g., rash, hives, joint pain, nausea, vomiting) and chronic dependency on the drug. Remission is not achieved in many patients, and alternative treatments are required. The most serious side effect of ATDs is agranulocytosis (severe leukopenia), which generally occurs within the initial weeks or months of therapy. It is usually accompanied by a sore throat and fever. Treatment involves immediate discontinuation of the drug and the administration of antibiotics and glucocorticoids until symptoms resolve.

Thyroidectomy

Surgical treatment involves surgical ablation of the thyroid (thyroidectomy). Although this approach has the advantage of being a long-lasting form of therapy, it has a number of serious disadvantages. Hypothyroidism and the need for thyroxine therapy may result. Infrequently, recurrent laryngeal nerve palsy, permanent hypoparathyroidism, keloid formation, and surgical morbidity and mortality do occur. Surgery in most centers is reserved for children who fail ATD therapy or who are prone to recurrence.

Radioiodine Therapy

Radioiodine may be a therapy of choice in young patients with GD who relapse after medical treatment (Cheetham, Hughes, Barnes, et al, 1998). Low-dose RAI is administered to children to treat hyperthyroidism without resulting in hypothyroidism. The relapse rate is high in this case and may require multiple doses throughout life. RAI should be avoided in very young children due to the increased risk of cancer. More research on RAI in children is needed due to concerns over its potential long-term side effects, including thyroid cancer, hyperparathyroidism, and high mortality rates (Leger and Carel, 2013).

Thyrotoxicosis

Thyrotoxicosis (thyroid "crisis" or thyroid "storm") may occur from sudden release of TH. Although thyrotoxicosis is unusual in children, it can be life threatening. Clinical signs of thyroid storm are acute onset of severe irritability and restlessness, vomiting, diarrhea, hyperthermia, hypertension, severe tachycardia, and prostration. There may be rapid progression to delirium, coma, and death. A crisis may be precipitated by acute infection, surgical emergency, or discontinuation of antithyroid therapy. In addition to ATD therapy, the administration of beta blockers is used to control symptoms until normal thyroid function is achieved (Leger and Carel, 2013). Therapy is usually required for 2 to 3 weeks.

Nursing Care Management

Because the clinical manifestations of GD often appear gradually, the goiter and ophthalmic changes may not be noticed. Excessive activity may be attributed to behavioral problems. Nurses in ambulatory settings, particularly schools, need to be alert to signs that suggest this disorder. Weight loss despite an excellent appetite, inattention, hyperactivity, unexplained

*6066 Leesburg Pike, Suite 550, Falls Church, VA 22041; 800-THYROID, 703-998-8890; e-mail: thyroid@thyroid.org; **www.thyroid.org**.

fatigue, sleepiness, and difficulty with fine motor skills may be seen. Exophthalmos may develop long before the signs and symptoms of hyperthyroidism and may be the only presenting sign (Thompson, 2002).

Nursing care focuses on treating physical symptoms before a response to drug therapy is achieved. These children need a quiet, unstimulating environment that is conducive to rest.

QUALITY PATIENT OUTCOMES

Hyperthyroidism

- Early recognition of signs and symptoms of hyperthyroidism
- Physical symptoms managed
- Regular routine established for child during recovery period
- Adherence to antithyroid drugs as prescribed

Until hyperthyroidism is controlled, symptoms often interfere with daily life. Emotional lability is often manifested by sudden episodes of crying or elation. Such behavior, coupled with irritability, disrupts interpersonal relationships, creating difficulties within and outside the home. The nurse can help parents understand the medical reason for behavior changes and offer ways to minimize them. A consultation with the child's teachers is important to provide education and suggest ways of helping the child adjust at school.

Heat intolerance may cause a child to dress differently. The use of light cotton clothing in the home, good ventilation, air conditioning or fans, frequent baths, and adequate hydration is helpful in providing comfort. Although the need for calories is increased, these should be provided in wholesome foods rather than "junk" foods.

Nurses should know the side effects of ATD therapy, including urticarial rash, fever, arthritis, or arthralgia. There may be enlargement of the salivary and cervical lymph glands, a diminished sense of taste, hepatitis, and edema of the lower extremities. Parents should also be aware of the signs of hypothyroidism, which can occur from overdose of the drugs. The most common indications are lethargy and somnolence.

DRUG ALERT

Propylthiouracil and Methimazole

Children being treated with propylthiouricil or methimazole must be carefully monitored for side effects. Because sore throat and fever accompany the grave complication of leukopenia, these children should be examined if such symptoms occur. Parents and children should learn to recognize and report symptoms immediately.

Surgical Care

If surgery is anticipated, iodine is administered for a few weeks before the procedure. Because oral iodine preparations are unpalatable, they should be mixed with a strong-tasting fruit juice, such as grape or punch flavors, and be given through a straw. Compliance with iodine therapy is essential to avoid the danger of thyroid crisis after sudden discontinuation.

Psychologic preparation of children for thyroidectomy is similar to that for any other surgical procedure. (See Chapter 23.) However, the fear of having one's throat cut is unique to thyroidectomy. The nurse should explain that the throat is not cut, only the skin, to remove the gland. Showing children a picture of the anatomic location of the thyroid around the trachea is often helpful. Children should be prepared for the dressing around the neck and the possibility of an endotracheal or "breathing" tube after surgery.

Postoperative care involves positioning with the neck slightly flexed to avoid strain on the sutures and observation for bleeding and complications. The children learn to support the neck in this position when they sit up. Damage to the laryngeal nerve is evidenced by severe stridor or hoarseness, although some hoarseness is expected. **Laryngospasm**, a spasmodic contraction of the larynx, can be a life-threatening complication of thyroidectomy. Signs of laryngospasm are stridor, hoarseness, and a feeling of tightness in the throat. Place a tracheostomy set near the bed for emergency use. The nurse should observe for signs of hypoparathyroidism, which causes hypocalcemia, in the immediate postoperative period.

NURSING ALERT

The earliest indication of hypoparathyroidism may be anxiety and mental depression, followed by paresthesia and evidence of heightened neuromuscular excitability, such as:

Chvostek sign—Facial muscle spasm elicited by tapping the facial nerve in the region of the parotid gland

Trousseau sign—Carpal spasm elicited by pressure applied to nerves of the upper arm

Tetany—Carpopedal spasm (sharp flexion of wrist and ankle joints), muscle twitching, cramps, seizures, and stridor

DISORDERS OF PARATHYROID FUNCTION

The parathyroid glands secrete parathyroid hormone (PTH). Along with vitamin D and calcitonin, PTH regulates the homeostasis of serum calcium concentrations (Perheentupa, 2003). The effect of PTH on calcium is opposite that of calcitonin. Box 33-8 lists the principal effects of PTH on its target sites.

PTH and vitamin D work together to maintain serum calcium levels within a narrow normal range and mineralization of bone. Secretion of PTH is controlled by a negative feedback system involving the serum calcium ion concentration. Low ionized calcium levels stimulate PTH secretion, causing absorption of calcium by the target tissues; high ionized calcium concentrations suppress PTH.

BOX 33-8 PHYSIOLOGIC EFFECTS OF PARATHYROID HORMONE

Bones—Increases osteoclastic activity, causing phosphate-producing bone demineralization

Kidneys—Increases absorption of calcium and excretion of phosphate

Gastrointestinal tract—Promotes calcium absorption

HYPOPARATHYROIDISM

Hypoparathyroidism is a spectrum of disorders that result in deficient PTH. Congenital hypoparathyroidism may be caused by a specific defect in the synthesis or cellular processing of PTH or by aplasia or hypoplasia of the gland (Perheentupa, 2003).

Hypoparathyroidism can occur secondary to other causes. Postoperative hypoparathyroidism may follow thyroidectomy with acute or gradual onset. It may be transient or permanent. Two forms of transient hypoparathyroidism may be present in the newborn, both of which are the result of a relative PTH deficiency. One type is caused by maternal hyperparathyroidism. A more common form appears almost exclusively in infants fed a milk formula with a high phosphate-to-calcium ratio.

Clinical Manifestations

Symptoms vary from none to significant morbidity if treatment is not initiated. Mild deficiency may be identified through laboratory studies. Muscle cramps are an early symptom, progressing to numbness, stiffness, and tingling in the hands and feet. A positive Chvostek or Trousseau sign or laryngeal spasms may be present. Convulsions with loss of consciousness may occur. These episodes may be preceded by abdominal discomfort, tonic rigidity, head retraction, and cyanosis. Headaches and vomiting with increased intracranial pressure and papilledema may occur and may suggest a brain tumor (Kliegman, Stanton, St. Geme, et al, 2011).

Children with long-standing hypoparathyroidism may have dry, scaly, coarse skin with eruptions often caused by *Candida* organisms (Kliegman, Stanton, St. Geme, et al, 2011). Dental and enamel hypoplasia often occurs. Cataracts develop in patients with untreated disease. Because hypoparathyroidism results in decreased bone resorption and inactive osteoclastic activity, skeletal remodeling and bone turnover are diminished. This may be the pathophysiology of poor growth that is associated with hypoparathyroidism in children (Waller, 2011).

Diagnostic Evaluation

The diagnosis of hypoparathyroidism is made on the basis of clinical manifestations associated with decreased serum calcium and increased serum phosphorus. Levels of plasma PTH are low in idiopathic hypoparathyroidism but high in pseudohypoparathyroidism. End-organ responsiveness is tested by the administration of PTH with measurement of urinary cyclic adenosine monophosphate. Kidney function tests are included in the differential diagnosis to rule out kidney disease. Although bone radiographs are usually normal, they may demonstrate increased bone density and suppressed growth.

Therapeutic Management

The objective of treatment is to maintain normal serum calcium and phosphate levels with minimum complications. Acute or severe tetany is corrected immediately by IV and oral administration of calcium gluconate and follow-up doses as necessary to achieve normal calcium levels. When diagnosis is confirmed, vitamin D therapy is begun. Vitamin D therapy is somewhat difficult to regulate because the drug has a prolonged onset and a long half-life. Some authorities advocate beginning with a lower dose with stepwise increases and careful monitoring of serum calcium until stable levels are achieved. Others prefer rapid induction with higher doses and rapid reduction to lower maintenance levels.

Long-term management administration of massive doses of vitamin D and oral calcium may be useful in maintaining adequate serum calcium levels. Blood calcium and phosphorus are monitored frequently until the levels have stabilized; they are then monitored monthly and less often until the child is seen at 6-month intervals. Renal function, blood pressure, and serum vitamin D levels are measured every 6 months. Serum magnesium levels are measured every 3 to 6 months to permit detection of hypomagnesemia, which may raise the requirement for vitamin D.

Nursing Care Management

The initial objective is recognition of hypocalcemia. Unexplained convulsions, irritability (especially to external stimuli), gastrointestinal symptoms (e.g., diarrhea, vomiting, cramping), and positive signs of tetany should lead the nurse to suspect this disorder. Initial nursing care includes institution of seizure and safety precautions and observation for signs of laryngospasm such as stridor, hoarseness, and a feeling of tightness in the throat. A tracheostomy set and injectable calcium gluconate should be located near the bedside for emergency use. The administration of calcium gluconate requires precautions against extravasation of the drug.

After initiation of treatment, the nurse discusses with the parents the need for continuous daily administration of calcium salts and vitamin D. Because vitamin D toxicity can be a serious consequence of therapy, parents should watch for signs that include weakness, fatigue, lassitude, headache, nausea, vomiting, and diarrhea. Polyuria, polydipsia, and nocturia are signs of early renal impairment.

HYPERPARATHYROIDISM

Hyperparathyroidism is rare in childhood but can be primary or secondary. The most common cause of primary hyperparathyroidism is adenoma of the gland (Kliegman, Stanton, St. Geme, et al, 2011). Primary hyperparathyroidism is rarely seen in children, but when it occurs, it is often due to a single parathyroid adenoma (Lietman, Germain-Lee, and Levine, 2010). The most common causes of secondary hyperparathyroidism are chronic renal disease, renal osteodystrophy, and congenital anomalies of the urinary tract. The common symptom of hyperparathyroidism is hypercalcemia. Box 33-9 lists the manifestations of hyperparathyroidism.

Diagnostic Evaluation

Blood studies to identify elevated calcium and decreased phosphorus levels are routinely performed. Measurement of PTH, as well as several tests to isolate the cause of the hypercalcemia, such as renal function studies, should be included. If parathyroid adenoma is suspected, imaging using ultrasound and a sestamibi nuclear substraction study are recommended (Igbal

BOX 33-9 CLINICAL MANIFESTATIONS OF HYPERPARATHYROIDISM

Gastrointestinal—Nausea, vomiting, abdominal discomfort, and constipation
Central nervous system—Delusions, confusion, hallucinations, impaired memory, lack of interest and initiative, depression, and varying levels of consciousness
Neuromuscular—Weakness, easy fatigability, muscle atrophy (especially proximal muscles of the lower limbs), twitching of the tongue, and paresthesias in extremities
Skeletal—Vague bone pain, subperiosteal resorption of phalanges, spontaneous fractures, and absence of lamina dura around the teeth
Renal—Polyuria and polydipsia, renal colic, and hypertension

BOX 33-10 PHYSIOLOGIC EFFECTS OF GLUCOCORTICOIDS

- Stimulation of gluconeogenesis by the liver (a hyperglycemic effect)
- Increased protein catabolism with resulting reduction in protein stores (except in the liver)
- Increased mobilization and utilization of fatty acids for energy
- Increased storage of adipose tissue in certain sites
- Decreased inflammatory and allergic reactions
- Regulation of fluid and electrolytes by promoting sodium retention and potassium excretion by the kidneys and by water diuresis through direct antagonistic action against antidiuretic hormone
- Increased gastric acid and pepsin production
- Suppression of lymphocytes, eosinophils, and basophils, but elevation of neutrophils, erythrocytes, and thrombocytes

and Wahoff, 2009). Other procedures used to substantiate the physiologic consequences of the disorder include electrocardiography and radiographic bone surveys.

Therapeutic Management

Treatment depends on the cause of hyperparathyroidism. The treatment of primary hyperparathyroidism is surgical removal of the tumor or hyperplastic tissue (Lietman, Germain-Lee, and Levine, 2010). Parathyroidectomy may cause recurrent laryngeal nerve damage, voice impairment, hypoparathyroidism, hypocalcemia, and tetany (Wang, Roman, and Sosa, 2008). Treatment of secondary hyperparathyroidism is directed at the underlying contributing cause, which subsequently restores the serum calcium balance. However, in some instances, such as in chronic renal failure, the underlying disorder is irreversible. In this case treatment is aimed at raising serum calcium levels to inhibit the stimulatory effect of low levels on the parathyroids. This includes oral administration of calcium salts, high doses of vitamin D to enhance calcium absorption, a low-phosphorus diet, and administration of a phosphorus-mobilizing aluminum hydroxide to reduce phosphate absorption.

Nursing Care Management

The initial nursing objective is recognition of hyperparathyroidism. Because secondary hyperparathyroidism is a consequence of chronic renal failure, the nurse is always alert to signs that suggest this complication, especially bone pain and fractures. Because urinary symptoms are the earliest indication, assessment of other body systems for evidence of high calcium levels is indicated when polyuria and polydipsia coexist. Clues to the possibility of hyperparathyroidism include change in behavior, especially inactivity; unexplained gastrointestinal symptoms; and cardiac irregularities.

Much of the initial nursing care is related to the physical symptoms and prevention of complications. To minimize renal calculi formation, hydration is essential. Encourage the child to drink fruit juices that maintain a low urinary pH, such as cranberry or apple juice, since acidity of body fluids promotes calcium absorption. All urine should be strained for evidence of renal casts. Children with renal rickets (osteodystrophy) may wear braces to minimize skeletal deformities. These should be worn as prescribed. If the child is confined to bed, the nurse should consult with the physical therapist regarding proper use of orthopedic appliances.

Vital signs should be taken frequently, and the pulse should be counted for 1 full minute to detect irregularities. Report a decrease in pulse rate, since it may signal severe bradycardia and cardiac arrest. The diet needs supervision to ensure compliance with low-phosphate foods, particularly dairy products.

If parathyroidectomy is anticipated, care is similar to that discussed for the child with hyperthyroidism. Because hypocalcemia is a potential complication, observing for signs of tetany, instituting seizure precautions, and having calcium gluconate available for emergency use are part of the nursing care.

DISORDERS OF ADRENAL FUNCTION

ADRENAL HORMONES

The adrenal glands consist of two distinct portions: the cortex, or outer section, and the medulla, or inner core. The adrenal cortex secretes hormones, called steroids, that are essential to life. The adrenal medulla, the inner core, produces the catecholamines epinephrine and norepinephrine. These three chemicals are also produced by the sympathetic nervous system, so if the adrenal supply fails, the body will continue to function.

Adrenal Cortex

The cortex secretes three groups of hormones that are classified according to their biologic activity: (1) glucocorticoids (cortisol, corticosterone), (2) mineralocorticoids (aldosterone), and (3) sex steroids (androgens, estrogens, and progestins). The glucocorticoids and mineralocorticoids influence metabolic regulation and stress adaptation. The sex steroids influence sexual development but are not essential because the gonads secrete the major supply of these hormones.

Glucocorticoids

The most important glucocorticoids in humans are cortisol and corticosterone, the principal effects of which are listed in Box 33-10. Normally the hypothalamus secretes CRF, which causes

the pituitary gland to produce ACTH, which stimulates the adrenal glands to produce glucocorticoids (primarily cortisol). The switch that controls this feedback is cortisol. When blood levels of cortisol are low, the system turns on. When blood levels of cortisol rise, the system turns off.

In times of stress the anterior pituitary is stimulated by CRF from the hypothalamus, which causes the release of increased amounts of ACTH. Stressful stimuli capable of provoking this response include trauma; anesthesia; surgical intervention; sepsis; acute anoxia; hypothermia; hypoglycemia; and emotional states, especially panic, anxiety, or anger.

Body rhythms also regulate secretion of the glucocorticoids. Blood levels of cortisol demonstrate a typical diurnal or circadian pattern. In individuals who follow a regular routine of nighttime sleeping, cortisol levels are highest in the early morning hours after arising and lowest in the evening hours before bedtime.

Mineralocorticoids

The most important mineralocorticoid is aldosterone. Like cortisol, it promotes sodium retention and potassium excretion in the renal tubules. Aldosterone is significantly more potent than that of the glucocorticoids in maintaining extracellular fluid volume, acid-base balance, and normal potassium levels.

Aldosterone synthesis is regulated primarily by the renin-angiotensin system of the kidney. A block in aldosterone synthesis causes high plasma renin activity levels (Huether, 2000). The juxtaglomerular cells of the kidney respond to decreased arterial pressure or blood volume and to decreased sodium concentrations by secreting the enzyme renin into the blood. Renin in turn converts angiotensinogen to angiotensin I and then to angiotensin II. Increased levels of angiotensin stimulate the adrenal cortex to secrete aldosterone, which preserves sodium, thereby retaining water. The renin-angiotensin mechanism also results in increased blood pressure.

Sex Steroids

Except for the first few days of life, the sex hormones are normally secreted in only minimum amounts until adolescence, at which time they play a role in pubertal changes. Their actions are the same as those of the gonadal hormones on internal and external sexual structures and skeletal growth.

Adrenal Medulla

The adrenal medulla secretes the catecholamines epinephrine and norepinephrine. Both hormones have essentially the same effects on different organs as those caused by direct sympathetic stimulation, except the hormonal effects last several times longer. Their major actions are listed in Box 33-11.

Although the catecholamines evoke similar responses from target sites, there are some important differences. Epinephrine has a greater effect on cardiac activity than norepinephrine, but it causes only weak constriction of the blood vessels of muscles in comparison with the effect of norepinephrine. As a result, norepinephrine elevates blood pressure, whereas epinephrine increases cardiac output. Another important difference is their effect on metabolism. Epinephrine increases the metabolic rate to a much greater extent than norepinephrine. These differences in action have been attributed to the catecholamines' effects on α- or β-adrenergic receptors. Supposedly norepinephrine can only affect those effector cells that contain α-receptors, which are mostly excitatory (constriction and contraction). Epinephrine, however, can affect both α- and β-receptors, and β-receptors are mostly inhibitory (dilation and relaxation). Control of secretion of catecholamines, primarily in response to physiologic or emotional stress, is through the hypothalamus. Also, stimulation of the sympathetic nervous system results in the release of epinephrine and norepinephrine from the sympathetic nerves and adrenal medulla. Both systems support each other, and one can be substituted for the other. For this reason no condition is attributable to hypofunction of the adrenal medulla. Even in bilateral adrenalectomy, catecholamine replacement is not necessary because the sympathetic release of these chemicals is sufficient to meet all the physiologic functions required to cope with stressful events.

BOX 33-11 PHYSIOLOGIC EFFECTS OF CATECHOLAMINE SECRETION

- Increased cardiac activity
- Vasoconstriction of blood vessels (elevation of blood pressure)
- Increased rate and depth of respirations
- Bronchial dilation
- Inhibition of gastrointestinal activity
- Increased muscular contraction
- Pupillary dilation
- Increased metabolic rate
- Heightened sensory awareness
- Diaphoresis

Catecholamine-secreting tumors are the primary cause of adrenal medullary hyperfunction. In children the most common neoplasms of this type are pheochromocytoma (see p. 1518), neuroblastoma, and ganglioneuroma. Ganglioneuromas are neuroblastomas that have undergone maturation into a benign tumor composed of ganglion cells. These tumors are associated with less abnormal catecholamine secretion than the other two types, but persons with ganglioneuromas may have a clinical picture of chronic diarrhea, failure to thrive, skin rash, hypokalemia, persistent cough, and abdominal distention. The exact reason for these symptoms is unknown, although they are attributable to the tumor because they disappear after surgical removal of the mass.

ACUTE ADRENOCORTICAL INSUFFICIENCY

The acute form of adrenocortical insufficiency (adrenal crisis) may have a number of causes during childhood. Although a rare disorder, some of the more common etiologic factors include hemorrhage into the gland from trauma, which may be caused by a prolonged, difficult labor and rapidly progressing infections, such as meningococcemia, which result in hemorrhage and necrosis (Waterhouse-Friderichsen syndrome). Abrupt

withdrawal of exogenous sources of cortisone or failure to increase endogenous supplies during stressor congenital adrenogenital hyperplasia of the salt-losing type can also cause adrenal crisis.

Clinical Manifestations

Early symptoms of adrenocortical insufficiency include increased irritability, headache, diffuse abdominal pain, weakness, nausea and vomiting, and diarrhea. Generalized hemorrhagic manifestations are present in Waterhouse-Friderichsen syndrome. Abnormal serum electrolyte levels include hyponatremia and hyperkalemia. Fever increases as the condition worsens and is accompanied by signs of CNS involvement, such as nuchal rigidity, convulsions, stupor, and coma. The child is in a shocklike state with a weak, rapid pulse; decreased blood pressure; shallow respirations; cold, clammy skin; and cyanosis. Circulatory collapse is the terminal event.

In the newborn, adrenal crisis is accompanied by extreme hyperpyrexia (high temperature), tachypnea, cyanosis, and seizures. Usually there is no evidence of infection or purpura. However, hemorrhage into the adrenal gland may be evident as a palpable retroperitoneal mass.

Diagnostic Evaluation

There is no rapid, definitive test for confirmation of acute adrenocortical insufficiency. Samples for measurement of plasma cortisol and ACTH levels should be sent for analysis, but this is too time consuming to be practical for initial diagnosis. Therefore, diagnosis is usually made based on clinical presentation, especially when hemorrhagic manifestations and signs of circulatory collapse despite adequate antibiotic therapy accompany a fulminating sepsis. Serum electrolytes can be helpful in narrowing the diagnosis as well. Because there is no real danger in administering a cortisol preparation for a short period, it is important to institute treatment immediately. Improvement with cortisol therapy confirms the diagnosis.

Therapeutic Management

Treatment involves replacement of cortisol, replacement of body fluids to combat dehydration and hypovolemia, administration of glucose solutions to correct hypoglycemia, and specific antibiotic therapy in the presence of infection. Initially IV hydrocortisone (Solu-Cortef) is administered as a bolus, followed by a continuous infusion for 24 hours. Normal saline containing 5% glucose with no potassium is given parenterally to replace lost fluid, electrolytes, and glucose. Persistent hyperkalemia that is associated with electrocardiographic changes may require the use of insulin and glucose or Kayexalate to reduce the potassium levels. If hemorrhage has been severe, whole blood may be replaced. In the event that these measures do not reverse the circulatory collapse, vasopressors are used for immediate vasoconstriction and elevation of blood pressure.

Once the child's condition is stabilized, oral doses of cortisone, fluids, and salt are given, similar to the regimen used for chronic adrenal insufficiency. To maintain sodium retention, synthetic salt-retaining steroids replace aldosterone.

Nursing Care Management

Because of the abrupt onset and potentially fatal outcome of this condition, prompt recognition is essential. Vital signs and blood pressure are taken every 15 minutes to monitor the hyperpyrexia and shocklike state. Seizure precautions are instituted, since convulsions from the elevated temperature are not uncommon. As soon as therapy is instituted, the nurse should monitor the child's response to fluid and cortisol replacement. Too-rapid administration of fluids can precipitate cardiac failure, whereas overdosage with cortisol produces hypotension and a sudden fall in temperature.

QUALITY PATIENT OUTCOMES

Acute Adrenocortical Insufficiency

- Early recognition of signs and symptoms of acute adrenal crisis
- Hypokalemia or hyperkalemia prevented
- Fluid balance maintained
- Sufficient cortisol replacement

The nurse should regulate IV infusions carefully to guard against too-rapid administration of drugs. The nurse should also record intake and urinary output and monitor electrolytes frequently.

Once the acute phase is over and the hypovolemia is corrected, give the child oral fluids, such as small quantities of ginger ale, fruit juice, or ice pops. Too-rapid ingestion of oral fluids may induce vomiting, which increases dehydration. Therefore, the nurse should plan a gradual schedule for reintroducing liquids. For children who refuse to drink, the prospect of having the IV infusion removed once oral fluids are increased is often a motivating factor.

! NURSING ALERT

Monitor serum electrolyte levels and observe for signs of hypokalemia or hyperkalemia (e.g., weakness, poor muscle control, paralysis, cardiac dysrhythmias, and apnea). The condition is rapidly corrected with IV or oral potassium replacement.

DRUG ALERT

Oral Potassium

When an oral potassium preparation is given, mix it with a small amount of strongly flavored fruit juice to disguise its bitter taste.

The sudden, severe nature of this disorder necessitates a great deal of emotional support for the child and family. The child may be placed in an intensive care unit where the surroundings are strange and frightening. Despite the need for emergency intervention, the nurse must be sensitive to the family's psychologic needs and prepare them for each procedure, even if this is as brief as a statement such as "The IV infusion is necessary to replace fluid that the child is losing." Because recovery within 24 hours is often dramatic, the nurse should keep the parents apprised of the child's condition, emphasizing signs of

improvement, such as a lowered temperature and normal blood pressure.

If treatment needs to be continued past the acute stage, parents require the same preparation as in the case of children with chronic adrenal insufficiency. Preparation for discharge should begin as soon as possible after the child's condition has stabilized.

CHRONIC ADRENOCORTICAL INSUFFICIENCY (ADDISON DISEASE)

Chronic adrenocortical insufficiency is rare in children. Causes include infections (e.g., fungal, human immunodeficiency virus, tuberculosis), destructive lesions of the adrenal gland or neoplasms, and autoimmune processes, or the cause is idiopathic. At one time, generalized tuberculosis was the leading cause of adrenal gland destruction.

Evidence of this disorder is usually gradual in onset, since 90% of adrenal tissue must be nonfunctional before signs of insufficiency are manifested. However, during periods of stress, when demands for additional cortisol are increased, symptoms of acute insufficiency may appear in a previously well child (Table 33-1).

TABLE 33-1 CLINICAL MANIFESTATIONS OF ADRENOCORTICAL INSUFFICIENCY

SIGNS AND SYMPTOMS	CLINICAL MANIFESTATIONS
Glucocorticoid	
Fasting hypoglycemia	Headache, diaphoresis, weakness, trembling, hunger, seizures (rare)
Decreased gastric acidity	Anorexia, nausea, vomiting
Fatigue	Increased sleeping, listlessness
Psychologic symptoms	Irritability, apathy, negativism
Mineralocorticoid	
Muscle weakness	Generalized weakness that is aggravated by slight additional exertion or minor illness
Weight loss	Dehydration and anorexia
Fatigue	Increased sleeping, listlessness
Gastrointestinal symptoms	Nausea, vomiting, anorexia
Nutritional symptoms	Salt craving
Circulatory symptoms	Hypotension, small heart size, syncope (fainting), dizziness
Electrolyte imbalances	Hyperkalemia, hyponatremia, acidosis
Psychologic symptoms	Irritability, apathy, negativism
Androgen Deficiency (Older Children and Adults)	
Integumentary changes	Decreased pubic and axillary hair
Psychologic symptoms	Decreased libido
Increased ACTH and β-Lipotropin	
Dermatologic changes	Hyperpigmentation (elbow, knees, waist), pigmentary changes of previous scars, palmar creases

ACTH, Adrenocorticotropic hormone.

The initial step in the laboratory diagnosis of adrenal insufficiency is measurement of a fasting serum cortisol and ACTH in the early morning. An ACTH stimulation test can confirm the diagnosis. The cortisol and urinary 17-hydroxycorticosteroid levels are low and fail to rise, whereas plasma ACTH levels are elevated with corticotropin (ACTH) stimulation, the definitive test for the disease.

Therapeutic Management

Treatment involves replacement of glucocorticoids (cortisol) and mineralocorticoids (aldosterone). Some children are able to be maintained solely on oral supplements of cortisol (cortisone or hydrocortisone preparations) with a liberal intake of salt. During stressful situations, such as fever, infection, emotional upset, or surgery, the dosage must be tripled to accommodate the body's increased need for glucocorticoids. Failure to meet this requirement will precipitate an acute crisis. Overdosage produces appearance of cushingoid signs (Fig. 33-4).

Children with more severe states of chronic adrenal insufficiency require mineralocorticoid replacement to maintain fluid and electrolyte balance. Other forms of therapy include monthly injections of desoxycorticosterone acetate or implantation of desoxycorticosterone acetate pellets subcutaneously every 9 to 12 months.

FIG. 33-4 A, Boy before development of Cushing syndrome. **B,** Same boy 4 months after onset of Cushing syndrome. (From Zitelli BJ, Davis HW: *Atlas of pediatric physical diagnosis*, ed 5, St. Louis, 2007, Mosby.)

Nursing Care Management

Once the disorder is diagnosed, parents need guidance concerning drug therapy. They must be aware of the continuous need for cortisol replacement. Sudden termination of the drug because of inadequate supplies or inability to ingest the oral form because of vomiting places the child in danger of an acute adrenal crisis. Therefore, parents should always have a spare supply of the medication in the home. Ideally they will have a prefilled syringe of hydrocortisone and be instructed in proper technique for intramuscular administration of the drug in case of crisis. Unnecessary administration of cortisone will not harm the child, but if it is needed, it may be lifesaving. Report any evidence of acute insufficiency to the practitioner immediately.

Parents also need to be aware of side effects of the drugs. Undesirable side effects of cortisone include gastric irritation, which is minimized by ingestion with food or the use of an antacid; increased excitability and sleeplessness; weight gain that may require dietary management to prevent obesity; and, rarely, behavioral changes, including depression or euphoria. Parents should be aware of signs of overdose and report these to the practitioner. In addition, the drug has a bitter taste, which creates a challenge for nurses and parents in its administration.

NURSING TIP Taste a drop of the different preparations of cortisone; some are less bitter than others. Although using the concentrated form means a smaller volume of liquid to ingest, this form is also the most bitter.

DRUG ALERT

Mineralocorticoids

The side effects of mineralocorticoids are primarily caused by overdosage and include generalized edema, which is first noticed around the eyes; hypertension, which may cause headaches; cardiac arrhythmias; and signs of hypokalemia. Evaluate the child periodically for evidence of excessive medication. Emphasizing the importance of routine follow-up care is a significant nursing responsibility.

Because the body cannot supply endogenous sources of cortical hormones during times of stress, the home environment should be stable and relatively unstressful. Parents need to be aware that during periods of emotional or physical crisis the child requires additional hormone replacement. The child should wear medical identification, such as a bracelet, to permit medical personnel to adjust requirements during emergency care.

CUSHING SYNDROME

Cushing syndrome is a characteristic group of manifestations caused by excessive circulating free cortisol. It can result from a variety of causes, which generally fall into one of five categories (Box 33-12 and Table 33-2). Cushing syndrome in young children may be due to an adrenal tumor (Moshang, 2003).

BOX 33-12 ETIOLOGY OF CUSHING SYNDROME

- **Pituitary**—Cushing syndrome with adrenal hyperplasia, usually attributed to an excess of adrenocorticotropic hormone (ACTH)
- **Adrenal**—Cushing syndrome with oversecretion of glucocorticoids, generally the result of adrenocortical neoplasms
- **Ectopic**—Cushing syndrome with autonomous secretion of ACTH, most often caused by extrapituitary neoplasms
- **Iatrogenic**—Frequently the result of administration of large amounts of exogenous corticosteroids
- **Food dependent**—Inappropriate sensitivity of adrenal glands to normal postprandial increases in secretion of gastric inhibitory polypeptide

Cushing syndrome is uncommon in children. When seen, it is often caused by excessive or prolonged steroid therapy that produces a cushingoid appearance (see Fig. 33-4). This condition is reversible once the steroids are gradually discontinued. Abrupt withdrawal precipitates acute adrenal insufficiency. Gradual withdrawal of exogenous supplies is necessary to allow the anterior pituitary an opportunity to secrete increasing amounts of ACTH to stimulate the adrenals to produce cortisol.

Clinical Manifestations

Because the actions of cortisol are widespread, clinical manifestations are equally profound and diverse (see Table 33-2). Those symptoms that produce changes in physical appearance occur early in the disorder and are of considerable concern to school-age and older children (Fig. 33-5). The physiologic disturbances, such as hyperglycemia, susceptibility to infection, hypertension, and hypokalemia, may have life-threatening consequences unless recognized early and treated successfully. Children with short stature may be responding to increased cortisol levels, resulting in Cushing syndrome. Cortisol inhibits the action of GH.

Diagnostic Evaluation

Several tests are helpful in confirming Cushing syndrome. Serum cortisol levels should be measured at midnight and in the morning, along with corticotropin hormone, urinary free cortisol, fasting blood glucose levels for hyperglycemia, serum electrolyte levels for hypokalemia and alkalosis, and 24-hour urinary levels of elevated 17-hydroxycorticoids and 17-ketosteroids. Imaging of the pituitary and adrenal glands to assess for tumors, bone density studies for evidence of osteoporosis, and skull x-rays examination to determine enlargement of the sella turcica may also aid in the diagnosis. Another procedure used to establish a more definitive diagnosis is the dexamethasone (cortisone) suppression test (Batista, Riar, Keil, et al, 2007). Administration of an exogenous supply of cortisone normally suppresses ACTH production. However, in individuals with Cushing syndrome, cortisol levels remain elevated. This test is helpful in differentiating between children who are obese and those who appear to have cushingoid features.

TABLE 33-2 CLINICAL MANIFESTATIONS OF CUSHING SYNDROME

SIGNS AND SYMPTOMS	PHYSIOLOGIC CAUSE
Centripetal fat distribution	Increased appetite and deposition of fat
Truncal obesity	
Supraclavicular fat pads	
Fat pads on neck and back (buffalo hump)	
Rounded or "moon" face	
Muscular wasting	Increased protein catabolism resulting in negative nitrogen balance
Thin extremities	
Pendulous abdomen	
Muscle weakness	
Thin skin and subcutaneous tissue	
Poor wound healing	
Increased frequency of infection	Decreased production and circulating levels of antibodies by lysis of fixed plasma cells and lymphocytes
Decreased inflammatory response	
Excessive bruising	Capillary weakness resulting from loss of protein
Petechial hemorrhages	
Facial plethora ("red cheeks")	Thin skin that allows capillary blood to be visible; increased color from polycythemia
Reddish purple abdominal striae	
Hypertension—arteriosclerosis	Increased salt and water retention (hypervolemia)
Hypokalemia	Increased excretion of potassium and hydrogen ions
Alkalosis	
Osteoporosis	Increased glomerular filtration rate and excretion of calcium and decreased absorption of calcium from intestinal tract
Compression fractures of vertebrae	
Kyphosis	
Backache	
Stunted linear growth (short stature)	Increased levels of cortisol interfering with action of growth hormone
Delayed bone age	
Hypercalciuria—renal calculi	Excessive amount of calcium in urine
Psychoses	Cause unknown
Irritability	
Insomnia	
Euphoria	
Depression	
Frank psychoses	
Peptic ulcer	Increased production of hydrochloric acid and pepsin and decreased gastric mucus production
Hyperglycemia	
Glycosuria	Increased gluconeogenesis by liver and decreased rate of glucose utilization by cells
Latent or overt diabetes	Overstimulation of islets of Langerhans
Virilization	Excess production of androgens
Hirsutism (excessive body hair)	
Acne	
Deepening of voice	
Clitoral enlargement	
Tendency toward male physique in female	
Amenorrhea	
Impotence	

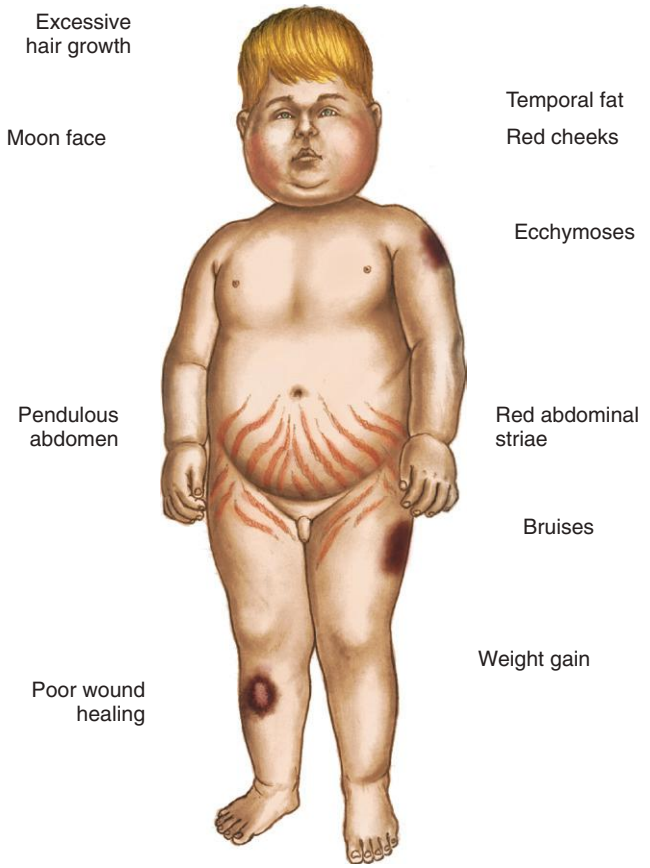

FIG. 33-5 Characteristics of Cushing syndrome.

Therapeutic Management

Treatment depends on the cause. In most cases surgical intervention involves bilateral adrenalectomy and postoperative replacement of the cortical hormones (the therapy for this is the same as that outlined for chronic adrenal insufficiency). If a pituitary tumor is found, surgical extirpation or irradiation may be chosen. In either of these instances, treatment of panhypopituitarism with replacement of GH, thyroid extract, ADH, gonadotropins, and steroids may be necessary for an indefinite period.

Nursing Care Management

Nursing care also depends on the cause. When cushingoid features are caused by steroid therapy, the effects may be lessened with administration of the drug early in the morning and on an alternate-day basis. Giving the drug early in the day maintains the normal diurnal pattern of cortisol secretion. If given during the evening, it is more likely to produce symptoms because endogenous cortisol levels are normally low and the additional supply exerts more pronounced effects. An alternate-day schedule allows the anterior pituitary an opportunity to maintain more normal hypothalamic-pituitary-adrenal control mechanisms.

If an organic cause is found, nursing care is related to the treatment regimen. Although a bilateral adrenalectomy permanently solves one condition, it reciprocally produces another syndrome. Before surgery, parents need to be adequately informed of the operative benefits and disadvantages.

Postoperative teaching regarding drug replacement is the same as discussed in the previous section.

NURSING ALERT

Postoperative complications of adrenalectomy are related to the sudden withdrawal of cortisol. Observe for shock-like symptoms (e.g., hypotension, hyperpyrexia).

Anorexia and nausea and vomiting are common and may be improved with the use of nasogastric decompression. Muscle and joint pain may be severe, requiring use of analgesics. The psychologic depression can be profound and may not improve for months. Parents should be aware of the physiologic reasons behind these symptoms in order to be supportive of the child.

CONGENITAL ADRENAL HYPERPLASIA

Congenital adrenal hyperplasia (CAH) is a family of disorders caused by decreased enzyme activity required for cortisol production in the adrenal cortex. The most common defect (accounting for over 90% of all cases) is 21-hydroxylase deficiency (Kaye and Committee on Genetics, 2006). This deficiency is an autosomal recessive disorder that results in improper steroid hormone synthesis. It occurs in approximately 1 per 12,000 to 15,000 births. In its most severe form, it can be life threatening (Glatt, Garzon, and Popovic, 2005).

Pathophysiology

Interference in the biosynthesis of cortisol during fetal life results in an increased production of ACTH, which stimulates hyperplasia of the adrenal gland. Depending on the enzymatic defect, increased quantities of cortisol precursors and androgens are secreted. There are six major types of biochemical defects. The most common is partial or complete 21-hydroxylase deficiency. With partial deficiency, enough aldosterone is produced to preserve sodium, and adequate cortisol is produced to prevent signs of adrenocortical insufficiency.

In the complete, or salt-losing, form, insufficient amounts of aldosterone and cortisol are produced. If salt-losing CAH is not diagnosed and thus not treated at birth, infants will exhibit symptoms of failure to thrive, weakness, vomiting, and dehydration, and a salt-losing crisis will ensue (Kliegman, Stanton, St. Geme, et al, 2011). In 11-hydroxylase deficiency there is an increase in the mineralocorticoid 11-desoxycorticosterone, which leads to hypertension. In each of these types excess production of androgens causes ambiguous genitalia in females and precocious genital development in males. Other forms of CAH do not result in excess production of androgens but cause various degrees of hypoaldosteronism or hyperaldosteronism.

Clinical Manifestations

Excessive androgens cause masculinization of the urogenital system at approximately the tenth week of fetal development. The most pronounced abnormalities occur in the female, who is born with varying degrees of ambiguous genitalia. Masculinization of external genitalia causes the clitoris to enlarge so that it appears as a small phallus. Fusion of the labia produces a saclike structure resembling the scrotum without testes. However, no abnormal changes occur in the internal sexual organs, although the vaginal orifice is usually closed by the fused labia. The label ***ambiguous genitalia*** should be applied to any infant with hypospadias or micropenis and no palpable gonads, and a diagnostic evaluation for CAH should be contemplated. In 2006, the term disorders of sex development was proposed to indicate congenital conditions with atypical development of chromosomal, gonadal, or anatomic sex (Lee, Houk, Ahmed, et al, 2006). Mixed gonadal dysgenesis, in which affected infantants are sex chromosome mosaics, is the second most common cause for disordered sex development. Males do not display genital abnormalities at birth (New and Ghizzoni, 2003), so it may go undetected.

Increased pigmentation of skin creases, and genitalia caused by increased ACTH may be a subtle sign of adrenal insufficiency. A salt-wasting crisis frequently occurs, usually within the first few weeks of life (Kliegman, Stanton, St. Geme, et al, 2011). Infants fail to gain weight, and hyponatremia and hyperkalemia may be significant. Cardiac arrest can occur.

Untreated CAH results in early sexual maturation, with enlargement of the external sexual organs; development of axillary, pubic, and facial hair; deepening of the voice; acne; and marked increase in musculature with changes toward an adult male physique. However, in contrast to precocious puberty, breasts do not develop in the female, and she remains amenorrheic and infertile. In the male the testes remain small, and spermatogenesis does not occur. In both sexes linear growth is accelerated, and epiphyseal closure is premature, resulting in short stature by the end of puberty.

Diagnostic Evaluation

Clinical diagnosis is initially based on congenital abnormalities that lead to difficulty in assigning sex to the newborn and on signs and symptoms of adrenal insufficiency. Newborn screening is currently done in all 50 U.S. states by measurement of the cortisol precursor 17-hydroxyprogesterone. Definitive diagnosis is confirmed by evidence of increased serum levels of 17-ketosteroid in most types of CAH (Kaye and Committee on Genetics, 2006). In complete 21-hydroxylase deficiency, blood electrolytes demonstrate loss of sodium and chloride and elevation of potassium. In older children bone age is advanced, and linear growth is increased. DNA analysis for positive sex determination and to rule out any other genetic abnormality (e.g., Turner syndrome) is done in any case of ambiguous genitalia.

Another test that can be used to visualize the presence of pelvic structures is ultrasonography, a noninvasive imaging technique that does not require anesthesia or sedation. It is especially useful in CAH because it readily identifies the presence of female reproductive organs or male testes in a newborn or child with ambiguous genitalia. Because ultrasonography yields immediate results, it has the advantage of determining the child's gender before the more complex laboratory results for chromosome analysis or steroid levels are available.

Therapeutic Management

After diagnosis is confirmed, medical management includes administration of glucocorticoids to suppress the abnormally

high secretions of ACTH and adrenal androgens (Glatt, Garzon, and Popovic, 2005). If cortisone begins early enough, it is very effective. Cortisone depresses the secretion of ACTH by the adenohypophysis, which in turn inhibits the secretion of adrenocorticosteroids, which stems the progressive virilization. The signs and symptoms of masculinization in the female gradually disappear, and excessive early linear growth is slowed. Puberty occurs normally at the appropriate age.

The recommended oral dosage is divided to simulate the normal diurnal pattern of ACTH secretion. Because these children are unable to produce cortisol in response to stress, it is necessary to increase the dosage during episodes of infection, fever, or other stresses. Acute emergencies require immediate IV or intramuscular administration. Emergency situations include bacterial and viral infections, vomiting, surgery, fractures, major injuries, and sometimes insect stings.

Children with the salt-losing type of CAH require aldosterone replacement, as outlined under chronic adrenal insufficiency, and supplementary dietary salt. Frequent laboratory tests are conducted to assess the effects on electrolytes, hormonal profiles, and renin levels. The frequency of testing is individualized to the child.

Gender assignment and surgical intervention in the newborn with ambiguous genitalia are complex and controversial. It is a significant stress for families, who need support and education from a multidisciplinary team of experienced specialists. Factors that influence gender assignment include genetic diagnosis, genital appearance, surgical options, fertility, and family and cultural preferences. Generally, genetically female (46XX) infants should be raised as girls. Early reconstructive surgery should be considered only in the case of severe virilization (Lee, Houk, Ahmed, et al, 2006). Emphasis is on functional rather than cosmetic outcomes, and surgery can often be delayed. Reports concerning sexual satisfaction after partial clitoridectomy indicate that the capacity for orgasm and sexual gratification is not necessarily impaired. Male infants may require phallic reconstruction by an experienced surgeon.

Unfortunately, not all children with CAH are diagnosed at birth and raised in accordance with their genetic sex. Particularly in the case of affected females, masculinization of the external genitalia may have led to sex assignment as a male. In children with milder forms of CAH, especially males, diagnosis may be delayed until early childhood, when signs of virilism appear. In these situations it is usually advisable to continue rearing the child as a male in accordance with assigned sex and phenotype. Hormone replacement may be required to permit linear growth and to initiate male pubertal changes. Surgery is usually indicated to remove the female organs and reconstruct the phallus for satisfactory sexual relations. These individuals are not fertile.

Nursing Care Management

Of major importance is early recognition of ambiguous genitalia and diagnostic confirmation in newborns. As with any congenital defect, the parents require an adequate explanation of the condition and time to grieve for the loss of perfection. In this instance they may also need to grieve for the loss of the desired-sex child. For example, the birth of a phenotypically male infant may fulfill their wish for a son. Knowledge of the child's actual sex may leave them disappointed. Such situations may also lead them to discuss the possibility of raising the child as a boy despite the actual sex. This is a difficult question that requires thoughtful discussion among the parents and members of the health team.

In general, rearing the genetically female child as a girl is preferred because of the success of surgical intervention and the satisfactory results with hormones in reversing virilism and providing a prospect of normal puberty and the ability to conceive. This is in contrast to the choice of rearing the child as a boy, in which case the child is sterile and may never be able to function satisfactorily in heterosexual relationships. If the parents persist in their decision to assign a male sex to a genetically female child, request a psychologic consultation to explore their motivations and ensure their understanding of the future consequences for the child.

Parents need appropriate information regarding this disorder to help them explain it to others. When referring to the external genitalia, it is preferable to refer to them as sex organs and to emphasize the similarity between the penis-clitoris and scrotum-labia during fetal development. Explain that the sex organs were overdeveloped because of too much male hormone secretion. Using a correct vocabulary allows parents to explain the abnormalities to others in a straightforward manner, just as if the defect involved the heart or an extremity.

Parents often fear that the infant will retain "male behavioral characteristics" because of prenatal masculinization and will not be able to develop female characteristics. It is important to stress that gender identity and psychosexual development depend on multiple influences. Because the prognosis for normal sexual development is excellent after early treatment, the nurse should foster identification with the child as one sex only. Ambiguous genitalia have no relationship to sexual preference for partners later in life.

As soon as the sex is determined, inform parents of the findings and encourage them to choose an appropriate name and identify the child as a male or female, with no reference to ambiguous sex. If the appearance of the enlarged genitalia in a girl concerns the parents, encourage them to discuss their feelings. Suggesting ways to avoid questioning remarks from visitors, such as diapering the child in a separate room, is also helpful. If surgery is anticipated, showing parents before-and-after photographs of reconstruction helps to reinforce the expected cosmetic benefits.

Nursing care management regarding cortisol and aldosterone replacement is the same as that discussed for chronic adrenocortical insufficiency. A follow-up visit by a home health nurse may be desirable to ensure that parents understand and comply with the treatment regimen. Nurses in well-child facilities should assume responsibility for guidance and supervision regarding this aspect of care during each visit. Monitor vital signs closely for early signs of hypertension due to cortisol therapy.

Because infants are especially prone to dehydration and salt-losing crises, parents need to be aware of signs of dehydration

and the urgency of immediate medical intervention to stabilize the child's condition. Parents should have injectable hydrocortisone available and know how to prepare and administer the intramuscular injection. (See Chapter 23.) Parents, and later the child, need to understand that the medical regimen must be a lifelong commitment; therefore provide them with the education and counseling that is most likely to ensure informed and willing compliance. They also need to know that growth retardation that may have occurred before therapy cannot be overcome and that normal stature is not a realistic expectation, even though growth velocity may improve with medication. Assess males for development of testicular tumors.

In the unfortunate situation in which the sex is erroneously assigned and the correct sex determined later, parents need a great deal of help in understanding the reason for the incorrect sex identification and the options for sex reassignment or medical-surgical intervention.

! NURSING ALERT

Advise the parents that there is no physical harm in treating for suspected adrenal insufficiency that is not present, whereas the consequence of not treating acute adrenal insufficiency can be fatal.

Because the hereditary form of adrenal hyperplasia is an autosomal recessive disorder, refer parents for genetic counseling before they conceive another child. The nurse's role is to ensure that parents understand the probability of transmitting the trait or disorder with each pregnancy. Prenatal diagnosis and treatment for CAH are available. Affected offspring also require genetic counseling, since both sexes are generally able to reproduce. (See Chapter 3 for recurrence risks and genetic counseling.)

HYPERALDOSTERONISM

Excessive secretion of aldosterone may be caused by an adrenal tumor or, in some types of adrenogenital syndromes, result from enzymatic deficiency. The signs and symptoms are caused by increased sodium levels, water retention, and potassium loss. Hypervolemia causes hypertension and resultant headaches. Paradoxically, funduscopic changes resulting from increased blood pressure and edema from water retention are minimal. Hypokalemia results in muscular weakness, paresthesia, episodes of paralysis, and tetany and may be responsible for polyuria and consequent polydipsia.

The clinical diagnosis is suspected when there are findings of hypertension, hypokalemia, and polyuria that fail to respond to ADH administration. Renin and angiotensin titers are abnormally low. Urinary levels of 17-hydroxycorticosteroids and 17-ketosteroids are normal in primary hyperaldosteronism caused by an aldosterone-secreting tumor but are usually abnormal in adrenogenital syndrome.

Therapeutic Management

Temporary treatment of the disorder involves replacement of potassium and administration of spironolactone (Aldactone), a diuretic that blocks the effects of aldosterone, thereby promoting excretion of sodium and water, while preserving potassium. Definitive treatment is similar to that for chronic adrenocortical insufficiency.

Nursing Care Management

An important nursing consideration is recognition of the syndrome, particularly in children with high blood pressure. Other clues include bed-wetting, excessive thirst, and unexplained weakness. After the diagnosis, nursing care is related to the treatment regimen. If diuretics are used, they should be administered in the morning to avoid accidents during the night. Children need unrestricted restroom privileges at school. Potassium supplements should be mixed with fruit juice such as grape juice to increase their acceptability, and potassium-rich foods should be encouraged. Parents need to be aware of the signs of hypokalemia and hyperkalemia. After an adrenalectomy, nursing care is similar to that for chronic adrenocortical insufficiency.

PHEOCHROMOCYTOMA

Pheochromocytoma is a rare tumor characterized by secretion of catecholamines. The tumor most commonly arises from the chromaffin cells of the adrenal medulla but may occur wherever these cells are found, such as along the paraganglia of the aorta or thoracolumbar sympathetic chain. In children they are frequently bilateral or multiple and are generally benign. Often there is a familial transmission of the condition as an autosomal dominant trait (Kliegman, Stanton, St. Geme, et al, 2011).

Clinical Manifestations

The clinical manifestations of pheochromocytoma are caused by an increased production of catecholamines, producing hypertension, tachycardia, headache, decreased gastrointestinal activity with resultant constipation, increased metabolism with anorexia, weight loss, hyperglycemia, polyuria, polydipsia, hyperventilation, nervousness, heat intolerance, and diaphoresis. In severe cases, signs of congestive heart failure are evident.

Diagnostic Evaluation

The clinical manifestations mimic those of other disorders, such as hyperthyroidism or DM. Tests specific to these conditions may be performed as part of the differential diagnosis. In a small number of instances a palpable tumor suggests the diagnosis. Usually the tumor is identified by a CT scan or MRI. Definitive tests include 24-hour measurement of urinary levels of the catecholamine metabolites; histamine stimulation, which provokes a hypertensive attack from sudden release of large amounts of catecholamines; and β-adrenergic blocking agents, which produce a hypotensive episode by inhibiting the action of circulating catecholamines.

Therapeutic Management

Definitive treatment consists of surgical removal of the tumor. In children the tumors may be bilateral, requiring a bilateral

adrenalectomy and lifelong glucocorticoid and mineralocorticoid therapy. The major complications that can occur during surgery are severe hypertension, tachyarrhythmias, and hypotension. The first two are caused by excessive release of catecholamines during manipulation of the tumor, and the latter results from catecholamine withdrawal and hypovolemic shock.

Preoperative medication to inhibit the effects of catecholamines is begun 1 to 3 weeks before surgery to prevent these complications. The major group of drugs used are the α-adrenergic blocking agents with or without β-adrenergic blocking agents. The most commonly used α-adrenergic blocker is phenoxybenzamine (Dibenzyline), a longer-acting medication given orally every 12 hours. The shorter-acting phentolamine (Regitine) is equally effective but less satisfactory for long-term use, although it is useful for acute hypertension. To control catecholamine release when α-adrenergic blocking agents are inadequate, the child is given β-adrenergic blocking agents.

Success of therapy is judged by lowering of blood pressure to normal, absence of hypertensive attacks (e.g., flushing or blanching, fainting, headache, palpitations, tachycardia, nausea and vomiting, profuse sweating), heat tolerance, decrease in perspiration, and disappearance of hyperglycemia. A disadvantage of these drugs is their inability to block the effects of catecholamines on β-receptors.

Nursing Care Management

An initial nursing objective is identification of children with this disorder. Outstanding clues are hypertension and hypertensive attacks. Because of behavioral changes (e.g., nervousness, excitability, overactivity, even psychosis), increased cardiac and respiratory activity may appear to be related to an acute anxiety attack. Therefore, a careful history of the onset of symptoms and association with stressful events is helpful in distinguishing between an organic and a psychologic cause for the symptoms.

Preoperative nursing care involves frequent monitoring of vital signs and observation for evidence of hypertensive attacks and congestive heart failure. Therapeutic effects are evidenced by normal vital signs and absence of glycosuria. Note daily blood glucose levels and urine acetone; report any signs of hyperglycemia immediately.

The environment is made conducive to rest and free of emotional stress. This requires adequate preparation during hospital admission and before surgery. Encourage parents to room-in with their child and to participate in care. Play activities need to be tailored to the child's energy level without being overly strenuous or challenging because these can increase metabolic rate and promote frustration and anxiety.

! NURSING ALERT

Do not palpate the mass. Preoperative palpation of the mass releases catecholamines, which can stimulate severe hypertension and tachyarrhythmias.

After surgery observe the child for signs of shock from removal of excess catecholamines. If a bilateral adrenalectomy was performed, the nursing interventions are those discussed for chronic adrenocortical insufficiency.

DISORDERS OF PANCREATIC HORMONE SECRETION

DIABETES MELLITUS

DM is a chronic disorder of metabolism characterized by a partial or complete deficiency of the hormone insulin. It is the most common metabolic disease, resulting in metabolic adjustment or physiologic change in almost all areas of the body. Approximately one in three children born in the United States will develop diabetes. The odds are higher for African-American and Hispanic children: nearly 50% of them will develop diabetes (Urrutia-Rojas and Menchaca, 2006). The age of presentation of childhood-onset type 1 DM has a bimodal distribution, with one peak at 4 to 6 years of age and another at early puberty (10 to 14 years of age) (Felner, Klitz, Ham, et al, 2005). The incidence in boys is slightly higher than in girls (1:1 to 1.2:1).

Type 1 DM is more prominent in Caucasians, with an incidence of 24 per 100,0000 (Dabelea, Bell, and D'Agostino, 2007). The incidence in African-Americans is 11 per 100,0000; the incidence in Hispanics is 15.2 per 100,0000; and the incidence in Cubans is 2.6 per 100,0000. Native Americans tend to develop type 2 DM rather than type 1 DM, even when diagnosed in childhood. The incidence of type 1 DM in Americans under 20 years old has increased by 23% between 2003 and 2009.

Classification

Traditionally DM had been classified according to the type of treatment needed. DM used to be classified as insulin-dependent diabetes mellitus (IDDM), or type I; and non–insulin-dependent diabetes mellitus (NIDDM), or type II. In 1997 these terms were eliminated because treatment can vary (some people with NIDDM require insulin) and because the terms do not indicate the underlying problem. The new terms are type 1 and type 2. The characteristics of type 1 DM and type 2 DM are compared in Table 33-3.

Type 1 diabetes is characterized by destruction of the pancreatic beta cells, which produce insulin; this usually leads to absolute insulin deficiency (Fig. 33-6). Type 1 diabetes has two forms. Immune-mediated DM results from an autoimmune destruction of the beta cells; it typically starts in children or young adults who are normal weight, but it can arise in adults of any age. Idiopathic type 1 refers to rare forms of the disease that have no known cause.

Type 2 diabetes usually arises because of insulin resistance, in which the body fails to use insulin properly, combined with relative insulin deficiency. People with type 2 can range from predominantly insulin resistant with relative insulin deficiency to predominantly deficient in insulin secretion with some insulin resistance. It typically occurs in people over 45, who are overweight, sedentary, and have a family history of diabetes.

Several other specific types of DM have been defined, such as those resulting from genetic defects of beta cell function, pancreatic diseases (e.g., cystic fibrosis), and defects in insulin

TABLE 33-3 CHARACTERISTICS OF TYPES 1 AND 2 DIABETES MELLITUS

CHARACTERISTIC	TYPE 1	TYPE 2
Age at onset	<20 yr	Increasingly occurring in younger children
Type of onset	Abrupt	Gradual
Sex ratio	Males slightly more than females	Females outnumber males
Percentage of diabetic population	5% to 8%	85% to 90%
Heredity:		
Family history	Sometimes	Frequently
Human leukocyte antigen	Associations	No association
Twin concordance	25% to 50%	90% to 100%
Ethnic distribution	Primarily Caucasians	Increased incidence in Native Americans, Hispanics, African-Americans
Presenting symptoms	3Ps common: polyuria, polydipsia, polyphagia	May be related to long-term complications
Nutritional status	Underweight	Overweight
Insulin (natural):		
Pancreatic content	Usually none	>50% normal
Serum insulin	Low to absent	High or low
Primary resistance	Minimum	Marked
Islet cell antibodies	80% to 85%	<5%
Therapy:		
Insulin	Always	20% to 30% of patients
Oral agents	Ineffective	Often effective
Diet only	Ineffective	Often effective
Chronic complications	>80%	Variable
Ketoacidosis	Common	Infrequent

action. **Maturity-onset diabetes of the young (MODY)** is associated with monogenetic defects in beta cell function that are characterized by impaired insulin secretion with minimum or no defects in insulin action. The disease is inherited as an autosomal dominant pattern, and the onset of hyperglycemia occurs at an early age (generally before age 25 years).

Etiology

The clinical syndrome of DM results from a large variety of etiologic and pathogenic mechanisms. Type 1 DM is an autoimmune disease that arises when a person with a genetic predisposition is exposed to a precipitating event, such as a viral infection. Type 2 DM is more likely to be influenced by stronger, but as yet unknown, genetic factors. Thus its origin is considered to be polygenic.

Genetic Factors

Type 1 DM is not inherited, but heredity is a prominent factor in the etiology. In more than 40 rare genetic syndromes, diabetes is a major feature (Harris, 2003). No simple mendelian pattern is found for DM. Children born to fathers with type 1 DM are about three times more likely to develop type 1 DM (approximately 7% frequency) than children born to mothers with type 1 DM (approximately 2% frequency) (see Research Focus box).

At least 60% of the genetic susceptibility to type 1 DM is conferred by human leukocyte antigen (HLA) on chromosome 6. Several alleles have been implicated, including *DR3, DR4,* and *DQ8.* The highest-risk alleles (*DR3* and *DR4*) are found in 95% of patients with diabetes. Only 50% of nondiabetic persons have these alleles.

RESEARCH FOCUS

Genetic Factors and Diabetes

Studies of type 2 diabetes mellitus (DM) in identical twins demonstrated a 100% concordance throughout the life span, whereas studies of type 1 DM in identical twins demonstrated a 30% to 50% concordance rate, suggesting that both environmental and genetic factors are important in the development of type 1 DM (Stephenson, 2003). Children diagnosed with type 1 DM before 5 years of age may have different autoimmune and genetic characteristics related to their diabetes than older children (Hathout, Hartwick, Fagoaga, et al, 2003).

Autoimmune Mechanisms

Pancreatic islet cell antibodies (ICAs) are found in about 70% to 85% of patients newly diagnosed with type 1 DM. The antibodies disappear by 1 year after diagnosis in most persons, but in some they may persist for years. The current theory is that the presence of the HLA genes causes a defect in the immune system that renders the possessor susceptible to a trigger event, which can be a dietary source, a virus, bacteria, or a chemical irritant. The predisposing factor initiates an autoimmune process that gradually destroys beta cells. Without beta cells, the body cannot produce insulin. It is unclear whether the ICAs are a result of the inflammatory process or a significant aspect of the beta cell destruction. Controversy exists regarding whether the autoimmune response is primarily mediated by the lymphocyte response or the humoral (antibody) response or is a result of the two.

There is a strong association between type 1 DM and other autoimmune endocrine disorders. An increased incidence of other autoimmune endocrine disorders, such as thyroiditis and Addison disease, has been found in families of children with *DR3*-associated type 1 DM.

Researchers have also found anti-ICAs in a number of unaffected first-degree relatives of children with type 1 DM (Bingley and Gale, 2006). These findings offer hope of identifying persons at risk for diabetes with the eventual possibility of screening and implementation of therapy. Research is also continuing to identify genetic risk and environmental triggers with the hope of developing prevention strategies such as immunizations.

Treatment with cyclosporine or other forms of immunosuppression has been tested as an early intervention in the newly diagnosed person with type 1 DM. The effects of lifelong

PATHOPHYSIOLOGY REVIEW

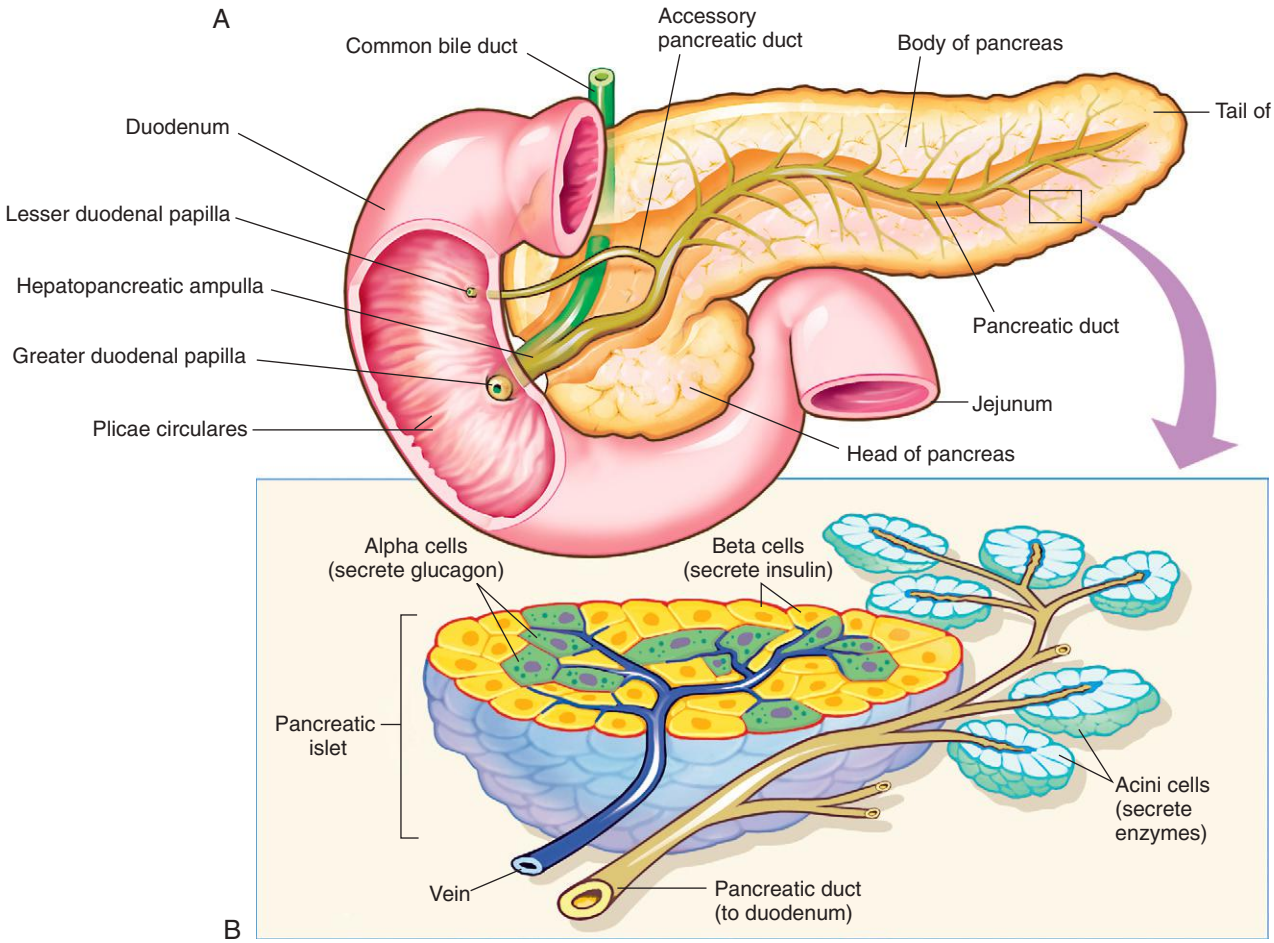

FIG. 33-6 The pancreas. **A,** The main and accessory ducts. **B,** Glandular cells of the pancreatic islets. (From Patton KT, Thibodeau GA: *Anatomy and physiology*, ed 7, St. Louis, 2010, Mosby.)

immunosuppression must be carefully weighed against the lifelong effects of diabetes.

Diet

Cow's milk has been implicated as a possible trigger of the autoimmune response that destroys pancreatic cells in genetically susceptible hosts, thus causing DM (Goldfarb, 2008). Further research is needed.

Viruses

A variety of viruses, including mumps, coxsackievirus B, and congenital rubella, have been implicated as the prime environmental factor in the etiology of DM. Islet cells appear to be particularly susceptible to either direct viral damage or chemical insult. A virus serves as a precipitating factor, or "trigger," that causes an autoimmune response in the patient. A viral etiology also helps explain the seasonal variation in the onset of DM. Although this seasonal variation is not evident in children under 5 years of age, the marked increase in older children during the winter months strongly suggests an infectious disease relationship in either cause or expression of diabetes in children.

Type 2 Diabetes

Type 1 DM is the predominant form of diabetes in the pediatric age-group. However, changes in food consumption and exercise patterns have increased the rate of type 2 DM in children and adolescents in the Unites States (Kiess, Bottner, Raile, et al, 2003; Ramchandani, 2004; Steinberger and Daniels, 2003; Stephenson, 2003). The disturbed carbohydrate metabolism of type 2 DM may be a result of a sluggish or insensitive secretory response in the pancreas or a defect in body tissues that requires unusual amounts of insulin, or it may be that the insulin secreted is rapidly destroyed, inhibited, or inactivated in affected persons. Children with type 2 diabetes often have other features of insulin resistance syndrome: polycystic ovary syndrome and acanthosis nigricans (AN). AN is found in as many as 90% of children with type 2 diabetes and is characterized by velvety hyperpigmented areas in skinfolds. Risk factors include non-European ancestry, family history of type 2 DM, obesity, insulin resistance, and older age (American Diabetes Association, 2007). While performing routine scoliosis screenings, school nurses often identify AN on the child's neck. Refer such

children to their primary care provider for further metabolic evaluation.

Pathophysiology

Insulin is needed to support the metabolism of carbohydrates, fats, and proteins, primarily by facilitating the entry of these substances into the cell. Insulin is needed for the entry of glucose into the muscle and fat cells, prevention of mobilization of fats from fat cells, and storage of glucose as glycogen in the cells of liver and muscle. Insulin is not needed for the entry of glucose into nerve cells or vascular tissue. The chemical composition and molecular structure of insulin are such that it fits into receptor sites on the cell membrane. Here it initiates a sequence of poorly defined chemical reactions that alter the cell membrane to facilitate the entry of glucose into the cell and stimulate enzymatic systems outside the cell that metabolize the glucose for energy production.

With a deficiency of insulin, glucose is unable to enter the cell, and its concentration in the bloodstream increases. The pathophysiology review in Fig. 33-6 shows the cells responsible for secreting glucagon and insulin. The increased concentration of glucose (hyperglycemia) produces an osmotic gradient that causes the movement of body fluid from the intracellular space to the interstitial space, then to the extracellular space and into the glomerular filtrate in order to "dilute" the hyperosmolar filtrate. Normally the renal tubular capacity to transport glucose is adequate to reabsorb all the glucose in the glomerular filtrate. When the glucose concentration in the glomerular filtrate exceeds the renal threshold (180 mg/dl), glucose spills into the urine (glycosuria) along with an osmotic diversion of water (polyuria), a cardinal sign of diabetes. The urinary fluid losses cause the excessive thirst (polydipsia) observed in diabetes. This water "washout" results in a depletion of other essential chemicals, especially potassium.

Protein is also wasted during insulin deficiency. Because glucose is unable to enter the cells, protein is broken down and converted to glucose by the liver (glucogenesis); this glucose then contributes to the hyperglycemia. These mechanisms are similar to those seen in starvation when substrate (glucose) is absent. The body is actually in a state of starvation during insulin deficiency. Without the use of carbohydrates for energy, fat and protein stores are depleted as the body attempts to meet its energy needs. The hunger mechanism is triggered, but increased food intake (polyphagia) enhances the problem by further elevating blood glucose (Fig. 33-7).

Ketoacidosis

When insulin is absent or there is altered insulin sensitivity, glucose is unavailable for cellular metabolism, and the body chooses alternate sources of energy, principally fat. Consequently, fats break down into fatty acids, and glycerol in the fat cells is converted by the liver to ketone bodies (e.g., β-hydroxybutyric acid, acetoacetic acid, acetone). Any excess is eliminated in the urine (ketonuria) or the lungs (acetone breath). The ketone bodies in the blood (ketonemia) are strong acids that lower serum pH, producing ketoacidosis.

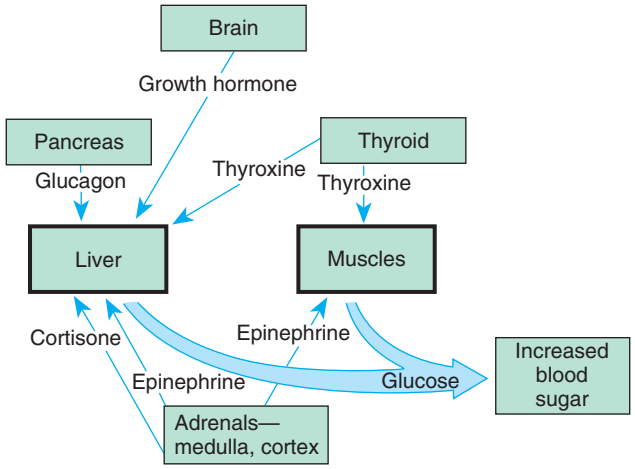

FIG. 33-7 Body systems respond to hypoglycemia in various ways to increase blood glucose level.

Ketones are organic acids that readily produce excessive quantities of free hydrogen ions, causing a fall in plasma pH. Then chemical buffers in the plasma, principally bicarbonate, combine with the hydrogen ions to form carbonic acid, which readily dissociates into water and carbon dioxide. The respiratory system attempts to eliminate the excess carbon dioxide by increased depth and rate—**Kussmaul respirations**, or the hyperventilation characteristic of metabolic acidosis. Sodium and potassium in the plasma buffer the ketones. The kidney attempts to compensate for the increased pH by increasing tubular secretion of hydrogen and ammonium ions in exchange for fixed base, thus depleting the base buffer concentration.

With cellular death, potassium is released from the cell (intracellular fluid) into the bloodstream (extracellular fluid) and excreted by the kidney, where the loss is accelerated by osmotic diuresis. The total body potassium is then decreased, even though the serum potassium level may be elevated as a result of the decreased fluid volume in which it circulates. Alteration in serum and tissue potassium can lead to cardiac arrest.

If insulin therapy in combination with correction of the fluid deficiency and electrolyte imbalance does not reverse these conditions, progressive deterioration occurs with dehydration, electrolyte imbalance, acidosis, coma, and death. **Diabetic ketoacidosis (DKA)** should be diagnosed promptly in a seriously ill patient and therapy instituted in an intensive care unit.

Long-Term Complications

Long-term complications of diabetes involve both the microvasculature and the macrovasculature. The principal microvascular complications are nephropathy, retinopathy, and neuropathy. Microvascular disease develops during the first 30 years of diabetes, beginning in the first 10 to 15 years after puberty, with renal involvement evidenced by proteinuria and clinically apparent retinopathy.

With poor diabetic control, vascular changes can appear as early as 2½ to 3 years after diagnosis; however, with good to excellent control, changes can be postponed for 20 or more years. Intensive insulin therapy appears to delay the onset

and slow the progression of clinically important retinopathy, including vision-threatening lesions, nephropathy, and neuropathy, by 35% to more than 70%, according to studies on treatment and complications of type 1 DM (American Diabetes Association, 2002).

The postpubertal duration, not the total duration, of type 1 DM is implicated as a risk factor for the development of microvascular disease. The process appears to be one of glycosylation, wherein proteins from the blood become deposited in the walls of small vessels (e.g., glomeruli), where they become trapped by "sticky" glucose compounds (glycosyl radicals). The buildup of these substances over time causes narrowing of the vessels, with subsequent interference with microcirculation to the affected areas (Rosenson and Herman, 2008). Macrovascular disease develops after 25 years of diabetes and creates the predominant problems in patients with type 2 DM.

Other complications have been observed in children with type 1 DM. Hypertension and atherosclerotic cardiovascular disease also contribute to the mortality and morbidity of type 1 DM (Karik, Fields, and Shannon, 2007). Hyperglycemia appears to influence thyroid function, and altered function is frequently observed at the time of diagnosis, as well as in poorly controlled diabetes. Limited mobility of small joints of the hand occurs in 30% of 7- to 18-year-old children with type 1 DM and appears to be related to changes in the skin and soft tissues surrounding the joint as a result of glycosylation.

Clinical Manifestations

The symptomatology of diabetes is more readily recognizable in children than in adults, so it is surprising that the diagnosis may sometimes be missed or delayed. Diabetes is a great imitator; influenza, gastroenteritis, and appendicitis are the conditions most often diagnosed when it turns out that the disease is really diabetes. Diabetes should be suspected in children with a strong family history of diabetes, especially if another child in the family has the disease.

The sequence of chemical events described previously results in hyperglycemia and acidosis, which produce weight loss and the three "polys" of diabetes—polyphagia, polydipsia, and polyuria—the cardinal symptoms of the disease. In type 2 DM the insulin values are elevated. Eighty percent to 90% of this population are overweight, and fatigue and frequent infections (such as candidal infections in females) are often present.

! NURSING ALERT

Recurrent vaginal and urinary tract infections, especially with *Candida albicans*, are often an early sign of type 2 DM, especially in adolescents.

The variability of clinical manifestations in type 1 DM at diagnosis is best understood if the autoimmune destruction of islet cells is considered an ongoing process (Box 33-13). Symptoms of hyperglycemia may be apparent only during stress (such as an illness) in early stages of disease because of near-normal levels of insulin production. Progressive islet cell destruction of later stages produces more obvious signs and symptoms. By the time there are overt diabetic symptoms, 80% to 90% of islet cell function has been destroyed. Frequently identified symptoms of overt diabetes include enuresis, irritability, and unusual fatigue.

BOX 33-13 CLINICAL MANIFESTATIONS OF TYPE 1 DIABETES MELLITUS

Polyphagia
Polyuria
Polydipsia
Weight loss
Enuresis or nocturia
Irritability; "not himself" or "herself"
Shortened attention span
Lowered frustration tolerance
Fatigue
Dry skin
Blurred vision
Poor wound healing
Flushed skin
Headache
Frequent infections
Hyperglycemia
- Elevated blood glucose levels
- Glucosuria

Diabetic ketosis
- Ketones and glucose in urine
- Dehydration in some cases

Diabetic ketoacidosis
- Dehydration
- Electrolyte imbalance
- Acidosis
- Deep, rapid breathing (Kussmaul)

Abdominal discomfort is common. Weight loss, though observable on the charts, may be a less frequent presenting complaint because the family might not have noticed the change over time. Another outstanding feature of diabetes is thirst. One couple reported that during a trip from California to Kansas, their child drank the contents of a gallon jug of water between each gas station stop. As abdominal discomfort and nausea increase, the child may actually refuse fluid and food, increasing the state of dehydration and malnutrition. Other symptoms include dry skin, blurred vision, and sores that are slow to heal. More commonly in children, fatigue and bed-wetting are the chief complaints that prompt parents to take their child for evaluation.

At diagnosis, the child may be hyperglycemic, with elevated blood glucose levels and glucose in the urine; ketotic, with ketones measurable in the blood and urine, with or without dehydration; or suffering from DKA, with dehydration, electrolyte imbalance, and acidosis.

Diagnostic Evaluation

Three groups of children who are candidates for diabetes are children who have glycosuria, polyuria, and a history of weight loss or failure to gain despite a voracious appetite; those with transient or persistent glycosuria; and those who display

manifestations of metabolic acidosis, with or without stupor or coma. In every case consider diabetes if there is glycosuria, with or without ketonuria, and unexplained hyperglycemia.

Glycosuria by itself is not diagnostic of diabetes. Other sugars, such as galactose, can produce a positive result with certain test strips. Other conditions, such as infection, trauma, emotional or physical stress, hyperalimentation, and some renal or endocrine diseases can cause a mild degree of glycosuria.

An 8-hour fasting blood glucose level of 126 mg/dl or more, a random blood glucose value of 200 mg/dl or more accompanied by classic signs of diabetes, or an oral glucose tolerance test (OGTT) finding of 200 mg/dl or more in the 2-hour sample is almost certain to indicate diabetes (American Diabetes Association, 2005). Postprandial blood glucose determinations and the traditional OGTTs have yielded low detection rates in children and are not usually necessary for establishing a diagnosis. Serum insulin levels may be normal or moderately elevated at the onset of diabetes; delayed insulin response to glucose indicates the presence of impaired glucose tolerance.

Ketoacidosis must be differentiated from other causes of acidosis or coma, including hypoglycemia, uremia, gastroenteritis with metabolic acidosis, salicylate intoxication encephalitis, and other intracranial lesions. DKA is a state of relative insulin insufficiency and may include the presence of hyperglycemia (blood glucose level 330 mg/dl), ketonemia (strongly positive), acidosis (pH 7.30 and bicarbonate 15 mmol/L), glycosuria, and ketonuria (Dunning, 2009). Tests used to determine glycosuria and ketonuria are the glucose oxidase tapes (Keto-Diastix).

Therapeutic Management

The management of the child with type 1 DM consists of a multidisciplinary approach involving the family; the child (when appropriate); and professionals, including a pediatric endocrinologist, diabetes nurse educator, nutritionist, and exercise physiologist. Often psychologic support from a mental health professional is also needed. Communication among the team members is essential and extends to other individuals in the child's life, such as teachers, school nurse, school guidance counselor, and coach (see Community and Home Health Considerations box).

Insulin Therapy

Insulin replacement is the cornerstone of management of type 1 DM. Insulin dosage is tailored to each child based on home blood glucose monitoring. The goal of insulin therapy is maintaining near-normal blood glucose values, while avoiding too-frequent episodes of hypoglycemia. Insulin is administered as two or more injections per day or as continuous subcutaneous infusion using a portable insulin pump.

Healthy pancreatic cells secrete insulin at a low but steady basal rate with superimposed bursts of increased secretion that coincide with intake of nutrients. Consequently, insulin levels in the blood increase and decrease coincidentally with the rise and fall in blood glucose levels. In addition, insulin is secreted directly into the portal circulation; therefore, the liver, which is the major site of glucose disposal, receives the largest concentration of insulin. No matter which method of insulin replacement is used, this normal pattern cannot be duplicated. Subcutaneous injection results in absorption of the drug into the general circulation, thus reducing the concentrations of insulin to which the liver is exposed.

COMMUNITY AND HOME HEALTH CONSIDERATIONS

The Adolescent with Type 1 Diabetes Mellitus

As a nurse caring for adolescents with type 1 diabetes mellitus (DM), I am constantly aware of the wide range of adolescent behaviors that affect the course of this disease. Education of the child and the parents can often make the difference between a disease in control of the teen and a teen in control of the disease.

I have cared for many adolescent girls who have episodes of hyperglycemia at the time of menstruation that can result in diabetic ketoacidosis. I have found that education regarding sick-day protocol with sliding-scale regular insulin instituted at the first sign of hyperglycemia, which may occur 1 to 2 days before onset of menses, can keep the adolescent girl out of the intensive care unit and in control of her diabetes.

Eating disorders, such as bulimia or anorexia nervosa, in the teenager with type 1 DM pose a serious health hazard (Mannucci, Rotella, Recca, et al, 2005). Also, insulin manipulation or omission has been identified as a weight-loss method used by some adolescent girls (Hoffman, 2001). Nurses working with these adolescents, especially females, must be aware of the hazards and openly discuss the risks with the young person. A referral for specialized intervention may be needed.

Another group of adolescents with diabetes who are at risk are those who drink alcohol. I have found that confusion about the effects of alcohol on blood glucose is common. Teens may believe that alcohol will increase blood glucose levels, when in fact the opposite occurs. Ingestion of alcohol inhibits the release of glycogen from the liver, thereby resulting in hypoglycemia. Teens with diabetes who drink alcohol may become hypoglycemic but be treated as though they were inebriated. Behaviors may be similar, such as shakiness, combativeness, slurred speech, and loss of consciousness.

Education regarding the effects of alcohol is important and must be included in a teaching plan. If teens insist on drinking alcohol, they can be cautioned to use sweetened mixers or eat snacks when consuming alcoholic beverages.

Episodes of hyperglycemia or hypoglycemia may become a serious issue for adolescents who are leaving home for the first time. One teenager confided that her mother always recognized her combative, antisocial behavior as impending hypoglycemia and treated her with the appropriate intervention. The teen feared that a college roommate might be offended by the behavior and leave her alone with impending hypoglycemia.

One young man realized he could not live alone when he took a nap because he "felt tired" and woke up 4 days later in the hospital. Fortunately, his family realized he was in a coma and summoned emergency medical service. The fatigue signaled the beginning of a viral infection, which led to a blood glucose level of 410 mg/dl. Nurses need to address these fears openly and facilitate ways in which the teen can enlist the aid of significant peers who may be available during hyperglycemic or hypoglycemic episodes.

The definitive treatment is replacement of insulin that the child is unable to produce. However, insulin needs are also affected by emotions, nutritional intake, activity, and other life events such as illnesses and puberty. The complexity of the disease and its management requires that the child and family incorporate diabetes needs into their lifestyle. Medical and nutritional guidance are primary, but management also includes continuing diabetes education, family guidance, and emotional support.

BOX 33-14 TYPES OF INSULIN

There are four types of insulin, based on the following criteria:

- How soon the insulin starts working (onset)
- When the insulin works the hardest (peak time)
- How long the insulin lasts in the body (duration)

However, each person responds to insulin in his or her own way. That is why onset, peak time, and duration are given as ranges.

- Rapid-acting insulin (lispro) reaches the blood within 15 minutes after injection. The insulin peaks 30 to 90 minutes later and may last as long as 5 hours.
- Short-acting (regular) insulin usually reaches the blood within 30 minutes after injection. The insulin peaks 2 to 4 hours later and stays in the blood for about 4 to 8 hours.
- Intermediate-acting (NPH and Lente) insulins reach the blood 2 to 6 hours after injection. The insulins peak 4 to 14 hours later and stay in the blood for about 14 to 20 hours.
- Long-acting (Ultralente) insulin takes 6 to 14 hours to start working. It has no peak or a very small peak 10 to 16 hours after injection. The insulin stays in the blood between 20 and 24 hours.

Some insulins come mixed together. For example, you can buy regular insulin and NPH insulins already mixed in one bottle, which makes it easier to inject two kinds of insulin at the same time. However, you cannot adjust the amount of one insulin without also changing how much you get of the other insulin.

Insulin Preparations. Insulin is available in highly purified pork preparations and in human insulin biosynthesized by and extracted from bacterial or yeast cultures. Most clinicians suggest human insulin as the treatment of choice. Insulin is available in rapid-, intermediate-, and long-acting preparations, and all are packaged in the strength of 100 units/ml. Some insulins are available as premixed insulins, such as 70/30 and 50/50 ratios, the first number indicating the percentage of intermediate-acting and the second number the percentage of rapid-acting insulin. Box 33-14 lists the different types of insulin.

Lispro-H (Humalog) and insulin aspart (NovoLog) are human insulin analogs. One unit of the analog has the same glucose-lowering effect as 1 unit of human rapid-acting insulin, but the effect is even more rapid and of shorter duration. One benefit is a decreased risk of hypoglycemia, since the peak effect is reached in 1 to 1½ hours. Because of its rapid onset, each of the analogs must be injected within 15 minutes before eating.

DRUG ALERT

Insulin Preparations

The human insulins from various manufacturers may be interchangeable, but human insulin and pork insulin or pure pork insulin should never be substituted for one another.

Dosage. Conventional management is a twice-daily insulin regimen combining rapid-acting (regular) and intermediate-acting (NPH or Lente) insulin drawn up into the same syringe and injected before breakfast and before the evening meal. The amount of morning regular insulin is determined by patterns in the late morning and lunchtime blood glucose values. The morning intermediate-acting dosage is determined by patterns in the late afternoon and supper blood glucose values. Fasting blood glucose patterns at breakfast help determine the evening dose of intermediate insulin, and the blood glucose patterns at bedtime help determine the evening dose of rapid-acting (regular) insulin. For some children, better morning glucose control is achieved by a later (bedtime) injection of intermediate-acting insulin.

Regular insulin is best administered at least 30 minutes before meals. This allows sufficient time for absorption and results in a significantly greater reduction in the postprandial rise in blood glucose than if the meal were eaten immediately after the insulin injection. Intensive therapy consists of multiple injections throughout the day with a once- or twice-daily dose of long-acting (Ultralente) insulin to simulate the basal insulin secretion and injections of rapid-acting insulin before each meal. A multiple daily injection program reduces microvascular complications of diabetes in young, healthy patients who have type 1 DM. The precise dose of insulin needed cannot be predicted. Therefore, the total dosage and percentage of regular- to intermediate-acting insulin should be determined empirically for each child. Usually 60% to 75% of the total daily dose is given before breakfast, and the remainder before the evening meal. Furthermore, insulin requirements do not remain constant but change continuously during growth and development; the need varies according to the child's activity level and pubertal status. For example, less insulin is required during spring and summer months, when the child is more active. Illness also alters insulin requirements. Some children require more frequent insulin administration. This includes children with difficult-to-control diabetes and children undergoing the adolescent growth spurt.

Methods of Administration. Daily insulin is administered subcutaneously by twice-daily injections, by multiple-dose injections, or by means of an insulin infusion pump. The insulin pump is an electromechanical device designed to deliver fixed amounts of regular or lispro insulin continuously (basal rate), thereby more closely imitating the release of the hormone by the islet cells (Olohan and Zappitelli, 2003). Although the pump delivers a programmed amount of basal insulin, the child or parent must program a dose for the pump to deliver before each meal.

The system consists of a syringe to hold the insulin, a plunger, and a computerized mechanism to drive the plunger. The insulin flows from the syringe through a catheter to a needle inserted into subcutaneous tissue (the abdomen or thigh), and the lightweight device is worn on a belt or a shoulder holster. The child or parent changes the needle and catheter every 48 to 72 hours, using aseptic technique, and tapes it in place.

Although the pump provides more consistent insulin delivery, it has certain disadvantages. Pump therapy is expensive and requires commitment from the parent and child. A certain level of math skills is required to calculate infusion rates. It should not be removed for more than 1 hour at a time, which may limit some activities. Skin infections are common, and, as with any other mechanical device, the pump is subject to malfunction.

However, the pumps are equipped with alarms that signal problems that may arise, such as a depleted battery, an occluded needle or tubing, or a microprocessor malfunction.

Future Therapies

Islet cell or whole pancreas transplantation may offer hope to patients in the future. Viable insulin-producing cells have been injected into the portal vein, where they are transported via the circulation to the liver and eventually produce up to two thirds of the required insulin. The major use of transplants has been in persons who have serious complications, particularly those whose deteriorating kidneys have required renal transplantation and who are receiving immunosuppressive therapy. However, islet cell and pancreatic transplants tend not to be sustainable over time despite continuation of therapy. The use of nonhuman islet cells encapsulated in immunoprotective, semipermeable membranes may have a future in the treatment of type 1 DM (Campbell, 2004).

Other routes for insulin administration are being studied. Inhaled insulin, for instance, has been an effective and safe means to control postprandial glucose levels (Garg, Rosenstock, Silverman, et al, 2006).

Monitoring

Daily monitoring of blood glucose levels is an essential aspect of appropriate DM management.

Blood Glucose. Self-monitoring of blood glucose (SMBG) has improved diabetes management and is used successfully by children from the onset of their diabetes. By testing their own blood, children are able to change their insulin regimen to maintain their glucose level in the euglycemic (normal) range of 80 to 120 mg/dl. Diabetes management depends to a great extent on SMBG. In general, children tolerate the testing well. Table 33-4 lists plasma blood glucose and hemoglobin A_{1c} goal ranges.

Glycosylated Hemoglobin. The measurement of glycosylated hemoglobin (hemoglobin A_{1c}) levels is a satisfactory method for assessing the control of the diabetic patient. As red blood cells circulate in the bloodstream, glucose molecules gradually attach to the hemoglobin A molecules and remain there for the lifetime of the red blood cell, approximately 120 days. The attachment is not reversible; therefore, this glycosylated hemoglobin reflects the average blood glucose levels over the previous 2 to 3 months. The test is a satisfactory method for assessing control, detecting incorrect testing, monitoring effectiveness of changes in treatment, defining patients' goals, and detecting nonadherence. Nondiabetic hemoglobin A_{1c} values are generally between 4% and 6% but can vary by laboratory. Diabetes control for children depends on age, with hemoglobin A_{1c} levels of 6.5% to 8% indicating a slightly elevated but acceptable result (American Diabetes Association, 2005). Table 33-5 gives comparisons of hemoglobin A1c to blood glucose levels.

Urine. Urine testing for glucose is no longer used for diabetes management. There is poor correlation between simultaneous glycosuria and blood glucose concentrations. However, urine testing can be carried out to detect evidence of ketonuria.

! NURSING ALERT

It is recommended that urine be tested for ketones every 3 hours during an illness or whenever the blood glucose level is over 240 mg/dl when illness is not present.

Nutrition

Essentially the nutritional needs of children with diabetes are no different from those of healthy children. Children with diabetes need no special foods or supplements. They need sufficient calories to balance daily expenditure for energy and to satisfy the requirement for growth and development. Unlike the child without diabetes, whose insulin is secreted in response to food intake, insulin injected subcutaneously has a relatively predictable time of onset, peak effect, duration of action, and absorption rate, depending on the type of insulin used. Consequently, the timing of food consumption must be regulated to correspond to the time and action of the insulin prescribed.

Meals and snacks must be eaten according to peak insulin action, and the total number of calories and proportions of basic nutrients must be consistent from day to day. The constant

release of insulin into the circulation makes the child prone to hypoglycemia between the three daily meals unless a snack is provided between meals and at bedtime. Calculate the distribution of calories to fit the activity pattern of each child. For example, a child who is more active in the afternoon needs a larger snack at that time. This larger snack might also be split to allow some food at school and some food after school. Food intake should be altered to balance food, insulin, and exercise. Extra food is needed for increased activity.

The food intake may be planned in a variety of ways but is based on a balanced diet that incorporates six basic food groups: milk, meat, vegetables, fat, fruit, and starch. There are several meal-planning approaches, including the exchange system and carbohydrate counting. The exchange system from the American Diabetes Association groups foods by nutrient content. Within each group, portion sizes of foods are calculated to give an equivalent amount of the nutrient. In the fruit list, for instance, one small apple has the equivalent amount of carbohydrate as a half banana. In the exchange system, food groups are important: fruits exchange with fruits, starches exchange with starches.

Carbohydrate counting has been popular since the Diabetes Control and Complications Trial. Portion sizes are still important, but all carbohydrates are considered equivalent. In this system, food groups are not as important as carbohydrate content. For example, one small apple and one slice of bread have the same carbohydrate amount (15 g) and may be used interchangeably.

BOX 33-15 NUTRITIONAL MANAGEMENT IN TYPE 1 DIABETES MELLITUS

Goal

Attain metabolic control of glucose and lipid levels

Objectives

Appropriate meal and snack planning:

- Achieve a dietary balance of carbohydrates, fats, and proteins.
- Provide extra food during periods of exercise.
- Time meals consistently to prevent hypoglycemia.
- Avoid high-sugar, high-carbohydrate foods to prevent hyperglycemia.

Develop an appropriate insulin regimen and physical activity program:

- Administer insulin as directed before eating.
- Increase insulin dose or activity level when extra food is eaten.
- Decrease insulin dose during periods of strenuous activity.

Concentrated sweets are discouraged, and because of the increased risk for atherosclerosis in persons with DM, fat is reduced to 30% or less of the total caloric requirement. Dietary fiber has become increasingly important in dietary planning because of its influence on digestion, absorption, and metabolism of many nutrients. It has been found to diminish the rise in blood glucose after meals.

Correctly used, the diet allows for flexibility and the incorporation of preferred foods in most instances. For the growing child, never use food restriction for diabetic control, although caloric restrictions may be imposed for weight control if the child is overweight. In general, the child's appetite should be the guide for the amount of calories needed, with the total caloric intake adjusted to appetite and activity. Box 33-15 outlines basic principles of diet management.

Exercise

Exercise is encouraged and never restricted unless indicated by other health conditions. Exercise lowers blood glucose levels, depending on the intensity and duration of the activity. Consequently, exercise should be included as part of diabetes management, and the type and amount of exercise should be planned around the child's interests and capabilities. However, in most instances children's activities are unplanned, and the resulting decrease in blood glucose can be compensated for by providing extra snacks before (and, if the exercise is prolonged, during) the activity. In addition to a feeling of well-being, regular exercise aids in utilization of food and often results in a reduction of insulin requirements.

Physical training tends to increase tissue sensitivity to insulin, even in the resting state. Consequently, it is especially important to understand the relationship between the activity and the diabetic regimen. Vigorous muscular contraction increases regional blood flow and accelerates the absorption and circulation of insulin that is injected into the area, which can

contribute to development of hypoglycemia. If exercise involving leg muscles is planned, it is recommended that nonexercised sites (arm or abdomen) be used for insulin injection. This practice may replace the need for further increased carbohydrate intake or a reduced insulin dose (or both) to avoid exercise-induced hypoglycemia.

Children with poorly controlled diabetes are particularly at risk for hyperglycemia with exercise, or exercise may actually stimulate ketoacid production. Therefore, discourage the child who has marked hyperglycemia (blood glucose level >240 mg/dl) and ketonuria from strenuous physical activity until the diabetes is controlled by appropriate adjustments of insulin and diet.

Athletes and youngsters who regularly participate in organized sports should adjust their insulin dosage in anticipation of sustained physical activity during the part of the day devoted to strenuous exercise. Team sports may encourage overexertion and subsequent hypoglycemia. Insulin dosages are decreased for participation in organized sports or prolonged activities, such as swimming for several hours. It is important that the patient consult with the practitioner for advice on insulin dose adjustment.

Hypoglycemia

Occasional episodes of hypoglycemia are an integral part of insulin therapy, and an objective of diabetes management is to achieve the best possible glycemic control, while minimizing the frequency and severity of hypoglycemia. Even with good control, a child may frequently experience mild symptoms of hypoglycemia. If the signs and symptoms are recognized early and promptly relieved by appropriate therapy, the child's activity should be interrupted for no more than a few minutes.

! NURSING ALERT

Hypoglycemic episodes most commonly occur before meals, or when the insulin effect is peaking.

The most common causes of hypoglycemia are bursts of physical activity without additional food, or delayed, omitted, or incompletely consumed meals. Reglycosylation of muscles may occur over the ensuing 24 hours. Particular vigilance related to hypoglycemia may be necessary during the night after vigorous exertion. Occasionally, hypoglycemic reactions occur unexpectedly and without apparent cause. They may be the result of an inadvertent or deliberate error in insulin administration.

Gastroenteritis, in which there is gastric stasis, may impede the absorption of food, even though the child is eating reasonably well. It can also occur when the blood glucose level is so low that it causes stasis. Then the child may eat a meal or snack and still have an insulin reaction. Continued feeding does not seem to alter the blood glucose level because the simple glucose or sugar remains in the stomach.

The signs and symptoms of hypoglycemia are caused by both increased adrenergic activity and impaired brain function. The increased adrenergic nervous system activity plus increased secretion of catecholamines produces nervousness, pallor, tremulousness, palpitations, sweating, and hunger. Weakness, dizziness, headache, drowsiness, irritability, loss of coordination, seizures, and coma are more severe responses and reflect CNS glucose deprivation and the body's attempts to elevate the serum glucose levels.

It is often difficult to distinguish between hyperglycemia and a hypoglycemic reaction (Table 33-6). Because the symptoms are similar and usually begin with changes in behavior, the simplest way to differentiate the two is to test the blood glucose level. The blood glucose level is low in hypoglycemia, whereas in hyperglycemia the glucose level is significantly elevated. Urinary ketones may be present after hypoglycemia as a result of starvation ketone production. In doubtful situations it is safer to give the child some simple carbohydrate. This will help

TABLE 33-6 COMPARISON OF MANIFESTATIONS OF HYPOGLYCEMIA AND HYPERGLYCEMIA

VARIABLE	HYPOGLYCEMIA	HYPERGLYCEMIA
Onset	Rapid (min)	Gradual (days)
Mood	Labile, irritable, nervous, weepy	Lethargic
Mental status	Difficulty concentrating, speaking, focusing, coordinating Nightmares	Dulled sensorium Confusion
Inward feeling	Shaky feeling, hunger Headache Dizziness	Thirst Weakness Nausea and vomiting Abdominal pain
Skin	Pallor Sweating	Flushed Signs of dehydration
Mucous membranes	Normal	Dry, crusty
Respirations	Shallow, normal	Deep, rapid (Kussmaul)
Pulse	Tachycardia, palpitations	Less rapid, weak
Breath odor	Normal	Fruity, acetone
Neurologic	Tremors	Diminished reflexes Paresthesia
Ominous signs	Late: hyperreflexia, dilated pupils, seizure Shock, coma	Acidosis, coma
Blood:		
Glucose	Low: <60 mg/dl	High: 250 mg/dl
Ketones	Negative	High, large
Osmolarity	Normal	High
pH	Normal	Low (≤7.25)
Hematocrit	Normal	High
Bicarbonate	Normal	<20 mEq/L
Urine:		
Output	Normal	Polyuria (early) to oliguria (late)
Glucose	Negative	Enuresis, nocturia
Ketones	Negative or trace	High
Visual	Diplopia	Blurred vision

alleviate the symptoms in the case of hypoglycemia but will do little harm if the child is hyperglycemic.

Children are usually able to detect the onset of hypoglycemia, but some are too young to implement treatment. Parents should become adept at recognizing the onset of symptoms—for example, a change in a child's behavior, such as tearfulness or euphoria. In the majority of cases, 10 to 15 g of simple carbohydrate, such as 1 tbsp of table sugar, will elevate the blood glucose level and alleviate the symptoms. The simpler the carbohydrate, the more rapidly it will be absorbed (8 oz of milk equals 15 g of carbohydrate). The rapid-releasing sugar is followed by a complex carbohydrate such as a slice of bread or a cracker and by a protein such as peanut butter or milk.

For a mild reaction, milk or fruit juice is good to use in children. Milk supplies them with lactose or milk sugar, as well as a more prolonged action from the protein and fat (helps decrease absorption). Other glucose sources include Insta-Glucose (cherry-flavored glucose), carbonated drinks (not sugarless), sherbet, gelatin, or cake icing. All children with diabetes should carry with them glucose tabs, Insta-Glucose, sugar cubes, or sugar-containing candy such as LifeSavers or Charms. A difficulty with candies or icing is that the child may learn to fake a reaction to get the sweets; therefore, commercial treatment products such as Insta-Glucose or glucose tabs may be preferred.

When in doubt, it is best to assume hypoglycemia and treat, but overtreatment could result in hyperglycemia. The treatment may be repeated in 10 to 15 minutes if the initial response is not satisfactory. Rest and the addition of food should be part of the plan.

An insulin reaction is often the most feared aspect of diabetes because severe brain symptoms may develop. In a severe reaction the various areas of the brain respond in sequence: the forebrain with increased drowsiness and perspiration, the hypothalamus and thalamus with tachycardia and loss of consciousness, the midbrain with seizure activity that may be started from stimulation initially from the hypothalamus, and finally the hindbrain with responses of deeper coma and decreasing reflexes. The treatment of choice for severe hypoglycemia is 50% glucose administered intravenously.

Glucagon is sometimes prescribed for home treatment of hypoglycemia. It is available as an emergency kit that must be mixed at the time of use and is administered intramuscularly or subcutaneously. Glucagon functions by releasing stored glycogen from the liver and requires about 15 to 20 minutes to elevate the blood glucose level.

! NURSING ALERT

Vomiting may occur after administration of glucagon; therefore, take precautions against aspiration (e.g., placing the child on the side), since the child will be unconscious.

Once the child is responsive, the lost glycogen stores are replaced by small amounts of sugar-containing fluid administered frequently until the child feels comfortable about trying solid foods.

Morning Hyperglycemia. The management of elevated morning blood glucose levels depends on whether the increase is a true dawn phenomenon, insulin waning, or a rebound hyperglycemia (the **Somogyi effect**). Insulin waning is a progressive rise in blood glucose levels from bedtime to morning. It is treated by increasing the nocturnal insulin dose. The true dawn phenomenon shows a relatively normal blood glucose level until about 3 am, when the level begins to rise. The Somogyi effect may occur at any time but often entails an elevated blood glucose level at bedtime and a drop at 2 AM with a rebound rise following. The treatment for this phenomenon is decreasing the nocturnal insulin dose to prevent the 2 AM hypoglycemia. The rebound rise in the blood glucose level is a result of counterregulatory hormones (epinephrine, GH, and corticosteroids), which are stimulated by hypoglycemia. More frequent blood monitoring (especially at times of anticipated peak insulin action) usually identifies these conditions. Trace amounts of urinary ketones aid in identifying undetected hypoglycemia.

Illness Management

Illness alters diabetes management, and maintaining control is usually related to the seriousness of the illness. In the well-controlled child an illness runs its course as it does in the unaffected child.

The goals during an illness are to restore euglycemia, treat urinary ketones, and maintain hydration. Monitor blood glucose levels and urinary ketones every 3 hours. Some hyperglycemia and ketonuria are expected in most illnesses, even with diminished food intake, and are an indication for increased insulin. Insulin should never be omitted during an illness, although dosage requirements may increase, decrease, or remain unchanged, depending on the severity of the illness and the child's appetite. Often the child needs supplemental insulin between usual dose times. If the child vomits more than once, if blood glucose levels remain above 240 mg/dl, or if urinary ketones remain high, notify the health care practitioner. Simple carbohydrates may be substituted for carbohydrate-containing exchanges in the meal plan. Although insulin and diet are important tools in sick-day care, fluids are the most important intervention. Fluids must be encouraged to prevent dehydration and to flush out ketones.

Surgery

The physiologic and emotional stresses related to surgery require careful adjustment of insulin. Because the child receives IV glucose during surgery and the stress of the surgery itself also raises the blood glucose level, the risk of an insulin reaction is slight. Short-acting insulins should be continued until the child is able to tolerate oral feedings and return to the routine pattern of insulin administration.

Prevention

Major advances have been made in the ability to detect susceptibility to type 1 DM, and animal studies indicate that the disease can be prevented by various immunologic interventions (Skyler and Marks, 2003). Early immunosuppression may preserve long-term endogenous insulin secretion in individuals with type 1 DM.

Cyclosporine, mycophenolic acid, and nicotinamide have shown promise in delaying beta cell destruction or lowering the incidence of type 1 DM in relatives of children with the disease. Much progress has been made in the identification of islet cell antigens targeted by the immune response. Many potential treatments to prevent type 1 DM have appeared, and human trials have begun.

Therapeutic Management: Diabetic Ketoacidosis

DKA, the most complete state of insulin deficiency, is a life-threatening situation. Management consists of rapid assessment, adequate insulin to reduce the elevated blood glucose level, fluids to overcome dehydration, and electrolyte replacement (especially potassium).

DKA constitutes an emergency situation; therefore, the child should be admitted to an intensive care facility for management. The priority is to obtain venous access for administration of fluids, electrolytes, and insulin. The child should be weighed, measured, and placed on a cardiac monitor. Blood glucose and ketone levels are determined at the bedside, and samples are obtained for laboratory measurement of glucose, electrolytes, blood urea nitrogen, arterial pH, PO_2, PCO_2, hemoglobin, hematocrit, white blood cell count and differential, calcium, and phosphorus.

Oxygen may be administered to patients who are cyanotic and in whom arterial oxygen is less than 80%. Gastric suction is applied to unconscious children to avoid the possibility of pulmonary aspiration. Antibiotics may be administered to febrile children after appropriate specimens are obtained for culture. A Foley catheter may or may not be inserted for urine samples and measurement. Unless the child is unconscious, a collection bag is usually sufficient for accurate assessments.

Fluid and Electrolyte Therapy

All patients with DKA suffer from dehydration (10% of total body weight in severe ketoacidosis) because of the osmotic diuresis, accompanied by depletion of electrolytes, sodium, potassium, chloride, phosphate, and magnesium. Serum pH and bicarbonate reflect the degree of acidosis. Prompt and adequate fluid therapy restores tissue perfusion and suppresses the elevated levels of stress hormones.

The initial hydrating solution is 0.9% saline solution. Traditionally deficits have been replaced at a rate of 50% over the first 8 to 12 hours and the remaining 50% over the next 16 to 24 hours. Current trends suggest more cautious fluid management to reduce the risk of cerebral edema. Consequently, the recommendations now are to replace the deficit evenly over 36 to 48 hours (Cooke and Plotnick, 2004).

DRUG ALERT

Potassium and Serum Potassium Levels

Potassium must never be given until the serum potassium level is known to be normal or low and urinary voiding is observed. All maintenance IV fluids should include 30 to 40 mEq/L of potassium unless the potassium concentration is elevated or urinary output is absent (Cooke and Plotnick, 2004). Never give potassium as a rapid IV bolus, or cardiac arrest may result.

Serum potassium levels may be normal on admission, but after fluid and insulin administration the rapid return of potassium to the cells can seriously deplete serum levels, with the attendant risk of cardiac arrhythmias. As soon as the child has established renal function (is voiding at least 25 ml/hr) and insulin has been given, vigorous potassium replacement is implemented. The cardiac monitor is used as a guide to therapy, and the nurse should observe the configuration of T waves every 30 to 60 minutes to determine changes that might indicate alterations in potassium concentration (widening of the Q-T interval and the appearance of a U wave following a flattened T wave indicate hypokalemia; an elevated and spreading T wave and shortening of the Q-T interval indicate hyperkalemia).

Insulin should not be given until after obtaining urine ketones and a blood glucose level. Continuous IV regular insulin is given at a dosage of 0.1 units/kg/hr. Insulin therapy should be started after the initial rehydration bolus, since serum glucose levels fall rapidly after volume expansion. Blood glucose levels should decrease by 50 to 100 mg/dl/hr. When blood glucose levels fall to 250 to 300 mg/dl, dextrose is added to the IV solution. The goal is to maintain blood glucose levels between 120 and 240 mg/dl by adding 5% to 10% dextrose. Sodium bicarbonate is used conservatively; it is used for pH less than 7.0, severe hyperkalemia, or cardiac instability. Because sodium bicarbonate has been associated with increased risk for cerebral edema, children receiving this substance must be carefully monitored for changes in level of consciousness (Brown, 2004). If bicarbonate treatment is necessary, 1 to 2 mEq/kg should be added to the IV fluids to run over 1 to 2 hours (Cooke and Plotnick, 2004).

When the critical period is over, the task of regulating insulin dosage in relation to diet and activity is started. Children should be actively involved in their own care and are given responsibility according to their ability and the guidance of the nurse.

DRUG ALERT

Insulin and Tubing

Because insulin can chemically bind to plastic tubing and in-line filters, thereby reducing the amount of medication reaching the systemic circulation, an insulin mixture is run through the tubing to saturate the insulin-binding sites before the infusion is started.

Nursing Care of the Child with Diabetes Mellitus: Acute Care

Children with DM may be admitted to the hospital at the time of their initial diagnosis; during illness or surgery; or for episodes of ketoacidosis, which may be precipitated by any of a variety of factors. Many children are able to keep the disease under control with periodic assessment and adjustment of insulin, diet, and activity as needed under the supervision of a practitioner. Under most circumstances these children can be managed well at home and require hospitalization only for a serious illness or upset (see Research Focus box).

However, a small number of children with diabetes exhibit a degree of metabolic lability and have repeated episodes of

DKA that require hospitalization, which interferes with education and social development. These children appear to display a characteristic personality structure. They tend to be unusually passive and nonassertive and to come from families that are inclined to smooth over conflicts without resolution. Children in this type of setting experience emotional arousal with little, if any, opportunity or ability to resolve it. Other children from psychosocially dysfunctional families display behavioral and personality problems. This emotional stress causes an increased production of endogenous catecholamines, which stimulate fat breakdown, leading to ketonemia and ketonuria.

Loving discipline is a supportive measure for any child; however, children with poorer diabetic control come from predominantly disruptive family units with little or no discipline. Lack of control is psychologically harmful. Because many of the psychosocial problems are not immediately apparent, psychosocial assessment by professionals is required, together with ongoing emotional support and counseling to reverse the patterns of ketoacidosis (Wolsdorf, Glaser, and Sperling, 2006).

Hospital Management

The child with DKA requires intensive nursing care. Observe vital signs and record them frequently. Hypotension caused by the contracted blood volume of the dehydrated state may cause decreased peripheral blood flow, which can be particularly hazardous to the heart, lungs, and kidneys. An elevated temperature may indicate infection and should be reported so that treatment can be implemented immediately.

Maintain careful and accurate records, including vital signs (pulse, respiration, temperature, and blood pressure), weight, IV fluids, electrolytes, insulin, blood glucose level, and intake and output. Use a urine collection device or retention catheter to obtain the urine measurements, which include volume, specific gravity, and glucose and ketone values. The volume relative to the glucose content is important because 5% glucose in a 300-ml sample is a significantly greater amount than a similar reading from a 75-ml sample. A diabetic flow sheet maintained at the bedside provides an ongoing record of the vital signs, urine and blood tests, amount of insulin given, and intake and output. Assess the level of consciousness and record it at frequent intervals. The comatose child generally regains consciousness fairly soon after initiation of therapy but is managed like any unconscious child during that time.

When the critical period is over, the task of regulating insulin dosage to diet and activity begins. The same meticulous records of intake and output, urine glucose and acetone levels, and insulin administration are maintained. Capable children should be actively involved in their own care and are given responsibility for keeping the intake and output record, testing the blood and urine, and, when appropriate, administering their own insulin—all under the nurse's supervision and guidance (see Nursing Care Plan).

RESEARCH FOCUS

Outpatient Treatment of Type 1 Diabetes

A Cochrane systematic review of seven studies evaluating whether children newly diagnosed with type 1 diabetes should be admitted to a hospital or treated in the outpatient setting found no disadvantages to allowing the child to remain as an outpatient. Studies evaluated metabolic control, acute diabetic complications and hospitalizations, psychosocial variables and behavior, and total care costs (Clar, Waugh, and Thomas, 2007).

Nursing Care of the Child with Diabetes Mellitus: General Care

Diabetes management involves a constant state of assessment. Daily monitoring of blood glucose levels; periodic urinalysis for

NURSING CARE PLAN

The Child with Diabetes Mellitus

NURSING DIAGNOSIS	EXPECTED PATIENT OUTCOMES	NURSING INTERVENTIONS	RATIONALE
Risk for Injury related to insulin deficiency	Child will demonstrate normal blood glucose levels.	Obtain blood glucose level.	To determine most appropriate dose of insulin
Child's/Family's defining characteristics	**The following NOC concept applies to these outcomes:**	Administer insulin as prescribed.	To maintain normal blood glucose level
(Subjective and Objective Data)	Blood Glucose Control	Understand the action of insulin: differences in composition, time of onset, and duration of action for the various preparations.	To ensure accurate insulin administration
See Box 33-13.		Employ aseptic techniques when preparing and administering insulin.	To prevent infection

ketones; and observation for signs of hypoglycemia, hyperglycemia, or other complications are part of the daily life of children with diabetes and their families. Suspect diabetes in any child who exhibits the manifestations of hypoglycemia or hyperglycemia, and refer the child for further assessment and appropriate testing.

QUALITY PATIENT OUTCOMES

Diabetes Mellitus

- Blood glucose levels maintained within normal range
- HbA_{1c} range from 6.5% to 8%
- DKA prevented

The nurse should be alert to evidence of complications, although these are usually not manifested until adulthood. Assessment of skin for evidence of breakdown is important so that appropriate care can be implemented to facilitate healing and prevent infection. Because illnesses such as respiratory tract infections or gastrointestinal upsets complicate the diabetes management, they should be detected early.

Education is the cornerstone of diabetes management and the major responsibility in diabetes nursing care. This includes education and reinforcement of information for the family and for children who are old enough to participate in self-management of the disease. With younger children, parents must supervise and manage their therapeutic program, but children should assume some responsibility for self-management as soon as they are capable. Children can assist with blood glucose testing at a relatively young age, and most should be able to administer their own insulin at about 9 years of age. In situations in which the parents are inconsistent or unreliable, the child can learn self-care at an earlier age. However, education programs cannot be conducted as one-time activities with the expectation that they will achieve permanent behavior changes. Education is an ongoing nursing activity as family and patient needs change and new findings are applied.

Concepts of Child and Family Education

Children and their families vary in educational background and the capacity to learn and understand the various aspects of the therapeutic program. Some families respond best to simple explanations and directions, whereas others expect thorough, in-depth information about the physiologic processes and responses associated with the disease and its therapy. All the principles of teaching and learning are applied in the educational process; therefore, before beginning, the nurse must determine the optimum time, place, method, and content to be taught. Self-management, the ultimate goal for children with diabetes, is more likely to occur when children understand the disease and the care it requires. Properly educated and motivated, most families should be able to follow a program of regulated control satisfactorily.

When to teach a family and child is best judged by their psychologic state and emotional readiness. When a child is newly diagnosed, the psychologic adjustment to the disease can block the learning process completely. For example, in a follow-up visit family members may state that they are hearing a certain bit of information for the first time even though the material had been covered several times in the course of teaching.

Certainly the first 3 or 4 days after diagnosis are not an optimum time for complex learning. In fact, the later the more complex material is presented, the better. For example, one successful program teaches only essential, or survival, information first and intense information a month later. Another program advocates teaching 1 week after diagnosis, followed by a review of survival techniques 2 weeks after discharge. Probably the worst time for teaching is the day or so after diagnosis, when the education must be compressed into a few hours or days so that the child can be discharged early.

Regardless of the teaching plan, the nurse must accurately assess individual ability to learn. This includes assessment of the individuals' educational background and emotional stability and the use of appropriate measurement tools, such as a pretest or an objective assessment of the learners' educational level. The stepped approach to patient education employs the method of simple to complex. The stepped approach involves using good interpersonal skills, teaching about the illness and regimen, and overcoming obstacles to behavior change.

The setting for the educational process can facilitate learning. If the child must be hospitalized, bedside education may be necessary in some cases, but the coming and going of a number of people can be distracting. At times in the educational process individual instruction is needed, but contact with other children or parents can assist in adjustment to the reality of the disease and the implications of having a chronic condition.

A child learns best when sessions are short, no more than 15 to 20 minutes. The parents do best with periods of 45 to 60 minutes, or longer if they are inquisitive. Education should involve all the senses. Although visual aids are valuable tools, participation is the most effective method for learning. For example, to teach blood glucose testing, the nurse explains the technique, demonstrates the procedure, and allows the learner to perform the procedure; this is followed by a review of the material using visual aids, with learning validated by some testing method that includes feedback. A variety of teaching methods and teaching aids can be used. Some visual aids may be beautifully illustrated but miss a major point; therefore, materials should be previewed for accuracy and appropriateness. Varying the presentation with a variety of audiovisual materials, including films, slide-tape programs, and books, stimulates the senses and helps the individual learn.

Several organizations are prepared to assist with education and dissemination of knowledge about diabetes. The American Diabetes Association,* Canadian Diabetes Association,† Juvenile Diabetes Research Foundation International,‡ and

†1400-522 University Ave., Toronto, Ontario, Canada M5G 2R5; 800-226-8464; **www.diabetes.ca**.

‡26 Broadway, 14th Floor, New York, NY 10004; 800-533-2873; **www.jdf.org**.

American Association of Diabetes Educators* are valuable resources for a wide variety of educational materials. The National Institute of Diabetes and Digestive and Kidney Diseases† publishes a number of comprehensive annotated bibliographies, including "Educational Materials for and About Young People with Diabetes," a compilation of resource materials for children, siblings, parents, teachers, and health professionals; and "Sports and Exercise for People with Diabetes."

The content of the educational course must include all aspects of the disease as they relate to the individual child. Many aspects of the disease may not be covered in an initial educational course but can be postponed until subsequent office or clinic visits or can be done through referral sources such as the American Diabetes Association. The minimum information needed should help the family manage from one day to the next; expanded information helps the individual with long-term adjustment to the disease. The more the family understands about the disease in relation to body needs, the better they are able to maintain a high degree of control. Important content needed for minimum management is discussed briefly in the following sections.

Identification

One of the first things the nurse should call to the parents' attention is the need for the child to wear some means of medical identification. Usually recommended is the MedicAlert identification, a stainless steel, silver, or gold-plated identification bracelet that is visible and immediately recognizable. It contains a collect telephone number that medical personnel can call around the clock for medical records and personal information.

Nature of Diabetes

The better the parents understand the pathophysiology of diabetes and the function and action of insulin and glucagon in relation to caloric intake and exercise, the better they will understand the disease and its effects on the child. Parents need answers to a number of questions (voiced or unvoiced) to increase their confidence in coping with the disease. For example, they may want to know about the various procedures performed on their child and treatment rationale, such as what is being put in the IV bottle and the expected effect.

Meal Planning

Normal nutrition is a major aspect of the family education program. The nutritionist usually conducts diet instruction, with reinforcement and guidance from the nurse. The emphasis is on adequate intake for age, consistent menus, complex carbohydrates, and consistent eating times. The family learns how the meal plan relates to the requirements of growth and development, the disease process, and the insulin regimen. Meals and snacks are modified based on the child's preferences and current menu, preserving cultural patterns and preferences as much as possible. Extensive exchange lists are available that include foods compatible with most lifestyles.

Learning about foods within specific food groups helps in making choices. Weights and measures of foods are used as eye-training devices for defining serving sizes and should be practiced for about 3 months, with gradual progression to estimation of food portions. Even when the child and family become competent in estimating portion sizes, reassessment should take place weekly or monthly and when there is any change of brands.

Family members should also be guided in reading labels for the nutritional value of foods and food content. They need to become familiar with the carbohydrate content of food groups. Substitution with foods of equal carbohydrate content is the skill needed for successful carbohydrate counting. Substitution might be necessary if a food is not available in sufficient quantity or for the teenager who wishes to eat fast food with peers. The use of a multiple daily injection program lends flexibility to the timing of meals.

Educating children or teenagers to make healthy food choices is an ongoing task. Teach younger children to choose from a special treat box stocked with sugar-free items when others bring high-sugar treats to the classroom. Discussions with school-age children might include situations encountered at school or parties, such as choosing food in the cafeteria or bringing substitute treats to parties. Role-playing and discussion help teenagers deal with food choices when on dates, with friends, or on a food break after school.

Lists of popular fast-food items and items served at the major fast-food chains can be obtained from the restaurants to help guide food selections. It is important that the child know the nutritional value of these items (the major chains are remarkably uniform), but the child should be cautioned to avoid high-fat, high-sugar, and high-carbohydrate items. For example, the child could choose a plain hamburger instead of a double cheeseburger.

Children should use sugar substitutes with moderation in items such as soft drinks. Artificial sweeteners have been shown to be safe, but if there is any question about amounts, the physician, dietitian, or nurse specialist can provide guidelines based on body weight. Sugar-free chewing gum and candies made with sorbitol may be used in moderation by children with DM. Although sorbitol is less cariogenic than other varieties of sugar substitutes, it is an alcohol sugar that is metabolized to fructose and then to glucose. Furthermore, large amounts can cause osmotic diarrhea. Most dietetic foods contain sorbitol. They are more expensive than regular foods. Also, although a product may be sugar free, it is not necessarily carbohydrate free.

Traveling

Traveling requires advance planning, especially when a trip involves crossing time zones. A number of tips are included in pamphlets available free of charge. Suggestions for traveling encompass what will be needed from the practitioner before leaving, what and how much to take along, needs in transit,

*200 W. Madison St., Suite 800, Chicago, IL 60606; 800-338-3633; www.aadenet.org.

†Office of Communications and Public Liaison, NIDDK, NIH, Building 31, Room 9A06, 31 Center Dr., MSC 2560, Bethesda, MD 20892-2560; 301-496-3583; www.niddk.nih.gov.

what to consider at the destination, and planning for when the child returns home. Planning is needed no matter what type of travel is considered—automobile, plane, bus, or train.

Insulin

Families need to understand the treatment method and the insulin prescribed, including the effective duration, onset, and peak action. They also need to know the characteristics of the various types of insulins, the proper mixing and dilution of insulins, and how to substitute another type when their usual brand is not available (insulin is a nonprescription drug). Insulin need not be refrigerated but should be maintained at a temperature between 15° and 29.5° C (59° and 85° F). Freezing renders insulin inactive.

Insulin bottles that have been "opened" (i.e., the stopper has been punctured) should be stored at room temperature or refrigerated for up to 28 to 30 days. After 1 month these vials should be discarded. Unopened vials should be refrigerated and are good until the expiration date on the label. Diabetic supplies should not be left in a hot environment.

Injection Procedure

Learning to give insulin injections is a source of anxiety for both parents and children. It is helpful for the learner to know that this important aspect of care will become as routine as brushing the teeth. First, the basic injection technique is taught, using an orange or similar item and sterile normal saline for practice. To gain children's confidence, the nurse can demonstrate the technique by giving a skillful injection to the parent and then having the parent return the demonstration by giving the nurse an injection. With practice and confidence, the parents soon are able to give the insulin injection to their children, and their children trust them. Another effective strategy is to instruct the children and then have them teach the technique to the parents while the nurse observes. Both parents should participate, and as little time as possible should elapse between instruction and the actual injection, especially with parents and teenage learners.

Insulin can be injected into any area in which there is adipose (fat) tissue over muscle; the drug is injected at a 90-degree angle. Newly diagnosed children may have lost adipose tissue, and care should be exerted not to inject intramuscularly. The pinch technique is the most effective method for tenting the skin to allow easy entrance of the needle to subcutaneous tissues in children. The site selected sometimes depends on whether children or parents administer the insulin. The arms, thighs, hips, and abdomen are usual injection sites for insulin. The children can reach the thighs, abdomen, and part of the hip and arm easily but may require help to inject other sites. For example, a parent can pinch a loose fold of skin of the arm while the child injects the insulin.

The parents and child are helped to work out a rotation pattern to various areas of the body to enhance absorption, since insulin absorption is slowed by fat pads that develop in overused injection areas. The most efficient rotation plan involves giving about four to six injections in one area (each injection about 2.5 cm [1 inch] apart, or the diameter of the insulin vial from the previous injection) and then moving to another area.

TABLE 33-7 ONSET AND DURATION OF ACTION RELATED TO INJECTION SITE

	SITE OF INJECTION			
	ABDOMEN	ARM	LEG	BUTTOCK
Rate	Very fast	Fast	Slow	Very slow
Duration	Very short	Short	Long	Very long

From Albisser AM, Sperlich M: Adjusting insulins, *Diabetes Educ* 18(3):211-218, 1992.

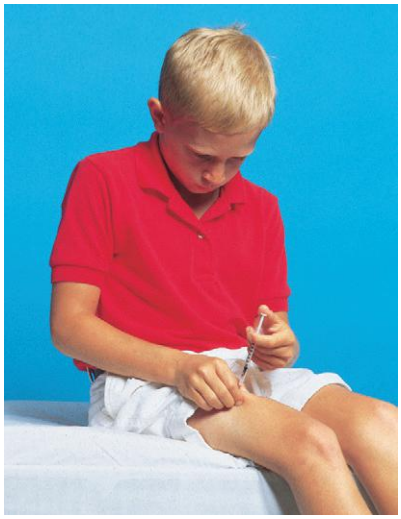

FIG. 33-8 School-age children are able to administer their own insulin.

Remember that the absorption rate varies in different parts of the body (Table 33-7). Methodically using one anatomic area and then moving to another (as described in the previous paragraph) minimize variations in absorption rates. However, vigorous exercise, which enhances absorption from exercised muscles, also alters absorption. Therefore, it is recommended that a site be chosen other than the exercising extremity (e.g., avoiding legs and arms when playing in a tennis tournament).

Injection sites for an entire month can be determined in advance on a simple chart. For example, the "paper doll" (body outline) can be constructed and insulin sites marked by the child. After injection, the child places the date on the appropriate site. To keep in practice, it is a good idea for the parent to give two or three injections a week in areas that are difficult for the child to reach.

The same basic methodology is used when teaching children to give their own insulin injections (Fig. 33-8). They should practice first on an orange or a doll, building courage gradually. The first attempt is usually awkward because children tend to slowly push the needle through the skin rather than using a quick approach. It is best not to pressure them into assuming this responsibility until they are ready. When

children participate in a group learning situation or have an opportunity to observe their peers giving their own injections, they may become more motivated. Warn parents that at some time children will give themselves an uncomfortable injection at home and that they will need parental support and encouragement. Otherwise children may not wish to give themselves injections for some time.

Other devices are available for insulin injection and may offer advantages to some children. Children who do not wish to give themselves injections can learn to use a syringe-loaded injector (Inject-Ease). With the device, puncture is always automatic. Adolescents respond well to a self-contained and compact device resembling a fountain pen (NovoPen), which eliminates conventional vials and syringes. Preloaded pens may also improve adherence to intensive insulin regimens, improve lifestyle flexibility, and decrease pain (Rex, Jensen, and Lawton, 2006).

Teaching includes the proper way to equalize pressure in the bottle by injecting an amount of air equal to the amount of solution withdrawn and how to remove air bubbles from the syringe. When insulin doses are small, an air bubble in the syringe can displace a significant amount of medication. Since the introduction of the 0.5-ml and 0.3-ml syringes, the risk of incorrect dosage has diminished. Advise patients who have small doses of mixed insulins to use one of these syringes. Insulin syringes should be compared for accuracy, comfort, and strength. The family and child should be able to choose both "their" insulin and "their" syringe from a variety of samples. The needle length and gauge are also factors to consider from the point of view of comfort (e.g., use the shortest and smallest-gauge needle available). Some brands of syringes may be more comfortable than others. When currently available syringes are used, insulin injections of less than 2 units of U100 may have an unacceptably large error. Diluted insulin is sometimes used if the prescribed dose is less than 2 units. Special diluent is available from the insulin manufacturers (Eli Lilly, 2007).

When the child's dosage requires the injection of both short- and intermediate-acting insulin at the same time, most families prefer to mix the two and use a single injection. Insulin can be premixed and stored in the refrigerator for later use. Commercially prepared insulin mixtures are also available (e.g., 70/30 and 50/50). To obtain maximum benefit from mixing insulins, the recommended practice is to (1) inject the measured amount of air (equivalent to the dosage) into the long-acting insulin; (2) inject the measured amount of air into the rapid-acting (clear) insulin and, without removing the needle; (3) withdraw the clear insulin; and (4) insert the needle (already containing the clear insulin) into the long-acting (cloudy) insulin and then withdraw the desired amount.

DRUG ALERT

Mixing Insulin

When mixing types of insulin, always withdraw the clear, rapid-acting insulin into the syringe first, then the long-acting insulin. This avoids contaminating the short-acting insulin with the longer-acting insulin.

Inject the mixture either less than 5 minutes after mixing (before the zinc content of the long-acting insulin affects the action time of the short-acting insulin) or 15 or more minutes after mixing (to allow the insulins to resume long-acting and short-acting properties).

Nurses should also teach proper disposal of equipment after use in the home. Although not standard practice in the hospital, the use of a needle clipper is recommended to safely remove and house the used needle. The syringe plunger can be broken before disposal. An excellent means for syringe disposal is in an opaque, puncture-resistant container, such as an empty coffee can, bleach bottle, or milk carton. The container is labeled "biohazardous waste" and is discarded with similar material only, not with household refuse and consistent with local regulations.

Continuous Subcutaneous Insulin Infusion. Some children are candidates for use of a portable insulin pump, and even some young children with unsatisfactory metabolic control can benefit from its use. The child and the parents learn to operate the device, including the mechanics of the pump, battery changes, and alarm systems. A number of devices are available on the market that vary in the basal rates they are able to deliver and in the cost of the equipment. Families can investigate the various devices and select the model that best suits their needs. Product information is available from pump manufacturers and distributors.

Parents and children learn (1) the technical aspects of the pump and self-monitoring of blood glucose; (2) prevention and treatment for hyperglycemia, sick-day management, and meal planning; (3) the effects of exercise, stress, and diet on blood glucose levels; and (4) decision-making strategies to evaluate blood glucose patterns and how to make adjustments in all aspects of the regimen.

Numerous blood glucose measurements (at least four times per day) are an essential part of infusion pump use. Intensive education and supervision are critical to obtaining maximum efficiency and control. This is particularly important if the family has been accustomed to a conventional insulin regimen. They must realize that simply wearing the pump will not normalize blood glucose. The pump is merely an insulin delivery device, and frequent, routine blood glucose determinations are necessary to adjust the insulin delivery rate.

The major problem with use of the insulin pump is inflammation from irritation or infection at the insertion site. The site should be cleaned thoroughly before the needle is inserted and then covered with a transparent dressing. The site is changed and rotated every 48 to 72 hours (this may vary) or at the first sign of inflammation. Nurses working where pumps are part of the therapeutic regimen should become familiar with the operation of the specific device being used and the protocol of disease management. Others should be aware of this management technique and be prepared to assist patients using the pump.

Monitoring

Nurses should also be prepared to teach and supervise blood glucose monitoring. SMBG is associated with few

FIG. 33-9 Child using finger-stick device to obtain blood sample.

FIG. 33-10 Child using blood glucose monitor and reagent strips to test blood for glucose.

ATRAUMATIC CARE

Minimizing Pain of Blood Glucose Monitoring

- To enhance blood flow to the finger, hold it under warm water for a few seconds before the puncture.
- When obtaining blood samples, use the ring finger or thumb (blood flows more easily to these areas), and puncture the finger just to the side of the finger pad (more blood vessels and fewer nerve endings).
- To prevent a deep puncture, press the platform of the lancet device lightly against the skin and avoid steadying the finger against a hard surface.
- Use lancet devices with adjustable-depth tips. Begin with the shallowest setting.
- Use glucose monitors that require small blood samples (e.g., Ascensia Elite) to avoid repeated punctures.

complications, and although it does not necessarily lead to improved metabolic control, it provides a more accurate assessment of blood glucose levels than can be obtained with the historical urine testing. Blood glucose monitoring has the added advantage that it can be performed anywhere (see Atraumatic Care box).

Blood for testing can be obtained by two different methods: manually or with a mechanical bloodletting device. A mechanical device is recommended for children, although the child and family should learn to use both methods in the event of mechanical failure. Several lancet devices are available from which to choose, and each provides a means for obtaining a large drop of blood for testing (Fig. 33-9).

! NURSING ALERT

Caution children not to allow anyone else to use their lancet because of the risk of contracting hepatitis B virus or human immunodeficiency virus infection.

The blood sample may be obtained from fingertips or alternate sites such as the forearm. Alternate site testing requires a meter that can test a small volume of blood. Not all meters are capable of this.

The practitioner should examine signs of redness and soreness at the site of finger puncture. It may be evidence of poor technique, poor hygiene, or poor skin healing relative to poor control. Many types of blood-testing meters are available for home use. Newer technology has brought about improvements in meter size and ease of use. The family should be shown features of several meters, including advantages and disadvantages, and allowed to choose equipment that best meets their needs.

The least expensive testing method uses a reagent strip to which blood is applied (Fig. 33-10). After blotting, the color change is compared to a color scale for an estimation of the blood glucose level. The strips can be cut in half (although not all professionals recommend this) to obtain two readings per strip. This method is not accepted practice but may be necessary for some families or situations.

Urine Testing. Testing for urinary ketones is recommended during times of illness or when blood glucose values are elevated. Information on a specific ketone-testing product should include correct procedure, storage, and product expiration. Families need a clear understanding of home management of ketones: fluids and additional insulin as directed by the health care team.

Shopping

Diabetic maintenance is an expensive necessity. Families should investigate all sources of obtaining supplies for managing the disease. Prices are often lower when supplies are purchased in volume; however, it is not advisable to buy bulk items that are unfamiliar, since the new items may not be satisfactory for the individual child or may become outdated before they are used. Costs vary considerably among pharmacies and other suppliers, including the numerous discount mail-order establishments. When buying by mail, it is important to find a supplier that responds to the family's satisfaction and to allow ample time for delivery to avoid running out of supplies. Parents are also

cautioned not to substitute insulins or the type of insulin syringe (e.g., a 1-ml syringe for the low-dose type) simply to save money. Parent groups and the local American Diabetes Association can offer some suggestions for investigation. Most states have legislation mandating that insurance companies cover the cost of diabetes supplies and education.

Hyperglycemia

Severe hyperglycemia is most often caused by illness, growth, emotional upset, or missed insulin doses. Emotional stress from school finals or examinations and physical response to immunizations are examples of causes of hyperglycemia. With careful glucose monitoring, any elevation can be managed by adjustment of insulin or food intake. Parents should understand how to adjust food, activity, and insulin at the time of illness or when the child is treated for an illness with a medication known to raise the blood glucose level (e.g., steroids). The hyperglycemia is managed by increasing insulin soon after the increased glucose level is noted.

Hypoglycemia

Hypoglycemia is caused by imbalances of food intake, insulin, and activity. Ideally hypoglycemia should be prevented, and parents need to be prepared to prevent, recognize, and treat the problem. They should be familiar with the signs of hypoglycemia and instructed in treatment, including care of the child with seizures. (See Chapter 32.) Early signs are adrenergic, including sweating and trembling, which help raise the blood glucose level, much like the reaction when an individual is startled or anxious. The second set of symptoms that follow an untreated adrenergic reaction are neuroglycopenic (also called brain hypoglycemia). These symptoms typically include difficulty with balance, memory, attention, or concentration; dizziness or lightheadedness; and slurred speech. Severe and prolonged hypoglycemia leads to seizures, coma, and possible death (Cryer, 2003). In particular, infants are at an increased risk because of the developing brains' vulnerability to the potential neurotoxic insult of hypoglycemia (Cooke and Plotnick, 2004). Hypoglycemia can be managed effectively (see Emergency Treatment box).

It is advisable for parents to plan for anticipated excitement or exercise. In addition, gastroenteritis may decrease insulin needs slightly as a result of poor appetite, vomiting, or diarrhea. If the blood glucose level is low but urinary ketones are present, the family should be aware of the increased need for simple carbohydrates and liquids.

Hygiene

All aspects of personal hygiene should be emphasized for the child with diabetes. Caution the child against wearing shoes without socks, wearing sandals, or walking barefoot. Correct nail and extremity care tailored to the individual child (with the guidance of a podiatrist) can begin health practices that last a lifetime. Eyes should be checked once a year unless the child wears glasses, and then as directed by the ophthalmologist. Regular dental care is emphasized, and cuts and scratches should be treated with plain soap and water unless otherwise indicated. Diaper rash in infants and candidial infections in teens may indicate poor diabetes control.

EMERGENCY TREATMENT

Hypoglycemia

Mild Reaction: Adrenergic Symptoms

Give child 10 to 15 g of a simple, high-carbohydrate substance (preferably liquid—e.g., 3 to 6 oz of orange juice).
Follow with starch-protein snack.

Moderate Reaction: Neuroglycopenic Symptoms

Give child 10 to 15 g of a simple carbohydrate as above.
Repeat in 10 to 15 minutes if symptoms persist.
Follow with larger snack.
Watch child closely.

Severe Reaction: Unresponsive, Unconscious, or Seizures

Administer glucagon as prescribed.
Follow with planned meal or snack when child is able to eat, or add a snack of 10% of daily calories.

Nocturnal Reaction

Give child 10 to 15 g of a simple carbohydrate.
Follow with snack of 10% of daily calories.

Exercise

Exercise is an important component of the treatment plan. If the child is more active at one time of the day than at another time, food or insulin can be altered to meet that activity pattern. Food should be increased in the summer, when children tend to be more active. Decreased activity on return to school may require a decrease in food intake or increase in insulin dosage. The child who is active in team sports needs a snack about a half hour before the anticipated activity. Races or other competition may call for a slightly higher food intake than practice times.

Food intake usually needs to be repeated for prolonged activity periods, often as frequently as every 45 minutes to 1 hour. Families should be informed that if increased food is not tolerated, decreased insulin is the next course of action. If the timing of the exercise is changed so that the supper meal is delayed, the insulin in the second or third dose of the day may be moved back to precede the mealtime. Sugar may sometimes be needed during exercise periods for quick response. Elevated blood glucose levels after extreme activity may represent the body's adrenergic response to exercise. If the blood glucose level is elevated (>240 mg/dl) before planned exercise, urine ketones should be checked and the activity may need to be postponed until the blood glucose is controlled.

Without adequate insulin levels the cells are unable to receive glucose, the preferred fuel, despite the high level of blood glucose. The low insulin level allows glucagon to act, uninhibited, to increase hepatic glucose production, further raising the blood glucose level with no means to use sugar at the muscle site. Breakdown of fat (lipolysis) is the alternative, and the end product of lipolysis is ketone body production (Cooke and Plotnick, 2008).

! NURSING ALERT

Ketonuria in the presence of hyperglycemia is an early sign of ketoacidosis and a contraindication to exercise.

Record Keeping

Home records are an invaluable aid to diabetes self-management. The nurse and family devise a method to chart insulin administered, blood glucose values, urine ketone results, and other factors and events that affect diabetes control. The child and family should observe for patterns of blood glucose responses to events such as exercise. If lapses in management occur (such as eating a candy bar), the child should be encouraged to note this and not be criticized for the transgression.

Complications

The nurse should present the implications of the disease in a tactful, clear, and nonthreatening manner. Knowledge of the complications of diabetes and their relationship to control provides a basis for good decision making. Eye and kidney diseases are the greatest threats, with neurologic complications close behind. Clear explanations of these problems clarify false information often given by well-meaning friends. The information should include discussion of research so that the family is left with the positive impression that others are concerned about finding answers and preventing complications. It also gives them hope that somehow, some way, a prevention or cure will be possible.

Self-Management

Self-management is the key to close control. Being able to make changes when they are needed rather than waiting until the next contact with health care professionals is important for self-management and gives the individual and family the feeling they have control over the disease. Psychologically this helps family members feel they are useful and participating members of the team. Allowing the child to learn to look at records objectively promotes independence in self-management support. As children grow and assume more responsibility for self-management, they develop confidence in their ability to manage their disease and confidence in themselves as persons. They learn to respond to the disease and to make more accurate interpretations and changes in treatment when they become adults.

Self-management techniques to be mastered are the testing and adjustment of insulin and diet with alterations in day-to-day activities and anticipation of unusual occurrences. However, the nurse should provide guidelines regarding when to consult with the health care professionals. For instance, the degree of metabolic control before an illness is a determining factor in seeking medical help during the illness. In an individual with poor control, it takes only a few hours before the trouble is severe, whereas if control is good before the illness, several days may elapse before help is needed. Also caution patients and families to seek assistance if glucose levels are elevated and urine is not clear of ketones after 24 hours of self-management.

Child and Family Support

Just as the physiologic responses affect the child, the parents and other family members of the child with newly diagnosed DM experience various emotional responses to the crisis. Care in the acute setting is short but may create fears and frustrations. The prospect of a chronic illness in their child engenders all the feelings and concerns that are faced by parents of children with other chronic illnesses. (See Chapter 19.) The threat of complications and death is always present, as well as the continuing drain on emotional and financial resources.

NURSING TIP Ongoing motivation to adhere to a regimen is difficult. An older child and parent (or another caregiver) may enjoy negotiating a day off when the responsibility for testing and recording blood glucose is delegated from the child to the caregiver (or vice versa).

Adolescents appear to have the most difficulty adjusting. Adolescence is a time of stress in trying to be perfect and like one's peers, and no matter what others say, having diabetes is being different. Some adolescents are more upset about not being able to have a candy bar than about injections, diet, and other aspects of management. If children can accept the difference as a part of life—in other words, that each person is different in some way—then with adequate parental support they should be able to adjust well.

Problems of adjustment to diabetes are especially difficult for the young person whose disease is diagnosed in adolescence. Denial is sometimes expressed by omitting insulin, not performing tests, and eating incorrectly, although denial of the disease usually diminishes during this period as the adolescent with DM begins to feel competent and worthy. Diabetes makes the teenager different when conformity and sameness are desired; having the disease emphasizes vulnerability and imperfection when the search for identity is the foremost developmental task of adolescence. It is often difficult for the adolescent to know what to tell friends.

Camping and other special groups are useful. At diabetes camp, children learn that they are not alone. As a result, they become more independent and resourceful in other settings. Useful information about such camps and organizations can be obtained from the American Diabetes Association. A list of accredited camps specifically for children and teenagers with diabetes is also available from the American Camp Association.*

Puberty is associated with decreased sensitivity to insulin that normally would be compensated for by an increased insulin secretion. Health care professionals should anticipate that pubertal patients will have more difficulty maintaining

*5000 State Road 67 N., Martinsville, IN 46151; 765-342-8456; www.ACAcamps.org.

glycemic control. Insulin doses commonly need to be increased, often dramatically (Tfayli and Arslanian, 2007). Patients should learn to give themselves additional doses of rapid-acting insulin (5% to 10% of their daily dose) when their blood glucose levels are increased. The use of supplemental rapid-acting insulin is preferred to withholding food in the adolescent.

Eating disorders, such as bulimia or anorexia nervosa, in the teenager with type 1 DM (see Chapter 18) pose a serious health hazard (Ackard, Vik, Neumark-Sztainer, et al, 2008). The nurse should be alert to a history of preoccupation with weight, food faddism, excessive caloric restriction, or unexplained hypoglycemia. Moreover, insulin manipulation or omission has been identified as a weight loss tool used by some female adolescents (Tierney, Deaton, Webb, et al, 2008).

Inaccurate doses of insulin may occur inadvertently or, if they occur frequently, may be an attention-seeking device; in a number of cases they may demonstrate adolescent depression and, more seriously, a subconscious but socially accepted method of suicide. Excessive intake of food leads to obesity and may also be symptomatic of depression. Psychiatric counseling may be needed if suicidal tendencies are amplified by the diabetes.

Rehospitalizations are most often related to poor control of the disease, although they may be indirectly related to poor coping and are a method of avoiding the pressures caused by family and peers. The hospital may represent an environment that is peaceful and free of stress. The goal for this problem is to determine the cause of the hospitalization. It may be related to poor control, poor self-management, or the need for better supportive management at home. Evaluation should be based on the physiologic and psychologic adjustment of the child and family.

Parents. Parents develop guilt feelings when they have a child with any chronic disease, especially one with a hereditary component. They cope with these feelings in a number of ways. For example, they may be overprotective or neglectful. Guilt-ridden parents may blame themselves for the disease, consciously or subconsciously. Nevertheless, they must come to realize through education and counseling that they could not have done anything to prevent the disease and it was not their fault, since both environmental and hereditary factors may be involved in the development of diabetes.

Children who are sufficiently mature may be seen alone by the health care professional, although the parents should not be made to feel left out. Time should be set aside during the child's health visit or afterward to meet the parents' needs. Parents should also be included in special sessions to keep them abreast of the child's management, to help them continue to participate in the child's care, and to provide an opportunity to express their feelings concerning their own or their child's adjustment to the disease. The amount of information that they offer at this time can give clues to their level of support of the child and assist in decisions concerning therapeutic management. This helps guide the child through the most disruptive time of life: the teenage years.

Health care professionals must be aware of parents who voice support and appear to be supporting the child to the optimum level but who, with more in-depth interviewing, are found not to be supportive. These parents seldom see the need for following through from verbalizing to meeting the child's real needs, and they unknowingly place obstacles in the child's path. They may be helping the child grow up too fast and therefore insecurely. These parents urgently need counseling so they can realize how their behavior affects the child. The classroom experience, group therapy, or parenting programs can guide the parents' relationships with their children. All parents should be helped to recognize that as children grow and develop, they are children first and children with diabetes second. The ultimate goal for these parents is to be supportive of their children, to communicate more effectively with them, and to help their children develop in an acceptable manner (Wysocki, Harris, Buchloh, et al, 2006).

CRITICAL THINKING CASE STUDY

Type 1 Diabetes

Rebecca, a 15-year-old with a 3-year history of type 1 diabetes, has been admitted to the pediatric intensive care unit for treatment of diabetic ketoacidosis (DKA). This is her fifth hospital admission for DKA in the past year. Rebecca's parents are divorced, and she has four younger siblings, none of whom has diabetes. Rebecca's mother has maintained two jobs for the past 5 years and frequently leaves Rebecca in charge of the household. In anticipation of her discharge you are planning a patient education program for Rebecca and her mother. What important issues regarding Rebecca's unstable diabetes management must you consider to plan the education program?

1. What evidence should you consider regarding this condition?
2. What additional information is required at this time?
3. List the nursing intervention(s) that have the highest priority. (If more than one intervention, number the interventions in order of priority, with 1 having the highest, 2 the next highest, and so on).
4. Identify important patient-centered outcomes with reference to your nursing interventions.

Answers are available at http://evolve.elsevier.com/wong/ncic.

NCLEX REVIEW QUESTIONS

1. Discharge teaching for parents of a school-age patient with diabetes insipidus (DI) should include which of the following? Select all that apply.
   - **A.** Education and support regarding the rationale for fluid restrictions
   - **B.** Information for school personnel regarding the diagnosis so they can grant children unrestricted use of the lavatory
   - **C.** A thorough explanation regarding the condition with specific clarification that DI is a different condition from diabetes mellitus (DM)
   - **D.** Understanding that treatment will only be needed until the child reaches puberty
   - **E.** Knowing that school-age children may assume full responsibility for their care
2. You are working with a nurse who is new to your endocrine unit and has never worked with an infant born with congenital adrenal hyperplasia (CAH). You want to make sure he has a full understanding of this diagnosis. Which statement by the nurse indicates a need for further teaching?
   - **A.** "Definitive diagnosis is confirmed by evidence of increased 17-ketosteroid levels in most types of CAH."
   - **B.** "Blood studies to identify elevated calcium and decreased phosphorus levels are routinely performed."
   - **C.** "Another test that can be used to visualize the presence of pelvic structures such as female reproductive organs is ultrasonography."
   - **D.** "This deficiency is an autosomal recessive disorder that results in improper steroid hormone synthesis."
3. A father calls the pediatrician's office concerned about his 5-year-old type 1 diabetic child who has been ill. He reports that upon checking the child's urine, it was positive for ketones. What is the nurse's best response to this father?
   - **A.** "Come to the office immediately."
   - **B.** "Encourage the child to drink calorie-free liquids."
   - **C.** "Hold the next dose of insulin."
   - **D.** "Administer an extra dose of insulin now."
4. A nurse working on a pediatric unit is assigned to an infant with hypothyroidism. She knows that the assessment may include:
   - **A.** Thyroid function tests that are usually normal, although TSH levels may be slightly or moderately elevated
   - **B.** Increased secretion of pituitary TSH in response to decreased circulating levels of TH or from infiltrative neoplastic or inflammatory processes
   - **C.** Dry skin, puffiness around the eyes, sparse hair, constipation, sleepiness, lethargy, and mental decline
   - **D.** Clinical features, including irritability, hyperactivity, short attention span, tremors, insomnia, and emotional lability
5. You are working in the emergency department, and a 10-year-old child with type 1 diabetes mellitus has just been admitted. He has been diagnosed with diabetic ketoacidosis. Which assessment data will you expect to note in this child?
   - **A.** Shallow or normal respirations, hypertension, and tachycardia
   - **B.** Fruity breath odor and decreasing level of consciousness
   - **C.** Headache, hunger, and excessive irritability
   - **D.** Normal urine output with specific gravity less than 1.020 and a trace of ketones

Correct Answer

1. B, C, E
2. B
3. B
4. C
5. B

THE CHILD AND TRAUMA

TRAUMA MANAGEMENT

Epidemiology of Trauma

Trauma is a leading cause of death in children older than age 1 year (see Chapter 1) and an important cause of disability during childhood and adolescence. In many ways, childhood trauma differs little from trauma in adults. However, the child's developmental stage affects many aspects of injury, including the type of injury incurred and the physiologic response to injury.

Unintentional injuries are the leading cause of death in children 1 year to 19 years of age in the United States. Thirty-seven percent of all deaths in this age-group in 2009 were from unintentional injuries, with motor vehicle crashes accounting for the largest percentage of deaths (Gilchrist and Ballesteros, 2012; Theurer and Bhavsar, 2013).

Childhood Characteristics

Certain developmental characteristics of children at various ages render them more susceptible to injury. For example, the large head of infants and toddlers predisposes them to head injury, especially in falls or motor vehicle injuries. Also, the relatively large spleen and liver and the broad costal arch make these structures prone to direct trauma. Because of their lightweight and small size, infants and small children are easily thrown around in a moving vehicle. Their natural curiosity and their propensity for using large muscles lure them to attempt potentially hazardous activities.

Later, in school-age children and adolescents, whose bone growth outstrips muscle growth, difficulty controlling movement can contribute to physical injury. This is also a time when many children attempt to engage in activities beyond their physical capabilities to keep up with more agile companions and to meet the expectations of adults and older siblings. They are also vulnerable to a "dare." Risk taking compounded by a feeling of invulnerability is also characteristic of adolescence. Children of school age and early adolescence may also be encouraged to continue engaging in sports activities after suffering a contusion or sprain and are therefore subject to repetitive sprain injuries.

Unintentional or Accidental Injury

Among the leading causes of morbidity in children are medical problems resulting from traumatic injury that occurs at home or school, in an automobile, or in association with recreational activities. Children's everyday activities include vigorous play that may involve such things as climbing, falling, running into immovable objects, and receiving blows to any part of the body. All of these activities make them prone to injury. School-age

children and adolescents are vulnerable to multiple and severe trauma because they are mobile on bikes and motorcycles and in automobiles; they are also active in sports. Speed and congested surroundings often increase the chance of injury.

Young children and adolescents usually do not calculate risks as they learn to manipulate their environment and achieve developmental goals. Therefore, accidents are a part of many childhood experiences. Fortunately, when children fall or are hit, their body's resilience protects them from serious damage to soft tissue, the musculoskeletal system, or other body organs. Their bones are more flexible than those of adults and therefore do not offer the rigid resistance to external forces that are likely to cause fractures (as occurs in more mature bones).

Child Abuse or Nonaccidental Trauma

Unfortunately, careless handling of an infant or child (in some instances intentional physical abuse) is not uncommon. A multitude of different types of bone and soft tissue injury are inflicted on children by adults, and smaller children who are unable to protect themselves are most vulnerable.

A traumatic incident that produces physical injury to an infant or child may be the outcome of an accident that was no one's fault, or it may be associated with child abuse. A well-documented history and a careful examination are essential to determine the cause of the injury. Emergency department and pediatric office personnel should be alert to situations in which the child's injuries are not congruent with the parent's description of the incident; in which the child's behaviors, such as fearful mannerisms or lack of crying, are not the expected ones; or in which radiographs show multiple healed fractures. Accounts of injury inconsistent with developmental abilities can alert the provider to possible abuse. For example, a 6-month-old infant cannot "climb out of the crib and break her leg." Reporting these incidents will aid in securing help for the child and family. (See Community and Home Health Considerations box; also see Physical Abuse, Chapter 16.)

Prevention of Injury

Increasingly, health care providers are recognizing the importance of injury prevention efforts in preserving the health and well-being of children. Nurses have an important role to play in these efforts.

Leading causes of injury to children include falls, being struck by or against an object, motor vehicle accidents, fires, pedestrian-vehicle accidents, drowning, and firearms. Falls were the leading cause of nonfatal injury among children ages 0 to 15 years. Being struck by or against a person or object was the leading cause of nonfatal injury in adolescents ages 15 to 19 years of age (Centers for Disease Control and Prevention, 2011). Poisonings also occur in young children, especially those between 1 and 4 years of age, and sports injuries occur in school-age children and adolescents.

Unintentional, preventable injury is the primary cause of pediatric mortality and a significant contributor to morbidity, including permanent disability. Both morbidity and mortality could be reduced dramatically by improved efforts at injury prevention. Studies have indicated a general lack of public awareness regarding risks, causes, and prevention of injury to children. Studies also show that injury prevention counseling is effective both in reducing hazards in the home and in increasing car seat use. Nurses can be active in legislative efforts, public awareness campaigns, group classes on injury prevention, and individual prevention counseling with children and families.

Many injury prevention strategies have been suggested for nurses. Nursing history or hospital admission forms can include screening questions about safety issues. Discharge planning or primary care visits might be a time to provide a family with information on safety practices. Well-child visits to the provider for physicals and immunizations are an excellent time to visit with children and parents about injury prevention in the home and the community. Home health care nurses can easily assist

COMMUNITY AND HOME HEALTH CONSIDERATIONS

Distinguishing Unintentional from Intentional Fractures

Distinguishing abusive (nonaccidental) from unintentional fractures can be challenging. The history, location of the injury, radiographs, and associated injuries must be carefully considered. Details of the history to consider include delay in seeking medical care and an inappropriate clinical history or the report of a change in the child's health, behavior, or activity level but no report of injury.

The child's age was determined to be a factor in one study. The demographics in children most likely to suffer abuse requiring orthopedic treatment were less than 1 year of age, 1 to 2 years of age, and Medicaid as primary payer; winter and weekday presentation was also a strong predictor of child abuse presentation in this study (Bullock, Koval, Moen, et al, 2009). Loder and Feinberg (2007) found that the most common fractures in nonaccidental trauma involved the femur and humerus, and most of these fractures occurred in infants less than 2 years of age. One study found a high incidence of fractures and traumatic brain injury in children under 12 months of age; infants between 2 and 7 months of age were more likely to have injuries attributed to nonaccidental trauma than those younger than 2 months of age (Leventhal, Martin, and Asnes, 2010).

Although not diagnostic of an intentional injury, the location of a fracture can raise suspicions about the actual cause. In an infant, midshaft or metaphyseal humerus fractures and radius-ulna, tibia-fibula, and femur fractures are not common and raise suspicion about the likelihood of abuse. Rib fractures, scapular fractures, bilateral fractures, complex skull fractures, and vertebral fractures or subluxations are also suspicious. In contrast, in children older than 1 year of age, supracondylar humerus fractures and fractures of the clavicle, distal extremity, and femur are most frequently related to an unintentional or accidental injury.

In children of all ages, radiographic evidence of previous fractures at different stages of healing may indicate repeated trauma and raise concern about intentional injuries. The presence of bruises, burns, and additional soft tissue injuries in children may also prompt further evaluation to determine whether the child has been subjected to intentional harm. One mnemonic used to prompt consideration of the possibility of intentional physical abuse is the 5 Bs:

- *Bumps*
- *Bruises*
- *Breaks*
- *Burns*
- Anything that happens in the *bathroom*

a family in conducting a home safety assessment. School nurses can develop safety education programs for different age-groups and discuss injury prevention with children that is applicable to their specific age-group. Additional resources for discussing injury prevention with adolescents include automobile insurance companies and the police and first-responder personnel.* Nurses in emergency department and outpatient clinic settings can provide instructions related to injury prevention on an individual basis as developmentally appropriate.

Accident prevention among adolescents presents a unique challenge to all health care workers. For accident prevention to be effective, adolescents must perceive the specific interventions as having an impact on their lives. Adolescents are concerned with body image and often feel indestructible unless their own life or the life of a close friend is touched by a catastrophic debilitating injury or death. With increased emphasis in society on having fun and enjoying life to its fullest (today) regardless of the consequences (tomorrow), it is difficult for adolescents to understand the need to follow the rules laid down by authority figures.

Concern is also increasing about injuries to older school-age children and adolescents from the use of all-terrain motor vehicles (for which many states have no laws on minimum age for riders), snowmobiles, personal water craft vehicles, in-line skates, trampolines, scooters, and motor vehicles. Activities involving such vehicles and equipment, although safe in and of themselves when conducted according to safety guidelines (of the manufacturer), may be dangerous for children and adolescents who are unable to appreciate the risks involved, not only to self but to others as well. Adolescents are known for taking risks, and the approval of their peers often compounds risk-taking behaviors in games such as car surfing and the choking game. Parents may not be aware that their teens are partaking in such games and a frank discussion between parents and adolescents may be required. Nurses who work with adolescents and their families need to be aware of such games and be ready to discuss the effects of risk taking with teens.

ASSESSMENT OF TRAUMA

The site of the injury usually influences the order of priority of interventions when emergency care is being instituted. Consider the safety of both the victim and the "Good Samaritan" rescuers to prevent further injury.

! NURSING ALERT

Always consider personal safety a top priority, since the victim cannot be helped if the rescuer is injured.

For example, removing a child from a burning building or the bottom of a swimming pool is an obvious, logical action, but anxious rescuers may not consider their own safety to be of prime importance. The major reason for thinking through the steps to be taken in an emergency before an incident actually occurs is to have preplanned actions available at a stimulus response level.

Emergency Management

The Emergency Treatment box outlines guidelines for care of the child at the scene of an injury. After level of consciousness is assessed, the concerns are for airway, breathing, and circulation (ABC), after which other injuries are managed as indicated by the assessment. When spinal trauma is a possibility, open the airway using the modified jaw thrust maneuver, which is accomplished by grasping the angles of the victim's lower jaw and lifting with both hands, one on each side, and displacing the mandible upward and outward (without head tilt or chin lift). Otherwise a head tilt–chin lift maneuver is effective in opening the victim's airway.

Spinal cord injury cannot be assessed adequately in the prehospital setting. Radiography, computed tomography (CT), or magnetic resonance imaging (MRI) is required for diagnosis.

Spinal cord injury is always suspected in a patient with head, trunk, or multisystem trauma. Only in a fully equipped trauma center with radiography and other diagnostic testing can spinal cord injury be ruled out. Therefore, the patient is treated as if injury were present. Immobilize the cervical spine by maintaining the head in a neutral position and not allowing movement of the head or body in any direction.

! NURSING ALERT

In any situation in which spinal cord injury is suspected or is a possibility, the child should be calmed, reassured, and told not to move. *No one should be allowed to move the child unless the entire spine is stabilized.* A rigid cervical collar is used to immobilize the cervical spine, and the child is placed supine on a rigid immobilization board. Infants and small children are removed in their car seats; no attempt should be made to take them out of their seats.

Assess the child for signs of responsiveness, and if there are none detected, check for a pulse. If unresponsive, call for help and emergency medical services (EMS) activation. Begin chest compressions within 10 seconds and compress at a rate of 100 times per minute. If the child is not breathing, give two breaths over 2 seconds, then resume chest compressions. Oxygen should be provided when possible. If an automatic external defibrillator (AED) is available, follow the directions for its use after first turning on the apparatus. (Follow the complete detailed guidelines for cardiopulmonary resuscitation [CPR] available from the American Heart Association [Hazinski and Hunter-Wilson, 2011].)

Control of bleeding is first attempted by application of direct pressure with a gloved hand. If this does not work, a pressure dressing is applied. The next step is to elevate the body part and then attempt to control hemorrhage by pressing on arterial pressure points. A tourniquet is used only when the bleeding cannot be controlled with a pressure dressing. If used, the tourniquet should be applied only to control bleeding. Once applied, it should not be removed or loosened. Below the tourniquet site, skin and tissue necrosis begins. If the tourniquet is loosened or removed, the toxins can be released into the circulation in high concentrations and may induce a systemic, deadly tourniquet shock. With the tourniquet in place, the patient has a better

*SafeKids USA is an excellent resource for those interested in child safety; **www.usa.safekids.org**.

EMERGENCY TREATMENT

Trauma

Before entering trauma area, observe for potential threats or dangers to rescuers and bystanders. Be aware of potential for further injuries to child.

Observe scene for signs and mechanism of injury (e.g., head-on motor vehicle injury), which helps to determine proper course of action for treating child's injuries.

Do not move child before arrival of emergency medical services (EMS) personnel unless child is in danger of further injury. If it is necessary to move child, follow appropriate steps to prevent further injury (e.g., stabilize cervical spine to avoid exacerbation of spinal injury during movement).

Primary Assessment and Intervention

Assess level of consciousness. Use the AVPU method:

A—Child is **a**lert.
V—Child responds to **v**erbal stimulus.
P—Child responds to **p**ainful stimulus.
U—Child is **u**nresponsive to any stimulus.

Open airway, using appropriate method:

- In child with head, trunk, or multisystem trauma, modified jaw thrust is preferred method.
- At this point, cervical spine should be manually immobilized and held in alignment with rest of spinal column and should not be released until EMS personnel have immobilized child with appropriate equipment.

Activate the EMS system if child appears to be 8 years old or older. If child is less than 8, perform 2 minutes of cardiopulmonary resuscitation (CPR) (as per assessment); then activate EMS and call for an automatic external defibrillator (AED).

If no response to stimulation and no pulse is detected, begin chest compressions. Compress at a rate of at least 100 compressions per minute.*

After 30 compressions administer 2 breaths –each breath is administered over 1 second. Avoid overventilating.*

Continue chest compressions and ventilations until person shows signs of responsiveness , breathing, or EMS arrives.

If an AED is available turn on the AED and follow the AED directions. Avoid interrupting chest compressions for more than 10 seconds.*

A pulse check may be made if 5 cycles of 30 compressions and 2 breaths have been administered.*

- Palpate carotid artery in children 1 year or older.
- Palpate brachial artery in infants younger than 1 year.

If pulse present, assess for breathing. If necessary, begin rescue breathing.*

Observe for hemorrhage. Control bleeding with a gloved or protected hand:

1. Apply direct pressure to wound site.
2. Elevate wound site.
3. Apply pressure to appropriate arterial pressure point.
4. Apply tourniquet only as a last resort. Once a tourniquet is applied, it should not be loosened.

Assess for further injury.

Do not remove objects protruding from child's body.

Check for evidence of decreased motor or sensory function in extremities:

- Infant and young child—Observe spontaneous movement in extremities.
- Older child—Ask if able to wiggle extremities.

Evaluate pain—Present, absent; severe, mild.

- Attempt to alleviate with nonpharmacologic techniques.
- Encourage use of analgesics when EMS personnel arrive.

Assess pulses in extremity distal to injury.

- Check color and temperature of extremities.

Manage any injuries appropriately (e.g., splint fractures) (see Emergency Treatment box, p. 1573).

Maintain body heat.

Identify child.

Obtain information regarding the injury from witnesses, if any.

*For detailed instructions for performing CPR, see Hazinski and Hunter-Wilson (2011).
AED-automatic external defibrillator

chance of survival, even though it may mean the loss of a limb. Tourniquet use in prehospital settings has been shown to be safe (Doyle and Taillac, 2008; Fitzgibbons, Digiovanni, Hares, et al, 2012; Lee, Porter, and Hodgetts, 2007).

Assessment of the child involves observation from head to toe, since infants and young children are unable to communicate except by crying and other behaviors. Therefore, pinpointing areas of pain is difficult. To check for any motor or sensory dysfunction in the extremities, the nurse should note any spontaneous movement, which provides the best clue in infants and young children. Older children are able to follow directions to wiggle toes or fingers, demonstrate a grasp, "push down on the gas pedal," or lift legs off the floor or stretcher. The child is identified as soon as feasible by anyone who knows the child. It is important to determine whether the child has any existing health problems that might have implications for the circumstances of the injury and for therapeutic management. Ask any witnesses for details about the incident to aid in assessment of the child's emotional responses.

In the prehospital setting the nurse's role consists of contacting emergency medical services (EMS) and providing basic life support until EMS personnel arrive on the scene. The nurse's role is limited to basic life support because the nurse has no standing orders or protocols under which to work in the prehospital setting (see Emergency Treatment box). Call EMS as soon as possible so that the patient can receive advanced life support before and during transport. A pediatric trauma triage system with personnel designated to care for an injured child is essential to provide excellent trauma patient care.

A paramedic-level ambulance provides at least one paramedic with skills in advanced cardiac life support, pediatric advanced life support, and neonatal resuscitation. A paramedic's skills include electrocardiogram interpretation and defibrillation, advanced airway management (including endotracheal intubation, as well as intravenous [IV] and pharmacologic therapy), placement of a pneumatic antishock garment (PASG), pleural decompression (with a chest tube), and placement of a nasogastric tube and Foley catheter. Other advanced life support skills include expertise in spinal immobilization, extrication, management of fractures and bleeding, and emergency scene management. The paramedic remains in constant contact with the emergency department physician by means of a radio or

cellular telephone for situations requiring medical control. Attempting to transport a child by automobile wastes valuable time in obtaining help. Transportation by EMS is recommended. Services in most large communities can institute advanced life support immediately or en route to a medical facility.

! NURSING ALERT

It is imperative that EMS be called to respond as soon as possible. Family, friends, or strangers should *not* transport the trauma victim.

Systematic Assessment

Several factors can affect a child's response to trauma. An undetected congenital anomaly can contribute to a complicated injury. Acute gastric distention occurs frequently in children because of the crying and screaming that accompany an injury. The temperature of young children is unstable because of their large surface area in relation to body mass, and temperature maintenance is critical in trauma management. Children also experience rapid metabolic changes. When they are ill, children are really ill, but as they recover, they change very rapidly. In addition, children have a small volume of blood in absolute terms. Whereas blood volume is 60% of total body weight in the adult, it is 70% to 85% in the child.

The first priority on admission to an emergency facility is rapid assessment of ABC status. Because the overwhelming majority of childhood injuries are the result of blunt-impact trauma, multiple organ involvement is a common finding. Therefore, it is essential to perform a systematic assessment of the trauma victim.

The secondary survey is a systematic head-to-toe search for any additional injuries not originally addressed in the primary survey. However, children are often an exception to the head-to-toe approach. It may be preferable to complete the secondary survey on the injured child in a toe-to-head direction. This approach may allow the rescuer to gain the child's trust as the survey progresses and the rescuer moves gradually into the child's personal space. Throughout the assessment, the nurse observes for areas of deformity, edema, ecchymosis, bleeding, hematoma, paralysis, or pain.

THE IMMOBILIZED CHILD

IMMOBILIZATION

One of the most difficult aspects of illness is the immobility it often imposes on a child. Children's natural tendency to be mobile influences all elements of growth and development—physical, social, psychologic, and emotional. Impaired physical mobility related to disability or imposed activity restrictions presents a definite challenge to the child, their families, and their caregivers.

Causes of Immobilization

For some children immobilization may be due to a disability. While for those children without disabilities, illness or injury is the usual reason for immobilization or restriction of activities. When children are ill, they are content to remain quiet, and most of them instinctively reduce their activity. It is children who are forced to remain inactive because of physical limitations or therapy who display the multiple effects of restricted movement.

The most frequent reasons for immobility are congenital defects (e.g., spina bifida); neuromuscular conditions (e.g., muscular dystrophy, spinal muscular atrophy); the need for prolonged mechanical ventilation and sedation; and infections or injuries that impair the integumentary system (e.g., severe burns), the musculoskeletal system (e.g., complex fractures or osteomyelitis), or the neurologic system (e.g., spinal cord injury, Guillain-Barré syndrome, or traumatic brain injury and coma). Sometimes therapies such as traction and spinal fusion are responsible for prolonged immobilization, although the trend is toward early mobilization, early discharge, and outpatient care.

Physiologic Effects of Immobilization

Many clinical studies, including space program research, have documented predictable consequences that occur after immobilization and the absence of gravitational force. Functional and metabolic responses to restricted movement occur in most of the body systems. Each has a direct influence on the child's growth and development, since homeostatic mechanisms thrive on normal use and need feedback to maintain dynamic equilibrium. Inactivity leads to a decrease in the functional capabilities of the whole body as dramatically as the lack of physical exercise leads to muscle weakness.

Immobilization from illness, injury, or a sedentary lifestyle can limit function and potentially delay a child from meeting age-appropriate milestones. Most of the pathologic changes that take place during immobilization arise from decreased muscle strength and mass, decreased metabolism, and bone demineralization. The three are closely interrelated, with one change leading to or affecting another. Some results of immobilization are primary and produce a direct effect; other pathophysiologic consequences occur frequently but seem to be more indirect and are therefore secondary effects. Many pathophysiologic changes affect more than one body system, with the primary or secondary effect being demonstrated in multiple systems.

The major effects of immobilization (Fig. 34-1) are related directly or indirectly to decreased muscle activity, which produces numerous primary changes in both muscular and bone structures, along with secondary alterations in the cardiovascular, respiratory, metabolic, and renal systems. The major consequences are:

- Significant loss of muscle strength, endurance, and muscle mass (atrophy)
- Bone demineralization leading to osteoporosis
- Loss of joint mobility and contracture

The larger the portion of the body immobilized and the longer the immobilization, the greater the hazards of immobility.

Muscular System

Inactive muscle loses strength at the rate of 3% per day, and several weeks or months are sometimes required for function

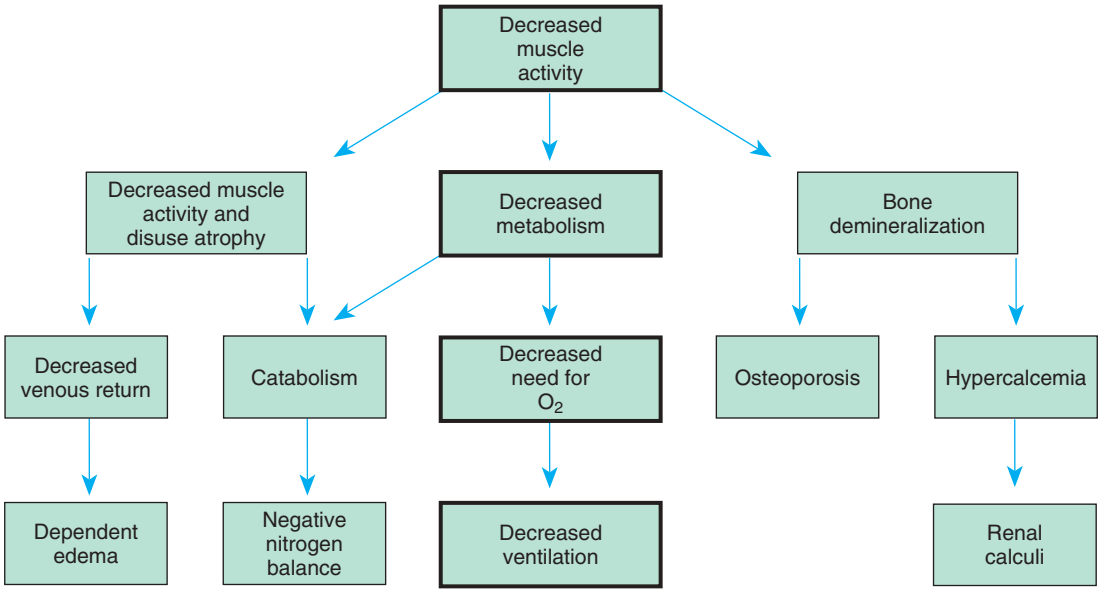

FIG. 34-1 Physiologic effects of immobilization.

to be regained when there is no primary neuromuscular deficit. Stretching can occur as muscle loses its tone or as excessive strain is put on weakened muscle (e.g., stretching by tight bed covers or poor body position that produces footdrop as experienced by some children with disability). The disuse leads to tissue breakdown and muscle **atrophy**. The chief intracellular muscle enzyme, creatine, is released into the serum as the muscle atrophies; therefore, serum levels provide an indication of the amount of muscle mass undergoing degeneration. Muscle inactivity also affects the cardiovascular system by decreasing venous return and cardiac output. In general, muscle atrophy causes decreased strength and endurance.

In children who have limited mobility, such as children who are unconscious or partially or fully paralyzed, joint mobility becomes restricted. In the absence of normal structural stretching, collagen fibers generated within the joint become fibrotic and further limit movement. This tissue fibrosis creates shortening of the muscles and contracture of the joint. Any decrease in circulation to the joint caused by edema, inflammation, or restrictive positioning contributes to further fibrotic changes. The problem rapidly becomes cyclic as the contracture leads to muscle fatigue and pain, which causes the child to protect the site, thus leading to more fibrosis. This process is further exaggerated because body flexor muscles are stronger than extensor muscles, and unless range of motion is reestablished within 3 to 7 days, contractures will develop. Passive or active range-of-motion exercises and proper positioning can help prevent joint stiffness and contractures. Frequent disabling contractures are hip flexion, knee flexion, plantar flexion of the feet, and shoulder stiffness.

Skeletal System

The daily stresses on bone created by motion and weight bearing maintain the balance between bone formation (osteoblastic activity) and bone resorption (osteoclastic activity). When these stresses are diminished, bone formation ceases, but bone destruction continues, so the state of equilibrium is disrupted. Bone calcium becomes severely depleted, and secretion of phosphorus and nitrogen is increased. This demineralization of the bone (osteopenia) makes the skeletal structures prone to pathologic fractures and increases calcium ion concentration in the blood (hypercalcemia).

Cardiovascular System

Immobility has three major cardiovascular consequences: orthostatic intolerance, increased workload of the heart, and thrombus formation. During movement, muscle contraction causes pressure on peripheral veins, which in turn causes the venous valves to close and thus assists in return of the blood to the heart when the individual is in an upright position. In the absence of this assistance, blood tends to pool in the dependent areas, reducing the blood supply to the trunk and brain. In addition, direct reflex stimulation to the splanchnic and peripheral vessels causes them to constrict when a person is upright. Impairment of this neurovascular orthostatic reflex activity from lack of motion causes further interference with venous return. The individual displays signs of excessive autonomic activity (e.g., pallor, sweating, and restlessness, which are frequently followed by fainting). The child with a spinal cord injury has unique problems with orthostatic intolerance, which is discussed in Chapter 35.

! NURSING ALERT

Carefully evaluate sudden chest pain and dyspnea; sudden onset of shortness of breath; air hunger; or pain and swelling in the lower extremities, which sometimes indicates deep vein thrombosis.

Changes in vascular resistance caused by the horizontal position and immobility alter the distribution of blood within the body. The reduction in gravity pressure to the extremities causes

much of the total blood volume to be redistributed from lower extremities to other parts of the body. Consequently, there is an increase in the venous return and the volume of blood to be handled by the heart, which is reflected in elevated blood pressure. As a result, cardiac output and stroke volume are increased, and a progressive increase in heart rate occurs. When immobilization extends over time, there is a compensatory decrease in blood volume and a decrease in heart rate and blood pressure.

Without muscle contraction, venous stasis and increased intravascular pressure in the extremities often lead to dependent edema. If undue pressure is exerted on the major veins by positioning or mechanical devices, the likelihood of interstitial edema is increased. Edematous tissue, especially tissue located over an area that receives much of the body's weight, is prone to skin breakdown.

Circulatory stasis combined with hypercoagulability of the blood, which results from factors such as damage to the endothelium of blood vessels (Virchow triad), can lead to thrombus and embolus formation. **Deep vein thrombosis** (DVT) involves the formation of a thrombus in a deep vein such as the iliac and femoral veins and can cause significant morbidity if it remains undetected and untreated. DVT may develop with prolonged venous stasis in conditions such as obesity, chronic heart failure, prolonged surgical procedure, long trips without exercise, or prolonged immobilization (Wipke-Tevis and Rich, 2007).

The state of deconditioned cardiac function, caused by skeletal muscle inactivity, can produce a variety of secondary problems in other systems. However, the major clinical manifestation is increased pulse and heart rate in response to an active exercise program. After prolonged immobility the child should build up activity tolerance slowly to allow the heart to regain optimum capabilities.

Respiratory System

Initially the effects of immobilization are compensatory or adaptive. The basal metabolic rate is decreased because with reduced expenditure of energy the cells require less oxygen and produce less carbon dioxide. Lessened demand for oxygen–carbon dioxide exchange causes the respirations to become slower and more shallow. In children chest expansion may be limited by the child's position (e.g., supine); by abdominal distention caused by accumulation of feces, gas, or fluid; and by mechanical restriction such as from a brace or constricting binder. Pain (e.g., chest tube in place) may also limit deep breathing and adequate chest expansion. Reduced muscle power and coordination secondary to altered innervation can also hinder respiratory movement. More effort is required to expand the lungs in the supine position.

Prolonged immobility also reduces the normal movement of secretions from the tracheobronchial tree, particularly in the presence of impaired muscle function and without positional changes that normally facilitate removal of secretions. A weak and ineffectual cough reflex contributes to stasis of secretions and the possibility of airway obstruction in the smaller airways of children. Shallow respirations and obstruction of the airway with thick mucus are factors in the development of secondary complications such as atelectasis and pneumonia.

Gastrointestinal System

Prolonged immobility produces a state of negative nitrogen balance resulting from the increased catabolic activity related to muscle atrophy. This and the reduced energy requirements contribute to a diminished appetite and a resulting decrease in ingestion of nutrients (anorexia). Eating and feeding become more difficult with immobility, and the risk of aspiration is increased. Associated psychologic factors further influence intake.

The process of elimination depends on the integration of smooth and skeletal muscle activity and on visceral reflex patterns. Immobility may interfere with these mechanisms, as well as with the gravitational effect on stool passing through the intestines. Slowing of stool in the colon causes the feces to become hard (**fecal impaction**), and the bowel wall is not stimulated to further its peristaltic movement down the tract to the rectum. Weakened muscles used in defecation (diaphragmatic and abdominal muscles) are unable to produce the intraabdominal pressure needed for elimination. Sometimes embarrassment in using a bedpan or bedside commode may be the cause of not responding to the urge to defecate.

Renal System

The urinary system is designed to function in an upright posture. When the gravitational force is altered by the reclining position, the peristaltic contractions of the ureters are insufficient to overcome gravitational resistance. Consequently, there may be stasis of urine in the renal pelves, and any particulate matter that settles in the calyces may serve as nuclei for calculi formation or as foci for infection.

In the horizontal position the individual has difficulty relaxing the perineal musculature and external sphincter sufficiently to initiate the integrated reflex micturition mechanism, which involves the external sphincter, the internal sphincter, and the detrusor muscle of the bladder wall. If adequate intraabdominal pressure is exerted, voiding can occur, but if the individual does not respond to the sensation to void, bladder distention leads to stasis, and its complications add to embarrassing overflow incontinence. In time, reflux and back pressure may impair renal function, and urinary tract infection is always a hazard with urine retention.

Normally the kidney is able to handle the increased metabolites from protein breakdown and bone demineralization. However, the increased level of calcium excreted may predispose the person to calculus formation. Formation of **renal calculi** (kidney stones) is further favored by urinary stasis, infection, and alkaline urine caused by the decreased production of the acid by-products of metabolism. Hematuria may be the only clue to the condition.

Metabolism

Immobility or severe restriction of activity is often accompanied by decreased or inappropriate nutritional intake, which frequently leads to a decreased basal metabolic rate, a negative nitrogen balance associated with catabolism, and a high serum calcium level.

All body systems are influenced by a decrease in metabolism. The altered energy level leads to further fatigue and lack of motivation for moving. Immobilized persons often feel sluggish and have a poor appetite, particularly for protein foods. The protein breakdown in the body related to a loss of muscle and other tissues is more apt to be severe after injury or surgery. Protein breakdown produces nitrogenous wastes, and on the fifth or sixth day of catabolic protein metabolism, an increase in urinary nitrogen level develops that contributes to anemia and delayed healing.

Another metabolic problem is **hypercalcemia** associated with bone catabolism. Completely immobilized children or adolescents are especially prone to hypercalcemia. Symptoms, which include nausea and vomiting, polydipsia, polyuria, and lethargy, usually appear 4 to 8 weeks after immobilization. In tetraplegia, symptoms may occur within 10 days and last for as long as 6 months. The accelerated rate of bone metabolism in children makes the bone demineralization a greater hazard. Larger amounts of calcium are released into the blood than the kidney can excrete, and calcium continues to accumulate in serum. High levels of serum calcium decrease neuronal permeability, which can lead to a depression of the central and peripheral nervous systems. Symptoms, including smooth and skeletal muscle fatigue, diminished reflexes, and atony of the gastrointestinal tract, are a result of the depressed nervous system.

A child with bone demineralization may not develop hypercalcemia, but the excess amount of calcium that the kidneys are required to excrete may produce a negative calcium balance, with more calcium than citric acid lost in the urine. This imbalance causes the urine to become alkaline, with the potential danger of renal calculi, especially if there is an accompanying retention of urine.

Integumentary System

The following factors play a major role in skin breakdown: moisture, friction, shear, and pressure (see also Chapter 23, Maintaining Healthy Skin). Circulation to the skin is reduced during inactivity and may be further impeded by dependent edema. Circulation is especially compromised in places where the bone surface is near the skin, such as areas over the sacrum, occiput, trochanter, and ankle, and continued impairment causes rapid necrosis with ulcer formation. Friction and mechanical irritation from appliances, such as straps, rods, and tubing, and the friction of bedclothes during turning or other movement can produce skin breakdown. Healing capacity is also impaired by poor circulation, negative nitrogen balance, and anemia. Immobilization often makes it difficult to carry out adequate cleansing and hygienic measures, which may also contribute to tissue breakdown in areas that are difficult to reach.

Cellular breakdown caused by prolonged pressure has several characteristics. Normally when pressure is applied to the skin, the skin appears pale but becomes very red, or hyperemic, after the pressure is removed. This reactive hyperemia should disappear within 5 to 15 minutes. Prolonged redness (>30 minutes) indicates that a pressure area is developing and treatment should begin. Other manifestations of tissue ischemia include an increase in temperature in the area, blistering, swelling, and dark purple or black areas. The pressure area may be limited to the skin and subcutaneous layers or may be deeper and more extensive. The skin changes observed may represent the top of a cone-shaped area with widespread tissue destruction, beneath which tissue rapidly ulcerates and creates a large pressure ulcer that sometimes extends to the bone. Fig. 34-2 illustrates the sequence of events in tissue breakdown.

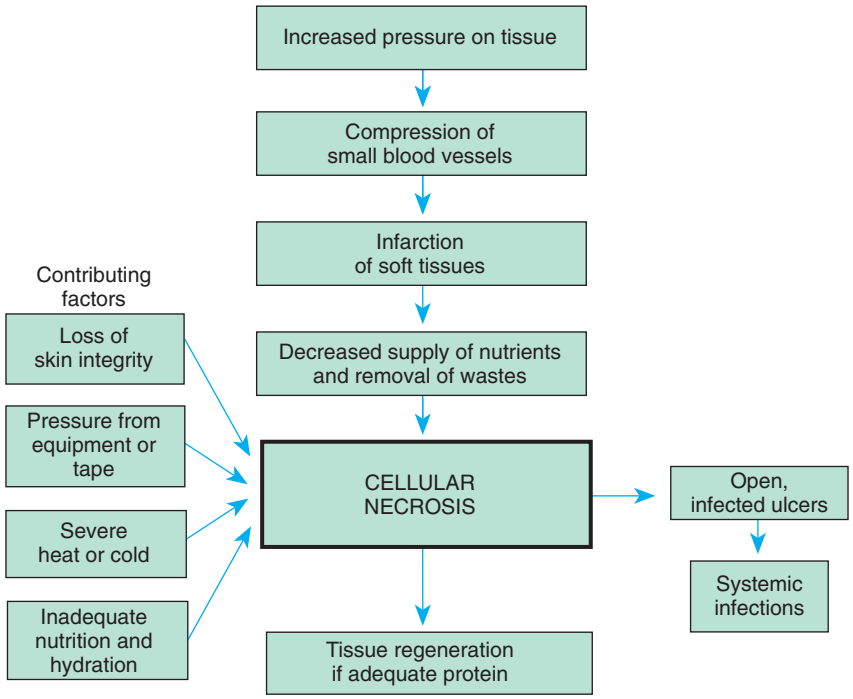

FIG. 34-2 Sequence of events in tissue breakdown.

Neurosensory System

Studies indicate that immobilization does not produce neurosensory consequences directly; however, two occurrences—loss of innervation and sensory and perceptual deprivation—are common.

Peripheral nerves, in contrast to skeletal muscles, do not degenerate with disuse, but loss of innervation takes place if nerves are damaged by pressure or if their blood supply is disrupted. Improper body positioning, improperly applied casts or restraints, or fluid buildup within a compartment (compartment syndrome) can place excessive pressure on nerves and blood vessels that can lead to ischemia and nerve degeneration. Frequent sites of nerve compression phenomenon are the peroneal nerve, where pressure results in **footdrop**, and the radial nerve, where pressure leads to **wristdrop**. These complications significantly interfere with attempts to regain functional use of the extremities, but they can be prevented by conscientious nursing assessment and intervention. Preventing pressure on vulnerable areas and avoiding extreme positions of flexion and extension that apply inappropriate pressure on nerves and blood vessels reduce the likelihood of compression injury. Periodic plantar flexion and dorsiflexion of the feet and hands by passive or active range of motion will stimulate circulation and keep nerves from becoming pinched. Numbness, tingling, change in sensation, and loss of motion are symptoms of neurologic impairment and should be evaluated immediately.

Psychologic Effects of Immobilization

For children, one of the most difficult aspects of illness is immobilization. Throughout childhood, physical activity is an integral part of daily life and is essential for physical growth and development. It also serves children as an instrument for communication and expression and as a means for learning about and understanding their world. Activity helps them deal with a variety of feelings and impulses and provides a mechanism by which they can exert control over inner tensions. Children respond to anxiety with increased activity. Removal of this power deprives them of necessary input and a natural outlet for their feelings and fantasies. Through movement children also gain sensory input, which provides an essential element for developing and maintaining a body image.

Active children have many opportunities for input from a wide variety of settings. When they are immobilized by disease or as a part of a treatment regimen, they experience diminished environmental stimuli with a loss of tactile, vestibular, and proprioceptive input and an altered perception of themselves and their environment. Sudden or gradual immobilization narrows the amount and variety of environmental stimuli they receive by means of all their senses: touch, sight, hearing, taste, smell, and proprioception. This sensory deprivation frequently leads to feelings of isolation, boredom, and being forgotten, especially by peers. Nursing interventions involving the use of diversional activities, schoolwork, structured television viewing, computer games, or interactive video programs can assist the child in maintaining usual activities. (See Chapter 22.)

BOX 34-1 BEHAVIORAL CHANGES IN IMMOBILIZED CHILDREN

Higher-than-normal level of anxiety leads to:
- Restlessness
- Difficulty with problem solving
- Inability to concentrate on activities
- Depression
- Regression
- Egocentrism

Monotony leads to:
- Sluggish intellectual responses
- Sluggish psychomotor responses
- Decreased communication skills
- Increased fantasizing
- Hallucinations
- Disorientation
- Dependence
- Acting-out behavior
- Depression

The struggle for independence is thwarted by imposed immobility. For toddlers, exploration and imitative behaviors are essential to developing a sense of autonomy; preschoolers' expression of initiative is evidenced by their penchant for vigorous physical activity; school-age children's development is strongly influenced by physical achievement and competition; and adolescents rely on mobility to achieve independence. The quest for mastery at every stage of development is related to mobility. To children, the inability to move is threatening to self-preservation and reactivates the struggle between activity and passivity, and between dependence and independence.

Behavioral changes occur when children experience prolonged sensory deprivation. Some of these behaviors are indications of a higher-than-normal level of anxiety (Box 34-1). Children are likely to become depressed over their loss of ability to function or the marked changes in body image. Significant others often notice regressive behavior and a greater reliance on them for tasks the children are able to perform. Children seek their attention by reverting to earlier developmental behaviors, such as wanting to be fed, bed-wetting, and baby talk. In many ways immobilized children are realistically dependent on others; therefore, intelligent and sensitive care is required to prevent major developmental regressions during the period of immobility.

Limbs that are immobilized by casts, traction, or paralysis transmit less sensory data than they do normally. Sensory impairment may be a concomitant problem of the involved part. Numbness or loss of feeling markedly alters proprioception. Children who have limited ability to feel others touching them not only experience less tactile stimulation in a physical sense but are also deprived of warm, loving feelings that arise from being touched. The loss of feeling from touch can further add to their sense of being isolated and unwanted.

Children often react to immobility with active protest, anger, and aggressive behavior, or they may become quiet, passive, and submissive. Often children believe that the immobilization is a justified punishment for misbehavior. Children should be

allowed to express their anger, but this expression should be within the limits of safety to their self-esteem and not damaging to the integrity of others.

Adults may be confused by, resent, and find it difficult to deal with the acting-out behavior of children. Too often this behavior is considered "bad" even when it is a release of tension. In some cases, such as with a paralyzed child, parents and nurses may feel inadequate to cope with the child's profound distress and feelings of hopelessness, and the professional help of a mental health specialist is necessary.

The most difficult situations are those involving major injuries and diseases that produce a disfigurement or a severe loss of function that directly affects a child's self-image, such as burns; amputation; or the sudden, catastrophic effects of an accident that leave a healthy, active child disabled. Children have difficulty expressing feelings of anger and hostility when they are at the mercy of the environment. They dare not speak out against or defy the authorities on which they depend so completely. Consequently, their aggression may be masked by cheerfulness or rigidity. When they are unable to express their anger, the aggression is often displayed inappropriately through regressive behavior and outbursts of crying or temper tantrums over insignificant irritations. Adolescents and older school-age children should vary their daily routine to fit their needs for independence; allowing this age-group to stay up late at night and sleep in during the daytime (within reasonable limits to accommodate treatment needs) may help decrease struggles over other inconsequential matters and at the same time allow a daily pattern of life. Encourage parents to continue setting limits and not abandon disciplinary measures with children who are confined to bed due to trauma or illness.

Effects of Immobilization on Families

Even brief periods of child immobilization may disrupt the functioning of a family, and a child's catastrophic illness or disability may severely tax their resources and coping abilities. The need for instruction concerning medical and nursing care, community resources to contact, and emotional support are paramount. Many families have unmet needs, operate from crisis to crisis, and are unable to use outside help appropriately. For these families the new situation can be disruptive; therefore, a multidisciplinary team must help the family members identify unmet needs and solve problems. The following are commonly occurring problems:

- Financial strains may decrease or totally eliminate the family's resources.
- Attention is focused, at least temporarily, on the affected member; therefore, other members of the family, especially siblings, may feel that they are being neglected or that their needs may not be met.
- The family may have difficulty accepting the child's altered body condition.
- Individual family members may be unable to express their feelings and may have difficulty coping with the crisis.
- Parents often experience guilt over their child's condition and need for immobilization. Their perception of failing to protect the child forms the basis for their difficulty coping.

The family's needs often must be met through the services of a multidisciplinary team, and nurses play a key role in anticipating the services the family will need and in coordinating appropriate care. In preparation for the child's discharge from the hospital home management is frequently planned weeks in advance of the actual discharge, including special provisions for meeting cultural, economic, physical, and psychologic needs. A child with a severe disability is dependent, and caregivers need rest periods to revitalize themselves. Individual and group counseling is beneficial for problem-solving situations and provides an emotional support system. Parent groups are also helpful and often allow nonthreatening social contact. The families of children with permanent disabilities need long-term resources, since some of the most difficult problems arise as they try to sustain high-quality care for many years. (See Chapter 19.)

Nursing Care Management

Physical assessment of the child who is immobilized for any number of reasons (e.g., injury or illness) includes a focus not only on the injured part (e.g., fracture) but also on the functioning of other systems that may be affected secondarily: the circulatory, renal, respiratory, muscular, and gastrointestinal systems. With long-term immobilization, there may also be neurologic impairment and changes in metabolism. In addition, the psychologic impact of immobilization should be assessed.

Encourage children to be as active as their condition and restrictive devices allow. This usually poses few problems for children, whose innate ingenuity and natural inclination toward mobility provide them with the impetus for physical activity. They need the opportunity, the materials or objects to stimulate activity, and the encouragement and participation of others. Those who are unable to move will need passive exercise and movement, often in consultation with a physical therapist. An occupational therapist and child life specialist may also assist in planning activities to decrease boredom and to help regain lost skills such as self-feeding. A child psychologist may be consulted to discuss with the child and family issues such as depression, anger management, and the effects of the illness on family function.

Children who require prolonged total immobility and are unable to move themselves in bed should be placed on a pressure reduction mattress to prevent skin breakdown. Frequent position changes also help prevent dependent edema and stimulate circulation, respiratory function, gastrointestinal motility, and neurologic sensation. Children at higher risk for skin breakdown include those with prolonged immobilization; mechanical ventilation; orthotic and prosthetic devices, including wheelchairs; and casts and children requiring intensive care. Additional risk factors include poor nutrition, friction (from bed linen with traction), and moist skin (from urine or perspiration) (Fig. 34-3). Nursing care of children at risk includes proactive strategies for preventing skin breakdown when such conditions are present. The Braden Q Scale is a reliable, objective tool the nurse can use in assessing for pressure ulcer development in children who are acutely ill or who are at risk for

FIG. 34-3 Immobilized child.

skin breakdown from neurologic conditions and immobilization (Noonan, Quigley, and Curley, 2011).

Circulatory stasis and DVT development are prevented by instructing patients to change positions frequently, dorsiflex their feet and rotate the ankles, sit in a bedside chair periodically, or ambulate several times daily. The use of antiembolism stockings or intermittent compression devices also prevents circulatory stasis and dependent edema in the lower extremities and the development of DVT. Anticoagulant therapy may also be implemented with low-molecular-weight heparin, vitamin K antagonists, or unfractionated heparin. Children who are unable to move should have passive range-of-motion exercises of the upper and lower extremities to increase circulation and minimize stasis.

Transporting the child by stretcher, wheelchair, stroller, or wagon outside the confines of the room whenever possible increases environmental stimuli and provides social contact with others. While hospitalized, the child benefits from frequent visitors, accessibility of clocks and calendars, and a program of diversional therapy to help the child function more normally. A child life specialist should be consulted for recreational planning. An activity center or slanting tray can be helpful for the child with limited mobility to use for drawing, coloring, writing, and playing with small toys such as trucks and cars. A child is able to express frustration, displeasure, and anger through play, which is helpful in the child's recovery. As soon as possible, the child should wear street clothes and resume school and preinjury hobbies. Play is the most useful tool of nursing (see Chapter 22), and activities should be selected on the basis of interest, ability, and limitations. They should include some form of physical activity that encourages the use of uninvolved muscles and joints. Any activity that is tolerated (e.g., turning in bed or changing the position of the bed in the room) helps to alter the monotony of immobilization and dissipates tension and frustration. Allow a parent or siblings to stay overnight and room-in with the hospitalized child to prevent the effects of family disruption from hospitalization. Make every effort to minimize family disruption resulting from the hospitalization. Although most of the suggestions discussed relate to hospital care, the same consultations (e.g., physical therapist, occupational therapist, child life specialist, speech/language pathologist) and environment may be considered in the home as well to help the child to gain independence and the family to achieve normalization.

One of the most useful interventions to help children cope with immobility is participation in their own care. Self-care to the maximum extent possible is usually well received by children. They can help plan their daily routine; select their diet (when possible); and choose the clothes they are to wear, including innovative adornment, such as a baseball cap, brightly colored stockings, or other items that express their autonomy and individuality. Encourage them to do as much for themselves as they are able to keep muscles active and their interest alive. If feasible, they should be placed where they can benefit from the company of other children, which assures them that they are not being singled out for this medical treatment.

It is important for children to understand behavioral limitations or rules. Their questions should be answered. For example, children need to know the reasons for medical, nursing, occupational, and physical therapy and to know that some schedules are necessary. In some areas they have a choice; in others they do not. They may or may not be permitted to sleep late, but they can choose their own clothing. Most of children's activities of daily living are play; therefore, therapies that incorporate play are more apt to gain their cooperation.

Visits from significant persons, such as family members and friends from school or the neighborhood, offer occasions for emotional support and also provide opportunities for learning how to care for the child. If a traumatic incident caused the child's disability, guilt feelings may be displayed overtly or masked behind regressive or aggressive behavior. The feeling that "I must have been bad to receive this fate" is common, and honest feedback, such as "It just happened—it was an accident," needs repeating many times. Additional aspects of grieving are involved if there was a loss of another person or if permanent disability occurred as a result of the accident. All these feelings need to be brought out and dealt with by the child and family. Nurses working with the child or adolescent must not overprotect them but must help them cope with an altered body image and reestablish self-esteem.

For a child with greatly restricted movement (e.g., a child with tetraplegia or a child with a bilateral hip spica cast), creativity in nursing care is often required to keep the child stimulated and prevent the effects of immobilization. These situations may require long-term care in the hospital, a rehabilitation center, or, increasingly, at home. Wherever the care occurs, consistent planning and coordination of activities with professionals and significant others is vital.

Nursing assessment includes gathering psychosocial data, in addition to assessing physical manifestations, since long-term immobilization has a profound effect on the child and the family. Nursing approaches are evaluated frequently and continued, discontinued, or modified to meet the changing problems and goals. Table 34-1 summarizes the physical effects of immobilization and appropriate nursing care management. With the increased trend toward early mobilization, early discharge, and home health care, many children are discharged home after a few days of hospitalization. Follow-up treatment

TABLE 34-1 SUMMARY OF PHYSICAL EFFECTS OF IMMOBILIZATION WITH NURSING INTERVENTIONS*

PRIMARY EFFECTS	SECONDARY EFFECTS	NURSING CONSIDERATIONS
Muscular System		
Decreased muscle strength, tone, and endurance	Decreased venous return and decreased cardiac output	Use antiembolism stockings or intermittent compression devices to promote venous return (monitor circulatory and neurovascular status of extremities when such devices are used).
	Decreased metabolism and need for oxygen	Plan play activities to use uninvolved extremities.
	Decreased exercise tolerance	Place in upright posture when possible.
	Bone demineralization	Perform passive range of motion exercises
Disuse atrophy and loss of muscle mass	Catabolism Loss of strength	Have patient perform range-of-motion, active, passive, and stretching exercises.
Loss of joint mobility	Contractures, ankylosis of joints	Maintain correct body alignment. Use joint splints as indicated to prevent further deformity. Maintain range of motion.
Weak back muscles	Secondary spinal deformities	Maintain body alignment.
Weak abdominal muscles	Impaired respiration	See nursing considerations for respiratory system.
Skeletal System		
Bone demineralization—osteoporosis, hypercalcemia	Negative bone calcium uptake Pathologic fractures Calcium deposits Extraosseous bone formation, especially at hip, knee, elbow, and shoulder Renal calculi	With paralysis use upright posture on tilt table. Handle extremities carefully when turning and positioning. Administer calcium-mobilizing drugs (diphosphonates) and normal saline infusions as ordered. Ensure adequate intake of fluid; monitor output. Acidify urine. Promptly treat urinary tract infections.
Negative bone calcium uptake	Life-threatening electrolyte imbalance	Monitor serum calcium levels. Provide electrolyte replacement as indicated.
Metabolism		
Decreased metabolic rate	Slowing of all systems Decreased food intake	Mobilize as soon as possible. Have patient perform active and passive resistance and deep-breathing exercises. Ensure adequate food intake. Provide a high-protein diet.
Negative nitrogen balance	Decline in nutritional state	Encourage small, frequent feedings with protein and preferred foods.
	Impaired healing	Monitor for and prevent pressure areas.
Hypercalcemia	Electrolyte imbalance	See nursing consideration for skeletal system.
Decreased production of stress hormones	Decreased physical and emotional coping capacity	Identify causes of stress. Implement appropriate interventions to lower physical and psychosocial stresses.
Cardiovascular System		
Decreased efficiency of orthostatic neurovascular reflexes	Inability to adapt readily to upright position (orthostatic intolerance) Pooling of blood in extremities in upright posture	Monitor peripheral pulses and skin temperature changes. Use antiembolism stockings or intermittent compression devices to decrease pooling when upright.
Diminished vasopressor mechanism	Orthostatic intolerance with syncope, hypertension, decreased cerebral blood flow, tachycardia	Provide abdominal support. In severe cases use antigravitational pants. Position horizontally.
Altered distribution of blood volume	Increased cardiac workload Decreased exercise tolerance	Monitor hydration, blood pressure, and urinary output.

TABLE 34-1 SUMMARY OF PHYSICAL EFFECTS OF IMMOBILIZATION WITH NURSING INTERVENTIONS—cont'd

PRIMARY EFFECTS	SECONDARY EFFECTS	NURSING CONSIDERATIONS
Venous stasis	Pulmonary emboli or thrombi	Encourage and assist with frequent position changes. Elevate extremities without knee flexion. Ensure adequate fluid intake. Have patient perform active or passive exercises or movement as needed. Prescribe routine wearing of antiembolism stockings or intermittent compression devices. Monitor for signs of pulmonary embolism—sudden dyspnea, chest pain, respiratory arrest. Promptly intervene to maintain adequate oxygenation if signs and symptoms of pulmonary emboli are noted. Measure circumference of extremities periodically. Give anticoagulant drugs as prescribed.
Dependent edema	Tissue breakdown and susceptibility to infection	Administer skin care. Turn every 2-4 hr. Monitor skin color, temperature, and integrity. Use pressure-reduction surface as necessary to prevent skin breakdown. (See Chapter 23.)
Respiratory System		
Decreased need for oxygen	Altered oxygen–carbon dioxide exchange and metabolism	Promote exercise as tolerated. Encourage deep-breathing exercises.
Decreased chest expansion and diminished vital capacity	Diminished oxygen intake Dyspnea and inadequate arterial oxygen saturation; acidosis	Position for optimum chest expansion. Semi-Fowler position may assist in lung expansion if patient can tolerate. Use prone positioning without pressure on abdomen to allow gravity to aid in diaphragmatic excursion. Ensure that patient maintains proper alignment when sitting to prevent pressure on respiratory mechanism.
Poor abdominal tone and distention	Interference with diaphragmatic excursion	Avoid restriction of chest and abdominal musculature. Supply torso support to promote chest expansion.
Mechanical or biochemical secretion retention	Hypostatic pneumonia Bacterial and viral pneumonia Atelectasis	Change position frequently. Use incentive spirometer. Monitor breath sounds. Encourage deep breathing exercises. Implement airway clearance techniques as necessary.
Loss of respiratory muscle strength	Poor cough	Encourage coughing and deep breathing. Support chest wall by splinting with pillow when patient coughs. Use incentive spirometer. Observe for signs of respiratory distress with pulse oximetry or blood gas measurement as necessary.
	Upper respiratory tract infection	Prevent contact with infected persons. Provide adequate hydration. Administer immunizations as necessary (pneumococcal, meningococcal).
Gastrointestinal System		
Distention caused by poor abdominal muscle tone	Interference with respiratory movements	Monitor bowel sounds. Encourage small, frequent feedings.
	Difficulty in feeding in prone position	Have patient sit in upright position in bedside chair if possible.
No specific primary effect	Possible constipation caused by gravitational effect on feces through ascending colon or weakened smooth muscle tone	Carry out bowel training program with hydration, stool softeners, increased fiber intake, and mild laxatives if necessary.
	Anorexia	Stimulate appetite with favored foods.

Continued

TABLE 34-1 SUMMARY OF PHYSICAL EFFECTS OF IMMOBILIZATION WITH NURSING INTERVENTIONS—cont'd

PRIMARY EFFECTS	SECONDARY EFFECTS	NURSING CONSIDERATIONS
Urinary System		
Alteration of gravitational force	Difficulty in voiding in prone position	Position as upright as possible to void.
Impaired ureteral peristalsis	Urinary retention in calyces and bladder infection	Hydrate to ensure adequate urinary output for age.
	Renal calculi	Stimulate bladder emptying with warm running water as necessary.
		Catheterize only for severe urinary retention.
		Administer antibiotics as indicated.
Integumentary System		
Altered tissue integrity	Decreased circulation and pressure leading to tissue injury	Turn and reposition at least every 2-4 hr.
		Frequently inspect total skin surface.
		Eliminate mechanical factors causing pressure, friction, moisture, or irritation.
		Place on pressure-relief mattress.
	Difficulty with personal hygiene	Assess ability to perform self-care and assist with bathing, grooming, and toileting as needed.
		Encourage self-care to potential ability.
		Ensure adequate intake of protein, vitamins, and minerals.

*Individualize care according to child's needs; interventions may vary in different institutions.

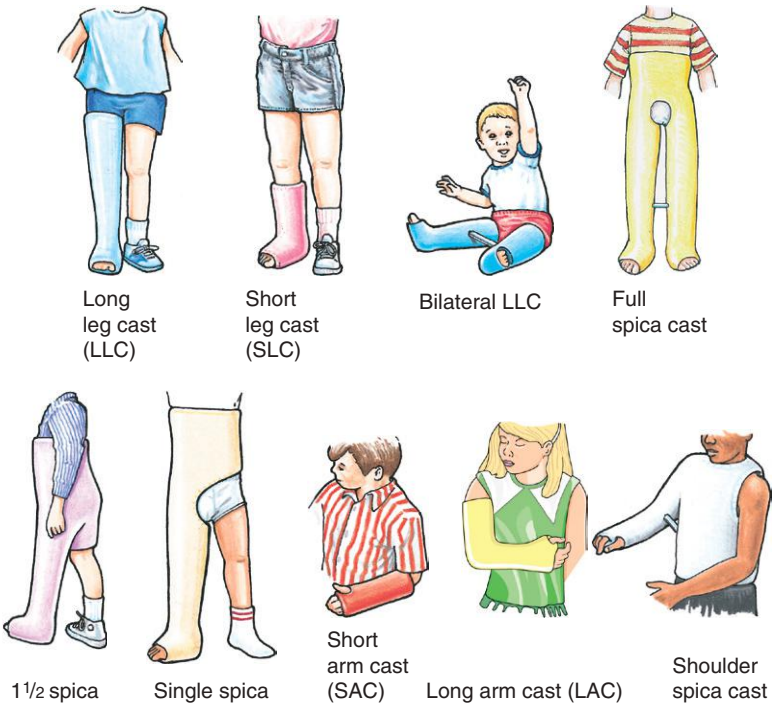

FIG. 34-4 Types of casts.

may take place in the home or in an outpatient ambulatory facility.

THE CHILD IN A CAST

Children may be placed into a cast for different reasons, including treatment of a fracture or following a surgery to maintain alignment. In many situations, the joints above and below the site of injury are immobilized to eliminate the possibility of movement that might cause displacement at the site; however, a torus fracture may only require a short arm splint or cast. Three major types of casts are used for immobilization: upper extremity to immobilize the wrist or elbow, lower extremity to immobilize the ankle or knee, and spica to immobilize the hip and knee (Fig. 34-4). Fig. 34-5 shows a full spica cast with a hip abduction, and Fig. 34-6 shows a single leg spica cast.

FIG. 34-5 Spica cast with hip abductor. Note casts on doll as well.

FIG. 34-6 Single spica cast. Note diaper to maintain dryness. (Courtesy Texas Children's Hospital, Houston.)

The Cast

Casts are constructed from gauze strips and bandages impregnated with plaster of Paris or, more commonly, synthetic lighter-weight and water-resistant materials (e.g., waterproof liners, fiberglass and polyurethane resin). Both types of casting material produce heat from a chemical reaction activated by water immediately after application. The lightweight casts are used more often for casting in children and are available in a variety of colors. Plaster casts are usually reserved for situations that require molding closely to the body part. Table 34-2 compares plaster and synthetic casts.

Cast Application

The child's developmental age should be considered before the cast is applied. For preschoolers who fear bodily harm and fantasize the loss of an extremity, use a plastic doll or stuffed animal to explain the procedure beforehand. Toddlers and preschoolers do not have easily defined body boundaries; if an extremity is wrapped in a bandage, cast, or splint, to the young child the extremity ceases to exist. Explain to the child that some synthetic cast material will become warm but will not burn. During the application of the cast, use various distraction methods, including discussing favorite pets or activities at school and blowing bubbles. In this age-group explanations such as "This will help your arm get better" are futile because the child has no concept of causality.

Before the cast is applied, check the extremities for any abrasions, cuts, or other alterations in the skin surface and for the presence of rings or other items that might cause constriction with swelling; such objects are removed. A tube of stockinette or waterproof liner is stretched over the area to be casted, and bony prominences are padded with soft cotton sheeting. Dry rolls of casting material are immersed in a pail of tepid water, and the wet rolls are applied in bandage fashion and molded to the extremity. During application of the cast, the underlying stockinette is pulled over the raw edges of the plaster cast and secured with a layer casting material to form a smooth, padded edge to protect the skin. If the operator does not form such a protective edge with the stockinette, the raw edges of the plaster cast can be protected by creating a "petaled" edge. Using a scissors, small pieces of moleskin or adhesive tape are cut with rounded edges; the individual "petals" are placed over the edge of the cast, with each petal slightly overlapping the previous one to form a smooth, neat edge.

! NURSING ALERT

Heated fans or dryers are not used because they cause the cast to dry on the outside and remain wet beneath or cause burns from heat conduction by the cast to the underlying tissue.

Cast Removal

Cutting the cast to remove it or to relieve tightness is frequently a frightening experience for children. They fear the sound of the cast cutter and are terrified that their flesh, as well as the cast, will be cut. Because it works by vibration, a cast cutter cuts only the hard surface of the cast. The oscillating blade vibrates back and forth very rapidly and will not cut when placed lightly on the skin. Children have described it as producing a "tickly" sensation. The vibration also generates heat that the child may feel. Explain both of these sensations to the child.

Preparation for the procedure helps reduce anxiety, especially if the nurse has established a trusting relationship with the child. Many young children come to regard the cast as part of themselves, which intensifies their fear of removal (Fig. 34-7). They need continual reassurance that all is going well and that their behavior is accepted.

After the cast is removed, the skin surface is caked with desquamated skin and sebaceous secretions. Simple soaking in a bathtub is usually sufficient for their removal, but it may take several days to completely eliminate the accumulation. The parents and child should be instructed to not pull or forcibly remove this material with vigorous scrubbing, since this

TABLE 34-2 COMPARISON OF PLASTER OF PARIS AND SYNTHETIC CASTS

	PLASTER OF PARIS	SYNTHETIC
Composition and preparation	Cotton tape permeated with calcium sulfate crystals that interlock as tape dries (tepid water activated)	Polyester-cotton tape permeated with polyurethane resin (cool water activated) Knitted fiberglass tape with polyurethane resin (tepid water activated or photoactivated) Knitted thermoplastic polyester fabric (hot water activated)
Setting time	3-8 min	3-15 min
Drying time	10-72 hr (varies with cast size)	5-20 min (varies with type of cast) NOTE: The more rapid the drying time, the greater the likelihood of burning; therefore, it is recommended to use tepid or cool water to slow drying time and decrease chemical heat produced; the warmer the water, the faster the material dries or hardens (Boyd, Benjamin, and Asplund, 2009).
Indentations	Slow drying time increases possibility of indentations or alteration of intended fit	Rapid drying time reduces likelihood of indentations; allows rapid use (see previous statement under Drying time: synthetic)
Weight	Relatively heavy; bulky; makes it difficult to wear regular clothing	Lightweight; less bulky; permits regular clothing to be worn; allows for greater range of activity
Conformity	Molds readily to body part	Does not mold easily to some body parts such as fingers and toes; may be unsuitable for some fractures
Surface	Smooth exterior; does not snag clothing or scratch furniture	Smooth exterior
Cost	Relatively inexpensive; an advantage if cast changes anticipated	Inexpensive unless Gore-Tex added
Stability	Relatively stable; cast must be kept dry	Some cast material may tolerate being wet or immersed in water with permission from practitioner *(only those with use of nonabsorbent synthetic lining);* can be cleaned with small amount of mild soap and water, dried with towel followed by blow dryer on cool or warm setting; takes considerable time to dry if immersed
Miscellaneous	Child may feel uncomfortable warming or burning sensation under cast while it dries (chemical reaction) Skin under cast may become irritated Cast must be protected when around water (bathing)	Child may feel uncomfortable warming or burning sensation under cast while it dries (chemical reaction) but this lasts only a few minutes (see Drying time) Skin under cast may become macerated from inadequate drying after water immersion

FIG. 34-7 Young children come to regard a cast as part of their body.

may cause excoriation and bleeding. If the cast has been in place for a lengthy period of time, decreased muscle mass may be noted. The child and family should be reassured that resuming exercise and routine activities will gradually return function and appearance (provided there was no significant trauma beforehand).

Nursing Care Management

The complete evaporation of the water from a hip spica cast can take 24 to 48 hours when plaster materials are used. Drying occurs within minutes with fiberglass materials. The cast must remain uncovered to allow it to dry from the inside out. A wet plaster cast should be supported by a pillow covered with plastic and handled by the palms of the hands to avoid indenting the cast and creating pressure areas. Turning the child in a plaster cast at least every 2 hours will help to dry a body cast evenly and prevent complications related to immobility. Use of a regular fan or a hair dryer on the cool setting to circulate air may be helpful when the humidity is high. A dry plaster of Paris cast produces a hollow sound when tapped with the finger.

! NURSING ALERT

Immediately report any observations that include the five *P*s of ischemia: pain, especially with passive range of motion; pallor; pulselessness (an ominous and late sign); paresthesia; and paralysis.

During the first few hours after a cast is applied, the chief concern is that the extremity may continue to swell to the extent that the cast becomes a tourniquet, shutting off circulation and producing neurovascular complications (compartment syndrome). One measure to reduce the likelihood of this problem is to elevate the body part and thereby increase venous return. If edema is excessive, casts are bivalved (i.e., cut to make anterior and posterior halves that are held together with an elastic bandage). The cast and the involved extremity are observed frequently to assess neurovascular integrity and detect any signs of compromise. Within hours permanent muscle and tissue damage can occur.

Appropriate cast care guidelines for the child's parents and caregivers are necessary before discharge. Instructions are also given for checking for signs and symptoms that indicate the cast is too tight (see Family-Centered Care box). Parents should also know to take the child to the health care professional for attention if the cast becomes too loose, since a loose cast no longer serves its purpose.

Nurses can help families adapt the child's home environment to meet the temporary inconvenience of a large cast or one that restricts the child's mobility (e.g., a hip spica cast or long leg cast). Common situations (e.g., transporting a child safely and comfortably in a car) can become problematic. Standard seat belts and car seats may not be readily adapted for use by children in some casts. Specially designed car seats and restraints are available that meet safety requirements. Baths are possible only if the cast is kept out of the water and covered to prevent it from becoming wet from splashes. Some synthetic casts are waterproof, but proper care is necessary to avoid skin irritation beneath the cast.

Sitting can be impossible in a spica cast, and lower extremity casts require extra space in a small room, under a table, and in a bathroom. Children in spica casts may experience difficulty with feeding, and the prone position may be easier for self-feeding from a small table; alternatively, they may manage a semisitting position in bed or in a wheelchair (see Figs. 34-5 and 34-6). Use of a conventional toilet is almost impossible for a child in a spica cast. Small bedpans or other containers offer alternatives for elimination. The nurse may suggest waterproofing methods by using plastic wraps, a protective skin barrier, and absorbent pads as means of reducing urine burns and heat rash and improving hygiene with a hip spica cast.

FAMILY-CENTERED CARE

Cast Care

- Expose the plaster cast to air until dry.
- Keep the casted part of the body elevated on pillows or similar support for the first day or as directed by the health care professional.
- The wet plaster cast should be lifted and supported with the palms of the hands only, to avoid indenting with the fingers.
- Observe the fingers or toes for any evidence of swelling or discoloration (darker or lighter than a comparable extremity), and contact the health care professional immediately if either is noted.
- Check the movement and sensation of the visible fingers or toes frequently, and contact the health care professional regarding any changes noted.
- Encourage frequent rest for a few days, and elevate the injured arm or leg while resting.
- Do not allow the affected limb to hang in a dependent position for more than 30 minutes (to prevent swelling and circulatory stasis).
- Keep an injured arm or hand elevated (e.g., in a sling) most of the time; supporting it on pillows at chest level is helpful.
- Elevate an injured leg when the child is sitting, and have the child avoid standing for more than 30 minutes.
- Do not allow the child to put anything inside the cast.
- Keep small items that might be placed inside the cast away from young children.
- Examine the skin at the cast edges to detect irritation or breakdown, and pad the cast accordingly.
- Relieve itching by an ice pack and administration of medication as recommended by the provider.
- Instruct the child and parents to avoid placing the cast in water (e.g., tub, shower, swimming pool).
- If the patient is incontinent, protect the cast with waterproof tape and plastic. Use diapers, pull-ups, or other guards.

THE CHILD IN TRACTION

With the increased emphasis on outpatient care of acute and chronic illnesses to cut health care costs, developmental and social considerations, immobilization problems, and advanced surgical techniques, traction is used with decreasing frequency. Most skeletal traction is applied in children after a severe or complex injury to allow physiologic stability, align bone fragments, and permit closer evaluation of the injured site. New technology has developed orthopedic fixation devices that allow for partial or full mobility, thus preventing long-term immobilization and the consequences of such. In many cases, surgical intervention is performed within a matter of hours or days; therefore, traction devices described here may be used infrequently in pediatrics.

Purposes of Traction

The primary purposes of traction are:

1. To realign bone fragments
2. To provide rest for an extremity
3. To help prevent or improve contracture deformity
4. To correct a joint deformity
5. To treat a dislocation
6. To allow preoperative or postoperative positioning and alignment
7. To provide immobilization of specific areas of the body
8. To reduce muscle spasms (uncommon in children)

When two forces of given direction and magnitude act on an object at the same point simultaneously from opposite directions, the object either changes its state of rest or motion or remains in equilibrium. The use of traction in the management of fractures is the direct application of such forces to produce

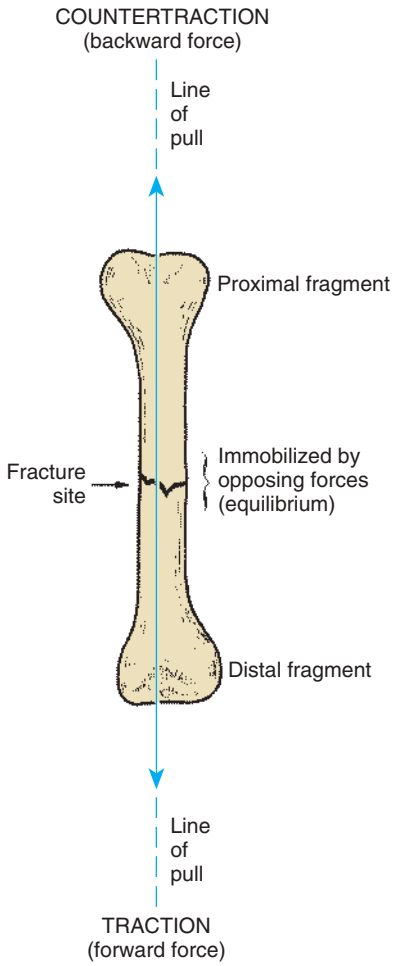

FIG. 34-8 Application of traction for maintaining equilibrium.

equilibrium at the fracture site. **Traction** (forward force) is produced by attaching weight to the distal bone fragment. This force is balanced by the backward force of the muscle pull (**countertraction**) and the frictional force between the patient and the bed (Fig. 34-8). To reduce or realign a fracture site, traction is provided by weights applied to the distal bone fragment; body weight provides countertraction. These forces are used to align the distal and proximal bone fragments by adjusting the line of pull upward or downward and by adducting or abducting the extremity. To attain equilibrium, the amount of forward force is adjusted by adding weight to or subtracting weight from the traction, or countertraction is increased by elevating the foot of the bed to create a greater gravitational pull in the backward force.

The three primary purposes of traction for reduction of fractures are:

1. To fatigue the involved muscle and reduce muscle spasm so that bones can be realigned
2. To position the distal and proximal bone ends in the desired realignment to promote satisfactory bone healing
3. To immobilize the fracture site until realignment has been achieved and sufficient healing has taken place to permit casting or splinting

BOX 34-2 TYPES OF TRACTION

Manual traction—Applied to the body part by the hands placed distal to the fracture site. Manual traction may be provided during application of a cast but more commonly when a closed reduction is performed.

Skin traction—Applied directly to the skin surface and indirectly to the skeletal structures. The pulling mechanism is attached to the skin with adhesive material or an elastic bandage. Both types are applied over soft, foam-backed traction straps to distribute the traction pull.

Skeletal traction—Applied directly to the skeletal structure by a pin, wire, or tongs inserted into or through the diameter of the bone distal to the fracture.

In some cases traction may be used to treat a pathologic joint condition such as developmental hip dysplasia. The muscle is fatigued by applying constant stress to the muscle so that the buildup of lactic acid will produce muscle relaxation. The all-or-none law, which characterizes muscle contractility, applies to muscle relaxation as well. When the muscle is stretched, muscle spasm ceases, which permits the realignment of the bone ends. The continuous maintenance of traction is important during this phase, since releasing the traction allows the muscle to contract normally and again cause malpositioning of the bone ends.

The realignment of the bone fragments is a gradual process that is achieved more rapidly in infants, who have limited muscle tone, than in muscular teenagers. The line of pull and callus formation are checked periodically by radiographic examination. The traction pull to some degree immobilizes the fracture site; however, adjunct immobilizing devices such as splints or casts are sometimes used with skeletal traction. In injuries in which there is severe soft tissue swelling or vascular and nerve damage, it is customary to use traction until these complications have been resolved and it is safe to apply a cast. Immobilization with traction is maintained until the bone ends are in satisfactory realignment, after which a less confining type of immobilization—a cast, pins, or external stabilization device—is applied.

Types of Traction

The two main types of traction are skin traction and skeletal traction. The pull needed for traction can be applied to the distal bone fragment in several ways (Box 34-2). The type of traction applied is determined primarily by the child's age, the condition of the soft tissues, and the type and degree of displacement of the fracture. Fractures most commonly treated by application of traction are those involving the femur and vertebrae.

Upper extremity traction is rarely used in children. Current surgical techniques allow for early mobilization and acceptable results without the use of traction. Nursing care of children with upper extremity traction is similar to that for lower extremity traction, discussed below.

The common site for a femoral fracture is the middle third of the shaft (Fig. 34-27, *A*). With such a fracture there may be significant overriding but minimal displacement. In a fracture in the lower third of the shaft, the pull of the gastrocnemius

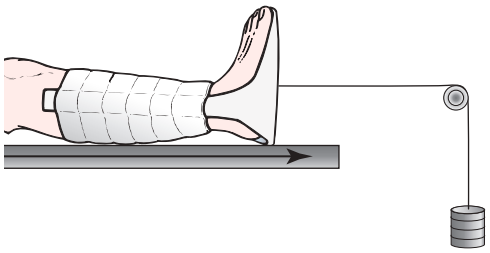

FIG. 34-9 Buck extension traction.

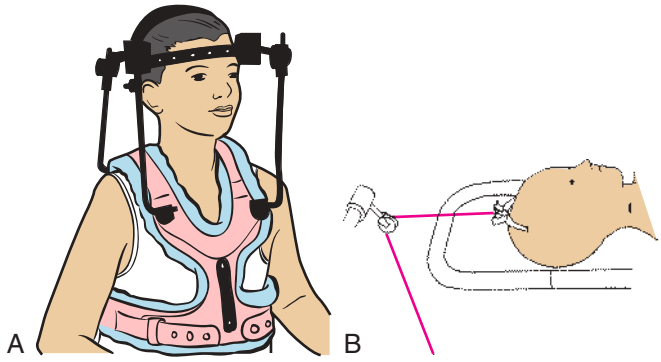

FIG. 34-10 **A,** Halo vest. **B,** Cervical traction with Gardner-Wells tong.

muscle causes the distal fragment to become downwardly displaced. Femur fractures in young children can often be reduced followed by application of a hip spica cast. When traction is necessary, several types may be used.

Buck extension traction is a type of skin traction applied with the legs in an extended position (Fig. 34-9). Buck extension traction is used primarily for short-term immobilization, such as preoperative management of a child with a dislocated hip, or for correction of contractures or bone deformities, such as in Legg-Calvé-Perthes disease. Except for fracture cases, a side-lying position may be permissible if the leg is stable. Buck extension traction can be utilized with either skin straps or a special boot designed for traction.

Russell traction uses skin traction on the lower leg and a padded sling under the knee. Two lines of pull, one along the longitudinal axis of the lower leg and one perpendicular to the leg, are produced. This combination of pulls allows realignment of the lower extremity and immobilizes the hip and knee in a flexed position. The hip flexion must remain at the prescribed angle to prevent fracture malalignment, since there is no direct support under the fracture and the skin traction may slip. Nursing measures include carefully monitoring the position of the traction so that the appropriate amount of hip flexion is maintained and damage to the peroneal nerve under the knee does not cause footdrop.

A common skeletal traction is 90-degree–90-degree traction (90-90 traction). The lower leg is supported by a boot cast or a calf sling, and a skeletal Steinmann pin or Kirschner wire is placed in the distal fragment of the femur. This type of traction results in a 90-degree angle at both the hip and knee. It achieves the desired line of pull for reducing the fracture and provides adequate immobilization of the fracture site. The use of 90-90 traction also supports the lower extremity in a desired position with good venous return. From a nursing standpoint, this type of traction facilitates position changes, toileting, and prevention of traction complications.

Balanced suspension traction may be used with or without skin or skeletal traction. Unless it is combined with another type of traction, balanced suspension traction merely holds the leg in a desired flexed position to relax the hip and hamstring muscles and does not exert any traction directly on a body part. A Thomas splint extends from the groin to midair above the foot, and a Pearson attachment supports the lower leg. Towels or pieces of felt covered with stockinette are clipped or pinned to the splints for leg support. Ropes are attached to create a balanced traction. When the child is lifted from the bed, the traction lifts as well, with no loss of alignment (see Fig. 34-3). The Pearson attachment stays wherever it is positioned. This type of traction requires very careful checking of splints and ropes to make certain that no slippage or fraying has occurred. This mode of traction is of great value when lifting the older and heavier child for care.

The cervical area is a vulnerable site for flexion or extension injuries to muscles, vertebrae, or the spinal cord. Cervical muscle trauma without other complications is treated with a cervical soft or hard collar to relieve the weight of the head on the fracture site. When a child's cervical vertebra is displaced or fractured, it may be necessary to reduce and immobilize the site with cervical skeletal traction. The spinal cord runs through the intravertebral canal, and dislocation or fracture of the vertebrae can also cause spinal cord injury. Nursing assessment, especially of neurologic function, is essential to prevent further injury during the application and use of cervical skeletal traction.

Most cervical traction may be accomplished with the use of a halo brace or halo vest (Fig. 34-10, *A*). This device consists of a steel halo attached to the outer skull by four screws; several rigid bars connect the halo to a vest that is worn around the chest. This provides greater mobility of the rest of the body, while limiting cervical spinal motion completely. Gardner-Wells tongs may also be used to immobilize the cervical spine (Fig. 34-10, *B*). Gardner-Wells tongs are spring-loaded, so making burr holes and shaving hair are not required; a local anesthetic may be used during application. The head is placed in a hyperextended position, and, as the neck muscles fatigue with constant traction pull, the vertebral bodies gradually separate so the spinal cord is no longer pinched between the vertebrae. Immobilization until fracture healing or surgical fixation can occur is an essential goal of cervical traction. If immobilization is needed in a young child, a special cervical spine cast (Minerva cast) may be applied.

! NURSING ALERT

Skeletal traction is never released by the nurse (except under direct supervision by the provider). This precaution includes not lifting the weights that are applying traction (e.g., for moving the child in bed, for repositioning).

Nursing Care Management

In order to assess the child in traction, it is essential to know the purpose or reason for application of traction and understand the basic principles of its use. Routine assessment of both the child and the traction apparatus is required. Many of the nursing problems associated with traction in a child are related to immobility. However, a number of physical needs related to traction require attention and vigilance.

In addition to routine skin observation and care, the child in skeletal traction will need special skin care at the pin site according to hospital policy or provider preference. Pin sites should be frequently assessed and cleaned to prevent infection; after the first 48 to 72 hours, pin site care may be performed once daily or weekly for mechanically stable pins. Several different methods and solutions can be used for cleaning pin sites; studies have shown no clear evidence that one pin care technique is better than another at reducing the chance of infection or complications (Lethaby, Temple, and Santy, 2008). Before the child's discharge, parents and caregivers are taught pin site care, including how to observe for infection or pin instability, using a return demonstration method. A pressure-reduction device, such as a foam overlay or an alternating-pressure mattress, reduces the chance of skin breakdown.

When the child is first placed in traction, increased discomfort is common as a result of the traction pull fatiguing the muscle. Orthopedic conditions are associated with a higher-than-average number of painful events and a higher percentage of bodily symptoms than other common conditions. Analgesics, including opioids, and muscle relaxants help during this phase of care and should be administered liberally with close attention paid to possible adverse effects.

DISTRACTION

Unlike traction, which helps bones realign and fuse properly, distraction is the process of separating opposing bone to encourage generation of new bone in the created space. Distraction can be used when limbs are of unequal lengths and new bone is needed to elongate the shorter limb.

EXTERNAL FIXATION

Monolateral, Taylor Spatial frame and Ilizarov external fixators are common external fixation devices. The Ilizarov external fixator uses a system of wires, rings, and telescoping rods that permits limb lengthening to occur by manual distraction (Fig. 34-11). In addition to lengthening bones, the device can be used to correct angular or rotational deformities or to immobilize fractures. The device is attached surgically by securing a series of external full or half rings to the bone with wires. External telescoping rods connect the rings to each other. Manual distraction is accomplished by manipulating the rods to increase the distance between the rings. A special osteotomy or corticotomy involves cutting only the cortex of the bone, while preserving its blood supply, bone marrow, endosteum, and periosteum. Capillary blood flow to the transected area is essential for proper bone growth. Cut bone ends typically grow at a rate of 1 cm (0.4 inch) per month. Use of the external fixator can result in a gain in length of up to 15 cm (5.9 inches).

FIG. 34-11 Child with Ilizarov external fixator (on right leg) during physical therapy on parallel bars.

Nursing Care Management

Successful use of external fixation depends on the child's and family's cooperation; therefore, before surgery, they must be fully informed about the appearance of the device, the way it accomplishes bone growth, required alterations in activities, and home and follow-up care. Children are involved in learning to adjust the device to accomplish distraction. Children and parents should be instructed in pin care, including observation for infection and loosening of pins.

Children who participate actively in their care report less discomfort. Because the device is external, the child and family need to be prepared for the reactions of others. Partial weight bearing is allowed, and the child needs to learn to walk with crutches. Alterations in activity include modifications at school and in physical education. Full weight bearing is not allowed until the distraction is completed and bone consolidation has occurred. Follow-up care is essential to maintain appropriate distraction until the desired leg length is achieved. The device is removed surgically after the bone has consolidated; the child may need to use crutches or have a cast for 4 to 6 weeks after removal of the device to reduce the risk of fracture.

INTERNAL FIXATION

Internal fixation methods require surgery and include screw and plate fixation and intramedullary fixation. Orthopedic surgery uses a variety of rods, screws, staples, and plates to improve the alignment of a fracture and allow for proper bone growth and healing. Usually rods are driven down the shaft of the long bones, whereas screws and plates are attached to the sides of the bone shaft. Postoperatively the bone healing takes

place with callus formation, as it does in a new fracture. Occasionally, supplemental casting or bracing is needed. Often, the hardware is surgically removed after the fracture has completely healed.

Generally, after placement of an internal fixation device, the child sits in a chair and walks with a walker or crutches within a few hours or days. The most common postoperative complication is infection. The nurse's responsibility includes close monitoring of neurovascular changes in the involved extremity and the prevention of postanesthesia problems. Alert the family to signs of infection and instruct them regarding appropriate weight-bearing and activity plans.

AMPUTATION

A child may be born with the congenital absence of a body part, experience a traumatic loss of an extremity, or require a surgical amputation for a pathologic condition such as osteosarcoma. With today's surgical technology and the quick thinking of bystanders who save a traumatically amputated body part, some children have had fingers and arms sewn back on with variable degrees of functional use regained.

Surgical amputation or the surgical repair of a permanently severed limb focuses on constructing an adequately nourished residual limb. For lower extremities the presence of a smooth, healthy, padded stump, free of nerve endings, is important for prosthesis fitting and subsequent ambulation. In some situations in which there is no vascular or neurologic deficit, a cast is applied to the stump immediately after the procedure, and a pylon, metal extension, and artificial foot are attached so that the patient can walk on the temporary prosthesis within a few hours.

! NURSING ALERT

For a traumatically amputated limb or body part, do the following:

1. Rinse limb gently with normal saline.
2. Loosely wrap limb in sterile gauze.
3. Place wrapped limb in a watertight bag.
4. Chill bag, without freezing, in ice water. Do not pack in ice because this may harm tissue.
5. Label with child's name, date, and time, and transport with the child to the hospital.

Nursing Care Management

Lower extremity stump shaping is done postoperatively with special elastic bandaging using a figure eight compression bandage, which applies pressure in a conical fashion. This technique decreases stump edema, controls hemorrhage, and aids in developing desired contours so that the child will bear weight on the posterior aspect of the skin flap rather than on the end of the stump. The stump may be elevated for the first 24 hours, but after this time the extremity should not be left in this position because contractures in the proximal joint will develop and seriously hamper ambulation. Monitoring proper body alignment further decreases the risk of flexion contractures.

Postoperatively, children who undergo amputation of a lower extremity should be turned not only from side to side but also from front to back. Postoperative complications for which the nurse should be vigilant include hemorrhage and infection of the operative site. As the child progresses, encourage him or her to lie prone at least three times a day, increasing the time prone to tolerance of an hour at a time.

For older children and adolescents, arm exercises, bed pushups, and exercises with parallel bars (which are used in prosthesis training programs) help to build up the arm muscles necessary for walking with crutches. An overhead trapeze bar enhances mobilization and upper body strength building in the early postoperative period when a lower limb has been amputated.

Full range-of-motion exercises of joints above the amputation must be performed several times daily, using active and isotonic exercises. Young children are spontaneously active and require little encouragement.

Depending on the child's age, the child or parents need to learn stump care, including careful washing with soap and water every day and checking for skin irritation, breakdown, or infection. A tube of stockinette or talcum powder is used to make the prosthesis slide on more easily. A careful skin check must be performed every time the prosthesis is removed, and prosthesis tolerance time must be adjusted to prevent skin breakdown.

For children who have had an amputation, phantom limb pain is an expected experience because the nerve-brain connections are still present. Phantom pain is real pain and should be treated appropriately with analgesics and other pain-relieving measures. Gradually these sensations fade, although in many amputees they persist for years. Preoperative discussion of this phenomenon helps a child understand these feelings and not hide the experience from others. Limb pain, especially pain that increases with ambulation, should be evaluated for the possibility of a neuroma at the free nerve endings in the stump or a poorly fitting prosthesis. Chronic pain may also be related to weakness or joint instability, injury to the nerve, or fibrosis of soft tissues. Pain in the contralateral extremity may result from asymmetric weight bearing.

MOBILIZATION DEVICES

Orthotics and Prosthetics

Developments in the fields of **orthotics** (fabrication and fitting of braces) and **prosthetics** (fabrication and fitting of artificial limbs) have resulted in lighter and better-fitting devices and thus greater patient compliance in using them. Orthoses are often used to prevent deformity, increase the energy efficiency of gait, and control alignment. Braces that facilitate walking can sometimes stabilize paralyzed or markedly weakened extremities. Special joint hinges permit the hip, knee, and ankle to flex while sitting, whereas the leg is held rigid during ambulation. Well-fitted orthoses promote ambulation, whereas ill-fitting braces throw off the child's balance and frequently cause muscle stress and tissue breakdown. In the growing child, braces need frequent adjustment and replacement if long-term use is necessary.

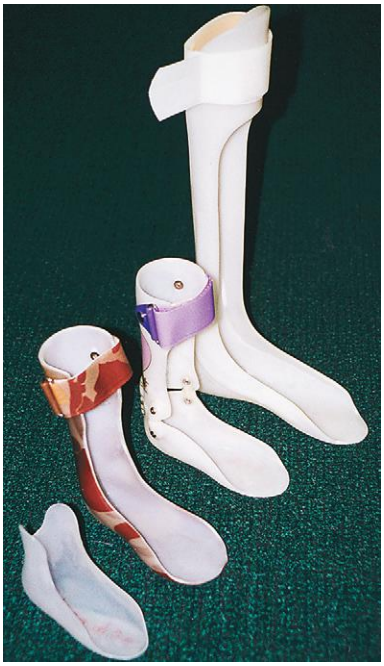

FIG. 34-12 *Left to right:* Supramalleolar orthosis (SMO), solid ankle-foot orthosis (AFO), articulating AFO, floor reaction AFO.

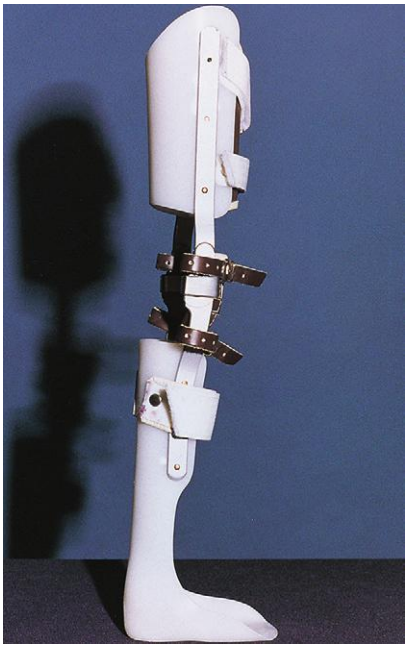

FIG. 34-13 Knee-ankle-foot orthosis (KAFO).

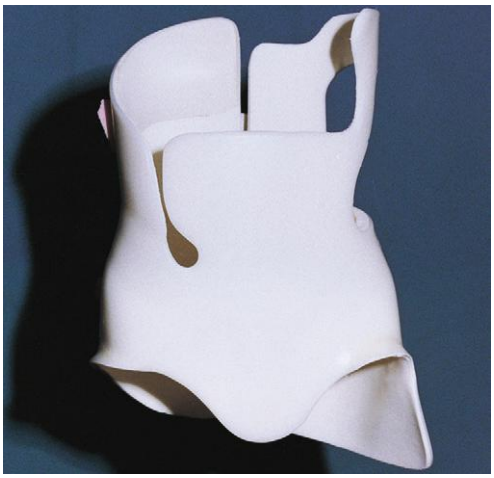

FIG. 34-14 Thoracolumbosacral orthosis (TLSO).

Types of orthoses are described based on the joints controlled by the orthosis. The ankle-foot orthosis (AFO) is used to prevent footdrop due to bed rest, trauma to the foot, or paralysis of the muscles in the foot; to prevent heel cord tightening; or to support the foot in proper position for standing and walking (Fig. 34-12). Shorter styles of bracing for the foot include a supramalleolar orthosis (SMO) and foot orthosis.

The knee-ankle-foot orthosis (KAFO) is used to prevent buckling of the knee, to support the extremity when there is paralysis or marked weakness of the quadriceps muscle, or to protect the limb when the bone structure is weak (Fig. 34-13). The hip-knee-ankle-foot orthosis (HKAFO) is used to provide various types of control for the knee and ankle joints as described earlier, as well as the hip (e.g., flail lower limb and paralysis). The reciprocal gait orthosis (RGO) is a type of HKAFO that has a mechanism allowing children with significant paraplegia to walk in a reciprocal fashion on a flat surface. RGOs are used in children with spinal cord injury, sacral agenesis, and spina bifida.

The thoracolumbosacral orthosis (TLSO) and cervical thoracolumbosacral orthosis (CTLSO) are custom molded and fit snugly around the trunk of the body to exert pressure on the ribs and back to support the spine in a straight position (Fig. 34-14). The Boston brace is an underarm orthosis customized from prefabricated plastic shells, with corrective forces for each patient supplied by lateral pads. These braces may prevent the progression of curves in the spine, such as scoliosis, or provide needed trunk support in a child with paraplegia. The Jewett-Taylor brace is sometimes used to support the spine and trunk during ambulation to prevent compression after fracture of the spinal column.

An orthosis must fit each body curvature to avoid undue pressure on tissues and imbalance between muscle groups. Bony prominences where a brace has contact, such as along the spine, chin, iliac crests, ankles, and feet, are observed closely for pressure or irritation and are padded as necessary.

When prostheses are prescribed, the provider considers many factors: level of amputation, age, weight, activity, agility, and skin condition. Each prosthesis is custom made or fabricated of various plastic and foam materials. The style of the prosthesis depends on the most distal joint involved in the amputation or prosthetic fitting.

Advances are constantly occurring in both the fabrication and fitting of prosthetics. Development of myoelectric devices, use of new cosmetic materials in terminal gloves and feet, and socket construction using computer-aided design and computer-aided manufacturing are but a few of the recent changes with positive effects for patients who require prostheses.

Nursing Care Management

Meticulous skin care under a brace is necessary. At times, protective clothing should be worn under braces to protect the skin from friction and pressure. Assessment of all areas that make contact with the brace every 2 to 4 hours for the first few days after application is recommended. If any area is reddened, the brace should be removed for ½ to 1 hour. If the redness does not disappear, the nurse should notify the provider or orthotist (see Family-Centered Care box).

Before a prosthesis is applied, the condition of the skin must be assessed, with special note taken of areas of redness or breaks in the integrity of the skin. Prevention of skin breakdown is best accomplished through good hygiene of the residual limb, proper fitting of the artificial limb, and prosthetic training (see Family-Centered Care box).

Safety is another important consideration. Parallel bars provide secure handrails on both sides as the child learns to walk again with or without braces or a prosthesis. As the child becomes more proficient, a walker with or without wheels is substituted for the bars, and the child is no longer confined to a limited territory. The child then progresses to crutches if age and condition permit it.

Crutches, Canes, and Walkers

Crutches, canes, and walkers are used when children are not allowed to bear weight; need support for balance while walking in braces; or can place only part of their body weight on an extremity, such as with most lower leg injuries. There are many types of crutches, and the selection depends on the child's individual needs. Axillary swing-through crutches are used most frequently as temporary assistance. Forearm crutches (Fig. 34-15) are the usual selection for children who anticipate permanent use, such as paraplegic children who are able to use braces. In children with limited hand and arm strength or function, the use of trough crutches allows the weight to be assumed by the elbow. For habilitating small children who have not yet learned to walk or who are unsteady, front- or rear-rolling walkers are typically used until the child can progress to crutches (Fig. 34-16).

Children must be properly fitted with a crutch, cane, or walker to prevent both poor posture and crutch pressure on the axilla during ambulation. A physical therapist usually measures the child and teaches crutch, cane, or walker use; however, nurses in some areas such as the emergency department do teach children crutch walking. Nurses also supervise the use of crutches and walkers in pediatric units and in the home. The type of crutch gait taught to a child depends on how stable the child is on crutches, whether or not the knees can be flexed, how much weight bearing is allowed, and what specific goal is established for the child.

FAMILY-CENTERED CARE

Orthoses

Care of Skin

AFO, KAFO, HKAFO

If the child has decreased sensation in the legs, check the skin condition more frequently than every 4 hours.

If the child complains of a burning sensation under the brace, remove the brace promptly and observe the skin for any reddened areas. If the child complains of burning several times, contact the provider or orthotist.

If a small blister or open area develops, cover it with a sterile bandage and check the skin more often. Do not put alcohol on open areas. The child should avoid wearing the device until the skin heals.

Sometimes open areas are slow to heal. If no sign of healing occurs after 3 days, contact the provider or orthotist.

Lotions and creams will soften the skin and should be used only if the skin is dry.

TLSO

Because the device works by pressing against the body and is kept very snug by straps and buckles, some skin pinkness is to be expected. The skin at the brace edges and under the pads should be inspected carefully and frequently, especially in the initial period when the child or adolescent is getting accustomed to the device. Any red mark that does not fade within 20 minutes, or any area that appears raw and sore, should be reported to the orthotist.

Have the child wear a cotton undershirt under the brace to protect the skin; keeping it clean, dry, and free of wrinkles will help prevent skin problems.

Care of Orthoses

AFO, KAFO, HKAFO

Clean the plastic sections of the brace with soap and water and dry them thoroughly.

Keep the joints of the brace well oiled; 3-in-1 oil is a good lubricant.

Check all screws or fasteners periodically to make certain they are tight.

If the brace is broken, out of alignment, or causing skin problems, notify the orthotist.

TLSO

Clean the brace with soap and water, followed by a good rinsing with water, on a weekly basis. Thoroughly dry the brace before it is put on.

It is important to avoid leaving it in hot places, such as in direct, strong sunlight or by a warm heater.

FAMILY-CENTERED CARE

Prostheses

Care of Residual Limb

Wash with mild, nonperfumed soap, rinse, and dry thoroughly daily.

A small amount of powder may be used on the skin, but no alcohol.

Check skin for redness, sensitive areas, or signs of infection.

Care of Prosthesis

Routinely wash the socket with water and mild soap, rinse, and dry thoroughly.

Check straps and rubber bands with each application.

Check joints to ensure that they operate smoothly.

Replace worn or broken parts (heels, soles, straps) as needed.

Use 100% cotton stump socks to absorb perspiration, prevent skin friction, and provide comfort.

Change socks daily, and wash and dry following instructions provided by prosthetist.

FIG. 34-15 Adolescent using forearm crutches for ambulation. (Courtesy Texas Children's Hospital, Houston.)

FIG. 34-16 Young child with rear-rolling walker. (Courtesy Texas Children's Hospital, Houston.)

Performing upper body strengthening exercises to condition and strengthen arms and shoulders before crutch use is important if immobilization has been prolonged. The child gains confidence in ambulating by wearing a safety belt held by the therapist. The types of gaits used and instructions given to children are similar to those for adults. Instructions are conveyed in language children understand and with a demonstration. Most children adapt to the techniques readily.

Wheelchairs

Wheelchairs are used temporarily or permanently as a means of transportation. A wheelchair for temporary use should fit the child and contain any adaptations needed, such as an elevating leg rest or reclining back. The child learns how to transfer in and out of the chair and how to move it safely. Prescribing

FIG. 34-17 Child in wheelchair, which should be scaled appropriately to child's size. Note AFOs and left wrist splint to prevent contractures. (Courtesy Texas Children's Hospital, Houston.)

a wheelchair for permanent use is the joint responsibility of the provider and therapist after an assessment of home and surroundings. A wheelchair should be neither too small nor too large and preferably should be adaptable as the child grows (Fig. 34-17).

Detachable or rotating armrests, which permit easy transfer in and out, are needed for children with spinal cord injuries, cerebral palsy, and spina bifida. Other desirable features are detachable and swing-away footrests and detachable desk arms. Elevating leg rests are required for children who are prone to contractures, and a reclining backrest is needed for those who may have poor trunk balance. A pressure-relief cushion should be provided for a child who has decreased sensation. Hand-rim and brake-lever projections are helpful for children with upper extremity weakness. For children who have the use of only one arm, a special "one-arm drive" wheelchair is available. Children with paraplegia require upper arm strengthening exercises and instruction on transfer techniques before wheelchair mobilization (Fig. 34-18). Often a tilt table is used to overcome the problem of orthostatic intolerance before the child is able to tolerate wheelchair sitting.

Various motorized chairs are available for children with marked upper extremity weakness, and mouth- or cheek-operated models are available for children who do not have the use of upper extremities so they can operate the wheelchairs independently. Very small children who have permanent paralysis of the lower extremities are provided with specially designed units that allow independent mobility. A detachable handle on these units permits their conversion to strollers.

Bicycles and tricycles (Figs. 34-19 and 34-20) can be modified for children with limited ambulatory mobility; these also promote muscle strengthening and prevent disuse contractures. Gait training may be accomplished with a number of special devices (Fig. 34-21).

FIG. 34-18 Wheelchair allows adolescent mobility and independence. (Courtesy Texas Children's Hospital, Houston.)

THE CHILD WITH A FRACTURE

The process of **ossification**, the gradual conversion of precursor substances (i.e., cartilage) to bony structures, begins in the embryo and continues until the child is 18 to 21 years of age. In long bones this process progresses outward from the **diaphysis**, the hard, shaftlike portion that constitutes the major part of the bone. Within this hard, compact shaft is the hollow medullary canal composed of the bone marrow. The **epiphyses**, located at the ends of long bones, consist of layers of cartilage, subchondral bone, and sponge-like cancellous bone. Situated between the diaphysis and the epiphysis is the **physis (growth plate)**, which plays a major role in the longitudinal growth of the developing child (Fig. 34-22). The **periosteum**, or thin, tough membrane covering all bones, contains blood vessels that nourish the living bone. Damage to this thin membrane can be a major problem in bone growth and healing.

Bones fracture when the resistance of the bone against the stress being exerted yields to the stress force. Fractures are a common injury at any age but are more likely to occur in children and the elderly. Because childhood is a time of rapid bone growth, the patterns of fractures, problems of diagnosis, and methods of treatment are different in children compared with adults. An adult's bones are strong and require a violent traumatic force to fracture, which is accompanied by massive injury to surrounding soft tissues. In children the bones are more

easily injured, and fractures may result from minor falls or twists and are less likely to be accompanied by soft tissue damage. Features of children's fractures not observed in adults are listed in Box 34-3.

Aside from motor vehicle accidents or falls from heights, true injuries causing fracture are uncommon in infancy; therefore, bony injuries in children of this age-group warrant further investigation. In any small child, radiographic evidence of fractures at various stages of healing, with few exceptions, indicates a nonaccidental trauma or child abuse (see Community and Home Health Considerations box, on p. 1554). Any investigation of fractures in infants and young children, particularly multiple fractures, should include the suspicion of osteogenesis imperfecta (OI) after nonaccidental trauma has been ruled out.

A distal forearm (radius, ulna, or both) fracture is the most common fracture in children. The clavicle is also a common fracture in childhood, with approximately half of clavicle fractures occurring in children younger than 10 years of age. A common mechanism of injury is a fall with an outstretched hand or direct trauma to the bone (Fig. 34-23). In neonates, fractures of the clavicle may occur with a large newborn and a small maternal pelvis. Hip fractures are uncommon in children and require a great deal of force to produce. A femoral neck fracture may be sustained in children 6 or 7 years of age as a result of pedestrian-automobile accidents because in these children the hip is at the same level as an automobile bumper. In older children, the femur is the most likely target; in adolescents knee injuries are common with this type of accident.

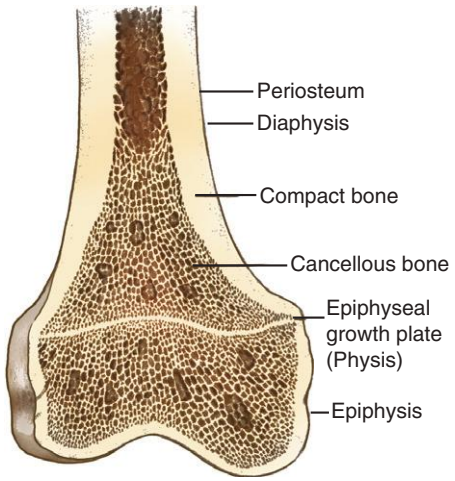

FIG. 34-22 Diagram of bone showing relationships of compact and cancellous bone, epiphysis, physis, and diaphysis.

BOX 34-3 FEATURES OF FRACTURES IN CHILDREN

- The growth plate, a thick, elastic portion of bone where growth takes place, serves to absorb shock and protect joint surfaces from injury and is the means by which the limb is able to grow and to straighten itself. Growth is stimulated by a fracture in the diaphysis, whereas damage to the growth plate can cause shortening and often a progressive angular deformity.
- The periosteum of a child's bone is thicker and stronger and has more active osteogenic potential than that of an adult's bone.
- The pliable bones of the growing child are more porous than those of the adult, which allows them to bend, buckle, and break in a "greenstick" manner. The greater porosity increases the flexibility of the bone and dissipates and absorbs a significant amount of the force on impact.
- Healing is more rapid in children, and the rapidity is inversely related to the child's age. The younger the child, the more rapid the healing process. Nonunion of bone fragments is uncommon except in severe injuries in children.
- Stiffness is unusual and, unlike in adults, an uninjured joint in a child can be immobilized for a long period without producing stiffness that lasts longer than a few minutes. Injured joints do become stiff, however, and the current trend is toward early mobilization and active range-of-motion exercises as preventive measures.
- Children only complain when something is wrong. Unreasonable crying, restlessness, and calling for the parents are usually indications that something is amiss and requires investigation.

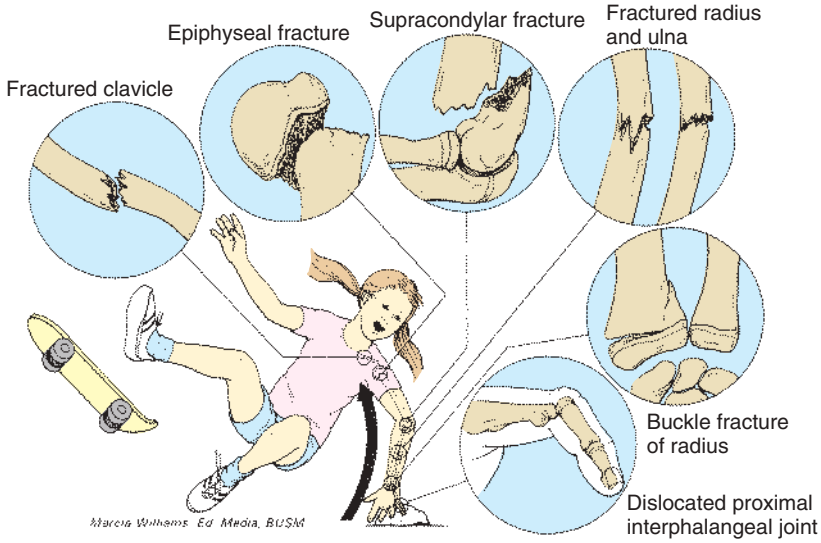

FIG. 34-23 Trauma resulting from progression of force in fall on outstretched hand.

Types of Fractures

A fractured bone consists of fragments: the fragment closest to the midline, or the proximal fragment, and the fragment farthest from the midline, or the distal fragment. When fracture fragments are separated, the fracture is **complete**; when fragments remain attached, the fracture is said to be **incomplete**. The fracture line can be any of the following:

Transverse—Crosswise, at right angles to the long axis of the bone

Oblique—Slanting but straight, between a horizontal and a perpendicular direction

Spiral—Slanting and circular, twisting around the bone shaft

The twisting of an extremity while the bone is breaking results in a **spiral** fracture. If the fracture injury does not produce a break in the skin, it is a **simple**, or closed, fracture. Open, or **compound** fractures are those with an open wound through which the bone protrudes. If the bone fragments cause damage to other organs or tissues (e.g., the lung or bladder), the injury is said to be **complicated**. When small fragments of bone are broken from the fractured shaft and lie in the surrounding tissue, the fracture is called **comminuted**. This type of fracture is rare in children. The types of fracture that occur most often in children are shown in Box 34-4 and Fig. 34-24.

Growth Plate or Physeal Injuries

The weakest point of long bones is the cartilage growth plate or the physis. Consequently, this is a frequent site of injury during childhood trauma. The Salter-Harris classification is typically used to describe growth plate injuries, as indicated in Fig. 34-25. Detection of physeal injuries is sometimes difficult but critical in determining whether bone growth will be affected. Close monitoring and early treatment, if indicated, are essential to prevent longitudinal or angular growth deformities (or both). Treatment of these fractures may include surgical management with an open reduction and internal fixation to prevent or reduce growth disturbances.

Immediately after a fracture occurs, the muscles contract and physiologically splint the injured area. This phenomenon accounts for the muscle tightness observed over a fracture site and the deformity that is produced as the muscles pull the bone ends out of alignment. This muscle response must be overcome by traction or complete muscle relaxation (i.e., anesthesia) in order for the distal bone fragment to be realigned to the proximal bone fragment.

Bone Healing and Remodeling

Bone healing follows a patterned sequence. Fig. 34-26 shows three broad overlapping phases: inflammatory, restorative, and

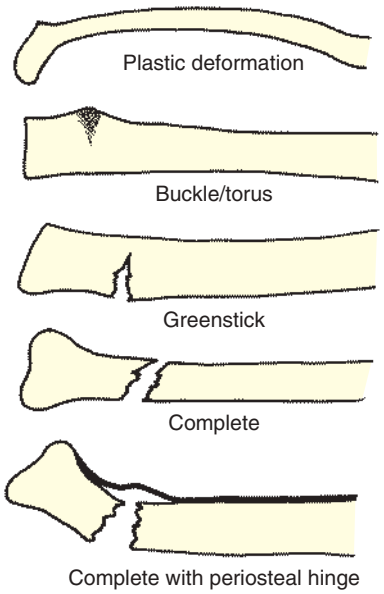

FIG. 34-24 Common types of fracture in children. Note that there are subclassifications of complete fractures based on characteristics of the fracture line.

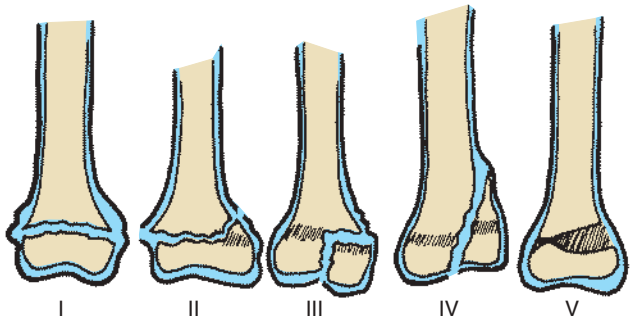

FIG. 34-25 Types of physeal injuries developed by orthopedists RB Salter and WR Harris: type I, separation or slip of growth plate without fracture of the bone; type II, separation of growth plate and breaking off of section of metaphysis; type III, fracture of physis extending through the epiphysis into the joint surface; type IV, fracture of growth plate, epiphysis, and metaphysis; type V, crushing, comminuted fracture of the physis.

BOX 34-4 TYPES OF FRACTURE IN CHILDREN

Plastic deformation—Occurs when the bone is bent but not broken. A child's flexible bone can be bent 45 degrees or more before breaking. However, if bent, the bone will straighten slowly but not completely to produce some deformity but without the angulation seen when the bone breaks. Bends occur most commonly in the ulna and fibula, often in association with fractures of the radius and tibia.

Buckle, or torus, fracture—Produced by compression of the porous bone; appears as a raised or bulging projection at the fracture site. These fractures occur in the most porous portion of the bone near the metaphysis (the portion of the bone shaft adjacent to the epiphysis) and are more common in young children.

Greenstick fracture—Occurs when a bone is angulated beyond the limits of bending. The compressed side bends, and the tension side fails, causing an incomplete fracture similar to the break observed when a green stick is broken.

Complete fracture—Divides the bone fragments. These fragments often remain attached by a periosteal hinge, which can aid or hinder reduction.

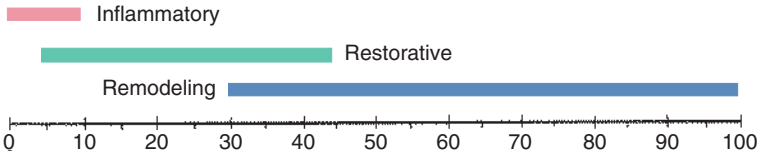

FIG. 34-26 Approximate time spent in inflammatory, restorative, and remodeling phases of bone healing. Scale indicates percentage of healing time.

remodeling. Bone healing can be described more definitively in terms of five stages (Table 34-3). When the bone breaks, the envelope of subcutaneous tissue, muscle, and periosteal tissue surrounding the site is torn; blood vessels rupture; and a hematoma forms. The ends of the fractured bone segments, deprived of circulation, die as far back as the nearest collateral circulation. Necrotic tissue accumulates, and an inflammatory response takes place at the site, with its characteristic vasodilation, plasma exudation, and edema. The organization and reabsorption of the hematoma proceeds, and the restorative phase begins with the reestablishment of local circulation. Repair requires an adequate blood supply and immobilization of the fracture fragments.

When there is a break in the continuity of bone, the periosteal and intraosseous osteoblasts are stimulated to maximum activity. New osteoblasts are formed in immense numbers almost immediately after the injury and begin building a bridge, as evidenced by a bulging growth of osteoblastic tissue and new bone matrix between the fractured bone fragments. This is followed by deposition of calcium salts to form callus, which provides stability (Fig. 34-27, *B*).

Bone healing is characteristically rapid in children because of the thickened periosteum and generous blood supply. In the young child, for example, there is frequently a solid union of the femoral shaft in 3 to 4 weeks, whereas in the adult, callus sufficient to avoid deformities from the constant muscle contraction associated with movement may not form in fewer than 10 to 16 weeks. The approximate healing times for a femoral shaft fracture are as follows:

- Neonatal period—2 to 3 weeks
- Early childhood—4 weeks
- Later childhood—6 to 8 weeks
- Adolescence—8 to 12 weeks

Remodeling is a unique process that occurs in the healing of long bone fractures in growing children. When a bone remodels, the irregularities produced by the fracture become distinct because hollows are filled in and angles are rounded off in the healing process, which gives the bone a straighter, more typical appearance. The buildup of new bone or callus restores a portion of the normal bone structure in most cases despite observable malalignment.

The younger the child and the closer the proximity of the fracture to the growth plate, the greater the degree of remodeling that is able to take place. Various factors such as the type and location of the fracture, the child's age, and the amount of fragment angulation or rotation influence the degree of correction in alignment that can be obtained by remodeling.

TABLE 34-3 STAGES OF BONE HEALING

TIME*	PHYSIOLOGIC EVENTS
Stage 1: Hematoma Formation	
Impact	Fracture occurs. Injury to soft tissue envelops site. Periosteal tissue tears. Vessels rupture.
3-5 min	Bleeding occurs from bone and tissues into area between and around bone fragments.
First 24 hr	Hematoma forms and clots; fibrin assists in clotting periosteal membrane to aid in repair. Clot provides fibrin network for cellular invasion. Granulation tissue forms by fibroblasts and new capillaries. Osteoblastic activity stimulated.
Stage 2: Cellular Proliferation	
After 24 hr	Blood supply increases, bringing available calcium, phosphate, and fibroblasts. Cells proliferate at ends of bone fragments and differentiate into cartilage and connective tissue.
Next few days	Hematoma becomes granulation tissue, which develops into a framework for bone-forming substances. Fibroblasts convert to osteoblasts (bone marrow–forming cells).
2-3 days	*Halisteresis* (softening of bone ends) occurs for ⅛ to ¼ inch; bone cells are resorbed.
Stage 3: Callus Formation	
6-10 days	Fibroblasts form in granulation tissue; form bone in areas adjacent to surface of bone shaft; form cartilage at surfaces more distal to blood supply. *Provisional callus* develops, bridging fracture ends; holds bone together but will not support body weight.
14-21 days	*True callus* develops, seen on radiographs; more than needed is formed, but with remodeling, excess callus is resorbed. Cartilage differentiates to bone tissue.
Stage 4: Ossification	
3-10 wk	Callus forms into bone, which grows beneath periosteum of fragments; fuses (knits together) fracture defect. Also called *union stage*.
Stage 5: Consolidation and Remodeling	
After 9 mo	Bone marrow cavity is restored. Compact bone forms according to stress patterns. Remodeling occurs according to Wolff's law. Fracture line is always visible on radiographs.

*Healing time is more rapid in infants and in cancellous (spongy) bone; may be delayed if complications occur.

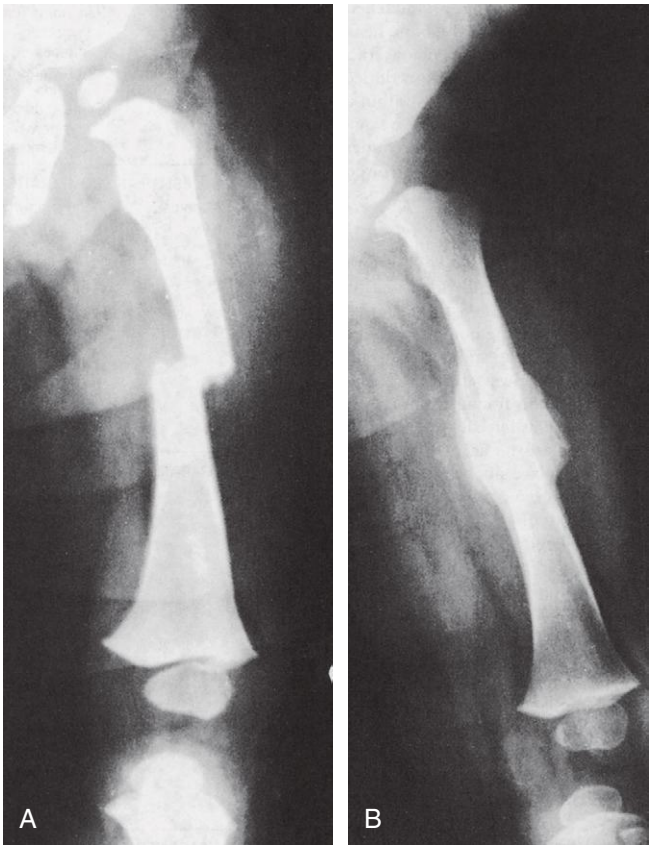

FIG. 34-27 Fractured femur. Most femur fractures in childhood are of the spiral type shown here. Note comparison of **A,** original x-ray film. **B,** 6-month postfracture film showing callus formation.

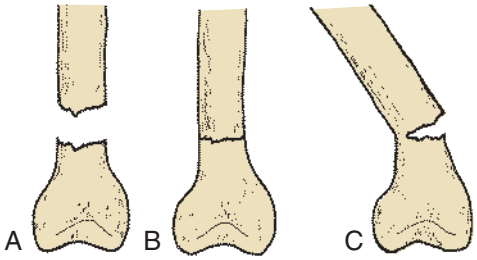

FIG. 34-28 Relationships of fracture fragments. **A,** Gap between fragments. **B,** End-to-end apposition. **C,** Angulation of incomplete fracture.

The position of the bone fragments in relation to one another influences the rapidity of healing and the residual deformity. For example, a gap between fragments delays (or prevents) healing (Fig. 34-28, *A*). Healing is prompt and complete with end-to-end apposition (Fig. 34-28, *B*), but the fracture can stimulate accelerated growth of the neighboring physis, causing bony overgrowth and increased length of the extremity. Angulation deformity caused by an incomplete fracture (Fig. 34-28, *C*) may remodel in the young child, but the degree of residual deformity depends on the relationship of the angulation of the bone fragments to the angle of the joint. This requires careful evaluation and reduction to prevent permanent deformity.

Wolff's law is applied in treating children with orthopedic problems. Paraphrased, it states that bone will grow in the direction in which stress is placed on it. Examples of the use of this law are the hip spica cast with an abduction bar for treating developmental dysplasia of the hip and application of casts or traction at a selected angle to influence the direction of bone healing.

Bone healing in any age-group is greatly influenced by the traumatized person's general health. The child with a fracture requires adequate nutrition for optimum bone healing. When nutritional intake is insufficient, vitamin and mineral supplementation may be necessary. Consumption of soda should be limited or completely eliminated as the phosphoric acid in these drinks may interfere with calcium absorption.

Diagnostic Evaluation

A history of the injury or events leading up to the injury is helpful but often may be lacking for childhood injuries. Infants and toddlers are unable to clearly communicate the details of what occurred. Older children may not be reliable informants or volunteer information (even under direct questioning) if the injury occurred during questionable activities. In cases of child abuse, parents or caregivers may deliberately give false information to protect themselves or family members. Whenever possible, it is helpful to get information from someone who witnessed the injury.

Children demonstrate the usual signs of injury: generalized swelling, pain or tenderness, and diminished functional use of the affected part. There may be bruising, severe muscular rigidity, and sometimes **crepitus** (a grating sensation at the fracture site), which are also frequent signs in adults. More often, the fracture is remarkably stable because of the usually intact periosteum. The child may even be able to use an affected arm or walk on a fractured leg.

Although neurologic and vascular damage is much less frequent in children than in adult patients, the integrity of these structures must be thoroughly assessed. This is often difficult in infants and young children, who are unable to cooperate. Vascular injury is most likely to occur with supracondylar fractures of the humerus and femur. Femoral and popliteal vessels and the sciatic nerve are prone to trauma in femoral fractures. Humeral fractures may cause damage to the medial, ulnar, or radial nerves and to the brachial artery.

Radiographic examination is the most useful diagnostic tool for assessing skeletal trauma. The calcium deposits in bone make the entire structure radiopaque. However, during normal growth and development, much of the skeleton of infants and young children is composed of radiolucent growth cartilage that does not appear on radiographs. Radiographs are sometimes less reliable than gross deformity and point tenderness in predicting extremity fractures. Health care providers may also obtain a film of the uninjured limb for a direct comparison to help identify minor alterations in alignment. Radiographic films are also taken after fracture reduction and during the healing process to confirm satisfactory progress.

BOX 34-5 FACTORS IN DETERMINING THE REDUCTION METHOD FOR FRACTURES

- Age of child
- Degree of displacement
- Amount of overriding (bone)
- Degree of edema
- Condition of skin and soft tissue
- Sensation and circulation distal to fracture

! NURSING ALERT

A fracture should be strongly suspected in a small child who refuses to walk or crawl. However, the fact that a child walks on a suspected fractured extremity does not rule out a fracture.

Therapeutic Management

The goals of fracture management are:

- To reestablish alignment and length of the bony fragments (reduction)
- To retain alignment and length (immobilization)
- To restore function to the injured parts
- To prevent further injury and deformity

The majority of children's fractures heal well, and nonunion is rare. Fractures are splinted (see Research Focus box) or casted to immobilize and protect the injured extremity. Children with displaced fractures may have a surgical reduction and fixation (internal or external) rather than being immobilized by traction. Box 34-5 describes factors that determine the type of reduction method for fractures. Some injuries may require immediate medical attention. These include open fractures, compartment syndrome with and without fracture, fractures associated with vascular or nerve injuries, and joint dislocations that cannot be reduced.

In children, immobilization is used until adequate callus is formed. Weight bearing and active movement for the purpose of regaining function can begin after the fracture site is stable. The child's natural tendency to be active is usually sufficient to restore normal mobility, and physical or occupational therapy is rarely indicated.

Children are most frequently hospitalized for fracture of the femur and supracondylar area of the distal humerus. If simple reduction cannot be achieved or a neurovascular problem is detected after injury, observation in a hospital setting may be indicated. The trend is to avoid hospitalization. See Box 34-6 for medical interventions for the child with a fracture injury.

Nursing Care Management

Nurses often conduct the initial assessment of a child with a suspected fracture (see Emergency Treatment box). The child and parents may be frightened and upset, and the child is often in pain. Therefore, if the child is alert and there is no sign of hemorrhage, the initial nursing interventions are directed at calming and reassuring the child and parents so that a more thorough assessment can be easily accomplished.

BOX 34-6 MEDICAL INTERVENTIONS FOR FRACTURE INJURY

- Control of pain, hemorrhage, and edema
- Relief of muscle spasms
- Realignment of fracture fragments
- Promotion of bone healing
- Immobilization of fracture until adequate healing has begun
- Prevention of secondary complications
- Limitation of disuse syndrome
- Restoration of function

RESEARCH FOCUS

Removable Splints

Boutis, Willan, Babyn, and colleagues (2010) randomized treatment of minimally displaced distal radius fractures in children with either a short arm cast or wrist splint for 4 weeks. There was no difference between the two groups in fracture displacement or functional outcomes. The children and families were more satisfied and preferred splinting over cast immobilization.

While maintaining a calm manner, the nurse can ask the parents and older child to describe what happened. The child may arrive with the limb supported in some manner; if not, carefully immobilize the affected site. If the limb is immobilized, it may be best not to touch the child initially but to ask him or her to point to the painful area and wiggle the fingers or toes distal to the injury. At this point, the child may feel relatively safe and allow someone to gently touch the area just enough to feel the pulses and test for sensation. A child's anxiety is greatly influenced by previous experiences with injury and health care personnel. However, the child needs to be told what will happen and what he or she can do to help. The affected limb need not be palpated and should not be moved unless properly splinted. A temporary splint should be applied carefully if the child must be transported to a medical facility or radiology department. Parental anxiety may heighten the child's reaction and fear. It is important to reassure the parents that their child will receive the necessary care, including pain management.

FRACTURE COMPLICATIONS

Circulatory Impairment

If the trauma or immobilizing device restricts blood flow in veins or arteries of the affected extremity, bone healing will be seriously impaired. Careful assessment of the pulses, capillary refill, skin color, and temperature is an important nursing responsibility. After injury, swelling of tissues occurs more rapidly in the child than in the adult. In the upper extremity, brachial, radial, ulnar, and digital pulses are felt. In the leg, femoral, popliteal, posterior tibial, and dorsalis pedis pulses are checked.

Closely associated with an inadequate blood supply is a low hematocrit value, which can result from the initial blood loss or surgically induced anemia. Although the blood flow may be

EMERGENCY TREATMENT

Fracture

Assess the extent of injury—5 *P*s:
- Pain and point of tenderness
- Pulselessness—distal to the fracture site (late and ominous sign)
- Pallor
- Paresthesia—sensation distal to the fracture site
- Paralysis—movement distal to the fracture site

Determine the mechanism of injury.
Move the injured part as little as possible.
Cover open wounds with sterile or clean dressing.
Immobilize the limb, including the joints above and below the fracture site; do not attempt to reduce the fracture or push protruding bone under the skin.
- Soft splint (with pillow or folded towel)
- Rigid splint (rolled newspaper or magazine)
- Uninjured leg can serve as splint for leg fracture if no splint is available

Reassess neurovascular status.
Apply manual traction if circulatory compromise is present.
Elevate the injured limb if possible.
Apply cold to the injured area (no longer than 20 minutes with each application).
Call emergency medical services or transport to medical facility.

adequate, a lowered amount of hemoglobin will not provide a sufficient supply of oxygen for tissue repair.

Nerve Compression Syndromes

Nerve damage can occur at the time of injury, develop in the process of realignment, or arise as a complication of use of an immobilizing apparatus. The syndromes are classified according to the anatomic area affected and can involve the median nerve (carpal tunnel syndrome), ulnar nerve (at wrist or elbow), radial nerve, posterior tibial nerve (tarsal tunnel syndrome), common peroneal nerve, or sciatic nerve. Peroneal nerve damage can result in footdrop, and radial nerve impairment produces wristdrop. Both these disabilities can significantly interfere with activities of daily living.

Sensory testing with touch and pinprick and evaluation of motor strength by asking the child to move the unaffected joint distal to the injury are common means of determining neurologic involvement. Subjective symptoms are pain or discomfort, muscular weakness, a burning sensation, limitation of motion, and altered sensation. Because the fear of pain limits the child's cooperation, play can be the nurse's most valuable tool.

Treatment is alleviation of pressure on the nerve. The health care provider determines whether correcting the alignment will alleviate pressure on the nerve or whether surgical intervention is necessary. At times, sensory or motor changes indicate ischemia, and the treatment is correction of the vascular disturbance.

Compartment Syndromes

A compartment is a group of muscles surrounded by tough, inelastic fascial tissue. **Compartment syndrome** occurs when pressure within this closed space increases and compromises circulation to the muscles and nerves within the space. Muscles and nerves of both upper and lower extremities are enclosed within such compartments. The most frequent causes of compartment syndrome are tight dressings or casts, skin traction, hemorrhage, trauma, burns, and surgery. Other causes include an increase in compartment contents (e.g., hemorrhage, venous obstruction, infiltrated IV infusion, exudate) and externally applied pressure, such as lying on the affected limb.

NURSING ALERT

Assessing for compartment syndrome includes monitoring for the five *P*s of ischemia (pain, pallor, pulselessness, paresthesia, and paralysis).

Signs and symptoms of compartment syndrome reflect a deficit in or deterioration of neuromuscular status in the anatomic area surrounding the involved structures. These include motor weakness and pain that is out of proportion to the injury. Clinical manifestations may be difficult to recognize in small children or in those who have a head injury. A palpable peripheral pulse and brisk capillary refill may be present despite increasing compartmental pressure. Sensory deficit in the affected limb is reported to be the most reliable physical finding in compartment syndrome (Green and Swiontkowski, 2008).

Clinical manifestations of compartment syndrome may occur as early as 30 minutes after the ischemia develops. Tenseness may be noted on palpation of the area. Because early detection is important in preventing permanent damage to tissues, in certain high-risk situations specialists may recommend continuous monitoring of compartment pressures by way of a small, slit-tip catheter; Wick catheter; or needle inserted into the compartment. Treatment of compartment syndrome is immediate relief of pressure, which sometimes requires fasciotomy.

Volkmann contracture (ischemic muscular atrophy) is a serious, persistent flexion contraction of the forearm and hand caused by massive infarction of muscle. Pressure caused by a cast or tight bandage or by swelling from the injury in the area of the elbow begins with arterial occlusion and then progresses to muscle anoxia and reflex vasospasms. Finally, the lack of blood supply leads to muscle necrosis and replacement with fibrous tissue, which produces paralysis and a clawlike hand contracture. Any fracture that requires excessive traction can be complicated by Volkmann contracture; however, it occurs most often in the elbow.

The neuromuscular symptoms of compartment syndrome are severe pain (although pain is not always a manifestation), pallor or cyanosis, edema, absence of pulses in the extremity, and loss of sensitivity. Unrelieved, the occlusive hypoxic process can cause some contracture if ischemia lasts as little as 6 hours. A great deal of muscle damage occurs after 12 to 24 hours; 48 hours of ischemia produces severe deformity, with muscle fibrosis and contractures in 5 to 10 days. If not treated, the contracture leads to severe deformity and paralysis.

The immediate treatment is to remove any mechanically obstructive materials, such as tight bandages, and extend the joint to free blood vessels. If the symptoms do not improve

within a few hours, arteriography is done in anticipation of a possible need for surgical intervention (**fasciotomy**) to decrease arterial spasms and to improve the blood supply by separation of the fascial sheaths of the involved muscles. Elevation of the affected extremity is not recommended and may further decrease blood flow to the area

Physeal Damage

Growth of bone originates from the physis or growth plate, and damage to this structure can result in unequal lengths of the extremities. This is most concerning in the lower extremities. Surgical intervention may be required if the limb length inequality becomes large enough. This may involve slowing the growth on the longer leg with a procedure called an epiphyseodesis or lengthening the bones in the shorter or affected extremity.

Nonunion

Bone healing and callus formation can span and repair only a limited space between bone fragments. When bone fragments cannot be maintained in correct alignment for repair due to inadequate reduction or poor immobilization, bone healing is impaired. The factors most likely to interfere with bone healing and to cause delayed union or nonunion, based on the physiologic needs for bone healing, are listed in Box 34-7.

The hematoma, which becomes the matrix for bone deposition in the break, must be free of infection or bits of adipose or connective tissue. Nutrients and bone-forming cells brought to the area by way of the bloodstream provide the vital ingredients for repair.

Sometimes artificial means are employed to facilitate bone healing. Bone grafting becomes necessary when bone nonunion occurs. The donor site is usually the tibia or the iliac crest. Bleeding of bone ends may need to be artificially stimulated, and at times holes are drilled near the bone ends in an attempt to increase circulation. Postsurgical immobilization of the recipient area is crucial to the success of the graft. The Ilizarov external fixator may also be used to assist bone healing in patients with nonunion (see p. 1562).

Malunion

Malunion is fracture union with increased angulation or deformity at the fracture site. It can be detected at any stage in the healing process or after complete healing. Unsatisfactory reduction is the usual reason for malunion. A cast or splint that allows fracture movement will also likely result in malunion. Periodic radiographic examinations help detect this complication and prevent it from becoming a major problem over a long period.

Excessive deformity can be corrected during the healing process through realignment and reimmobilization. However, attempts at correction may cause delayed union or nonunion; therefore, the degree of deformity is carefully evaluated in light of these complications. The probability that sufficient spontaneous alignment will occur with growth and continuation of the healing process also is considered. Correction of the malunion when healing is near completion requires surgical intervention.

BOX 34-7 FACTORS THAT INTERFERE WITH BONE HEALING

- Separation of bone fragments at fracture site
- Interposition of tissue between bone fragments
- Loss of bone tissue, especially from necrosis
- Infection
- Poor nutrition
- Interruption of blood supply
- Diseases that influence calcium metabolism (e.g., vitamin D deficiency)
- Bone cancer
- Administration of corticosteroids

Infection

Osteomyelitis, infection of the bone, is often secondary to a bloodstream infection but is a potential problem when the fracture is an open one, when pressure ulcers develop, or when bone surgery has been performed. Any bacterial organism can cause this infectious process; however, *Staphylococcus aureus* is the pathogen most frequently identified (American Academy of Orthopaedic Surgeons, 2012a) (see p. 1597 for a discussion of osteomyelitis).

Kidney Stones

Although uncommon in children, development of renal calculi is a potential risk whenever the child has a limb that is non–weight bearing for a long time, especially if the circumstances also produce urinary stasis. Measures to prevent the formation of renal calculi include maintaining optimal hydration, mobilizing the child as much as possible, and checking closely the amount and characteristics of urinary output. Any urinary tract infection should be treated promptly with appropriate antimicrobials and urine acidification, since the nucleus of a calculus is often composed of bacterial debris or calcium and the buildup of stone is precipitated by alkaline urine. An associated problem, hypercalcemia, was reviewed in the section on problems of the immobilized child.

Pulmonary Emboli

Blood, air, or fat emboli can be a hazard to the child with a fracture. As postinjury bleeding and clotting occur, a small piece of the clot has the potential to travel to vital organs, such as the lung, heart, or brain, and produce a life-threatening vascular obstruction and ischemia. Generally the pulmonary system is the most frequent site of emboli deposition, but it may not occur until 6 to 8 weeks after the injury.

Fat emboli are the greatest threat in an individual with multiple fractures, particularly fractures of the long bones such as the femur. Fat droplets from the marrow are transferred to the general circulation by the venous-arterial route, where they can be transported to the lung or brain. This type of embolism occurs within the first 24 hours, generally in the second 12 hours after the injury occurs. Adolescents are those usually affected in the pediatric age-groups.

Intermittent compression devices are used to prevent venous pooling in the lower extremities when prolonged immobilization is required. These devices are inflatable sleeves that

allow cyclic emptying and filling of leg veins; the devices are used in children with spinal cord injury once mobilization is initiated to decrease the effects of orthostatic intolerance. Anticoagulant drug therapy, passive and active range of motion, and early mobilization are also used to decrease venous stasis and prevent thrombus development.

! NURSING ALERT

Pulmonary embolism should be suspected in a child with a history of recent surgery, major trauma, or prolonged immobilization who suddenly develops chest pain and dyspnea. The severe dyspnea must be treated immediately by elevating the head when possible and administering oxygen by mask or nasal cannula; an intravenous line should be established. This is a medical emergency.

INJURIES AND HEALTH PROBLEMS RELATED TO SPORTS PARTICIPATION

Adolescents probably spend more time and energy practicing and participating in sports activities than members of any other age-group. Sports and game participation contributes significantly to growth and development, to the education process, and to good health. It provides exercise for growing muscles, interactions with peers, and a socially acceptable means of enjoying stimulation and conflict. In addition, competitive activities help the older child and adolescent engage in self-appraisal and develop self-respect and concern for others.

Every sport has some potential for injury to the participant—whether the young person participates in serious competition or purely for enjoyment. Serious injury is not limited to the athlete who competes in rough contact sports; a large number of severe or fatal injuries occur to those who engage in milder physical activity but are not physically prepared for it. For example, a person's body build may not be suited to the sport, muscles and support systems (respiratory and cardiovascular) may not have been sufficiently conditioned to withstand the rigors of the physical stress, or the child or adolescent may not possess the insight and judgment to recognize when an activity is beyond his or her capabilities. Rapidly growing bones, muscles, joints, and tendons are especially vulnerable to unusual strain (American Academy of Orthopaedic Surgeons, 2012b).

Awkward and inexperienced children or adolescents may suffer more injury than those who are more experienced. Strong muscles are less easily damaged than weak ones and provide better protection to the joints they cross. Fatigue significantly impairs muscle function and judgment. Although team sports give rise to frequent injuries, serious injuries resulting from recreational and individual sports are generally more common. The increase in strength and vigor in adolescence may tempt children to overextend themselves.

Not only does the activity itself pose a hazard of greater or lesser degree, but the environment and the sports or recreational equipment present additional risks. Adolescents participate in physical activities in a variety of environments, both indoors and outdoors, on floors, on the ground, on snow or ice, on or beneath water surfaces, and sometimes in free air space. These activities frequently involve equipment that increases risk.

PREPARATION FOR SPORTS

Among adolescents of the same age, the degree of physical maturation varies greatly, and many of the physical characteristics important in sports are related to hormone production. Consequently, physical strength, coordination, endurance, and size vary considerably among children and adolescents who wish to compete against one another. Sports competition between young people who differ markedly in strength and agility is unfair and hazardous. Matching of candidates for sports should be based on physical maturity, height, weight, and physical fitness and skills, particularly in sports involving rigorous body contact.

The American Academy of Pediatrics (Rice and Council on Sports Medicine and Fitness, 2008) has developed a classification that categorizes sports according to the probability of collision and strenuousness. Collision sports such as tackle football, basketball, hockey, and soccer have the highest injury rates, followed by other contact sports (Figs. 34-29 and 34-30). Cheerleading has one of the highest rates of injury with a high incidence of head injuries reported. In addition, the American Academy of Pediatrics (Rice and Council on Sports Medicine and Fitness, 2008) has published guidelines that provide criteria for determining inclusion or exclusion of the young athlete based on common medical and surgical conditions and relative risks in various sports categories. This serves as a useful guideline for the health professional in counseling youth regarding sports activities.

The American Academy of Pediatrics, Council on Sports Medicine and Fitness (2011) encourages sports participation by young persons and encourages adults close to sports activities to be aware of the early warning signs of fatigue, dehydration, and injury. Athletes should seek assistance when an injury is

FIG. 34-29 Football is an example of a strenuous collision sport with a high risk of serious injury.

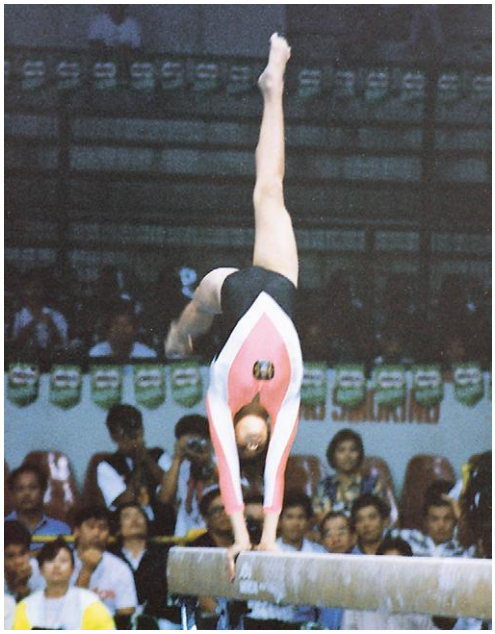

FIG. 34-30 Gymnastics is an example of a strenuous limited contact, limited collision sport with a high risk of serious injury.

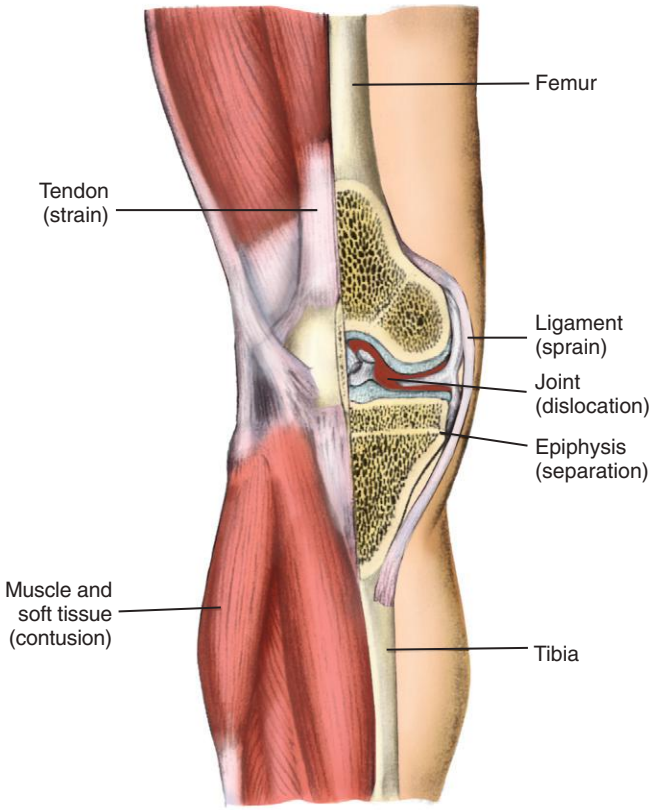

FIG. 34-31 Sites of injury to bones, joints, and soft tissues.

suspected and not "work through" injuries caused by overuse—for example, shin splints, stress fractures, tendinitis, and apophysitis.

The role of health care professionals, specifically nurses, in relation to sports injuries focuses on prevention, treatment, and rehabilitation. Of these areas, prevention is perhaps the most important. It is difficult to "sell" prevention, however, especially to children. Anticipatory guidance is an important aspect of preventive counseling for sports injuries, since many injuries occur when children are tired and are not concentrating on their activities. Injuries are also more common when participants are distracted by events off the field of play.

Youth who are actively involved in athletic programs need to undergo medical evaluation as a prerequisite to participation and to receive education in sports skills using correct training and conditioning methods. Children should use appropriate protective equipment, properly maintained and fitted. The sports environment should make maximum provision for safety and availability of first aid and medical services.

The same protective principles apply to enthusiasts in noncompetitive sports. They need the same education in basic safety precautions, encouragement to acquire proper instruction in the skills required for performing the activity (such as water safety, skiing techniques), and proper maintenance of equipment.

TYPES OF INJURY

The injuries sustained in sports or recreational activities can involve any part of the body and range from relatively minor cuts, bruises, and abrasions to severe closed head injuries such as concussion or totally incapacitating central nervous system injuries or death. Some of these injuries are discussed in chapters devoted to the major topic (e.g., spinal cord injuries [Chapter 35] and head injuries [Chapter 32]).

Some sports are particularly dangerous for children and adolescents. Snowmobiling, snowboarding, use of all-terrain motor vehicles, in-line skating, skateboarding, motorcycle riding, full contact hockey, bicycle riding, wave running, and using trampolines are examples of sports and recreational activities that can lead to significant injuries in connection with inappropriate use, failure to wear protective equipment, or participation by children who are under age. One study reported a high incidence of injuries in high school football athletic competition; boys' soccer had a high rate of head, neck, and face injuries; and high rates of concussion injuries occurred in boys' soccer (Rechel, Yard, and Comstock, 2008). Ankle injuries are the most common competitive sports-related injuries, with significant numbers occurring in boys' and girls' basketball (Nelson, Collins, Yard, et al, 2007). Recent attention has focused on the management and prevention of concussion injuries among adolescent as well as adult athletes. The majority of concussions occurred in boys' football and ice hockey, with girls' soccer being a major cause for collision injury and concussion (Marar, McIlvain, Fields, et al, 2012).

A variety of injuries can result when an external force is applied that causes severe stress on tissue, muscle, and skeletal structures (Fig. 34-31). The body structures attempt to absorb the force, but when they are unable to do so, injuries occur. Two general types of injury are recognized. The first is **acute trauma**, which is defined as a sudden, acute injury from a major force.

Among such injuries are fractures of long bones and the axial skeleton; sprains of joint ligaments; strains of muscle tendon units; and contusions, including those of muscle tendon units and overlying soft tissue. The second type is repetitive **overuse injuries**, or microtrauma, which result from repetitive injury to tissue over a long period. Overuse injuries include stress fractures, bursitis, tendonitis, apophysitis, and at times injuries of the joint surface.

CONTUSIONS

Contusions are probably the most common sports injuries and are often considered to be "part of the game." A contusion is damage to the soft tissue, subcutaneous structures, and muscle. The tearing of these tissues and small blood vessels and the ensuing inflammatory response lead to hemorrhage, edema, and associated pain when the child or adolescent attempts to move the injured part. The escape of blood into the tissues is observed as ecchymosis, a black-and-blue discoloration.

The most serious contusions are those involving the quadriceps; they are common in strenuous, collision-type sports and usually result from being kicked or kneed in the thigh. Large contusions cause gross swelling, pain, and disability and usually receive immediate attention from health care personnel. The less spectacular, smaller injuries may go unnoticed, so continued participation is allowed. They can become disabling after rest, however, because of pain and muscle spasm. The young athlete is frequently instructed to "work it out" or disregard the pain. *Myositis ossificans* may occur from deep contusions to the biceps or quadriceps muscles; this condition may result in a restriction of flexibility of the affected limb.

Immediate treatment of a contusion consists of application of cold as in the treatment of sprains described later. Return to participation is allowed when the strength and range of motion of the affected extremity are equal to those of the opposite extremity.

Although they are not always directly related to sports, crush injuries occur in children when they slam their fingers (in doors, folding chairs, or equipment) or hit their fingers (as when hammering a nail). A severe crush injury involves the bone, with swelling and bleeding beneath the nail (subungual) and sometimes laceration of the pulp of the distal phalanx.

DISLOCATIONS

Long bones are held in approximation to one another at the joint by ligaments. Joints can be tight or loose, and loose joints are more likely to be dislocated. One of the most vulnerable joints is the shoulder, which is structurally insecure, having only a rotator cuff to maintain the shoulder in place. The joint is shallow with relatively little muscle protection; therefore, the capsule becomes stretched and the joint is vulnerable to dislocation. There is a high incidence of shoulder injuries in male gymnasts and a greater incidence of shoulder injuries in players of contact sports, such as football. Temporary restriction of the joint with a sling or bandage that secures the arm to the chest can provide sufficient comfort and immobilization until the individual receives medical attention.

Dislocations are less common in children than in those who are skeletally mature, but some types are specific to the younger age-groups. Before final closure of the physis (growth plate), injuries to the joints are more likely to cause separation of the epiphysis from the metaphysis (growth plate injury) than dislocation.

A dislocation occurs when the force of stress on the ligament is great enough to disrupt the normal position of the opposing bone ends or the bone end and its socket. The predominant symptom is pain that increases with attempted passive or active movement of the extremity. In dislocations there may be an obvious deformity and inability to move the joint. Temporary restriction of the joint with a sling or bandage that secures the arm to the chest in a shoulder dislocation provides sufficient comfort and immobilization until the child or adolescent can receive medical help.

In children younger than 5 years of age, the hip can be dislocated by a fall. The greatest risk after this injury is the potential loss of blood supply to the head of the femur. Children with naturally lax joints, such as those with Down syndrome, are more prone to recurrent dislocation of the hip.

In hip dislocation the best chance for prevention of damage to the head of the femur is to relocate the hip within 60 minutes after the injury occurs. As the length of time between injury and hip relocation increases, the risk of irreparable damage increases. Simple dislocations should be reduced as soon as possible with the child under mild sedation and often local anesthesia. Increased swelling, which makes reduction difficult and increases the risk of neurovascular problems, can complicate an unreduced dislocation. Treatment depends on the location and severity of the injury.

Dislocation of the patella occurs spontaneously in some children; in others it is a result of injury. The patella is always dislocated laterally. Most dislocations are reduced either spontaneously or by a companion before a provider sees the child. Therapy is immobilization for 3 to 4 weeks. Surgery may be indicated to treat recurrent dislocations.

The most common dislocation injury is subluxation or partial dislocation of the radial head in the elbow, also called *pulled elbow* or *nursemaid's elbow*. In the vast majority of cases the injury occurs in a child between ages 1 and 3 years who receives a sudden longitudinal pull or traction at the wrist while the arm is fully extended and the forearm pronated. It usually occurs when an adult is holding the child by the hand or wrist and gives a sudden jerk to prevent a fall or attempts to lift the child by pulling the wrist, or the child suddenly pulls away by dropping to the floor (or ground). The child has an anxious expression, whines, complains of pain in the elbow and wrist, refuses to move the arm, and holds it with the opposite hand and in a slightly flexed and pronated position against his or her body.

The provider reduces the dislocation by applying firm finger pressure to the head of the radius and then supinates and flexes the forearm to return the bone structures to normal alignment. A click or clunk may be heard or felt, and functional use of the

arm returns within minutes. Immobilization of the arm is not necessary (Carrigan, 2011). The longer the subluxation is present, however, the longer it takes for the child to recover mobility after treatment. A radiograph may be needed if attempts to reduce the dislocation are not successful.

SPRAINS AND STRAINS

A sprain occurs when trauma to a joint is so severe that a ligament is either stretched or partially or completely torn by the force created as a joint is twisted or wrenched. This is often accompanied by damage to associated blood vessels, muscles, tendons, and nerves. As a guideline for management and prognosis, sprains are classified according to the degree of injury (Box 34-8). Because of the number of ligaments required to maintain knee stability, the knee is one of the joints most commonly injured in sports. It is also the largest joint and consequently is more prone to injury. Ankle sprains in children account for approximately 75% of all ankle injuries. These injuries are common in individuals who participate in sports, especially in the pediatric age-group (Guinta and Rocker, 2013).

The presence of joint laxity is the most valid indicator of the severity of a sprain. With a severe injury the athlete complains that the joint "feels loose" or as if "something is coming apart" and may describe hearing a "snap," "pop," or "tearing." Pain is seldom the principal subjective symptom. There is a rapid onset with swelling, often diffuse, accompanied by immediate disability and appreciable reluctance to use the injured joint.

A strain is a microscopic tear to the musculotendinous unit and has features in common with sprains. The area is painful to the touch and is swollen. The severity is evaluated as grade I, II, or III, as for sprains, except that the degree of laxity does not apply. Even with severe grade III injuries, complaints of laxity are rare. Most strains happen over time rather than suddenly, and the rapidity of the appearance provides clues regarding severity. In general the more rapidly the strain occurs, the more severe the injury. When the strain involves the muscular portion, there is more bleeding, often palpable soon after injury and before edema obscures the hematoma.

Therapeutic Management

The first 6 to 12 hours is the most critical period for virtually all soft tissue injuries. Basic principles for managing sprains and other soft tissue injuries are summarized in the acronyms RICE and ICES:

R—Rest	**I**—Ice
I—Ice	**C**—Compression
C—Compression	**E**—Elevation
E—Elevation	**S**—Support

The trend with ankle sprains is to encourage early mobilization and strengthening rather than prolonged immobilization and rest.

Soft tissue injuries should be iced immediately. This is best accomplished using crushed ice or a bag of frozen vegetables. An elastic wrap may be applied to provide compression and to keep the ice pack in place. A single layer of the wrap or cloth is placed over the injured area to protect the skin under the ice pack, and the remainder of the bandage secures the pack in place.

There is still controversy over whether heat or ice should be used during the rehabilitative phase of management. Regardless of the method used, it should be accompanied by appropriate exercise, depending on the severity of the injury, and carried out under the direction of a competent professional experienced in the care of sports injuries.

Ice has a rapid cooling effect on tissues that reduces pain and the magnitude of the stretch reflex by decreasing muscle spindle response, afferent nerve discharge, and the afferent loop response (monosynaptic reflex). Secondary effects are achieved by vasoconstriction, decrease in muscle nerve velocity, and increase in muscle viscosity. Also, the decreased temperature slows metabolism, which reduces tissue oxygen requirements. Edema formation is reduced when fewer histamine-like substances are released. Nine to 15 minutes of ice exposure produces deep-tissue vasodilation without increased metabolism. However, the effects last up to 7 hours. Ice therapy should be intermittent, and ice should never be applied for more than 30 minutes at a time to prevent tissue damage.

Elevating the extremity uses gravity to facilitate venous return and reduce edema formation in the damaged area. The point of injury must be kept several inches above the level of the heart for therapy to be effective (Fig. 34-32). Several pillows can be used effectively for elevation. Allowing the extremity to be dependent causes excessive fluid accumulation in the area of injury, which delays healing and causes painful swelling.

Major sprains or tears to the ligamentous tissue rarely occur in growing children. Ligaments are stronger than bone, and the physis (growth plate) is the weakest part of the bone. The more typical site of injury is at the growth plate (see Growth Plate or Physeal Injuries, p. 1569). Torn ligaments, especially those in the knee, are usually treated by immobilization with a knee immobilizer or range-of-motion brace until the child is able to walk without a limp. Crutches are used for mobility to rest the affected extremity. Passive leg exercises, gradually increased to active ones, begin as soon as sufficient healing has taken place. Caution parents and children against using any form of liniment or other heat-producing preparation before examination. If the injury requires casting or splinting, the heat generated in the enclosed space can produce extreme discomfort and may

BOX 34-8 CLASSIFICATION OF SPRAINS

Grade I—Mild injury; involves overstretching or microscopic tearing but without hemorrhage or increased instability of the involved joint. Swelling may develop later.

Grade II—Moderate injury; involves partial, overt tearing of the ligament with at least some ligamentous continuity remaining; usually immediate pain and swelling with decreased function.

Grade III—Severe injury; total loss of ligamentous continuity (i.e., disruption of one or more ligaments or the musculotendinous unit). Pain is immediate but subsides because none of the pain fibers is being stretched. Swelling may be minimal because hemorrhage extravasates outside of the area into soft tissues.

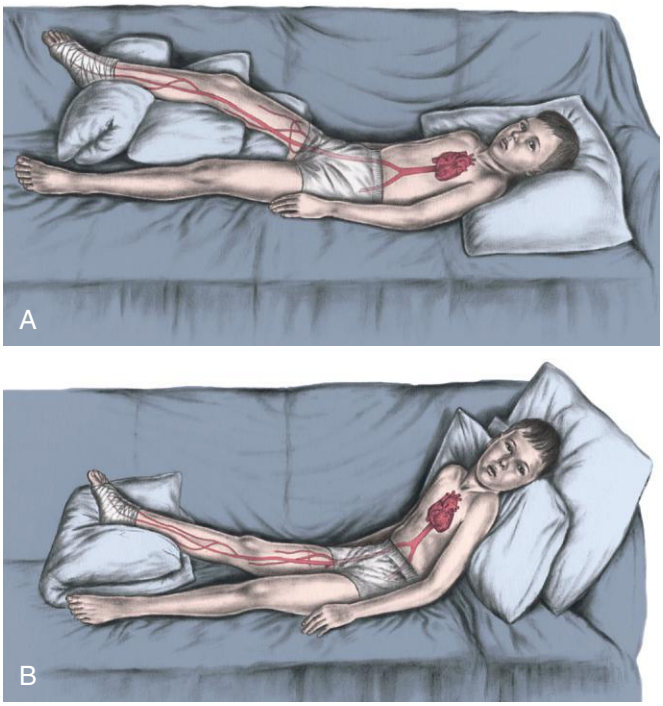

FIG. 34-32 Correct and incorrect methods for elevating a lower extremity. **A,** Correct method: lower leg elevated on pillows; ankle above heart level. **B,** Incorrect positioning: ankle below level of heart.

even cause tissue damage. In some cases torn knee ligaments are managed with arthroscopy and ligament repair or reconstruction as necessary, depending on the extent of the tear, the ligaments involved, and the person's age.

Sometimes postoperative mobilization of the affected joint is implemented immediately using a continuous passive motion device. This device provides passive range-of-motion exercise to the injured extremity and decreases postoperative complications related to restricted mobility. The patient often is ambulatory within hours on crutches and is discharged late on the day of surgery or the following day.

OVERUSE INJURY

To excel in sports, the young athlete is forced to train longer, harder, and earlier in life than previously. The rewards are an increased level of fitness, better performance, faster times, and the satisfaction of attaining a personal goal. With the increase in the number of children participating in a wide variety of sports year-round, more **overuse injuries** are being seen in the pediatric age-group (Brenner and Council on Sports Medicine and Fitness, 2007; Hoang and Mortazavi, 2012). More pediatric athletes are specializing in one sport, participating year-round.

The risk of overuse injury is always present and can be related to several factors: training errors, muscle-tendon imbalance, anatomic malalignment (e.g., femoral anteversion, excessive lumbar lordosis, tibial torsion), incorrect footwear or playing surface, an associated disease state, and growth (growth cartilage is less resistant to microtrauma). Athletes who run extensively frequently experience shin splints. The ligaments tear away from the tibial shaft, and this creates the pain. Ice, rest, and NSAIDs, such as ibuprofen or naproxen, are the usual treatment.

Chronic pain in athletes is often associated with overuse injury, which can occur at any level of athletic participation. The common feature in overuse injuries is the repetitive microtrauma that occurs to a particular anatomic structure (Brenner and Council on Sports Medicine and Fitness, 2007). Performing the same movements time and time again can cause several types of injury: (1) frictional, or rubbing of one structure against another; (2) tractional, or repeated pull on a ligament or tendon; and (3) cyclic, or repetitive loading of impact forces (stress fractures). The end result is inflammation of the involved structure with complaints of pain, tenderness, swelling, and disability.

Bursae, tendons, muscles, ligaments, joints, and bones are all subject to overuse. Some of the more common overuse syndromes include plantar fasciitis, tennis elbow, Little League elbow, Osgood-Schlatter disease, swimmer's shoulder, and shin splints. Osgood-Schlatter disease (at the tibial tubercle in growing children) often occurs in children who are actively moving—for example running and jumping. The occurrence of overuse-type injuries, such as sore shoulders and strained elbows, may indicate that too much is being asked of the child in too short a period.

Stress Fractures

Given the intensity and duration of sports training, many young athletes suffer stress fractures, especially after a recent increase in training regimens. These fractures occur as a result of repeated muscle contraction and occur most often in sports involving repetitive weight bearing such as running, gymnastics, and basketball. They occur less often in swimming (in the upper extremities). Tibial stress fractures are most common.

The most common symptom of stress fracture is a sharp, persistent, progressive pain or a deep, persistent dull ache located over the bone. Sometimes there is pain on impact (heel strike), but the most important clinical sign is pain over the involved bony surface. Diagnosis is based on clinical observation. Plain radiographs are rarely diagnostic of stress fractures during the initial few weeks, since callus formation is not yet evident. An MRI may more closely delineate a soft tissue injury/inflammation.

Therapeutic Management

Inflammation is common to all overuse syndromes; therefore, management involves rest or alteration of activities, physical therapies, and medication. Rest is the primary therapy, usually interpreted as reduced activity and the use of alternative exercise—not bed rest or immobilization with casting. The main purpose is to alleviate the repetitive stress that initiated the symptoms. It is important to keep the child or adolescent mobile, and training can be continued. Alternative exercise is selected that maintains conditioning without aggravating the

injury. For example, pool running (treading water in the deep end of a pool) utilizes the same movements as running but without the weight bearing. Bicycling, swimming, and rowing are viable alternatives.

Other modalities include cryotherapy and cold whirlpool baths, and sometimes taping, bracing, splinting, and other orthoses are employed, depending on the injury. Medications such as NSAIDs (see Table 5-4) are sometimes prescribed to reduce inflammation and pain. Topical medications are of questionable value.

EXERCISE-INDUCED HEAT STRESS

Infants, children, and adolescents are at greater risk for heat-related illness than adults (American Academy of Pediatrics, Council on Sports Medicine and Fitness, 2011). Several characteristics of infants and children render them more vulnerable to heat stress. The greater ratio of surface area to body mass in infants and young children leads to increased transfer of heat between the body and the environment. Although infants do not exercise they may become overheated through environmental exposure (e.g., being left in a closed car). Children produce more metabolic heat for body mass during exercise and have a reduced capacity to convey heat from the body core to the skin. Also, children do not have the sweating capacity of adults and take longer to become acclimated to hot conditions. Young children may not feel the need to drink a sufficient amount of fluid during extended exercise.

Heat cramps are caused by sodium depletion, which in turn potentiates the effects of calcium on skeletal muscle. They most often occur as a result of strenuous exercise in a hot environment. Cramps most frequently involve the leg muscles. Vital signs are usually normal, but the core temperature may be elevated. The child sweats profusely, but mentation is normal. Treatment consists of rest and replacement of fluid and electrolytes. Ingestion of dilute sports drinks or electrolyte replacement liquids is helpful. Electrolyte replacement solutions are now available as popsicles and gelatin (like Jell-O), which are well tolerated with less vomiting. Replacement electrolyte strips that easily dissolve in the mouth are also available; small sips of a clear fluid such as water can be taken as tolerated.

Heat exhaustion, or heat stress, is a common condition that usually occurs during vigorous exercise in a hot environment. It results from excessive loss of fluids, especially in poorly acclimated and dehydrated children. The onset may be gradual, with initial complaints that include thirst, headache, fatigue, dizziness, anxiety, or nausea and vomiting. The child usually has a clear sensorium but may be somewhat disoriented. The temperature can be normal or mildly elevated; sweating is profuse. Tachycardia, hypotension (usually postural), and syncope may be observed secondary to intravascular volume depletion. Treatment is to move the child to a cool environment, provide rest, and replace fluid volume. The child with a clear sensorium can receive oral replacement fluids, but often IV fluids are required due to vomiting. External cooling methods are not necessary.

Heatstroke represents a failure of normal thermoregulatory mechanisms. Heatstroke usually occurs during or immediately after physical activity, especially in the unacclimated adolescent who is exercising vigorously. The onset is rapid, with initial symptoms of headache, weakness, and disorientation. Central nervous system manifestations may be agitation, confusion, and lethargy. Loss of consciousness may occur without warning and may be accompanied by nuchal rigidity, posturing, and convulsions. Sweating may not be present. The temperature is typically higher than 104° F (40° C), and there is severe volume depletion. Immediate care is relocation to a cool environment, removal of clothing, application of cool water (wet towels or immersion), and use of fans. The child should be emergently transported to the nearest hospital.

Acute care includes rapid cooling until core temperature reaches 102° F (38.9° C) to prevent overcooling. Antipyretics are not used because they are metabolized by the liver, which is already not functioning properly. Renal and liver failure are common sequelae to heatstroke. Treatment includes careful monitoring of temperature and other vital signs, supportive care such as supplemental oxygen administration, and cautious fluid and electrolyte replacement. Prevention remains the best treatment for hyperthermia. If the temperature is elevated, time in the sun should be decreased. Activity should be stopped if the humidity is elevated as well. The athlete should drink plenty of fluids, preferably with low sugar content.

Nonexertional, or classic, heatstroke has a slow onset with insidious development of anorexia, nausea, vomiting, headache, mental manifestations, and loss of intravascular volume. Classic heatstroke occurs primarily in children with abnormal thermoregulation (e.g., children with cystic fibrosis) and infants subjected to prolonged neglect in a hot environment.

HEALTH CONCERNS ASSOCIATED WITH SPORTS

Nutrition

Some athletes are motivated to enhance their performance by any and all means available. They are eager to learn about nutrition, and many are influenced by misconceptions, fads, and superstitions regarding certain foods. Physical performance is affected by energy and body composition. The young athlete must maintain a diet that provides sufficient nutrients and energy to meet metabolic needs for optimum functioning. Physical training increases the need for energy and for more nutrients that convert food energy into chemical energy for physical performance.

There is no evidence to indicate that food supplements, extra vitamins, sports bars, or high-protein diets are needed to meet the demands of heavy physical exercise or improve physical performance in children or adolescents. In addition, there are no scientific data, other than anecdotal reports, supporting the benefits of such supplements in increasing physical performance. Athletes should be given accurate information regarding the lack of proven safety for such supplements

(Rodriguez, DiMarco, Langley, et al, 2009). Young athletes need considerably more calories than the recommended dietary allowance (RDA). When the basic requirements for growth and activity are met by a balanced diet of protein, grains and cereals, fruits and vegetables, and dairy products, the additional calories needed for the extra exertion can be selected as desired. The athlete can obtain these extra calories by eating additional helpings from any of the basic four food groups, but many of the additional calories are provided by complex carbohydrates found in foods such as vegetables, pastas, and bread.

The recommended dietary energy intake for adolescents involved in sports is at least 50% of caloric intake from carbohydrates (6 to 10 g/kg/day), protein intake of 1.2 to 1.7 g/kg/day (average intake for athletes is 1.4 g/kg/day), and 25% to 30% from fat (Kleinman and Greer, 2014). It should be noted, however, that energy requirements vary depending on the sport and the child's or adolescent's age and body build. Adolescent athletes need additional iron and calcium intake from appropriate food sources to meet growth and developmental needs and to replace amounts lost in competition.

Water and Electrolytes

Considerable water is lost from the body through perspiration, urination, and evaporation from the respiratory tract. Water losses, especially from the skin, increase as the duration and intensity of exercise increase and as environmental temperature rises. Although thirst is experienced early in dehydration, it is unreliable as an indicator of fluid deficit. Athletes should hydrate with water regardless of thirst during strenuous exercise or activity. Water is recommended as *the best drink* for most athletes (American Academy of Pediatrics, Committee on Nutrition and the Council on Sports Medicine and Fitness, 2011), and current recommendations are to take 5 to 8 oz of water every 15 to 20 minutes (150 ml for 40 kg [88 lb] athletes and 250 ml for athletes who weigh more than 40 kg). Fluids should never be restricted during activity. A flavored, colored sports beverage containing 6% to 8% carbohydrate, however, may be preferred by children for the taste (Kleinman and Greer, 2014). Drinking carbonated beverages is discouraged. Athletes participating in multiple daily exercise sessions in warm environments are at risk for dehydration and should receive all the water they desire.

Very little water is exchanged in the stomach, and it must reach the intestines for absorption. The best fluids for rapid gastric emptying are cold, have low osmolality, and have a large volume. Fluids containing 6% to 8% carbohydrates appear to have a faster gastric emptying time than water and may be tolerated by adolescent athletes (Kleinman and Greer, 2014). New sports drinks are commercially available that reportedly boost physical performance. While these may provide some benefits over energy drinks, the research in children and adolescents is limited, and their use is only recommended with parental consent and consideration of the amounts of carbohydrate, caffeine, and other nutrients found in the drink (Campbell, Wilborn, La Bounty, et al, 2013; Kleinman and Greer, 2014).

Small amounts of electrolytes, especially sodium and chloride, are lost during exercise. Because sweat is quite dilute relative to plasma, excessive perspiration can result in excessive loss of water and an increase in plasma concentrations of sodium chloride. Therefore, it is more important to replace water than sodium and chloride. Children should be well hydrated before beginning strenuous exercise or sports, especially in warm climates or environments. Periodic drinking breaks are encouraged, and adults or other team members should be alert to the child who has complaints such as headache, cramping, nausea, or vertigo. The use of salt tablets or table salt is unnecessary and may actually be harmful. Athletes usually derive sufficient salt replacement from the diet. Energy drinks are not recommended in children and adolescents participating in sports activities, and there is no evidence of an increase in performance with the use of such drinks in this population (American Academy of Pediatrics, Committee on Nutrition and the Council on Sports Medicine and Fitness, 2011; Kleinman and Greer, 2014).

Minerals

The basic diet does not satisfy the iron requirement of 10% to 15% of female athletes, most of whom are teenage girls who tend to become iron depleted after menarche. Young boys who are experiencing rapid adolescent growth and who have irregular and inadequate diets also are at risk of iron depletion. These children may need iron supplements; however, the American Academy of Pediatrics (Kleinman and Greer, 2014) does not recommend iron supplementation in athletes whose iron stores are adequate. Athletes who are participating in weight-restrictive sports or who are otherwise restricting dietary intake may need supplemental iron. There is currently no evidence that iron supplementation in healthy individuals enhances sports performance (Kleinman and Greer, 2014).

Adequate calcium intake during puberty is essential to promote mineralization of the growing skeleton. The recommended dietary reference intake (DRI) for calcium in adolescents ages 14 to 18 years is 1300 mg/day and vitamin D 400 to 1000 IU/day, yet few adolescents meet this goal. Calcium plays a vital role in nerve transmission, muscle contraction, and blood coagulation. Female athletes who engage in intensive training may develop amenorrhea, with subsequent decreased bone mineral density, osteopenia, and osteoporosis. Although the last two conditions may not occur immediately, stress fractures and impaired muscle contractions may be seen with low calcium intake. The best sources of additional calcium for athletes are nonfat dairy products. In addition, foods such as regular or low-fat yogurt and cheese, calcium-fortified orange juice, low-fat chocolate milk, and pudding may help meet daily calcium requirements. Consider the amount of calcium in the following: 1 glass of calcium-fortified orange juice contains 200 to 250 mg of calcium; 1 cup of skim milk has 300 mg of calcium; and 8 oz of yogurt contain approximately 410 mg of calcium. A well-balanced diet can provide the necessary calcium intake if adolescent athletes are made aware of the requirements and of the long-term consequences of poor nutrition.

Weight

Control of body weight by restricting water or food intake or increasing sweat loss is dangerous. Weight loss should not exceed 1.5% of total body weight per week (or 1 to 2 lb/week) (Kleinman and Greer, 2014). Young athletes need appropriate information about nutrition to dispel the allure of fads and fallacies about diet and performance. A sports nutritionist should be consulted for determining an optimal diet based on amount of energy expenditure and energy requirements. The optimum diet for an athlete is one that contains the essential food groups* and that is adjusted to the energy requirements of the sport in which the child or adolescent is engaged. Such a dietary plan should provide adequate nutrition for top physical efficiency and performance, maintenance of physical fitness and desirable body weight, and optimum function of all organ systems.

Considerations for the Female Athlete

The syndrome known as **female athlete triad** consists of amenorrhea, osteoporosis, and low caloric intake (Kleinman and Greer, 2014). Others have revised the definition to include the features of low energy availability (with or without eating disorders), altered bone mineral density, and menstrual dysfunction (Deimel and Dunlap, 2012; Nattiv, Loucks, Manore, et al, 2007). There is some evidence that endothelial dysfunction and subsequent cardiovascular disease may be a fourth component of this condition (Zach, Smith Machin, and Hoch, 2011). The triad has also been described as a continuum ranging from health to disease for each of the disorders (Deimel and Dunlap, 2012). The triad was originally described in athletes in sports for which thinness was desired (e.g., gymnasts, ballet dancers, figure skaters, and long-distance runners) but is now recognized in virtually all sports. The phenomenon has been attributed to a complex interplay of physical, genetic, hormonal, nutritional, psychologic, and environmental factors that include the stress of competition, decreased protein consumption, and altered lean-to-fat body ratio.

Amenorrhea has been reported among girls who engage in strenuous exercise. Except in swimmers, menarche is attained later in athletes than in nonathletes. Gymnasts, figure skaters, and ballet dancers have the latest mean ages of menarche; track athletes have less of a delay in maturity than do gymnasts and ballet dancers, who also tend to be smaller, lighter, and leaner than other female athletes. Swimmers, who tend to be larger, have a mean age of menarche that approximates that for nonathletes. Also, there appears to be an association between delayed menarche and more advanced competitive levels; that is, athletes at more advanced levels have a greater delay than those at lower competitive levels.

Osteoporosis from decreased levels of estrogen in these athletes, complicated by poor nutritional intake, leads to loss of bone density and stress fractures. The peak of bone density is reached in late adolescence and is related to circulating estrogen levels. Girls with diminished estrogen secretion in delayed menarche will reach late adolescence with low bone density and will be subject to stress fractures and osteoporosis.

Energy availability is defined as the amount of energy left in the body after exercise training; a spectrum of eating disorders is commonly seen, ranging from poor eating habits to eating disorders (Deimel and Dunlap, 2012). Disordered eating is less severe and more subtle than eating disorders such as anorexia and bulimia. Disordered eating includes food restrictions, rigid food patterns, fasting, vomiting, and the use of diet pills and laxatives. The goal is to achieve a specific body image that is seen as desirable for the sport and is influenced by others such as coaches, teammates, or peers. Disordered eating results in poor protein intake, low fat intake, and inadequate caloric intake. Adolescent females should increase calcium intake to four to six servings per day of low-fat dairy products (1500 mg of calcium and 400 to 1000 international units of vitamin D are the RDAs for amenorrheic athletes [Ackerman and Misra, 2011; Kleinam and Greer, 2014]) (see Nutrition, p. 1580). In such individuals, a 25OH vitamin D level greater than 30 ng/mL is considered adequate to promote bone health and prevent fractures (Ackerman and Misra, 2011). In addition, they should consume adequate protein and calories to meet the energy and metabolic needs of exercise. Trainers and coaches also need to be aware of the potentially long-term results of intensive, prolonged exercise in pubertal girls.

Treatment may be long term and often involves development of an appropriate nutritional plan with a multidisciplinary team approach. However, education alone may not provide adequate incentive to change behavior, and psychologic health interventions may be required.

Substance Misuse by Athletes

Young athletes have used various performance-enhancing substances in an attempt to augment their athletic performance. Athletes believe that these substances, also known as *ergogenic aids,* increase strength and endurance, delay the onset of fatigue, increase the ability to concentrate, and decrease sensitivity to pain. Although use of these substances is prohibited in international Olympic competition, there are no means at present to enforce a prohibition on their use in other sports settings.

Examples of substances athletes use include psychomotor stimulants (e.g., amphetamines), anabolic-androgenic steroids (AAS), ephedra, androstenedione (andro), dehydroepiandrosterone (DHEA), creatine, guarana, ginseng, amino acid and protein supplements, and excess amounts of vitamins (e.g., niacin, vitamin A, vitamin B_6). Because many of these substances are considered natural, many people willingly use them without further investigating potential hazards. The belief is that anything "natural," even if consumed in excess of the DRI (see Chapter 12), must be perfectly fine for the body because it will be rapidly metabolized and excreted without causing harm. This is not necessarily true for all substances, however, and parents, coaches, trainers, athletes, and health care workers should be knowledgeable about the effects of such substances. Rather than prohibiting their use, a better approach, especially for adolescents, is to provide open, informed discussion on the

*See ***ChooseMyPlate.gov*** for recommended food groups and tips for serving sizes based on child or adolescent's level of physical activity.

availability of appropriate substitutes that exist in foods that are indeed healthy to consume yet provide beneficial effects for athletic performance. Schools may include such discussions in existing curricula for their athletes and encourage participation in these educational programs.

Amphetamines and related drugs, such as methylphenidate (Ritalin), as well as caffeine and ephedra or other stimulants, may be taken to provide a sense of increased alertness and relief of fatigue; however, obscuring fatigue may permit participants to exceed their limits and precipitate a sudden collapse. Some stimulants such as ephedra are used to burn fat when used in combination with caffeine. These substances can also make the users more aggressive, which can contribute to injuries to themselves and others.

Other misused drugs include stimulants intended for bronchodilation, decongestants, agents for weight gain or loss, physiologic agents used to enhance oxygen-carrying capacity, and nutritional supplements taken in doses greater than required (American Academy of Pediatrics, 2005). Anabolic steroids are a source of concern to health professionals. Black market supplies of anabolic steroids are of poor quality and potency. In an attempt to enhance muscle strength, these drugs may be administered to athletes by coaches, managers, athletic trainers, and even physicians. The user develops larger-appearing muscles and increased body weight and body water, but reports on the side effects of these drugs outweigh any benefits for performance during athletic competition (Gregory and Fitch, 2007). Although the psychologic effect may be beneficial, many valid studies have failed to demonstrate any improvement in performance.

Creatine is reported to be the most commonly used performance enhancing substance among athletes; it is a naturally occurring compound that supplies energy to muscles, builds muscle mass, increases recovery after strenuous exercise, and improves strength (Castillo and Comstock, 2007).

The precise incidence of anabolic steroid use by adolescent athletes is unknown, but studies show that anabolic steroid prevalence ranges from 1% to 11.1% among middle school and high school athletes; creatine use was reported as high as 30% in high school football players (Castillo and Comstock, 2007). Middle school children are reporting an increased use of anabolic steroids to enhance athletic performance. Coaches and health professionals who work with youth report a trend toward increased use of these agents. Adolescents and young adults rely on poor sources of information about the potential hazards of steroid use (e.g., friends, television, muscle magazines) and are generally poorly informed about their potential negative side effects. Health care professionals need to be aware of the clinical manifestations of steroid use. Clinical signs such as severe acne, a sudden increase in strength and muscle mass, a sudden decrease in body fat, a male pattern of baldness, and water retention are common. In females a male pattern of hair growth and a deepening voice are significant observations.

The dangers of continued use are well known and include virilization in females; oligospermia, prostatic hypertrophy, myocardial infarction, stroke, testicular atrophy, infertility, and gynecomastia in males; and premature closure of the epiphyses, acne, increased blood cholesterol levels, hypertension, and hepatocellular carcinoma in both genders. Mood changes have been observed, including aggressiveness, changes in libido, depression, anxiety, and psychosis (Gregory and Fitch, 2007). Health hazards outweigh any potential gain that the drug might provide.

The American Academy of Pediatrics (2005) recommends that parents and coaches be involved in educating athletes about the adverse effects of performance-enhancing substances and that schools and other sports organizations discourage the use of such substances among athletes. In addition, it is recommended that interventions for encouraging substance-free competition that are positive, rather than punitive, are promoted and encourage sound nutrition and training practices. The pressure to win at all costs is high, and athletes face pressures not only from peers and immediate authority figures but also from others who promise financial gain and potential fame. The problem is often compounded by the existence of poor role models in professional sports activities who earn thousands or even millions of dollars yearly and are known by their colleagues to take performance-enhancing substances but deny the practice.

Sudden Death

A death associated with sports produces renewed anxiety in both parents and health care professionals. The term *sudden* or *instantaneous death* is applied to death that occurs within minutes of the onset of the cause of death or within 24 hours of the episode. *Sudden cardiac arrest* is also a term used to describe the athlete who experiences a sudden death. The incidence of sudden death among adolescent athletes has been estimated to be 2 to 7 per 100,000 per year (Angelini, Vidovich, Lawless, et al, 2013). Between 1980 and 2006 most causes of sudden death in athletes occurred as a result of cardiovascular disease (56%), followed by blunt trauma (22%), commotio cordis (3%), and heatstroke (2%) (Maron, Doerer, Haas, et al, 2009). Most studies show that causes of sudden cardiac death are due to hypertrophic cardiomyopathy (36%) and coronary anomalies (33%) (Angelini, Vidovich, Lawless, et al, 2013; Maron, Doerer, Haas, et al, 2009). One study of sudden cardiac deaths in young athletes reported an average of 69 cases per year during the years 2000 to 2006 (Drezner, Chun, Harmon, et al, 2008). Overall survival rates for young athletes experiencing sudden cardiac arrest during an athletic event between 2000 and 2006 were 11%, with a trend toward improved survival in the latter years of the study. More males (83%) than females (17%) experienced sudden cardiac arrest, and females were more likely to survive the arrest than were males (Drezner, Chun, Harmon, et al, 2008).

Causes of sudden death are related to three main risk factors: (1) sports with a high inherent risk for sports-related sudden death, (2) recognized or unknown underlying medical problems in child participants, and (3) the sports environment (e.g., the rules, equipment, practice fields or areas of sport participation, and ambient temperature of the geographic area).

Some experts advocate screening all youth athletes with a 12-lead ECG to detect disorders such as Brugada syndrome,

long QT syndrome, hypertrophic cardiomyopathy, and dilated cardiomyopathy, but this remains somewhat controversial (Morse and Funk, 2012). A comprehensive health history and physical exam may be helpful in identifying children and adolescents with risk factors for further diagnostic investigation, yet this has been reported to be inadequate for identifying risk factors (Morse and Funk, 2012). Chapter 20 discusses the impact of sudden death on the family and relevant nursing interventions.

Sports

Sports associated with the greatest risk of sudden death are those involving collision and frequent body contact. Examples of collision sports are football, ice hockey, rugby, and boxing. There is a high potential for serious injury or fatality in sports such as mountain or rock climbing and hang gliding. Sports that involve high-velocity objects, such as baseball and ice hockey, may result in death from serious head or chest injuries. Riding vehicles such as snowmobiles, mopeds, water jet skis, all-terrain vehicles, snowboards, minibikes, and motorcycles can also be considered high-risk sports.

Medical Conditions

The most frequent medical causes of sudden death during sports activity are cardiac abnormalities, especially idiopathic hypertrophic subaortic stenosis (hypertrophic cardiomyopathy). Manifestations suggestive of hypertrophic cardiomyopathy include a typical triad of severe chest pain, dizziness, and dyspnea. Unfortunately some affected individuals never display signs of disease until they collapse during a sports event. A history of sudden death of a relative or relatives in the second or third decade of life often offers a clue to recognition.

Well-trained athletes often display evidence of hypertrophic cardiomyopathy, the so-called athlete's heart, but the condition is not pathologic. Congenital coronary artery malformation is the second most common cause of sudden death in athletes. Additional causes include valvular heart disease, atherosclerotic coronary artery disease, dilated cardiomyopathy, Marfan syndrome, and myocarditis. Children with systemic hypertension, some types of cardiac arrhythmias such as prolonged QT syndrome, and some forms of heart block will face restrictions in the type and amount of exercise they can tolerate safely. Commotio cordis is a common cause of sudden death in athletes without previous history of heart disease. This occurs following a blunt, nonpenetrating blow to the chest, which produces ventricular fibrillation. Commotio cordis is more common in children and adolescents, with a mean age at occurrence of 13 years, and the blow may not be perceived as being that unusual or significant enough to produce such drastic results.

Appropriate use of an automatic external defibrillator (AED) by civilian bystanders or health care workers may save the life of an athlete who experiences a life-threatening cardiac emergency. A school-based AED program provides a high survival rate for student athletes and nonathletes who experience sudden cardiac arrest on school grounds (Drezner, Rao, Heistand, et al, 2009).

Environmental Causes

Environmental factors that are potential causes of sudden death include playing conditions, clothing, equipment, rules used by officials governing a sport, and outdoor temperature. Heatstroke and hypothermia (see Chapter 16) are the most serious environment-related causes of death in athletes.

The American Academy of Pediatrics has introduced an emergency response plan for schools that includes training teachers and school workers in cardiopulmonary resuscitation and first aid, collecting data to evaluate the risk for injuries in the school environment, and acting to reduce such risks (Hazinski, Markenson, Neish, et al, 2004). Encourage nurses in school programs and in the community to become involved in the establishment of such programs and to assist in training and in planning and implementation of effective risk prevention strategies designed to minimize child deaths in schools and local communities.

The American Academy of Pediatrics also recommends implementing a lay rescuer AED program in schools and that communication regarding the location of such equipment be properly managed (Hazinski, Markenson, Neish, et al, 2004). The National Athletic Trainers' Association developed a consensus statement in conjunction with 15 national health care organizations for emergency preparedness and response in the event of sudden cardiac arrest in young athletes. This statement includes recommendations for those involved in high school and collegiate athletics for the prompt recognition and treatment of sudden cardiac arrest, including the use of an AED (Drezner, Courson, Roberts, et al, 2007).

NURSE'S ROLE IN CHILDREN'S SPORTS

Nurses may become involved in children's sports activities in preparation and evaluation of children for activities, provision of anticipatory guidance and counseling about athletic competition and nutrition, prevention of injuries, treatment of injuries, and rehabilitation after injuries. Selecting an appropriate sport for both recreation and competition is a joint effort of the child or adolescent, parents, and health professionals. Children are introduced to sports as part of family activities, neighborhood games, and school physical education programs, and both parents and children are influenced by media exposure to a variety of sports. Children are highly influenced by the popularity of and exposure afforded athletics in the school setting, especially in high school.

The best approach to counseling children and parents regarding sports participation is to encourage activities that are most likely to provide pleasure and physical benefits throughout childhood and into adulthood. Exposure to a variety of sports activities is probably better for young children than limitation to only one sport. Caution parents against overprogramming children to allow ample time for other activities and associations. Burnout among children and adolescents who continuously participate in sports is increasing in the United States. Children and adolescent are encouraged to take periodic breaks from such activities to allow physical healing, refresh the

mind, and work on strength and conditioning (Brenner and Council on Sports Medicine and Fitness, 2007).

When children sustain athletic injuries, nurses are often responsible for instructing the children and their parents regarding care and rehabilitation. Instructions regarding, for example, the need and schedule for follow-up appointments, application of ice, and any restrictions in activity should be delivered clearly and preferably accompanied by written directions. Emphasize the importance of taking medications as prescribed, since they may be needed for an extended period, and compliance may be difficult. For children continuing with activities, nonnarcotic pain medication administration an hour before practice or competition is advantageous.

Prevention of sports injuries is the most important aspect of any athletic program. Nurses collaborate with coaches and athletic trainers to ensure that safety measures are carried out. Stretching exercises, warming-up and cooling-down activities, and an appropriate training program are only some of the requisites for safe participation. Protective measures, such as padding, taping, wrapping, or use of other devices, are employed for areas at risk. Nurses are also on the alert for environmental safety risks.

For some athletes, their whole life revolves around sports participation. When a serious injury occurs, the athlete's self-esteem and self-image may suffer a devastating blow. Nursing assessment may reveal an athlete who appears to have difficulty dealing with this event and actually rejects any positive reinforcement. The nurse may help the child and family in establishing a support system. The athlete may need to learn new coping skills and explore other avenues to foster feelings of increased self-worth and a sense of accomplishment.

Lack of participation, exercise aversion, and declining interest in sports are sometimes the aftermath of participation during the school years and adolescence. Motivation can be altered or permanently destroyed by failure to appreciate the child's or adolescent's needs related to sports activities. Ridicule or derogation during acquisition of motor skills can shatter a child's or adolescent's self-esteem, producing anxiety and self-doubt that may result in a lifelong aversion to sports.

MUSCULOSKELETAL DYSFUNCTION

TORTICOLLIS

Torticollis, or wry neck, which can be either congenital or acquired, is a condition of limited neck motion. The condition is characterized by the neck being in a flexed position and the head drawn or tilted laterally to the affected side, while the chin is pointed toward the opposite side. Congenital muscular torticollis often occurs as a result of abnormal positioning in utero, causing a contracture of the sternocleidomastoid muscle. Torticollis is a manifestation rather than a disease entity and may be associated with a number of conditions, including congenital abnormality of the cervical spine or a traumatic lesion of the sternocleidomastoid muscle.

In early infancy a firm, nontender mass may be felt in the midportion of the sternocleidomastoid muscle. The mass regresses and is replaced by fibrous tissue. If the condition remains untreated, permanent limitation of neck movement results. Plagiocephaly and facial asymmetry often occur as a result of the contractured sternocleidomastoid muscle. Children may have other associated musculoskeletal conditions, including foot deformities or developmental dysplasia of the hips; a thorough physical examination should be performed for all infants.

Treatment of simple torticollis consists of gentle stretching exercises. The face is turned toward the affected muscle, while the head is tilted in the opposite direction, with the neck extended. A physical therapist typically establishes the treatment regimen to be followed by the nurse and family. The exercises are best performed by two persons: one to control the torso and one to manipulate the head. If stretching exercises are unsuccessful, surgical release of the sternocleidomastoid muscle may be needed. Increasingly, surgical correction by age 12 to 18 months is recommended to prevent muscle contracture and further progression of plagiocephaly. Other forms of torticollis occur in infancy or may develop at a later age but are not discussed in the text.

Nursing Care Management

Nurses should be alert to the possibility of torticollis in infants with limited head movement. After diagnosis, it is frequently the nurse's responsibility to teach the exercises and supervise the family in performing them. The exercises require explicit instructions to the family, and compliance is mandatory. The nurse should also suggest that the child be positioned in a way that encourages turning the head away from the deformity to observe activities and interesting toys or items. Parents can encourage the child to turn the head in the direction desired for correction through feeding and playing with the child.

KYPHOSIS AND LORDOSIS

The spine, which consists of numerous segments, can acquire deformation curves of three types: kyphosis, lordosis, and scoliosis (Fig. 34-33). Kyphosis is the lateral convex angulation in the curvature of the thoracic spine (see Fig. 34-33, *B*). If it is increased (greater than 45 degrees), it may occur secondary to disease processes such as tuberculosis, chronic arthritis, osteodystrophy, or compression fractures of the thoracic spine. The most common form of hyperkyphosis is posture-related. Children, especially during the time when skeletal growth outpaces growth of muscle, are prone to exaggeration of a tendency toward kyphosis. This is particularly common in self-conscious adolescent girls who assume a round-shouldered slouching posture in an attempt to hide their developing breasts and increasing height. Scheuermann kyphosis is a thoracic curve of greater than 45 degrees, with wedging of more than 5 degrees of at least three adjacent vertebral bodies and vertebral irregularity.

Postural hyperkyphosis is almost always accompanied by a compensatory postural lordosis, an abnormally exaggerated concave lumbar curvature. Treatment of kyphosis consists of

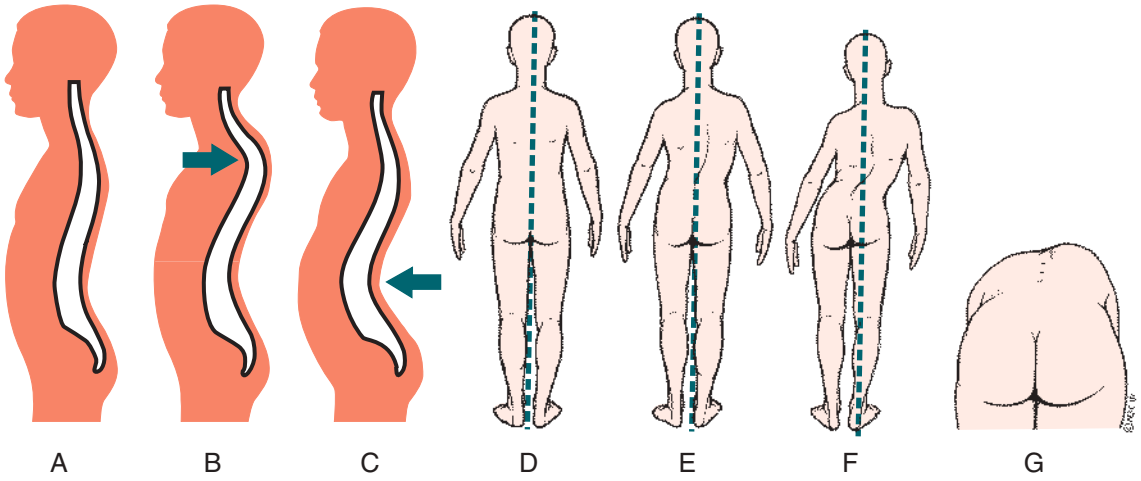

FIG. 34-33 Defects of spinal column. **A,** Normal spine. **B,** Kyphosis. **C,** Lordosis. **D,** Normal spine in balance. **E,** Mild scoliosis in balance. **F,** Severe scoliosis not in balance. **G,** Rib hump and flank asymmetry seen in flexion caused by rotary component.

exercises to strengthen shoulder and abdominal muscles and bracing for more marked deformity. With adolescents who are significantly self-conscious about their appearance, the best approach is to emphasize the cosmetic value of corrective therapy and to place the responsibility on the adolescent for carrying out an exercise program at home, with regular visits to and assessments by a physical therapist. Treatment with a brace may be indicated until skeletal maturity; surgical spinal fusion may be considered for severe, painful, or progressive deforming curves such as Scheuermann kyphosis.

Lordosis is the lateral inward curve of the cervical and lumbar spine (see Fig. 34-33, *C*). Hyperlordosis may be a secondary complication of a disease process, the result of trauma, or idiopathic. Hyperlordosis is a normal observation in toddlers, and in older children it is often seen in association with flexion contractures of the hip, obesity, congenital dislocated hip, and SCFE.

Spondylolysis is a fracture sustained at the pars interarticularis. Spondylolisthesis is the forward slipping of one vertebral body on another. It most often involves L5 moving forward over S1. Retrospondylolisthesis, or retrolisthesis, is the posterior slipping or displacement of one vertebral body on another. Either condition can have multiple causes, including congenital deficiency or spondylolysis. The condition may be asymptomatic, or it may cause lower back pain or neurologic compromise. Spondylolisthesis can usually be treated nonsurgically, although spinal fusion may be indicated in cases of severe, progressive slip.

IDIOPATHIC SCOLIOSIS

Scoliosis is a complex spinal deformity in three planes, usually involving lateral curvature, spinal rotation causing rib asymmetry, and when in the thoracic spine, often thoracic hypokyphosis (see Fig. 34-33, *E-G*, and Fig. 34-34). Scoliosis is the most common spinal deformity and is classified according to age of onset: *congenital* occurs in fetal development; *infantile* occurs at birth up to 3 years of age; *juvenile* occurs in children ages 3 to 10 years of age; and *adolescent* occurs at 10 years of age or older. Scoliosis may be caused by a number of conditions and may occur alone or in association with other diseases, particularly neuromuscular conditions (neuromuscular scoliosis). In most cases, however, there is no apparent cause, hence the name *idiopathic scoliosis.* The following discussion involves the adolescent type, which is often called adolescent idiopathic scoliosis. There appears to be a genetic component to the etiology of idiopathic scoliosis; however, the exact relationship has yet to be established.

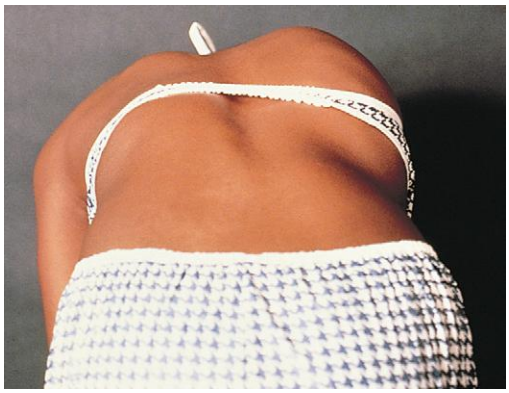

FIG. 34-34 Moderate thoracic idiopathic adolescent scoliosis. Forward flexion reveals a mild rib hump deformity.

Clinical Manifestations

Idiopathic scoliosis is most commonly identified during the preadolescent growth spurt. Parents frequently bring a child for follow-up on an abnormal school scoliosis screening or because of ill-fitting clothes, such as poorly fitting jeans. School screening is controversial, since there are no controlled studies to demonstrate improved outcomes and a reported number of false positives lead to referrals. The American Academy of Orthopaedic Surgeons and the American Academy

of Pediatrics published a joint position statement favoring scoliosis screening for preadolescents and adolescents in the school, physician's office, or nurses' clinic (Richards and Vitale, 2008). Girls should be screened at ages 10 and 12 years, whereas boys should be screened once either at age 13 or 14 years. The benefits of early detection, referral, and medical treatment are considered to be significant, but the persons performing the screenings must be educated in the detection of spinal deformity.

Diagnostic Evaluation

The standing child, wearing only shorts/briefs and viewed from behind, may exhibit asymmetry of shoulder height, scapular or flank shape, or hip height, or may demonstrate pelvic obliquity. Cutaneous changes may also be observed. When the child bends forward at the waist so that the trunk is parallel with the floor and the arms hang free (the Adams position), asymmetry of ribs and flanks may also be appreciated (see Fig. 34-33, *G*, and Fig. 34-34). A scoliometer is used in the initial screening to measure truncal rotation (as does the Adams test). Often a primary curve and a compensatory curve will place the head in alignment with the gluteal cleft. With an uncompensated curve, however, the head and hips are not aligned.

Definitive diagnosis is made by radiographs of the child in the standing position and use of the Cobb technique (standard measurement of angle curvature), which establishes the degree of curvature. The Risser scale is used to evaluate skeletal maturity on the radiographs. This scale assists in making a determination of the likely progression of the spinal curvature as the child's bones mature. The sexual maturity rating is also used to evaluate the risk of curve progression in adolescents. Not all spinal curvatures are scoliosis. A curve of less than 10 degrees is considered a postural variation. Curves of less than 25 degrees are mild and, if nonprogressive, do not require treatment (Hresko, 2013).

Intraspinal conditions or other disease processes that may cause scoliosis must be ruled out. The presence of pain, sacral dimpling or hairy patches, cutaneous vascular changes, absent or abnormal reflexes, bowel or bladder incontinence, or left thoracic curve may indicate an intraspinal abnormality such as syringomyelia, diastematomyelia, or tethered cord syndrome. An MRI scan is usually obtained for evaluation.

Therapeutic Management

Current management options include observation with regular clinical and radiographic evaluation, orthotic intervention (bracing), and surgical spinal fusion (Fig. 34-35). Treatment decisions are based on the magnitude, location, and type of curve; the age and skeletal maturity of the child or adolescent; and any underlying or contributing disease process.

Bracing and Exercise

For moderate curves (25 to 45 degrees) in the growing child and adolescent, bracing may be the treatment of choice. Historically bracing has not been shown to be curative; the goal is to slow the progression of the curvature to allow skeletal growth and maturity. The two most common types of bracing

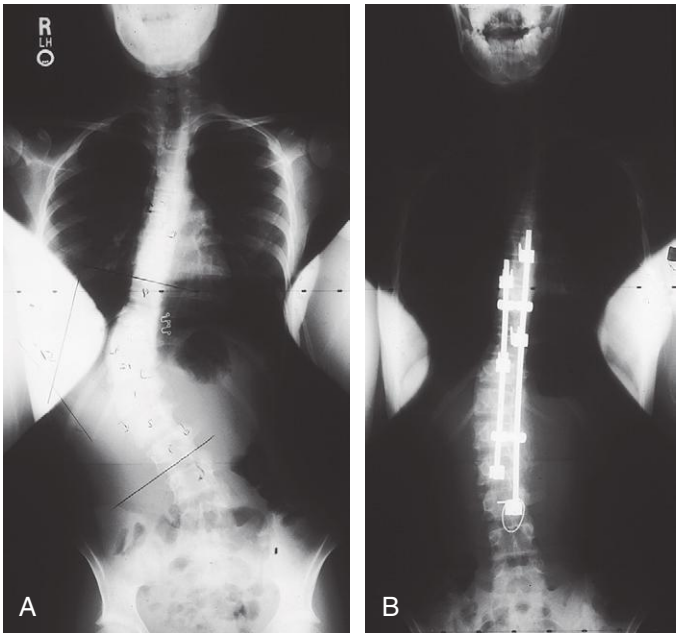

FIG. 34-35 Radiographs showing severe scoliosis before surgical correction (**A**) and after surgical correction of scoliosis, including internal fixation (**B**).

are the Boston and Wilmington braces, which are underarm orthoses customized from prefabricated plastic shells, with corrective forces for each patient using lateral pads and decreasing lumbar lordosis, and a TLSO, which is an underarm orthosis made of plastic that is custom molded to the body and then shaped to correct or hold the deformity (Fig. 34-36). The Milwaukee brace, which is an individually adapted brace that includes a neck ring, is rarely used in scoliosis but is sometimes used in the treatment of kyphosis. The Charleston nighttime bending brace is worn only when the child is in bed because it prevents walking because of the severity of the trunk bend.

Bracing, although used as the gold standard treatment for moderate curves in a growing child, has not proved to be entirely effective in the treatment of idiopathic scoliosis. Wearing the brace is challenging due to the child's age and preoccupation with body image and appearance. Experts recognize that brace treatment in some children with significant scoliosis may help avoid surgical intervention by slowing curve progression, but further studies are needed to clarify the effectiveness of bracing (Richards and Vitale, 2008). Some recent evidence suggests that bracing is effective in slowing a progressive spinal curvature in moderate scoliosis (Weinstein, Dolan, Wright, et al, 2013); however, the majority of studies involving bracing as the primary treatment of adolescent scoliosis are reportedly weak (Kotwicki, Chowanska, Kinel, et al, 2013).

There is very limited evidence regarding the effect of exercises and chiropractic treatment in the prevention of curve progression in scoliosis. Transcutaneous electrical nerve stimulation has proved to be an ineffective treatment. Exercises are of benefit when used in conjunction with bracing to

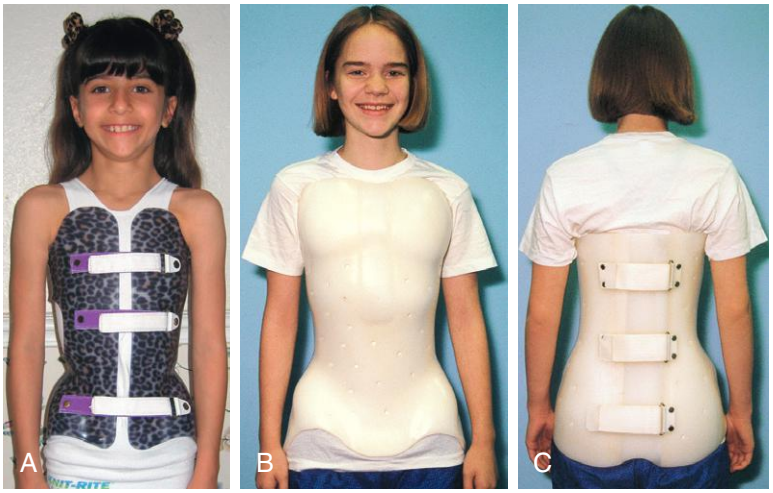

FIG. 34-36 **A,** Standard thoracolumbosacral orthosis (TLSO) brace for idiopathic scoliosis. Note the color and design incorporated into the brace to make it more acceptable to children and adolescents. **B** and **C,** Variation of a standard TLSO brace that fastens in the back to provide needed support for the spinal curvature.

maintain and increase the strength and range of motion of the spine.

Operative Management

Surgical intervention may be required for correction of severe curves (see Fig. 34-35, *A*) (usually 45 degrees or more [Spiegel and Dormans, 2011]). The child's age, the location of the curvature, and curve magnitude influence the decision for surgery. Any progressive or severe curve that does not respond to more conservative orthotic measures such as bracing requires surgical correction. Bracing and exercise have been universally disappointing in treating curves greater than 45 degrees, and neuromuscular, dysplastic and congenital curves, which eventually progress, are best treated with early surgical stabilization. Difficulties with balance or seating, respiratory excursion, or pain are also considered.

There are a number of surgical techniques for severe scoliosis. One surgical intervention consists of realignment and straightening of the spine with internal fixation and instrumentation combined with bony fusion (**arthrodesis**). Posterior and/or anterior surgical approaches may be implemented. The goals of spinal fusion surgery are to improve the curvatures on the sagittal and coronal planes to provide a solid, pain-free fusion in a well-balanced torso (balanced shoulders and pelvis), with maximum mobility of the remaining spinal segments.

Advances in surgical technology currently being evaluated include thoracoscopic spinal fusion and placement of implants; metallic staples may also be placed into the vertebral bodies to achieve spinal fusion and to correct the deformity (Spiegel and Dormans, 2011). The use of minimally invasive surgery techniques such as video-assisted thoracoscopic surgery has gained widespread acceptance for its decreased recovery time, decreased pain, fewer intraoperative and postoperative complications, small incision, less impact on pulmonary function, and less chest wall disruption (Lonner, 2007).

Nursing Care Management

Treatment for scoliosis extends over a significant portion of the affected child's period of growth. In adolescents this period is the one in which their identity, both physical and psychologic, is formed. The identification of scoliosis as a "deformity," in combination with unattractive appliances and a significant surgical procedure, can have a negative effect on the already fragile adolescent body image. The adolescent and family require excellent nursing care to meet not only physical needs but also psychologic needs associated with the diagnosis, surgery, postoperative recovery, and eventual rehabilitation .

Although adolescents are encouraged to participate in most peer activities, necessary therapeutic modifications are likely to make them feel different and isolated. Nursing care of the adolescent who is facing scoliosis surgery, potential social isolation, pain, and uncertainty, not to mention misunderstood emotions and body image issues, must be evaluated from the adolescent's perspective to be successful in meeting the individual's needs.

When a child or adolescent first faces the prospect of a prolonged period in a brace, jacket, or other device, the therapy program and the nature of the device must be explained thoroughly to both the child and the parents so that they will understand the anticipated results, how the appliance corrects the defect, the freedoms and constraints imposed by the device, and what they can do to help achieve the desired goal. The management involves the skills and services of a team of specialists, including the orthopedist, physical therapist, orthotist (a specialist in fitting orthopedic braces), nurse, social worker, and sometimes a thoracic or pulmonary specialist.

It is difficult for a child to be restricted at any phase of development, but the adolescent needs continual positive reinforcement, encouragement, and as much independence as can be safely assumed during this time. Guidance and assistance regarding anticipated problems, such as selection of clothing and participation in social activities, are appreciated by

adolescents. Socialization with peers is strongly encouraged, and every effort is expended to help the adolescent feel attractive and worthwhile.

Preoperative Care

The preoperative workup usually involves a radiographic series, including bending or traction spine films, possible pulmonary function studies, and serologic laboratory studies (including prothrombin, partial thromboplastin, and bleeding times; blood count; electrolyte levels; urinalysis and urine culture; and blood levels of any medications). Spinal surgery typically results in considerable blood loss, so several options are considered preoperatively to maintain or replace blood volume. These options include autologous blood donations obtained from the patient before the surgery; intraoperative blood salvage; intraoperative hemodilution; erythropoietin administration; and controlled induced hypotension, which must be carefully monitored at all times to prevent physiologic instability .

Surgery for spinal fusion is complex, and often adolescents who require the procedure due to idiopathic scoliosis are not familiar with medical terms or procedures. Preoperative teaching is critical for the adolescent to be able to cooperate and participate in his or her treatment and recovery. Since the surgery is extensive, the patient is taught how to manage his or her own PCA pump; how to log-roll; and the use and function of other equipment, such as a chest tube (for anterior spinal fusion) and Foley urinary catheter. It is recommended that the child or adolescent bring a favorite toy (age dependent) or personal items such as a favorite stuffed animal, laptop computer, cell phone (for web surfing, texting, and e-mailing), movie player, MP3 player, or portable compact disc player for postoperative use. Meeting with a peer and his or her family members who have undergone a similar surgery may also be of value.

Postoperative Care

Following surgery, patients are monitored in an acute care setting and log-rolled when changing position to prevent damage to the fusion and instrumentation. In some cases an immobilization brace or cast is used postoperatively depending on the type of surgical intervention. Skin care is important, and pressure-relieving mattresses or beds may be needed to prevent pressure wounds. (See Maintaining Healthy Skin, Chapter 23.)

In addition to the usual postoperative assessments of wound, circulation, and vital signs, the neurologic status of the patient's extremities requires special attention. Prompt recognition of any neurologic impairment is imperative because delayed paralysis may develop that requires surgical intervention. Common postoperative problems after spinal fusion include neurologic injury or spinal cord injury, hypotension from acute blood loss, wound infection, syndrome of inappropriate antidiuretic hormone, atelectasis, pneumothorax, ileus, delayed neurologic injury, and implanted hardware complications (Freeman, 2013). Superior mesenteric artery syndrome may occur several days after spinal surgery; this involves duodenal compression by the aorta and superior mesenteric artery and may result in acute partial or complete duodenal obstruction. Clinical manifestations include epigastric pain, nausea, copious vomiting, and eructation; symptoms are aggravated in the supine position and often relieved with the patient in a left lateral decubitus or prone position.

The adolescent usually has considerable pain for the first few days after surgery and requires frequent administration of pain medication, preferably opioids administered intravenously on a regular schedule. For children able to understand the concept, PCA is recommended. (See Pain Assessment; Pain Management, Chapter 5.) In most cases the patient begins walking as soon as possible. Depending on the instrumentation used and the surgical approach, most patients are walking by the second or third postoperative day and are discharged by 5 to 7 days. In addition to pain management, the patient is evaluated for skin integrity, adequate urinary output, fluid and electrolyte balance, and ileus. Discharge planning should include a timetable for follow-up with the practitioner and resumption of regular activities.

Encourage the family to become involved in the patient's care to facilitate the transition from hospital to home management (see Nursing Care Plan). An organization that provides education and services to both families and professionals is the National Scoliosis Foundation.*

SKELETAL LIMB DEFICIENCY

Congenital limb deficiencies, or reduction malformations, are manifested by varying degrees of loss of functional capacity. They are characterized by underdevelopment of skeletal elements of the extremities. The range of malformation can extend from minor defects of the digit to serious abnormalities such as amelia (absence of an entire extremity) or meromelia (partial absence of an extremity), which includes phocomelia (seal limbs), an interposed deficiency of long bones with relatively good development of hands and feet attached at or near the shoulder or the hips. Most reduction defects involve defects in the development of the limb, but prenatal destruction of the limb can occur, such as full or partial amputation of a limb in utero from constriction of an amniotic band (amniotic band syndrome). Neonates with congenital limb deficiencies often have associated malformations and should be thoroughly assessed for cardiovascular, central nervous system, renal, and digestive abnormalities (Stoll, Alembik, Dott, et al, 2010).

Pathophysiology

Limb deficiencies can be attributed to both heredity and environment and can originate at any stage of limb development. Formation of limbs may be suppressed at the time of limb bud formation, or there may be interference in later stages of differentiation and growth. Heredity appears to play a prominent

NURSING CARE PLAN

The Adolescent with Scoliosis

NURSING DIAGNOSIS	EXPECTED PATIENT OUTCOME	NURSING INTERVENTIONS	RATIONALE
Disturbed Body Image related to diagnosis of scoliosis and subsequent therapy and perceived defect in body structure **Child's/Family's defining characteristics** (Subjective and Objective Data) Verbalization of change in lifestyle Expression of negative feelings about body Verbalization of perceptions that reflect an altered view of one's body in appearance, structure, or function	Adolescent will cope effectively with therapy. **The following NOC concepts apply to these outcomes:** Psychosocial Adjustment: Life Change Self-Esteem	Allow adolescent to verbalize feelings about wearing brace and how it affects her lifestyle. Discuss a plan of action for participation in activities with peers. Discuss implications of not wearing brace and impact on appearance. Emphasize positive aspects of participation in activities of daily living with brace. Encourage self-care regarding activities of daily living; address with adjustments related to restrictions with brace, adjusting and removing brace. Encourage meeting periodically with other female adolescents who must wear brace. Encourage meeting with peers as before and performing activities as tolerated with peers. Assist parents and siblings with discussion of feelings about daughter's diagnosis, wearing of brace, and family and siblings' feelings regarding therapy. Discuss with family and siblings how they can support adolescent through therapy. **The following NIC concepts apply to these interventions:** Body Image Enhancement Socialization Enhancement Family Involvement Promotion Mutual Goal Setting Anticipatory Guidance	To promote expression of negative feelings To encourage participation and prevent self-isolation To provide information related to noncompliance To promote positive reinforcement of treatment plan To promote self-care To gain perspective and support of others like her who are affected by wearing brace To promote acceptance by peers and self To provide emotional support To promote family functioning
Risk for Injury (postoperatively) related to neurologic surgical intervention on spinal column **Child's/Family's defining characteristics** (Subjective and Objective Data) Spinal immobilization Tissue and bone trauma	Adolescent will be injury free and regain capability for ambulation. **The following NOC concepts apply to these outcomes:** Risk Control Personal Safety Behavior Neurologic Status: Spinal Sensory/Motor Function	Log roll with assistance. Implement aspiration precautions. Administer pain medications and/or assist with patient-controlled analgesia pump infusion of pain medications. Encourage isometric exercises of lower extremities as allowed. Assess neurologic signs as warranted or per protocol. Assist patient to a sitting position on side of bed and in ambulation as allowed as soon as possible (depending on type of instrumentation and surgery performed); medicate for pain 30 to 45 minutes before ambulation. Encourage patient to ambulate and assist with ambulation. Assess pressure points if patient is immobile for long period, and provide appropriate interventions (massage, special mattress, turning). **The following NIC concepts apply to these interventions:** Risk Identification Environmental Management: Safety Exercise Promotion Positioning Surveillance Vital Signs Monitoring Postanesthesia Care Skin Surveillance	To prevent injury To prevent aspiration while supine To promote comfort To promote muscle movement and tone To assess signs indicating further intervention required to prevent neurologic injury To prevent side effects of immobilization To prevent immobilization complications To prevent skin breakdown

role, and prenatal environmental insults have been implicated in a number of cases, such as the well-publicized thalidomide tragedy in the late 1950s and early 1960s, which demonstrated a clear relationship between the time of exposure of the pregnant woman to the antiemetic drug and the presence and type of limb deformity in the newborn. There are still drugs that may have similar teratogenic effects in the first trimester of pregnancy; medication administration during this time period should be carefully evaluated by the provider.

Therapeutic Management

The child with a limb deficiency should be fitted with prosthetic devices, and the devices should be applied at the earliest possible stage of development in an attempt to match the infant's motor readiness. This favors natural progression of prosthetic use. For example, an infant with an upper extremity deficiency is fitted with a simple passive device between 3 to 6 months of age, when limb exploration is active, sitting is beginning (with the extremities needed for support), and bilateral hand activities are encouraged. Lower limb prostheses are applied when the infant is ready to pull to a standing position.

In preparation for prosthetic devices, surgical modification may be necessary to ensure the most favorable use of the device, since severe deformity can interfere with its effective use. Phocomelic digits are preserved for controlling switches of externally powered appliances in the upper extremities. Digits (in both the upper and lower extremities) provide the child with surfaces for tactile exploration and stimulation. Prostheses are replaced to accommodate the child's growth and increasing capabilities.

Nursing Care Management

Prosthetic application, training, and habilitation are most successfully carried out in a center that specializes in meeting the special needs of these children, especially very young children and those with multiple amputations. Management involves a prosthetist, who specializes in the development, fitting, and maintenance of prosthetic limbs, and other health care providers such as physical and occupational therapists. Parents need support and are encouraged to assist the child in making age-commensurate adjustments to the environment. Although these children need assistance, overprotection may produce overdependence, with later maladjustment to school and other situations.

DEVELOPMENTAL DYSPLASIA OF THE HIP

The broad term **developmental dysplasia of the hip (DDH)** describes a spectrum of disorders related to abnormal development of the hip that may develop at any time during fetal life, infancy, and childhood. A change in terminology from *congenital hip dysplasia* and *congenital dislocation of the hip* to DDH more properly reflects the varying onset and types of hip abnormalities in which there is a shallow acetabulum, subluxation, or dislocation.

The incidence of hip instability is approximately 1 to 1.5 per 1000 live births, and approximately 15% to 50% of infants with DDH are born with a breech intrauterine position. Girls are more commonly affected (80%) than boys, and there is a positive family history in approximately 12% to 33% of affected individuals (Sankar, Horn, and Wells, 2011a). Two published meta-analyses have identified the following risk factors: breech birth, female gender, family history of DDH, left hip, first-born child, and positive clicking hips with clinical examination (De Hundt, Vlemmix, Bais, et al, 2012; Ortiz-Neira, Paolucci, and Donnon, 2012).

Pathophysiology

The cause of DDH is unknown, but certain factors such as female gender, first pregnancy, family history, breech intrauterine position, high birth weight, joint laxity, and postnatal positioning are believed to affect the risk of DDH. Predisposing factors associated with DDH may be divided into three broad categories: physiologic factors, including maternal hormone secretion and intrauterine positioning; mechanical factors, which involve breech presentation, multiple fetuses, oligohydramnios, and large infant size, as well as continued maintenance of the hips in adduction and extension that with time can cause dislocation (see Cultural Competence box); and genetic factors, which include a higher incidence of DDH in siblings of affected infants and even greater incidence of recurrence if a sibling and one parent were affected. One study found a twelvefold increase in risk of DDH for individuals with a first-degree relative affected (Stevenson, Mineau, Kerber, et al, 2009).

DDH can be categorized into two major groups: idiopathic, in which the infant is neurologically intact, and teratologic, which involves a neuromuscular defect such as arthrogryposis or myelodysplasia. The teratologic forms usually occur in utero and are much less common.

Three degrees of DDH are illustrated in Fig. 34-37 and are outlined below:

1. Acetabular dysplasia: This is the mildest form of DDH, in which there is a delay in acetabular development evidenced by osseous hypoplasia of the acetabular roof that is oblique and shallow. The femoral head remains in the acetabulum with no subluxation or dislocation.
2. Subluxation: The largest percentage of DDH, subluxation implies incomplete dislocation. The femoral head remains in contact with the acetabulum, but a stretched capsule and ligamentum teres cause the head of the femur to be partially

CULTURAL COMPETENCE

Developmental Dysplasia of the Hip and Infant Care Practices

A striking relationship exists between the development of dislocation and methods of handling infants. Among cultures with the highest incidence of dislocation (Navajo Indians and Canadian Natives [formerly referred to as Eskimos]), newly born infants are tightly wrapped in blankets or other swaddling material or are strapped to cradle boards. In cultures where mothers carry infants on their backs or hip in a widely abduction straddle position, such as the Far East and Africa, the disorder is virtually unknown.

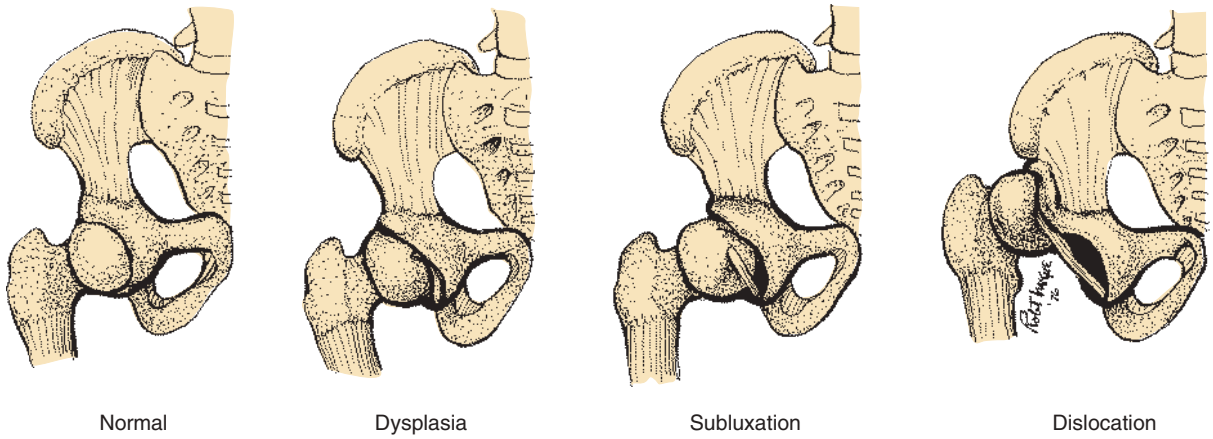

FIG. 34-37 Configuration and relationship of structures in developmental dysplasia of the hip.

displaced. Pressure on the cartilaginous acetabulum inhibits ossification and produces a flattening of the socket.

3. Dislocation: This is the most severe form of DDH. The femoral head loses contact with the acetabulum and is displaced posteriorly and superiorly.

Recently, it has been recommended that infants' hips be placed in slight flexion and abduction during swaddling. Further, it was recommended that infants' knees be maintained in slight flexion and that forced or prolonged passive hip extension in the first months of life be avoided (Price and Schwend, 2011). These recommendations were made based on evidence that demonstrated a significant relationship between tight swaddling and hip dysplasia and are aimed at decreasing the incidence of DDH in infants.

Diagnostic Evaluation

The diagnosis of DDH should be made in the newborn period if possible, since treatment initiated before 2 months of age achieves the highest rate of success. In the newborn period, hip dysplasia usually appears as hip joint laxity rather than outright dislocation. Subluxation and the tendency to dislocate can be demonstrated by the Ortolani and Barlow tests (Fig. 34-38, *D*). With the infant quiet and relaxed in the supine position on a firm surface with the legs facing the examiner, the hips and knees are flexed (not forced) at right angles. The examiner places the middle finger of each hand over the greater trochanter and the thumbs on the inner side of the thigh at a point opposite the lesser trochanter. The knees are carried to midabduction, and each hip joint is submitted, one at a time, first to forward pressure exerted behind the trochanter and then to backward pressure exerted from the thumbs in front as the opposite joint is held steady. If the femoral head can be felt to slip forward into the acetabulum on pressure from behind, it is dislocated (Ortolani test). If, on pressure from the front, the femoral head is felt to slip out over the posterior lip of the acetabulum, the hip is said to be dislocatable or "unstable" (Barlow test). Sometimes an audible "clunk" can be heard on exit or entry of the femur out of or into the acetabulum. The audible clunk is not pathologic and occurs as a result of breaking surface tension across the hip joint, knee rotation, snapping of gluteal tendons, or patellofemoral motion.

! NURSING ALERT

The Barlow and Ortolani maneuvers should be performed only by an experienced clinician to prevent an injury to the infant's hips.

The Ortolani and Barlow maneuvers are most reliable from birth to 4 weeks of age. Adduction contractures develop at about 6 to 10 weeks of age, and the Ortolani sign disappears. After this time, the most sensitive test is limited hip abduction (Fig. 34-38, *B*). Other signs are shortening of the thigh on the affected side (Galeazzi sign) (Fig. 34-38, *C*), asymmetric thigh and gluteal folds (Fig. 34-38, *A*), and broadening of the perineum (in bilateral hip dislocations).

In the older infant and child, the affected leg appears shorter than the other. In both unilateral and bilateral dislocations the greater trochanter is prominent and appears above a line from the anterosuperior iliac spine to the tuberosity of the ischium. There may be telescoping or piston mobility, meaning that the head of the femur can be felt to move up and down in the buttock when the extended thigh is pushed first toward the child's head and then pulled distally. Instability of the hip on weight bearing produces a characteristic waddling gait and marked lumbar lordosis in bilateral hip dislocations. When the child stands first on one foot and then on the other (holding onto a chair, rail, or someone's hand), bearing weight on the affected hip, the pelvis tilts downward on the normal side instead of upward as it would with normal stability (positive Trendelenburg sign) (Fig. 34-38, *E*).

Radiographic examination in early infancy is not reliable because ossification of the femoral head does not normally take place until 4 to 6 months of life. However, the cartilaginous femoral head can be visualized directly by ultrasonography. Universal newborn screening with ultrasonography has been proposed; however, numerous studies reveal this approach has a high rate of false-positives and subsequent overtreatment. Therefore, ultrasonography is considered an adjunct to the physical examination (American Academy of Pediatrics, 2000).

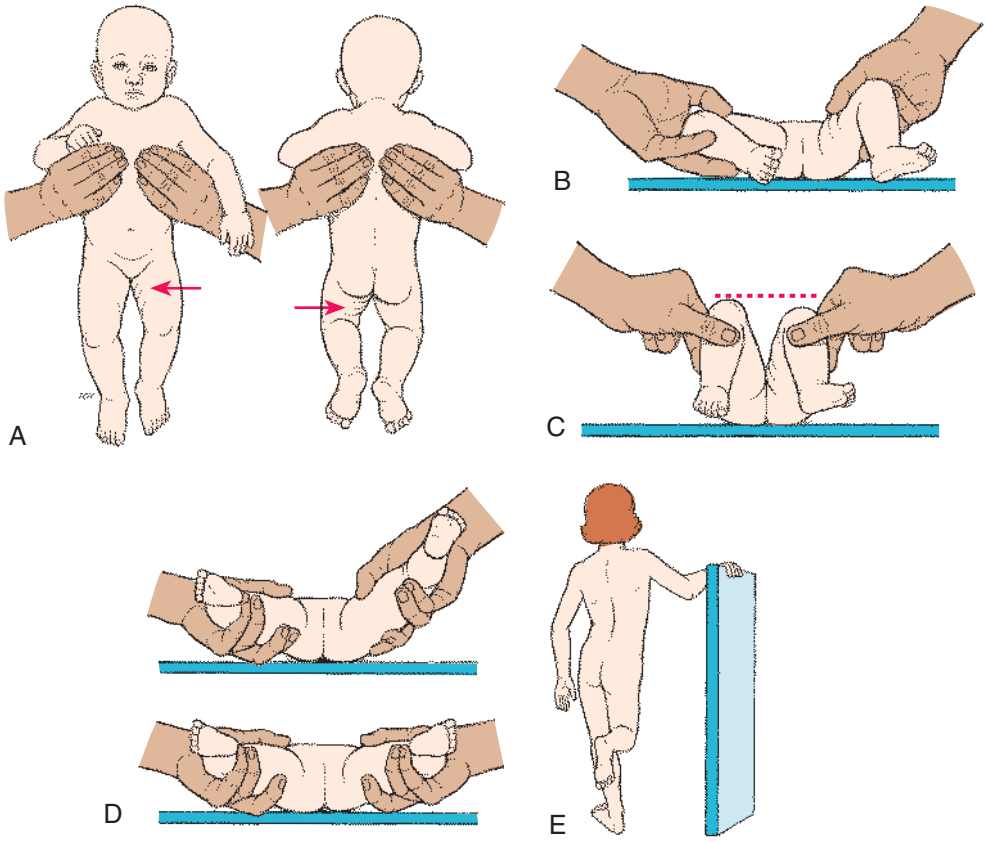

FIG. 34-38 Signs of developmental dysplasia of hip. **A,** Asymmetry of gluteal and thigh folds. **B,** Limited hip abduction, as seen in flexion. **C,** Apparent shortening of femur, as indicated by level of knees in flexion. **D,** Ortolani test. **E,** Positive Trendelenburg sign (if child is weight bearing).

In infants older than 6 months of age and in children, radiographic examination is useful in confirming the diagnosis. An upward slope in the roof of the acetabulum (acetabular angle) greater than 30 degrees with upward and outward displacement of the femoral head is seen (Sankar, Horn, Wells, et al, 2011a). The American Academy of Pediatrics (2000) has published extensive clinical guidelines for screening and early detection of DDH.

Therapeutic Management

Treatment is begun as soon as the condition is recognized because early intervention is more favorable to the restoration of normal bony architecture and function. The longer treatment is delayed, the more severe the deformity, the more difficult the treatment, and the less favorable the prognosis. The treatment varies with the child's age and the extent of the dysplasia. The goal of treatment is to obtain and maintain a safe, congruent position of the hip joint to promote normal hip joint development.

Newborn to 6 Months

The hip joint is maintained, by dynamic splinting, in a safe position with the proximal femur centered in the acetabulum in a degree of flexion. A variety of abduction devices are available; of these, the Pavlik harness is the most widely used, and

FIG. 34-39 Child in Pavlik harness.

with time, motion, and gravity, the hip works into a more abducted, reduced position (Fig. 34-39). The harness does not rigidly immobilize the hip but acts to prevent hip extension and adduction. The Pavlik harness is worn continuously until the hip is stable on both clinical and ultrasound examination, usually within 6 to 12 weeks. It is highly effective when the

device is well constructed, follow-up care is adequate, and the parents follow instructions in its use.

When adduction contracture is present, other devices (such as skin traction) are employed to slowly and gently stretch the hip to full abduction, after which wide abduction is maintained until stability is attained. When maintaining stable reduction is difficult, a hip spica cast is applied and changed periodically to accommodate the child's growth. After 3 to 6 months, sufficient stability is acquired to allow transfer to a removable protection abduction brace. The duration of treatment depends on development of the acetabulum.

6 to 24 Months

In this age-group, the dislocation is often not recognized until the child begins to stand and walk, when shortening of the limb and contractures of hip adductor and flexor muscles become apparent. A surgical closed reduction is performed, and the child is placed in a spica cast for approximately 12 weeks. If the hip is not reducible, a surgical open reduction may be necessary. A hip abduction orthosis may be used following spica casting in order to maintain the hip in an appropriate, stable position and further promote hip development.

Older Child

Correction of the hip deformity in the older child is inherently more difficult than in the preceding age-groups because secondary adaptive changes and other etiologic factors (such as juvenile arthritis or cerebral palsy) complicate the condition. Operative reduction, which may involve preoperative traction, tenotomy of contracted muscles, and pelvic osteotomy procedures designed to construct an acetabular roof, often combined with proximal femoral osteotomy, is usually required. After cast removal, range-of-motion exercises help restore movement. Other rehabilitation measures may include muscle strengthening, a period of crutch or walker use, and gait training.

Nursing Care Management

Nurses are in a unique position to detect DDH in the newborn. During the infant assessment process and routine nurturing activities, the nurse inspects the hips and extremities for any deviations from normal. These observations are reported to the attending practitioner for further examination. The ambulatory child who displays a limp or waddling gait is also referred for evaluation. Nonambulatory children with cerebral palsy or spina bifida should be assessed for evidence of hip problems as well.

The major nursing challenges in the care of an infant or child in a cast or other device are related to maintenance of the device and adaptation of nurturing activities to meet the child's needs. Generally, treatment and follow-up care of these children are carried out in an outpatient setting.

The primary nursing goal is teaching parents to apply and maintain the reduction device. The Pavlik harness allows for easy handling of the infant and usually produces less apprehension in the parent than heavy braces and casts. It is important that parents understand the correct use of the device, which may or may not allow for its removal during bathing. Removing the harness is determined individually on the basis of the provider's recommendations, the degree of hip instability, and the family's level of understanding. Parents should be instructed not to adjust the harness.

Skin care is an important aspect of the care of an infant in a Pavlik harness. The following instructions for preventing skin breakdown are stressed:

- Check frequently (at least two to three times per day) for red areas under the straps and at skin folds.
- Gently massage healthy skin under the straps once a day to stimulate circulation.
- In general, avoid lotions and powders because they can cake and irritate the skin.
- Always place the diaper under the straps.

Parents are encouraged to hold the infant who has a Pavlik harness and continue cares and activities. The nurse can assist by answering the parents' questions about necessary adaptations to daily care, thereby helping to decrease the parents' anxiety and fears. Problems reported by parents include difficulty reapplying the harness, carrying the child, skin-crease dermatitis, feet slipping out of the harness, and difficulty in clothing the child (Hassan, 2009). These findings highlight the importance of close follow-up and written take-home instructions for the parents to follow in managing the Pavlik harness.

Casts offer more challenging nursing and caregiver problems, since they cannot be removed for routine care and bathing. Care of an infant or small child with a cast requires nursing innovation to reduce irritation and to maintain cleanliness of both the child and the cast, particularly in the diaper area. The importance of spica cast care should be emphasized when providing instructions to parents and caregivers. The life of the cast should be prolonged to help prevent an unnecessary cast change.

It is important for nurses, parents, and other caregivers to understand that children in corrective devices need to be involved in all the activities of any child in the same age-group. Confinement in a cast or orthotic device should not exclude children from family activities. They can be held astride the lap for comfort and transported to areas of activity. The child may be allowed to walk in a cast or orthotic device. An adapted wheelchair or stroller can offer mobility to an older infant or child.

LEGG-CALVE-PERTHES DISEASE

Legg-Calve-Perthes disease is a self-limiting disorder in which there is avascular necrosis of the femoral head. The disease affects children ages 2 to 12 years, but most cases occur as an isolated event in boys between 4 to 8 years of age. In approximately 10% of cases, the involvement is bilateral; most of the affected children have a skeletal age significantly below their chronologic age (Sankar, Horn, Wells, et al, 2011b). The male-to-female ratio is 4:1 or 5:1. Caucasian children are affected 10 times more frequently than African-American children.

Pathophysiology

The cause of the disease is unknown, but a temporary disturbance of circulation to the femoral capital epiphysis produces

BOX 34-9 RADIOGRAPHIC STAGES OF LEGG-CALVE-PERTHES DISEASE

Stage I—Aseptic necrosis or infarction of the femoral capital epiphysis with degenerative changes producing flattening of the upper surface of the femoral head (the avascular stage)

Stage II—Capital bone resorption and revascularization with fragmentation (vascular resorption of the epiphysis) that gives a mottled appearance on radiographs (the fragmentation, or revascularization stage)

Stage III—New bone formation, which is represented on radiographs as calcification and ossification or increased density in the areas of radiolucency; this filling-in process appears to take place from the periphery of the head centrally (the reparative stage)

Stage IV—Gradual reformation of the head of the femur without radiolucency and, it is hoped, to a spherical form (the regenerative stage)

an ischemic aseptic necrosis of the femoral head. During middle childhood, circulation to the femoral epiphysis is more tenuous than at other ages, being supplied almost entirely by the lateral retinacular vessels. The pathologic events seem to take place in four stages (Box 34-9). The entire disease process may encompass as few as 18 months or continue for several years. The reformed femoral head may be severely altered or minimally impacted.

Clinical Manifestations and Diagnostic Evaluation

The onset of Legg-Calve-Perthes disease is usually insidious, and the history may reveal only intermittent appearance of a limp on the affected side or a symptom complex, including hip soreness, ache, or stiffness, which can be constant or intermittent. The parents may report seeing the child limping, and the limp may become more pronounced with increased activity. The pain may be experienced in the hip, along the entire thigh, or in the vicinity of the knee joint. The pain and limp are often more evident on arising and at the end of a long day of activities. The pain is usually accompanied by joint dysfunction and limited range of motion at the hip. There may be a vague history of trauma but not necessarily. The diagnosis is established by characteristic radiographic findings and, occasionally, by MRI.

Therapeutic Management

Because deformity occurs early in the disease process, the aims of treatment are to eliminate hip irritability; restore and maintain adequate hip range of motion; prevent capital femoral epiphyseal collapse, extrusion, or subluxation; and preserve as well-rounded femoral head as possible at time of healing. Treatment varies according to the child's age at the time of diagnosis and the appearance of the femoral head and position within the acetabulum. Activity causes microfractures of the soft ischemic epiphysis, which tends to induce synovitis, stiffness, and hip adductor contracture.

The initial therapy is rest or activity restrictions and limited-weight bearing, which helps reduce inflammation and irritability of the hip. The use of NSAIDs can provide relief of pain or discomfort; physical therapy or range of motion exercises help restore hip motion. In some cases, traction is applied to stretch tight adductor muscles and improve containment of the femoral head. Abduction braces or casting may also be utilized for containment. If nonsurgical or conservative management is unsuccessful, surgical reconstruction or containment procedures such as a pelvic or proximal femoral osteotomy may be necessary.

The disease is self-limiting, but the ultimate outcome of therapy depends on early and efficient treatment and the child's age at the onset of the disorder. Children 5 years and younger, whose epiphyses are more cartilaginous, tend to have the best prognosis or outcome. Children over 9 years old have a significant risk for degenerative arthritis, especially if they have femoral head deformity at the time of diagnosis. The later the diagnosis is made, the more femoral head damage will have occurred before treatment is implemented.

Nursing Care Management

Because these children are largely cared for on an outpatient basis, the major emphasis of nursing care is on teaching the family the required care and management. The family needs to comprehend the diagnosis and the importance of compliance with the prescribed regimen to achieve the desired outcome. The child and the family may rely on the nurse to help them understand and adjust to therapeutic measures.

One of the most difficult aspects associated with the disorder is the need to cope with a normally active child who feels well but must remain relatively inactive. It is important to emphasize that children should continue to attend school and engage in activities that can be adapted to the prescribed regimen. Suitable activities must be devised to meet the needs of the child in the process of developing a sense of initiative or industry. Activities that fulfill creative urges are well received.

SLIPPED CAPITAL FEMORAL EPIPHYSIS

Slipped capital femoral epiphysis (SCFE) refers to the spontaneous displacement of the proximal femoral epiphysis in a posterior and inferior direction. It develops most frequently shortly before or during accelerated growth and the onset of puberty (children between the ages of 10 and 16 years; median age 13 years for boys and 12 years for girls) and is commonly observed in boys and obese children. SCFE has a reported prevalence of 2 to 10 per 100,000 in the United States, with bilateral involvement occurring in up to 60% of cases (Sankar, Horn, Wells, et al, 2011c).

Pathophysiology

Most cases of SCFE are idiopathic, although it can be associated with endocrine disorders, growth hormone therapy, renal osteodystrophy, and radiotherapy. The cause of idiopathic SCFE is multifactorial and includes obesity, physeal architecture and orientation, and pubertal hormone changes that affect physeal strength. Although obesity stresses the physeal plate, SCFE can also occur in children who are not obese. Radiographs show medial displacement of the epiphysis and uncovered upper portion of the femoral neck adjacent to the physis. There are a

widened growth plate and irregular metaphysis. The capital femoral epiphysis remains in the acetabulum, but the femoral neck slips, deforming the femoral head and stretching blood vessels to the epiphysis.

Clinical Manifestations and Diagnostic Evaluation

SCFE is suspected when an adolescent or preadolescent displays clinical signs of a limp or complains of intermittent or continuous pain in the hip, groin, thigh, or knee. Onset may be acute, chronic or acute-on-chronic. The child or adolescent often lies stiff with the lower extremity flexed, abducted, and externally rotated because of the pain; any attempts to move the limb are met with significant resistance. In an unstable SCFE, the child may be unable to bear weight because of severe pain.

Physical examination reveals early restriction of internal rotation on adduction and external rotation deformity with loss of abduction and internal rotation as the severity increases. The diagnosis is confirmed by anteroposterior and frog-leg radiographs that reveal a change in the position of the proximal femoral epiphysis.

Therapeutic Management

The treatment goals of SCFE are to prevent further slipping of the femoral epiphysis until physeal closure, avoid further complications such as avascular necrosis, and maintain adequate hip function (Peck and Herrera-Soto, 2014; Sankar, Horn, Wells, et al, 2011c). Once the diagnosis is established, the child should be non-weight-bearing to prevent further slippage. SCFE is an emergency and requires early diagnosis and treatment to increase the likelihood of an acceptable outcome.

Surgical treatment is necessary and varies with the degree of displacement or slippage. Some surgeons prefer to take the child to surgery within 24 hours of the onset of acute symptoms and avoid further risk of avascular necrosis. Recommended treatment is surgical pinning in situ, which involves the placement of a single pin or alternatively multiple pins or screws through the femoral neck into the proximal femoral epiphysis to prevent further slippage (Peck and Herrera-Soto, 2014). Several other surgical treatment options are also available. Postsurgical care includes non-weight-bearing with crutch or walker ambulation until acceptable, painless range of motion is achieved.

Nursing Care Management

Nursing care involves preparing the child and family for the surgical procedure and recovery. Postoperative care involves hemodynamic stabilization, pain management, and assessment for complications. The adolescent is taught the proper use of crutches and the importance of avoiding any weight bearing on the affected hip. Self-care and performance of activities of daily living to capability are encouraged to promote confidence and decrease a sense of helplessness.

METATARSUS ADDUCTUS

Metatarsus adductus, sometimes also referred to as metatarsus varus, is probably the most common congenital foot deformity. The deformity is characterized by medial adduction of the toes and forefoot, frequently in association with inversion and convexity of the lateral border of the foot (kidney-shaped). In most instances, it is a result of abnormal intrauterine positioning, particularly in a firstborn child, and is usually detected at birth. A thorough hip examination should be performed for all infants with metatarsus adductus as an increased risk of hip dysplasia is associated with foot deformities. Metatarsus adductus can be divided into three categories: type I, in which the forefoot is flexible and corrects easily with manipulation; type II, in which the forefoot is only partially flexible and corrects passively past neutral position but only to neutral position with active manipulation; and type III, in which the forefoot is rigid and will not stretch to neutral position with manipulation. Unlike a clubfoot, with which it is often confused, the angulation occurs at the tarsometatarsal joint, while the heel and ankle remain in a neutral position. Ankle range of motion is normal. The deformity often causes a pigeon-toed or intoeing gait in the child.

Management depends on the rigidity and type of the deformity. Correction can usually be accomplished by gentle manipulation and passive stretching of the foot with types I and II, which the parent is taught to perform. With type III, the child usually requires serial manipulation and casting to correct the defect, after which a corrective shoe or orthosis may be used. Surgical correction is rarely required for the condition but may be performed in children over 4 to 6 years of age who have considerable pain on ambulation or difficulties with shoe wear as a result of the deformity.

Nursing Care Management

The nursing role primarily involves identifying the defect so that early therapy and instruction of the parents can be initiated. The nurse teaches the parents how to hold the heel firmly and to stretch only the forefoot; otherwise, undue force on the heel may produce a valgus deformity. If casting or an orthosis is needed, the nurse instructs the parents in cast care and observation of the brace.

CLUBFOOT

Clubfoot, also referred to as talipes equinovarus (TEV), is a complex deformity of the ankle and foot that includes forefoot adduction, midfoot supination, hindfoot varus, and ankle equinus (Fig. 34-40). Clubfoot involves bone deformity and malposition with soft tissue contracture. Clubfoot may occur as an isolated deformity or in association with other conditions or syndromes, such as spina bifida, arthrogryposis, cerebral palsy, or chromosomal abnormalities.

The incidence of clubfoot in the general population is approximately 1 per 1000 live births, with boys affected twice as often as girls. Bilateral clubfeet occur in 50% of the cases (Hosalkar, Spiegel, and Davidson, 2011). The precise cause of clubfoot is unknown. However, there is a strong familial tendency, with a 1 in 10 chance that a parent with clubfoot will have an affected offspring. Other possible theories as to the cause of clubfoot include arrested or abnormal fetal development or abnormal positioning and restricted movement in utero, although the evidence is inconclusive.

FIG. 34-40 Bilateral congenital talipes equinovarus (congenital clubfoot).

FIG. 34-41 Feet casted for correction of bilateral clubfeet.

Diagnostic Evaluation

A clubfoot deformity is readily apparent at birth if it has not been detected prenatally through ultrasonography. Once it is detected, a careful yet comprehensive physical assessment of the affected foot (or feet) should be completed to allow for appropriate decision making regarding treatment plans and prognosis. The affected foot (or feet) is usually smaller and shorter, with an empty heel pad and a transverse plantar crease. When the deformity is unilateral, the affected limb may be shorter, and calf atrophy is present. Generally, imaging such as radiographs or ultrasonography is not necessary for diagnosis. A thorough hip examination should be performed for all infants with a clubfoot; an increased risk of hip dysplasia is associated with clubfoot deformities.

Therapeutic Management

The goal of treatment for clubfoot is to achieve a painless, plantigrade, and stable foot. Once the diagnosis is established, treatment is ideally initiated in the newborn period and involves three stages: (1) correction of the deformity, (2) maintenance of the correction until normal muscle balance is regained, and (3) follow-up observation to avert possible recurrence of the deformity. Some feet respond to treatment readily; some respond only to prolonged, vigorous, and sustained efforts; and the improvement in others remains disappointing even with maximum effort. Parents should realize that outcomes are not always predictable and depend on the severity of the deformity, age of the child at initial intervention, compliance with treatment protocols, and development of bones, muscles, and nerves.

The common approach to clubfoot management and treatment is the Ponseti method (Ponseti, 1996). Serial casting is begun shortly after birth. Weekly gentle manipulation and stretching of the foot along with placement of serial long-leg casts allow for gradual repositioning of the foot (Fig. 34-41). The extremity or extremities are casted until maximum correction is achieved, usually within 6 to 10 weeks. The majority of the time, a percutaneous heelcord tenotomy is performed at the end of casting to correct the equinus deformity. After the tenotomy, a long-leg cast is applied and left in place for 3 weeks. Following the completion of casting, a Denis Browne bar with Ponseti sandals or straight last shoes (may fit on either foot) placed in abduction are fitted to maintain the correction and prevent recurrence. Inability to achieve an acceptable foot alignment and ankle range of motion after casting and tenotomy indicates the need for surgical intervention.

NURSING CARE MANAGEMENT

Nursing care of the child with clubfoot is the same as for any child who has a cast. Because the child will spend considerable time in a corrective device, nursing care plans include both long- and short-term goals. Careful observation of the skin and circulation is particularly important in young infants because of their rapid growth rate.

Since treatment and follow-up care are handled in the orthopedic clinic or outpatient department, parent education and support are important in the nursing care of these children. Parents need to understand the diagnosis, the overall treatment program, the importance of regular cast changes, and the role they play in the long-term effectiveness of the therapy. Nursing responsibilities include reinforcing and clarifying the orthopedic provider's explanations and instructions, teaching parents about care of the cast or bracing (including vigilant observation for potential problems), and encouraging parents to facilitate normal development within the limitations imposed by the deformity or therapy.

ORTHOPEDIC INFECTIONS

OSTEOMYELITIS

Osteomyelitis, an infectious process involving the bone, may occur at any age but most frequently is seen in children 10 years of age or younger. *S. aureus* is the most common causative organism (Box 34-10). Neonates are also likely to have osteomyelitis caused by group B streptococci. Since the advent of *Haemophilus influenzae* type b immunization in the late 1980s, *H. influenzae* has become a less common causative pathogen.

BOX 34-10 CAUSATIVE MICROORGANISMS OF OSTEOMYELITIS ACCORDING TO AGE

Newborns
Staphylococcus aureus
Group B streptococcus
Gram-negative enteric rods

Infants
S. aureus (methicillin-sensitive *S. aureus* 70, methicillin-resistant *S. aureus* 30)
Haemophilus influenzae

Older Children
S. aureus
Pseudomonas organisms
Salmonella organisms
Neisseria gonorrhoeae

Adolescents and Adults
Pseudomonas organisms
Mycobacterium tuberculosis

From McCance KL, Huether SE: *Pathophysiology: the biological basis for disease in adults and children,* ed 6, St. Louis, 2010, Mosby.

Children with sickle cell anemia may develop osteomyelitis from *Salmonella* organisms as well as *S. aureus*. *Neisseria gonorrhoeae* is a potential causative organism in the sexually active adolescent.

Acute hematogenous osteomyelitis results when a blood-borne bacterium causes an infection in the bone. Common foci include infected lesions, upper respiratory tract infections, otitis media, tonsillitis, abscessed teeth, pyelonephritis, and infected burns. Exogenous osteomyelitis is acquired from direct inoculation of the bone from a puncture wound, open fracture, surgical contamination, or adjacent tissue infection. Subacute osteomyelitis has a longer course and may be caused by less virulent microbes with a walled-off abscess or Brodie abscess, typically in the proximal or distal tibia. Chronic osteomyelitis is a progression of acute osteomyelitis and is characterized by the presence of dead bone, bone loss, and drainage and sinus tracts. Generally healthy bone is not likely to become infected. Factors that contribute to infection include inoculation with a large number of organisms, presence of a foreign body, bone injury, high virulence of an organism, immunosuppression, and malnutrition. Certain types and locations of bone are also more vulnerable to infection (American Academy of Orthopaedic Surgeons, 2012a). The limbs most commonly affected include the foot, femur, tibia, and pelvis.

Pathophysiology

In acute osteomyelitis, bacteria adhere to bone, causing a suppurative infection with inflammatory cells, edema, vascular congestion, and small-vessel thrombosis; the result is bone destruction, abscess formation, and dead bone (sequestra). Infection within the bone can rupture through the cortex into the subperiosteal space, stripping loose periosteum and forming an abscess. As dead bone is resorbed, new bone is formed along the live bone and infection borders. This surrounding sheath of live bone is called an involucrum. Sinus tracts from perforations in the involucrum may drain pus through soft tissue to the skin.

PATHOPHYSIOLOGY REVIEW

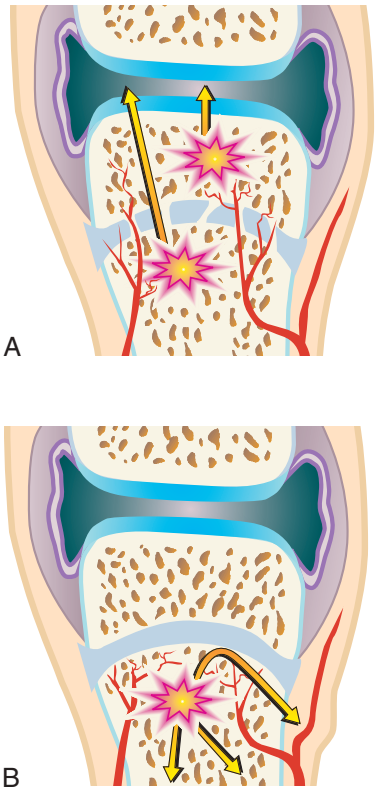

FIG. 34-42 Pathogenesis of acute osteomyelitis differs with age. **A,** In infants younger than 1 year, the epiphysis is nourished by penetrating arteries through the physis, allowing development of the condition within the epiphysis. **B,** In children up to 15 years of age, the infection is restricted to below the physis because of interruption of the vessels.

The pathology of osteomyelitis is different in infants, children older than 1 year of age, and adults. In infants blood vessels cross the growth plate into the epiphysis and joint space, which allows infection to spread into the joint. In children the infection is contained by the growth plate, and joint infection is less likely (unless the infection is intracapsular) (Fig. 34-42).

Clinical Manifestations

In children severe pain, fever, irritability, and tenderness with or without local signs of inflammation suggest osteomyelitis. The extremity is tender, and the child may hold it in a flexed position and resist movement. In infants these symptoms may be minimal or absent, and pain may be difficult to localize. The infant may demonstrate pain with movement of the extremity or hold it immobile. Fever is uncommon in infants, and they often do not appear to be ill (Kaplan, 2011). Infants may have an adjacent joint effusion. Typically the metaphysis of long bones—the tibia, femur, and/or humerus—is involved.

In a small portion of children more than one bone may be affected.

Diagnostic Evaluation

Organism identification and antibiotic susceptibility testing are essential for effective therapy. Obtain cultures of aspirated subperiosteal pus along with cultures of blood, joint fluid, and infected skin samples. Bone biopsy may be indicated if blood culture results and radiographic findings are not consistent with osteomyelitis. Supporting evidence for osteomyelitis includes leukocytosis, elevated erythrocyte sedimentation rate, and elevated C-reactive protein. Radiographic signs, except for soft tissue swelling, are evident only after 2 to 3 weeks. A three-phase technetium bone scan can show areas of increased blood flow, such as occurs in early stages in infected bone, and is useful in locating multiple sites; however, it is not a diagnostic test. CT can detect bone destruction, and MRI provides anatomic details useful in delineating the area of involvement, especially if surgical intervention is planned. The differential diagnosis includes trauma, malignant lesions, leukemia, juvenile rheumatoid arthritis, and acute rheumatic fever. Sometimes osteomyelitis may be unrecognized if it occurs as a complication of a severe toxic and debilitating disease.

Therapeutic Management

After culture specimens are obtained, empiric therapy is started with IV antibiotics covering the most likely organisms. For *S. aureus* nafcillin or clindamycin is generally used; methicillin-resistant *S. aureus* may require vancomycin. When the infective agent is identified, administration of the appropriate antibiotic is initiated and continued for at least 4 weeks, but the length of therapy is determined by the duration of the symptoms, the response to treatment, and the sensitivity of the organism. In selected cases oral antibiotic therapy may follow a shorter IV course. Due to the prolonged duration of high-dose antibiotic therapy, it is important to monitor for hematologic, renal, hepatic, ototoxic, and other potential side effects.

Surgery may be indicated if there is no response to specific antibiotic therapy, persistent soft tissue abscess, or infection that spreads to the joint. Opinions differ regarding surgical intervention, but many advocate sequestrectomy and surgical drainage to decompress the metaphyseal space before pus erupts and spreads to the subperiosteal space, forming abscesses that strip the periosteum from bone or form draining sinuses. When these complications occur, a chronic infection usually persists. When surgical drainage is carried out, polyethylene tubes are placed in the wound. One tube instills an antibiotic solution directly into the infected area by gravity, and the other, connected to a suction apparatus, provides drainage. (See Chapter 16 for a discussion of wound care.)

Nursing Care Management

During the acute phase of illness, any movement of the affected limb causes discomfort to the child, so the child is positioned comfortably with the affected limb supported. Moving and turning are carried out carefully and gently to minimize discomfort. The child may require pain medication (see Chapter 5) or sedation. Take vital signs and record them frequently, and implement measures to reduce a significant temperature elevation.

Antibiotic therapy requires careful observation and monitoring of the IV equipment and site. Because more than one antibiotic is usually administered, the compatibility of the drugs must be determined and care taken to avoid mixing incompatible drugs. The stability of the drugs and their toxic nature are also considered when determining the rate of administration. The infusion device must be well situated in the vein to ensure that the drug does not infiltrate into surrounding tissues, where it may produce tissue damage. For long-term antibiotic therapy, a venous access device, such as a peripherally inserted central catheter, is the preferred method of IV administration. (See Chapter 23.)

The wound is managed according to the provider's directions. Administration of antibiotic solution directly into the wound is most efficiently accomplished using a regular infusion setup that is prepared and regulated in the same manner as for any IV infusion. Intake and output are measured and recorded, and the character of both the wound and drainage is noted. The amount and character of drainage on the wound dressing are also noted.

As the infection subsides, physical therapy is instituted to ensure restoration of optimum function. The child is usually discharged on a regimen of antibiotics (either IV or oral), and progress is monitored closely.

SEPTIC ARTHRITIS

Septic (suppurative) arthritis is a bacterial infection in the joint. It usually results from hematogenous spread or from direct extension of an adjacent cellulitis or osteomyelitis. Direct inoculation from trauma accounts for 15% to 20% of septic arthritis cases. The most common causative organism is *S. aureus* (Kaplan, 2011). Community-acquired methicillin-resistant *S. aureus* is commonly a cause of septic arthritis (Gutierrez, 2005). In addition to *S. aureus,* pathogens seen in neonates include group B streptococci, *Escherichia coli,* and *Candida albicans*. In children 2 months to 5 years of age, *S. aureus, Streptococcus pyogenes, Streptococcus pneumoniae,* and *Kingella kingae* are the primary organisms causing infection, whereas children older than 5 years are more likely to be infected by *S. aureus* and *S. pyogenes*; sexually active adolescents may be infected by *N. gonorrhoeae* (Gutierrez, 2005).

Knees, hips, ankles, and elbows are the most commonly affected joints. Clinical manifestations include severe joint pain, swelling, warmth of overlying tissue, and occasionally erythema. The child is resistant to any joint movement. Features of systemic illness such as fever, malaise, headache, nausea, vomiting, and irritability may also be present.

Therapeutic and Nursing Care Management

The affected joint is aspirated and the specimen evaluated by Gram stain, culture (including separate cultures for *H. influenzae* and *N. gonorrhoeae*), and determination of leukocyte count. In addition, blood cultures and complete blood counts with

differential and erythrocyte sedimentation rate or C-reactive protein levels should be monitored. Early radiographic findings are limited to soft tissue swelling but may reveal a foreign body, and such films always provide a baseline for comparison. Technetium scans reveal areas of increased blood flow but will not differentiate between sites. MRI and CT scans provide more detailed images of inflammation, cartilage loss, joint narrowing, erosions, and ankylosis of progressive disease. An infection involving the hip, however, is considered a surgical emergency to prevent compromised blood supply to the head of the femur (Kaplan, 2011).

IV antibiotic therapy is based on Gram stain results and clinical presentation. The benefits of serial aspirations to demonstrate sterility of synovial fluid and reduce pressure or pain are controversial. Pain management is an important aspect of nursing care, particularly with involvement of a large joint such as the hip. Surgical intervention may also be required if there was a penetrating wound or a foreign object was possibly involved. Physical therapy may be initiated for the child who is immobilized in a cast or traction to maintain range of motion and prevent contractures, similar to the nursing care for osteomyelitis.

SKELETAL TUBERCULOSIS

In children tubercular infection of the bones and joints is acquired by lymphohematogenous spread at the time of primary infection. Occasionally it is from chronic pulmonary tuberculosis. Skeletal tubercular infection is not common in the United States but should be considered in communities with high tuberculosis case rates. The infection is most likely to involve the vertebrae, causing a tubercular spondylitis. If the spine infection is progressive, it results in destruction of the vertebral bodies and results in hyperkyphosis (**Pott's disease**). Symptoms are insidious. The child may report persistent or intermittent pain. Other findings include joint swelling and stiffness; fever and weight loss are not common. Tubercular arthritis can also affect single joints such as a knee or hip and tends to cause severe destruction of adjacent bone. Infection in the fingers causes spina ventosa, a tuberculous dactylitis.

As with pulmonary tuberculosis, the index case should be located. A family and environmental history needs to be obtained and skin tests performed. (See also Tuberculosis, Chapter 28.) Results of tuberculin skin tests are positive for the majority of children with tuberculous arthritis; however, the results are not diagnostic, and the clinical and laboratory features do not differentiate tubercular arthritis from a nontubercular septic arthritis. Diagnosis requires isolation of *Mycobacterium tuberculosis* from the site. Patients with the susceptible organism start treatment with combined antituberculosis chemotherapy (isoniazid, rifampin, and pyrazinamide); directly observed therapy is preferred.

Nursing care depends on the site and extent of infection. Tuberculous spondylitis and hip infection may require immobilization, casting, and fusion. Nursing care is the same as for osteomyelitis, with the addition of isolation requirements.

SKELETAL AND ARTICULAR DYSFUNCTION

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (OI) is the most common osteoporosis syndrome in children, characterized by excessive fractures and bone deformity; most affected children have moderate to severe growth restriction. There are at least eleven types of OI, accounting for significant disease variability. Clinical features include varying degrees of bone fragility, deformity, and fracture; blue sclerae; hearing loss; and dentinogenesis imperfecta (hypoplastic discolored teeth). The inheritance pattern is autosomal dominant in the majority of cases, although forms demonstrate autosomal recessive inheritance.

Most types of OI have defects in the *COL1A1* or *COL1A2* genes, which code for polypeptide chains in type 1 procollagen, a precursor of type 1 collagen, a major structural component of bone. The error results in faulty bone mineralization, abnormal bone architecture, and increased susceptibility to fracture. Recently, genetic studies have found OI types caused by genetic mutations not associated with defective collagen production (Marini and Blissett, 2013). Additional autosomal recessive genetic types of OI have been described and include *CRTAP, PPIB, SERPINH1, LEPRE1, PLOD2, FKBP10, LRP5,* and *SP7* (Laron and Pandya, 2013).

Classifications for OI are based on clinical features and patterns of inheritance (Box 34-11). Clinically, type I is the most common, with wide variability of bone fragility; some affected family members have significant deformity and disability, whereas others lead agile, active lives. Type II variants are the most severe and are considered lethal in infancy. Type III OI is characterized by multiple fractures, bone deformity, and severe disability; affected individuals rarely live to 30 years of age. Type IV is similar to type I with blue or white sclerae. Another variant, or type V, has been described in which those affected have a hyperplastic callus, a radiodense metaphyseal band, and calcification of the interosseous membrane of the forearm; no collagen mutations are noted in this group (Marini, 2011). A type VI has been described with a characteristic mineralization defect, which does not respond to pamidronate therapy as types I to V do (Land, Rauch, Travers, et al, 2007). However, a small group of children with OI VI responded favorably to denosumab, a RANK ligand inhibitor (Semler, Netzer, Hoyer-Kuhn, et al, 2012). Children affected with this type have no dental involvement and normal sclerae; a bone biopsy is the only way to establish a diagnosis because of the similarities to other types. Types VII and VIII overlap types II and III in relation to clinical features, but those who survive these types have white sclerae, a normal-to-small head circumference, short stature, and rhizomelia (Marini, 2011).

Therapeutic Management

The treatment for OI has historically been primarily supportive, although patients and families are optimistic about new research advances. Bone marrow transplant for severe OI was first reported in 1999 with positive results; however, this is still considered an experimental treatment and long-term follow up of

BOX 34-11 CLASSIFICATION OF OSTEOGENESIS IMPERFECTA†

Type I*
- **A**—Mild bone fragility; blue sclerae; normal teeth; hearing loss (occurs between ages 20 and 30 years); autosomal dominant inheritance
- **B**—Same as A except dentinogenesis imperfecta instead of normal teeth
- **C**—Same as B but no bone fragility

Type II—Lethal; stillborn or die in early infancy; severe bone fragility, multiple fractures at birth; 10% of cases of OI; autosomal recessive inheritance

Type III—Severe bone fragility leading to severe progressive deformities; normal sclerae; marked growth failure; most autosomal recessive inheritance; few autosomal dominant inheritance

Type IV
- **A**—Mild to moderate bone fragility; normal sclerae; normal teeth; short stature; variable deformity; autosomal dominant inheritance
- **B**—Same as A except dentinogenesis imperfecta instead of normal teeth; approximately 6% of cases of OI

Type V—Clinically similar to type IV; hyperplastic callus; collagen mutation negative

Type VI—Sclerae and dentition normal; moderate to severe bone fragility; diagnosis by bone biopsy because of similarities to other types (Land, Rauch, Travers, et al, 2007)

Types VII and VIII (recessive form)—Clinically overlap types II and III but have white sclerae, rhizomelia, and small to normal head circumference; severe osteochondroplasia and short stature in survivors (Marini, 2011). Type VII is associated with *CRTAP* gene and Type VIII is associated with the LEPRE1 genetic mutation.

OI, Osteogenesis imperfecta.
*Two thirds of cases are type I.
†This classification is based on that proposed by Sillence DO, Senn A, Danks DM: Genetic heterogeneity in osteogenesis imperfecta, *J Med Genet* 16(2): 101-116, 1979, which originally included OI types I-IV. Additional types have been described but are not included herein.

such children has not been published. The long-term effectiveness of BMT for OI in comparison to the complications of the treatment have yet to be fully explored (Madonia, 2012).

Therapeutic management should focus on decreasing the number of fractures, decreasing pain, increasing growth, improving bone metabolism, and optimizing function (Laron and Pandya, 2013). Bisphosphonate therapy with pamidronate, risedronate, olpadronate, neridronate, or alendronate to promote increased bone density and prevent fractures has become standard therapy for many children with OI. Bisphosphonate therapy reportedly is more beneficial for increasing vertebral bone density but is considered less effective for long bones (Marini, 2011). Others report effectiveness of pamidronate in children with moderate to severe OI (Alharbi, Pinto, Finidori, et al, 2009). Bachrach and Ward (2009) suggest that data are inadequate to recommend the use of bisphosphonate therapy in children with OI for sole treatment of bone mineral density reduction. Oral risedronate has been reported to be mildly effective in treating children with type I OI, but it is not superior to pamidronate therapy (Rauch, Munns, Land, et al, 2009).

The rehabilitative approach to management is directed to preventing positional contractures and deformities, muscle weakness and osteoporosis, and malalignment of lower extremity joints, prohibiting weight bearing. Lightweight braces and splints help support limbs, prevent fractures, and aid in ambulation. Physical therapy helps prevent disuse osteoporosis and strengthens muscles, which in turn improves bone density. Surgery is sometimes used to help treat the manifestations of the disease. Surgical techniques are used to correct deformities that interfere with bracing, standing, or walking. For the child with recurrent fractures, inserting an intramedullary rod provides stability to bones. Telescoping intramedullary rods may be used to accommodate normal growth; early reports show an improvement in ambulation, mobility, and gross motor function in OI patients with femoral deformities (Laron and Pandya, 2013). Because there is a 50% risk of an affected individual passing the gene to an offspring, genetic counseling is recommended.

Nursing Care Management

Infants and children with this disorder require careful handling to prevent fractures. They must be supported when they are being turned, positioned, moved, and held. Even changing a diaper may cause a fracture in severely affected infants. These children should never be held by the ankles when being diapered but should be gently lifted by the buttocks or supported with pillows; however, nurses should not be afraid to touch or handle the infant or child with OI. Such children need compassionate handling and care as much as any other patient. Parents who care for such children on a regular basis can often share tips for handling the child without causing fractures.

It is recommended that blood pressure be obtained with a manual cuff to prevent fractures. In addition nurses should be aware that such children, although smaller in stature than same-age children, have normal intelligence and should receive adequate information and instructions regarding their care. Involving parents in the daily care of the child is essential (Madonia, 2012). Children receiving bisphosphonate therapy should be closely monitored for respiratory infections and should receive appropriate immunizations for the prevention of childhood communicable diseases. Live virus vaccines may not be recommended in children on bisphosphonate therapy, and an infectious disease specialist should be consulted. Skin care for children with OI is essential; infants with OI may need frequent repositioning of the head to prevent posterior occipital flattening or other cranial molding. Oral and dental care should be performed on a regular basis and with extreme care due to bone and tooth fragility (Madonia, 2012). Parents of the child undergoing bone marrow transplant need adequate written information and instructions regarding special care in regard to the various chemotherapeutic drugs required (Madonia, 2012). (See also Bone Marrow Transplantation, Chapter 31.)

Children with current fractures or healing fractures should be screened for OI; the assumption that abuse or neglect is the cause of fractures in children must be carefully evaluated by a multidisciplinary team. A detailed history, no evidence of associated soft-tissue injury, and the presence of other symptoms related to OI help determine the diagnosis.

Both parents and the affected child need education regarding the child's limitations and guidelines in planning suitable activities that promote optimum development and protect the child from harm. Realistic occupational planning and genetic counseling are part of the long-term goals of care. The parents can obtain educational materials and information from the Osteogenesis Imperfecta Foundation, Inc.,* which also has a network to put families in contact with other families that have a similar problem.

JUVENILE IDIOPATHIC ARTHRITIS

Juvenile idiopathic arthritis (JIA) refers to chronic childhood arthritis. A group of heterogeneous chronic autoimmune diseases, JIA causes inflammation in the synovium, joints, and surrounding tissue. The cause of JIA is unknown. Some theories speculate that the disorder arises when an infectious agent activates an autoimmune inflammatory process in a genetically predisposed child. Although a genetic susceptibility to JIA is known, such as human leukocyte antigen (HLA) polymorphisms, the *PTPN22* gene, and the *IL2RA/CD 25* gene, the genetic contribution is complicated and still not well understood (Prahalad and Glass, 2008). The reported incidence of chronic childhood arthritis varies from 1 to 20 cases per 100,000 children, with a prevalence of 10 to 400 per 100,000 (Cassidy and Petty, 2011). JIA starts before age 16 years with two peak onsets: between 1 and 3 and between 8 and 10 years of age. There is a female predominance of 2:1.

Pathophysiology

The disease process is characterized by chronic synovial inflammation causing joint effusion and eventual erosion, destruction, and fibrosis of the articular cartilage. Adhesions between joint surfaces and ankylosis of joints occur if the process persists.

Clinical Manifestations

Whether single or multiple joints are involved, stiffness, swelling, and loss of motion develop in the affected joints. The swelling results from soft tissue edema, joint effusion, and synovial thickening. The affected joints may be warm and tender to touch, but it is not uncommon for pain not to be reported. Erythema is not typical, and a warm painful red joint is always suspect for infection. The limited motion early in the disease is a result of muscle spasm and joint inflammation; later it is caused by ankylosis or soft tissue contracture. Morning stiffness of the joint(s) is characteristic and present on arising in the morning or after inactivity. Functional change may be an obvious limp or subtle modifications of joint motion that protect the involved joint, such as fisting to avoid wrist extension with pressure. In severe, long-standing cases growth is significantly restricted. Corticosteroid therapy can be a contributing factor. There may be growth disturbances, either overgrowth or undergrowth, adjacent to the inflamed joints (e.g., altered leg length after knee involvement) and micrognathia (receding chin) from temporomandibular arthritis.

Classification

The International League of Associations for Rheumatology classification of JIA, developed in 1997, revised and published in 1998, and revised again in 2001, lists seven disease categories, each with its own set of criteria and exclusions: systemic arthritis, oligoarthritis, rheumatoid factor (RF)–negative polyarthritis, RF-positive arthritis, psoriatic arthritis, enthesitis-related arthritis, and undifferentiated arthritis (Petty, Southwood, Baum, et al, 1998; Petty, Southwood, Manners, et al, 2004) (Box 34-12).

Course and Prognosis

The outcome of JIA is variable and unpredictable. Even in severe forms, JIA is rarely life threatening and is significantly different from adult rheumatoid arthritis. Features that distinguish JIA from adult disease include onset before 16 years of age; a negative rheumatoid factor (in 90% of cases); classic symptoms of systemic arthritis, including quotidian fever, rash, and pericarditis; development of uveitis (inflammation of the iris and ciliary body) as a complication (in 8% to 20% of cases); and a tendency for the arthritis to become inactive.

Mortality is rare, occurring in less than 0.3% in North America. Deaths in the United States are typically associated with systemic JIA and infection. The arthritis tends to wax and wane and only becomes inactive in approximately 30% of the cases. These children may have severe or minimal joint damage remaining when active arthritis abates. Approximately 70% of the children have progressive arthritis into adulthood. Their arthritis can cause significant joint deformity and functional disability requiring medication, physical therapy, and perhaps future joint replacement. Chronic and acute uveitis is an extraarticular complication of JIA that may cause permanent vision loss if undiagnosed and not aggressively treated. Although many children have minimal arthritis, it can produce severe physical, functional, and emotional impairment.

Diagnostic Evaluation

JIA is diagnosis of exclusion; there are no definitive tests. Criteria include onset before 16 years, arthritis in one or more joints for 6 weeks or longer, and exclusion of other causes (Petty, Southwood, Manners, et al, 2004). Laboratory test results may provide supporting evidence of disease. An elevated sedimentation rate or C-reactive protein may or may not be present. Leukocytosis is frequently present during flares of systemic disease. Tests for RF give positive results in only 10% of the children with JIA. The presence of antinuclear antibodies is common in JIA, but they are not specific for arthritis; however, their presence helps to identify children with pauciarticular disease, who are at greater risk for uveitis.

Therapeutic Management

There is no cure for JIA. The major goals of therapy are to control pain, preserve joint range of motion and function, minimize the effects of inflammation such as joint deformity, and

BOX 34-12 INTERNATIONAL LEAGUE OF ASSOCIATIONS FOR RHEUMATOLOGY CLASSIFICATION OF JUVENILE IDIOPATHIC ARTHRITIS

Systemic Arthritis
Definition—Arthritis in one or more joints with or preceded by fever for at least 2 weeks' duration that is documented to be daily for at least 3 days, and accompanied by one or more of the following: evanescent (nonfixed) erythematous rash, generalized lymph node enlargement, hepatomegaly and/or splenomegaly, serositis.
Exclusions—a, b, c, d*

Oligoarthritis
Definition—Arthritis affecting one to four joints during the first 6 months of disease. Two subcategories are recognized: (1) persistent oligoarthritis, which never extends over four affected joints during disease course, and (2) extended oligoarthritis, which affects more than four joints after 6 months of disease.
Exclusions—a, b, c, d, e*

Polyarthritis (Rheumatoid Factor Negative)
Definition—Arthritis affecting five or more joints during the first 6 months of the disease and a negative rheumatoid factor.
Exclusions—a, b, c, e*

Polyarthritis (Rheumatoid Factor Positive)
Definition—Arthritis affecting five or more joints during the first 6 months of disease and two or more positive rheumatoid factor tests at least 3 months apart during the first 6 months of disease.
Exclusions—a, b, c, e*

Psoriatic Arthritis
Definition—Arthritis and psoriasis, or arthritis and at least two of the following: (1) dactylitis, (2) nail pitting or onycholysis, and (3) psoriasis in a first-degree relative.
Exclusions—b, c, d, e*

Enthesitis-Related Arthritis
Definition—Arthritis and enthesitis (inflammation at a tendon insertion site), or arthritis or enthesitis with at least two of the following: (1) presence or history of sacroiliac joint tenderness and/or inflammatory lumbosacral pain; (2) presence of HLA-B27 antigen; (3) onset of arthritis in a male over 6 years of age; (4) symptomatic anterior uveitis; and (5) a history of ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter syndrome, or acute anterior uveitis in a first-degree relative.
Exclusions—a, d, e*

Undifferentiated Arthritis
Definition—Arthritis that fulfills criteria in no category or in two or more of the above categories.

HLA, Human leukocyte antigen.
*Exclusions: (a) Psoriasis or a history of psoriasis in the patient or first-degree relative; (b) arthritis in an HLA-B27–positive male beginning after the sixth birthday; (c) ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter syndrome, or symptomatic anterior uveitis, or a history of one of these disorders in a first-degree relative; (d) the presence of immunoglobulin M rheumatoid factor on at least two occasions at least 3 months apart; (e) the presence of systemic juvenile idiopathic arthritis in the patient (Petty, Southwood, Manners, et al, 2004).
From Petty RE, Southwood TR, Manners P, et al: International League of Associations for Rheumatology classification of juvenile idiopathic arthritis: second revision, Edmonton, 2001, *J Rheumatol* 31(2):390-392, 2004.

promote normal growth and development. Achievement of these goals requires a family-centered approach with collaboration among the child, family, and health care team. The team includes the primary care physician; pediatric rheumatologist; rheumatology nurse educator; social worker; physical and occupational therapists; subspecialists (e.g., pediatric ophthalmologist); and a community of friends, relatives, and teachers. The treatment plan is individualized, but it can be complicated and intrusive, including medications, physical and occupational therapy, slit-lamp eye examinations, splints, comfort measures, dietary management, modification of school activities, and psychosocial support.

Outpatient care is the mainstay of therapy; lengthy hospital admissions for rehabilitation are seldom financially feasible. Chronic uveitis can cause permanent vision loss, glaucoma, and cataracts. Slit-lamp ophthalmologic examinations at regular intervals are required to diagnose chronic anterior uveitis (iridocyclitis), inflammation of the anterior segments of the eye, iris, and ciliary body. The majority of affected children have a relatively good visual prognosis if the inflammation is detected and treated early; however, most cases are asymptomatic. Consequently, routine slit-lamp examinations are critical. The children at greatest risk for development of uveitis have pauciarticular disease and a positive antinuclear antibody (Reininga, Los, Wulffraat, et al, 2008). Infections, injuries, and surgical procedures often precipitate a flare-up of the arthritis; therefore, prompt recognition and treatment of infections are necessary.

Medications

In 2011 The American College of Rheumatology published recommendations for the treatment of JIA intended to lend guidance to the provider. The guidelines are divided into four groups: children with four or fewer affected joints, five or more affected joints, systemic arthritis and active systemic features, and systemic arthritis with active arthritis. Each path provides recommendations for stepwise escalation of medication therapy (Beukelman, Patkar, Saag, et al, 2011). All tracks consider poor prognostic indicators, such as erosions on radiographs; arthritis of the hip, cervical spine, ankle, or wrist; and a positive rheumatoid factor. Additionally, each track takes into account disease activity levels that include elevated acute phase reactants and global assessments of both the provider and the patient/parent.

A variety of antirheumatic drugs are available. Nonsteroidal anti-inflammatory drugs (NSAIDs) are used alone or in combination with other drugs, depending on the amount of disease activity and poor prognostic features. Common NSAIDs include ibuprofen, naproxen, tolmetin, diclofenac, indomethacin, and meloxicam. (See Table 5-4.) NSAIDs offer an immediate analgesic effect, but the anti-inflammatory effect requires larger doses and more time to achieve. Patient and family education regarding potential gastrointestinal, renal, and hepatic side effects and reduced clotting is essential. Parents should monitor the child for abdominal pain and blood in the stool. Naproxen has the potential side effect of skin fragility; patients need to use sunscreen and report unusual skin lesions.

Additional medication is required in most children with arthritis. The agents used are **disease modifying antirheumatic drugs (DMARDs)** and include the nonbiologic drugs methotrexate and sulfasalazine. The decision to use DMARD at initiation of therapy or later in the escalation of therapy is guided by the amount of disease activity and poor prognostic features. Weekly low-dose methotrexate therapy is usually the first DMARD used. Families may be overwhelmed by the potential adverse effects, including liver disease, bone marrow suppression, gastrointestinal disturbance, teratogenic effects, and the alarming but unconfirmed risk of carcinogenesis. Methotrexate is effective, however, and the potential benefits outweigh the potential risks. Methotrexate therapy has also improved uveitis in children with uveitis resistant to steroid treatment. Laboratory monitoring of liver enzyme levels and blood counts is crucial. A daily folic acid supplement can help reduce the occurrence of oral ulcers. Taking methotrexate at bedtime may help reduce nausea.

Frank discussion about sexual activity and birth defects is critical. Sexually active teenagers need effective birth control and documented menstrual periods, as well as pregnancy tests if periods are not regular. As a precaution, pregnant caregivers and those trying to conceive need to avoid contact with methotrexate.

Alcohol consumption is another sensitive topic that needs to be discussed honestly because it increases the risk of hepatotoxicity. Patients should avoid additional over-the-counter NSAIDs and to take acetaminophen for episodes of fever. Parents should always discuss methotrexate drug interactions with providers prescribing medications for interval illness. During some illnesses, especially varicella, methotrexate should be discontinued because it can suppress the immune response. Sulfasazaline may be selected in children with axial arthritis, a positive test result for HLA-B27, or symptoms of inflammatory bowel disease, given this drug's success in these select groups of patients.

Biologic DMARDs. Biologic DMARDs are initiated when there is significant disease activity and/or poor prognostic indicators after unsuccessful treatment with methotrexate. Tumor necrosis factor alpha inhibitors (TNF-α) are the most frequently used biologic DMARDs and include etanercept, infliximab, and adalimumab. Etanercept blocks the binding of TNF-α with cell surface receptors, while adalimumab and infliximab are monoclonal antibody TNF-α blocking agents. All three reduce the proinflammatory response that promotes arthritis. Studies have shown TNF-α inhibitors to be effective and well tolerated (Lovell, Ruperto, Goodman, et al, 2008; Stoll and Gotte, 2008).

Although TNF-α inhibitors have been found safe and effective, parents need to inform providers of any unusual symptoms in the child given the relatively limited experience with these drugs and the potential for long-term side effects (Burmester, Mease, Dijkmans, et al, 2009; Lovell, Reiff, Ilowite, et al, 2008). The potential for malignancy, particularly lymphoma, is continuing to be monitored in children on TNF blockers. Increased infection risk is the most common adverse effect. Parents should withhold TNF-α inhibitors during a concurrent infection and promptly report symptoms of infection to their provider for assessment and treatment. A negative tuberculin skin test should be obtained before starting a biologic DMARD; yearly follow-up skin testing has been suggested. Interleukin-1 receptor antagonist, anakinra, is another biologic antirheumatic drug. In active systemic disease with poor prognostic features, anakinra may be initiated with systemic glucocorticoid steroids as initial therapy. Anakinra is approved by the U.S. Food and Drug Administration for the adult rheumatoid arthritis population and is available off-label for children with systemic JIA.

Glucocorticoids. Glucocorticoids are potent anti-inflammatory agents; however, systemic steroids will not cure arthritis, and the significant adverse effects of long-term steroid use are undesirable. Steroids are administered when there is high disease activity or poor prognostic features. Prednisone is given orally in a burst and taper or at the lowest effective dosage. Use of an alternate-day schedule may help reduce side effects. High-dose IV steroids may provide sustained improvement for children with severe arthritis and pericarditis associated with systemic disease. Intraarticular injections of long-acting steroids have proven effective in treating limited arthritis with minimal adverse effects and frequently provided sustained control and, in some, a remission. Children may require procedural sedation or general anesthesia, which affects risk-benefit considerations, but it is critical to have a cooperative patient for good procedure outcome.

Physical Management

Programs of physical therapy are individualized for each child and are designed to reach the ultimate goal of preserving function and preventing deformity. Physical therapy is directed toward specific joints and focuses on strengthening muscles, mobilizing restricted joints, and preventing or correcting deformities. Occupational therapists assume responsibility of evaluating and improving performance of activities of daily living.

General treatment and maintenance programs vary. Physical therapists may be involved several times per week, or their visits may be limited to monthly evaluations to review the home program for compliance, effectiveness, and need. Muscle strength is frequently lost around the involved joints, and inactivity leads to generalized weakness. However, performance of the normal activities of daily living and the child's natural tendency to be active are usually sufficient to maintain muscle

strength and joint mobility. Unless there is a specific risk of injury related to arthritis, the child should not be restricted from regular play, dance, exercise programs, and even individual and team sports. Activity modifications may be needed to accommodate joint limitations, but exercise should be encouraged; a sedentary lifestyle contributes to a deconditioned state, which further limits physical activity and ultimately influences the child's quality of life (Klepper, 2008).

Exercising in a pool is excellent because it allows freedom of movement with support. When joints are inflamed, heavy resistance aggravates the pain. At such times, simple isometric or tensing exercises that do not involve joint movement are generally tolerated. Range-of-motion exercises are an important aspect of therapy and are continued after evidence of disease has disappeared in order to detect any signs of recurrence.

Providers may recommend nighttime splinting to help minimize pain and prevent or reduce flexion deformity. Vigilance is required to detect loss of motion, and vigorous attention must be given to specialized passive stretching, positioning, and resting splints to prevent deformity.

Surgery

The benefits of synovectomy, an established therapeutic procedure in adults, are questionable in children with arthritis. Synovectomy is used primarily in pauciarticular disease when all other therapy has been unsuccessful. In cases of synovitis, intraarticular steroid injection is an alternative to synovectomy and may be tried once or twice before surgery is performed. Joint replacement is proving to be successful in older children who are fully grown.

Nursing Care Management

Nursing care of children with JIA involves assessment of their general health, the status of involved joints, and their emotional responses to all of the ramifications of the disease: pain, physical restrictions, therapies, and self-concept, especially in preadolescents and adolescents.

The effects of the disease are manifested in every aspect of the child's life, including physical activities, social experiences, and personality development. Children's adjustment to the stresses and demands of the disease and the level of functioning they achieve are related largely to the reaction and support they receive from their family and the health care professionals involved in their care and management (see Nursing Care Plan box).

Relieve Pain

Multiple factors influence the pain of arthritis: disease severity, functional status, individual pain threshold, family variables, and psychologic adjustment. Although complete pain relief is desirable, it is probably unrealistic. The aim is to provide as much relief as possible with anti-inflammatory medication and other therapies to help children tolerate the pain and complete the activities of daily living. At present, opioid administration is not a routine therapy for the chronic pain of arthritis. Nonpharmacologic modalities such as relaxation may be helpful. (See Pain Management, Chapter 5.)

Promote General Strength

Diet and Exercise. The general health of children with arthritis and their siblings must be considered but may be overlooked as parents and health personnel concentrate on the disease. Maintenance of a well-balanced diet and assessment of nutritional status are integral parts of health supervision. A daily children's complete multivitamin with iron is a reasonable dietary supplement, but there is no "arthritis diet" or foods to avoid that are specifically associated with arthritis. Unfortunately children with arthritis have not been spared the nationwide obesity epidemic. After assessing the child growth chart, make a referral to a dietitian for children who are underweight or overweight due to malnutrition. Excessive weight causes additional strain on inflamed joints. Joint pain during or after exercise impedes active play, which perpetuates the vicious cycle of inactivity and weight gain. Encourage daily physical exercise, starting with a gradual program of walking and slowly advancing to more active play as tolerated. During the school year this can be accomplished with participation in physical education classes as tolerated. When school is out, parents and children should devise a family plan for exercise that includes a variety of options such as games, sports, dance, yoga, swimming, bike riding, and walking. This builds good habits for an active lifestyle for the entire family.

Sleep and Rest. Children with JIA report frequent disrupted nighttime sleep, daytime sleepiness, fatigue, and sleep anxiety (Bloom, Owens, McGuinn, et al, 2002). Restorative sleep is essential. Children should get 8 to 10 hours of nighttime sleep. Daytime naps are discouraged, especially because inactivity provokes stiffness and prolonged naps can interfere with sleepiness at bedtime. Fatigue should be handled with rest rather than sleep. Thirty to 60 minutes of relaxation—viewing television, reading, playing video games, using the computer, or listening to music—is refueling and less likely to disrupt nighttime sleep than a nap.

Encourage School Attendance

School-aged children should attend school, even on days when there is joint pain. Staying home will not improve arthritis. If joint pain and stiffness prevent school attendance, the rheumatologist should be notified and the child assessed. The rheumatology team can make recommendations to the school to maximize attendance and participation. Enlisting the school nurse to administer scheduled medications and as-needed analgesics such as acetaminophen for pain rescue will help keep the child at school. Requesting one set of books for use at home and one for the classroom eliminates heavy backpacks and subsequent strain on arthritic joints. The child's participation in the physical education program as tolerated is another way to maximize attendance and performance. If more extensive modifications to the school routine are indicated, the development of an individualized education plan for the school setting (see Chapter 19) may ensure that the child's needs are met. Examples of provisions included in such plans are half-day programs, special transportation, and in-school physical therapy. Although home teaching is rarely indicated, in some circumstances it is

NURSING CARE PLAN

The Child with Arthritis

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALE
• Chronic Pain related to joint inflammation **Child's/Family's defining characteristics** • (Subjective and Objective Data) • Verbal report of pain • Guarding behavior • Change in sleep pattern	• Child is able to move (joints) and complete activities of daily living with no or minimal discomfort. **The following NOC concepts apply to these outcomes:** • Pain Control • Pain Level • Comfort Status • Knowledge: Pain Management	• Use pain-rating scale to evaluate pain (discomfort) level. • Administer anti-inflammatory medications (nonsteroidal anti-inflammatory drugs [NSAIDs]) promptly on report of pain and around the clock when discomfort is acute. • Administer other drugs such as methotrexate or disease-modifying antirheumatic drugs (DMARDs) • Schedule routine rest periods throughout the day. • Encourage child to eat a well-balanced diet and exercise daily. • Help child set up a routine of daily exercise. • Encourage nonpharmacologic pain-relief remedies such as use of heat pad, moist heat, and pool therapy. • Encourage child to discuss effect of pain on lifestyle and activities. **The following NIC concepts apply to these interventions:** • Analgesic Administration • Pain Management • Medication Management	• To provide objective assessment of pain level • To manage pain and prevent breakthrough pain • To provide relief from inflammation • To prevent obesity and promote wellness • To prevent further joint stiffness • To promote mobility of joints and relieve painful stiff joints • To prevent excessive weight gain • To provide outlet for emotions such as anger, frustration, depression at having a chronic illness
• Impaired Physical Mobility related to pain and swelling in joints **Child's/Family's defining characteristics** • (Subjective and Objective Data) • Limited ability to perform fine and gross motor skills • Limited range of motion • Verbal report of pain • Measurable pain on pain scale	• Child engages in activities of daily living. **The following NOC concepts apply to these outcomes:** • Activity Tolerance • Knowledge: Illness Care • Knowledge: Treatment Regimen • Ambulation	• Encourage ambulation and performance of activities of daily living to maximum potential every day. • Assist with range-of-motion exercises for child who is severely limited. • Encourage child to be as active as tolerated. • Help with planning and encourage rest periods during the day. • Encourage child to take pain medication such as NSAIDs before ambulation and activity. • Use nonpharmacologic pain adjuncts such as heat pad and hydrotherapy. • Encourage child to be active in self-care activities to maximum potential. **The following NIC concepts apply to these interventions:** • Family Support • Positioning • Medication Management • Exercise Therapy: Joint Mobility	• To keep joints limber and prevent disuse contractures • To promote muscle movement and keep joints limber • To promote independence • To prevent fatigue • To promote activity with minimum pain • To decrease pain and encourage mobility of joints • To enhance self-worth and independence

necessary; it is initiated with the goal of returning the child to the classroom as soon as possible.

Facilitate Compliance

For any medical or physical plan of therapy to be effective, the family must agree to it and understand the benefits of treatment and the problems associated with noncompliance. Review a simple written list of exercise benefits and complications of joint immobility. At the outset, elicit barriers to a plan from the child and parents. If a child cannot swallow pills or refuses injections, the given modality is not acceptable. If parents know they cannot monitor or enforce a complicated medication and physical therapy schedule, the plan needs to be simplified to honestly reflect the actual care that is being provided. If joint range-of-motion exercises are too painful and emotionally difficult for parents to implement despite use of pretherapy analgesics and comfort measures, then physical therapy home visits or outpatient physical therapy sessions need to be considered.

In addition to developing a plan that is attainable, recognizing a child's adherence by providing inexpensive weekly or monthly rewards fosters goal setting and ultimately boosts self-esteem. It is not just the child who needs therapy rewards; the

nonprimary child care provider needs to step in and offer relief to the primary caregiver to prevent burnout, as well as to verbally acknowledge the extra parenting responsibilities being performed.

Everyone needs reminders; a simple written schedule of medications and physical therapy exercises should be provided and reviewed with the family at each visit.

Encourage Comfort Measures and Activities of Daily Living

Application of heat has been beneficial to children with arthritis. Moist heat is best for relieving pain and stiffness, and the most efficient and practical method is via the bathtub. Sometimes a daily whirlpool bath, paraffin bath, or hot packs may be used as needed for temporary relief of acute swelling and pain. Hot packs are easily applied at home using a towel that is wrung out after being immersed in hot water or heated in a microwave oven. Painful hands or feet can be immersed in a pan of warm water for 10 minutes two or three times daily as an adjunct to tub baths. A paraffin bath also provides relief to painful hands.

Pool therapy is the easiest method for exercising a large number of joints. Swimming activities strengthen muscles and maintain mobility in larger joints. Very small children who are frightened of the water can perform their exercises in the bathtub. Small children love to splash, kick, and throw things in the water.

Activities of daily living provide satisfactory exercise for older children to maintain maximum mobility with minimum pain. These children should be encouraged in their efforts and patiently allowed to dress and groom themselves, to assume daily tasks, and to care for their belongings. It is often difficult for stiff fingers to manipulate buttons, comb or brush hair, and turn faucets, but parents and other caregivers should not readily offer assistance. In addition, children should be helped to understand why others do not assist them. Many helpful devices, such as self-adhering fasteners, tongs for manipulating difficult items, and grab bars installed in bathrooms for safety, can be used to facilitate tasks. An elevated toilet seat often makes the difference between dependent and independent toileting, since weak quadriceps muscles and sore knees inhibit the ability to raise the body from a low sitting position.

A child's natural affinity for play offers many opportunities for incorporating therapeutic exercises. Throwing or kicking a ball, hanging from monkey bars, and riding a tricycle (with the seat raised to achieve maximum leg extension) are excellent moving and stretching exercises for a young child whose daily living activities are physically limited.

The Arthritis Foundation and the American Juvenile Arthritis Organization* (an organization within the Arthritis Foundation) provide information and services for both parents and professionals, and nurses can refer families to these agencies as an added resource.

The Child. For some, arthritis affects every aspect of the child's daily life. The physical pain and limitations interfere with performance of normal tasks and provision of self-care. Even simple tasks, such as dressing, combing the hair, using the bathroom, cutting food, climbing stairs, manipulating doors and faucets, and using public transportation, are difficult or impossible. The child may have school difficulties related to transportation to and from school, stair climbing, and loss of time as a result of exacerbations and hospitalization. Physical limitations interfere with participation in many activities, both curricular and extracurricular, which limits peer contacts and interaction and increases social isolation. These problems are especially critical for adolescents, for whom peer acceptance and relationships are vital to personality development. Many children with arthritis increasingly turn to solitary activities and to the family at a time when they are expected to move into greater independence and relationships with peers.

Changes in personality may accompany JIA, as with any chronic illness. These changes may be temporary, such as demanding, irritable behavior, or they may be persistent, such as passive hostility, uncommunicativeness, and manipulativeness. Families need confirmation that adjusting to a chronic illness is difficult. Consider and encourage support referrals to social workers, counselors, and psychologists. (See Chapter 19.)

The Family. The diagnosis of chronic arthritis is often frightening for the family, and its variable course with cycles of remission and exacerbation is discouraging. Many parents become susceptible to experimenting with unorthodox cures advanced by advertisers and well-meaning friends. Access to the Internet and more than 200 sites dedicated to arthritis provides families a welcome relief to the isolation of living with arthritis, but the Internet is also a bottomless source of unsubstantiated information that necessitates frank discussion and review with the family to help them sort out what is opinion versus fact and safe versus dangerous. Sometimes health care providers do not know the benefits or risks of a nutritional, herbal, or other complementary therapy. It is hoped that the new surge of legitimate scientific investigations of complementary alternative therapy will provide future answers.

Parents and patients need to hear that nurses promote independence. The child's participation in extracurricular activities, including play with friends, scouting, youth groups, dancing, and sports, is recommended. Nurses also support assigning children family chores and allowing older children to hold a part-time job, which foster self-reliance. Attendance at one of the several juvenile arthritis camps available to children with JIA is a confidence-boosting experience they will never forget.

Most of the reactions, problems, and concerns of families of a child with JIA are those of any parents of a child with a chronic illness or disability. The impact of the diagnosis is felt most acutely by the parents, who demonstrate anxiety, guilt, and all the manifestations of the grief process. The concerns and needs of these families are discussed extensively in Chapter 22, and the reader is directed to this chapter for additional guidance in planning care.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a chronic multisystem autoimmune disease of the blood vessels and connective tissue. The Lupus Foundation of America (2009) estimates that 1.5 million individuals have lupus, and 10% to 15% of these adults were diagnosed with SLE as children or adolescents. The prevalence of childhood SLE is reportedly 3.3 to 8.8 per 100,000 children (Levy and Kamphuis, 2012). It typically manifests between the ages of 10 and 19 years, and onset before age 5 years is unusual. There is a 4:3 female/male predominance in the first 10 years of life, which increases to 4:1 in the second decade.

Its course and symptoms are variable and unpredictable, with mild to life-threatening complications. SLE in children tends to be more severe at onset and has a more aggressive clinical course than adult-onset disease (Mina and Brunner, 2010; 2013). Other types of lupus erythematosus include chronic cutaneous lupus erythematosus (discoid lupus erythematosus), drug-induced lupus erythematosus, subacute cutaneous lupus erythematosus, and neonatal lupus erythematosus. Neonatal lupus erythematosus occurs when maternal autoantibodies cross the placenta and cause transient lupus-like symptoms in the newborn, with the potential lethal complication of heart block. The remaining discussion focuses on SLE.

Etiology

The cause of SLE is not known. It appears to result from a complex interaction of genetics with an unidentified trigger that causes the disease to activate. Suspected triggers include exposure to ultraviolet light, estrogen, pregnancy, infections, and drugs. Complement deficiencies C1q, C4, and C1s are associated with an increased risk of developing SLE. The major histocompatibility complex (MHC) Class II and III alleles are associated with an increased risk for developing SLE. There is a racial difference, with non-Caucasian children at increased risk of developing SLE.

Pathophysiology

SLE is the result of an abnormal immune response causing production of abnormal antibodies and formation of immune complexes. These immune complexes are deposited in tissues, causing inflammation and inciting other proinflammatory mediators that result in tissue injury and damage. Immune complex deposition in the glomerulus of the kidney causes lupus nephritis, a life-threatening complication of SLE. Almost any tissue in the body can be damaged by this abnormal inflammatory response, including the brain, heart, lungs, liver, gastrointestinal tract, spleen, joint tissues, muscles, and skin.

Clinical Manifestations

The onset of SLE can be insidious, with intermittent constitutional symptoms such as fever, fatigue, weight loss, and arthralgia. However, rapid involvement of vital organs, primarily the kidneys, can herald an accelerated course with potentially fatal outcome. Reports suggest that survival rates in children with SLE have significantly improved; 5-year survival rates are over 90%, and 10-year survival rates are close to 90% (Levy and Kamphuis, 2012; Ravelli, Ruperto, and Martini, 2005). Box 34-13 lists the manifestations related to the various tissues involved.

BOX 34-13 MANIFESTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

- **Constitutional**—Fever, fatigue, weight loss, anorexia
- **Cutaneous**—Erythematosus butterfly rash over bridge of nose and across cheeks, discoid rash, photosensitivity, mucocutaneous ulceration, alopecia, periungual telangiectasias
- **Musculoskeletal**—Arthritis, arthralgia, myositis, myalgia, tenosynovitis
- **Neurologic**—Headache, seizure, forgetfulness, behavior change, change in school performance, psychosis, chorea, stroke, cranial and peripheral neuropathy, pseudotumor cerebri
- **Pulmonary and cardiac**—Pleuritis, basilar pneumonitis, atelectasis, pericarditis, myocarditis, and endocarditis
- **Renal**—Glomerulonephritis, nephrotic syndrome, hypertension
- **Gastrointestinal**—Abdominal pain, nausea, vomiting, blood in stool, abdominal crisis, esophageal dysfunction, colitis
- **Hepatic, splenic, and nodal**—Hepatomegaly, splenomegaly, lymphadenopathy
- **Hematologic**—Anemia, cytopenia
- **Ophthalmologic**—Cotton wool spots, papilledema, retinopathy
- **Vascular**—Raynaud phenomenon, thrombophlebitis, livedo reticularis

Rash is a common feature in SLE. The erythematous malar "butterfly" rash that spares the nasolabial fold is a suggestive feature but not pathognomonic. Maculopapular rashes are frequent and can occur anywhere but typically are found on sun-exposed skin. Nails and hair can be involved, with red, cracked cuticles; periungual telangiectasia; and patchy or diffuse alopecia. Raynaud phenomenon, or spasm of the blood vessels, causes cool hands and feet with pain and a characteristic tricolor (purple- or blue-white-red) change. Raynaud phenomenon usually appears as a response to cold exposure and can cause significant tissue damage. In addition to color changes in the extremities, vascular necrosis and digital ulceration can occur. Arthritis and tenosynovitis are common in SLE. The arthritis is usually painful and typically of short duration; joint deformity is unusual.

Renal involvement is a serious complication caused primarily by deposition of circulating immune complexes in the glomerular basement membrane with cellular infiltrates. Lupus nephritis is usually asymptomatic; consequently, monitoring of urine and renal function is required to detect disease. Kidney biopsy is required for lupus nephritis classification. There are six classes, depending on the type and extent of the renal lesion. Specific treatment is based on the class of nephritis. Although outcomes have improved for children with renal disease, the course is difficult to predict. Most children improve, while some remain the same or progress to renal failure, requiring dialysis and transplantation.

Neuropsychiatric lupus is another serious complication found in approximately 25% of pediatric SLE patients. The majority of these children manifest central nervous system involvement within the first or second year of diagnosis

(Benseler and Silverman, 2007; Levy and Kamphuis, 2012). Symptoms can vary from manifestations as subtle as inability to concentrate to frank psychosis and seizure. Headaches are common with variable severity. Assess school performance and emotional stability at each visit as possible indicators of central nervous system involvement.

Cardiovascular disease results in significant mortality and morbidity in lupus. The immune dysregulation of SLE directly contributes to premature atherosclerosis. Children with SLE have an increased rate of dyslipidemia complicated by the secondary effects of corticosteroids (Sandborg, Ardoin, and Schanberg, 2008) Treatment includes exercise and dietary changes to promote a healthy weight, cardiovascular fitness, and management of hypertension. Studies are currently underway to assess the usefulness of statins in pediatric lupus for future evidence-based treatment of premature atherosclerosis in SLE.

Diagnostic Evaluation

SLE is a clinical diagnosis supported by specific abnormal results on laboratory tests. The American College of Rheumatology criteria for the classification of SLE in adults has a sensitivity of 96% and a specificity of 96% if 4 of the 11 criteria are present (Box 34-14). The SLE workup includes an extensive history taking and physical examination with inquiry about school performance and behavior change. Initial laboratory tests include complete blood count with differential; comprehensive metabolic chemistry panel; microscopic urinalysis; rapid plasma reagin test; quantitative determination of immunoglobulin levels; and tests for antinuclear antibodies, anti–deoxyribonucleic acid antibodies, complement 3 (C3), complement 4 (C4), lupus anticoagulant, and antiphospholipid antibodies.

A diagnosis of lupus should not be made without consideration of all medications being taken and their side effects. Some commonly used drugs such as minocycline, procainamide, hydralazine, and chlorpromazine can cause lupus-like symptoms. Minocycline, a common acne treatment, may not be considered important by the teenager and omitted from the history, so an accurate recent past and present medication history is essential for treatment. Drug-induced lupus resolves with time after the triggering medication has been discontinued (Tucker, 2007).

BOX 34-14 CLASSIFICATION CRITERIA FOR SYSTEMIC LUPUS ERYTHEMATOSUS*

- **Malar rash**—Fixed malar erythema
- **Discoid rash**—Patchy erythematous lesions
- **Photosensitivity**—Rash with sunlight exposure
- **Oronasal ulcers**—Painless ulcers in mouth and nose
- **Arthritis**—Swelling, tenderness, or effusion in two or more peripheral joints (nonerosive)
- **Serositis**—Pleuritis, pericarditis
- **Renal disorder**—Proteinuria, casts in urine
- **Neurologic disorder**—Psychosis, seizures
- **Hematologic disorder**—Hemolytic anemia, thrombocytopenia, leukopenia, lymphopenia
- **Immunologic disorder**—Anti–double-stranded deoxyribonucleic acid, anti-Sm, antiphospholipid antibodies; lupus anticoagulant; false-positive result on syphilis test (rapid plasma reagin)
- **Antinuclear antibodies**—presence of antinuclear antibody by immunofluorescence or an equivalent assay

*The presence of four criteria is required for classification as systemic lupus erythematosus.

Therapeutic Management

There is no cure for SLE; the management goal is to reverse or minimize disease activity with appropriate medications while helping the child and family cope with the complications of the disease and treatment.

Medications

Since the 1950s, corticosteroids have been the mainstay of SLE therapy. They are effective anti-inflammatory and immunosuppressive agents. Unfortunately, the use of steroids is hampered by side effects, which include growth delay, decreased resistance to infection, osteoporosis, weight gain, hypertension, development of cushingoid features and cataracts, and diabetes risks. Generally, a dosage sufficient to control symptoms is prescribed, and then the dosage is tapered to the lowest level possible to achieve an acceptable balance between disease activity and steroid side effects. For severe disease, IV pulse (high-dose) steroids are given on an intermittent schedule, which may allow reduction in the daily steroid dose with better compliance and fewer cushingoid features. Topical steroids are used for cutaneous lesions, but prolonged therapy thins the skin; consequently, facial application needs to be brief or with medication of lower concentration. Because of increased immunosuppression with steroid use, a tuberculin skin test should be performed before starting steroid therapy, especially in high-risk communities. A medical identification tag should be worn by children undergoing chronic steroid therapy so that administration of stress steroids can be considered in emergency situations.

Other medications used include NSAIDs such as naproxen and ibuprofen for pain associated with arthritis, arthralgia, and myalgia. Nurses need to instruct patients to take NSAIDs with food to help prevent gastrointestinal side effects. Hydroxychloroquine, an antimalarial drug, is an effective therapy for skin and joint manifestations. Possible untoward effects include skin, gastrointestinal, and retinal toxicity. A complete ophthalmologic examination is indicated before treatment begins and every 6 to 12 months thereafter. Methotrexate may be used in patients with stubborn arthritis that has not responded to NSAIDs and hydroxychloroquine and allows a lower dose of glucocorticoids to be used. Azathioprine, another steroid sparer, has been useful in treatment of SLE thrombocytopenia. Both methotrexate and azathioprine have significant potential adverse effects, including potential for increased infection, malignancy risks, liver and lung toxicity, and birth defects. Well-documented discussions of these risks with patients and parents are required.

Cyclophosphamide, a potent immunosuppressive chemotherapy agent, used in combination with corticosteroids, is

effective in treating proliferative lupus nephritis and neuropsychiatric lupus. A detailed cyclophosphamide education session should be held for patient and family to clearly describe potential benefits and risks, including infertility and future malignancy.

Mycophenolate mofetil, a purine inhibitor, has been used with success in adult lupus nephritis and is currently being used as a steroid-sparing agent in active pediatric lupus and as maintenance therapy after standard cyclophosphamide treatment for lupus nephritis. It is also being evaluated as an alternative to standard treatment of lupus nephritis with cyclophosphamide (Paredes, 2007). Mycophenolate mofetil is an attractive alternative, if successful, because it is less toxic and better tolerated than cyclophosphamide; however, it is not without potential side effects, including increased infection risk, liver toxicity, and birth defects. Sexually active females need to be on effective birth control.

New biologic treatments are being developed that focus on the immune dysregulation in SLE, cancer, and other autoimmune diseases. Belimumab is an IgG1-lambda monoclonal antibody that reduces the activity of B cell–mediated immunity and the autoimmune response by blocking receptors on B lymphocytes. It has been approved in adults with SLE and may be used off-label in select pediatric lupus, while pediatric studies are ongoing (Furie, Petri, Zamani, et al, 2011). Rituximab is a monoclonal antibody that eliminates CD20-positive B cells without affecting early B cells or plasma cells. This results in decreased antibody formation and has been used off-label in pediatric lupus patients who have not responded to standard therapy (Nwobi, Abitbol, Chandar, et al, 2008). Individuals with neuropsychiatric involvement may require antidepressants, psychotropics, and antiepileptic drugs (Levy and Kamphuis, 2012).

General Measures

In addition to medication, treatment includes general measures such as patient and family education, rest and exercise, proper diet, sun avoidance, and social support. SLE is complex and requires ongoing patient education. Families and patients need up-to-date, understandable information so they can become informed decision makers and participate in disease management. Nurses are duty bound to discuss with families any information they bring to appointments from the Internet, friends, and family. As health care providers critically evaluate disease information with families, families learn the skills needed to become self-advocates. Families also want to hear about the impact of SLE on growth and development, childbearing, schooling, and career choice. The message should be optimistic and clear, with few exceptions: "Prepare for the future; you will attend school, graduate, have children, and work."

Diet, exercise, and rest are the daily elements under direct patient control. The family needs to maximize the power of these normal functions to their benefit. There is no specific SLE diet, but a balanced diet that does not exceed calorie expenditure is essential for maintaining appropriate weight on corticosteroid therapy. A low-salt diet may be required if the patient becomes nephrotic or hypertensive. A low-fat diet is indicated in children with dyslipidemia. Maximizing peak bone mass in adolescent SLE is essential, especially since both SLE and its treatment with glucocorticoids increase the risk of osteoporosis. A diet rich in calcium and vitamin D is essential to prevent osteoporosis. If dietary calcium is not sufficient, calcium and vitamin D supplements need to be recommended. Consultation with a registered dietitian will help the family develop an individualized diet that meshes with their lifestyle.

The benefits of a regular exercise program include weight maintenance, cardiovascular fitness, and osteoporosis prevention, all of which help minimize SLE complications and corticosteroid side effects. Unfortunately many children stop participation in sports after diagnosis. Children with SLE report more fatigue and have lower aerobic fitness (Houghton, Tucker, Potts, et al, 2008). Encourage continuation of sports and recreational activities, if possible; if not, try to modify the activity or find alternatives to encourage the child and parents to view daily exercise as an essential part of the treatment plan and a continuation of the child's normal lifestyle. Additional rest is necessary during disease exacerbations but not to the extent that it interferes with regular sleep patterns.

A photosensitive rash is common, and the dangers of excessive ultraviolet A and B light exposure (including exposure to uncovered fluorescent lights) need to be stressed. This can be a sensitive topic for sun-loving teenagers and outdoor athletes. Discuss the use of sunscreen (with an SPF [sun protection factor] ≥30), hats, and protective clothing. Cosmetics and moisturizers that contain sunscreen are attractive options for adolescent girls. One useful rule to share with the adolescent who may be surrounded by peers who regularly seek out sun exposure is the "slip, slop, slap" rule: slip on a shirt, slop on sunscreen, and slap on a hat before going out in the sun. (See Chapter 18.) Scheduling outdoor activities in the morning and evening can reduce exposure without limiting participation in recreational activities. Make every effort to encourage children to participate in peer activities and to make sun-shielding modifications as inconspicuous as possible.

Social support from family, friends, teachers, counselors, and professional social workers and therapists can help the child and family through difficult times and promote adaptation to an illness that is not going to go away. Destructive coping mechanisms need to be identified and replaced with behaviors that enhance adaptation and healthy outcomes. Organizations that can help children and families learn about and adjust to the disease are the Lupus Foundation of America* and the Arthritis Foundation† (see p. 1607).

Nursing Care Management

Fostering adaptation and self-advocacy is the primary nursing goal. Patient and family acceptance and understanding of this life-threatening and therapeutically intrusive disease are big challenges for any nurse. Patient education is started at

*2000 L St. NW, Suite 710, Washington, DC 20036; 202-349-1155; fax: 202-349-1156; **www.lupus.org**.

†A recommended booklet available from the Arthritis Foundation is *Meeting the Challenge: A Young Person's Guide to Living with Lupus.*

diagnosis and continued at every opportunity; repetition is good. Encourage family members to call with questions and concerns. Advise patients to write down their questions so they are prepared during the appointment. Consider adolescent development, with heightened concerns about body image and looking different. The nurse should be open about this. Skin care, cosmetics, and unobtrusive moisturizers with sunscreen and sunblock should be discussed.

Weight gain is an emotional issue, and it must be approached honestly with a workable plan for family dietary changes and a realistic exercise program. The nurse should work with a dietitian and a trainer or physical therapist to individualize a nutrition and fitness program for the child. A parent or sibling should be involved in the program, so the child does not feel that restrictions are punitive.

With older children, sexual activity and birth control must be discussed; birth defects are associated with mycophenolate and methotrexate. Additionally, pregnancy is a potential trigger for disease flare. Honest discussion about healthy, responsible reproductive choices with both the teenager and parents is important for establishing communication. The parents and teenager should know that the teenager can come to the nurse with reproductive concerns. Because estrogen can trigger disease flare, low-dose estrogen or progestin-only oral contraceptives are preferred. Some teenagers choose the compliance-friendly Depo-Provera (medroxyprogesterone) 3-month injections. Again, frank discussion about risks and benefits is essential.

Prevention of infection includes hand washing (especially at school) and preprocedure antibiotic coverage for routine events such as dental cleaning. Immunization vaccinations should be maintained in SLE, except live vaccines should be withheld in patients on immunosuppressive therapy.

To compensate for the side effects of some drugs, such as the corticosteroids, teenagers often go on fad or starvation diets. It is critical that nutritional counseling be available to ensure that the adolescent understands the role that a healthy diet plays in the management of SLE. School attendance may decrease because of loss of self-esteem, depression, feelings of inadequacy, or poor academic performance. Assessment of common adolescent risk-taking behaviors, including tobacco and recreational drug use, needs to be performed as it would for any teenage patient. Treatment compliance is a significant issue in adolescence, especially given the medication side effects and restrictions on sun exposure. Adolescents need to understand what the function of each drug is, how each drug helps to manage the disease, and what effect missing doses may have on their health. The nurse needs to keep track of prescription refills to evaluate compliance and medication efficacy. Barriers to medication compliance should be investigated, and patients should be helped to devise a workable plan. If friends are going to the beach, the patient should consider going late in the day with a beach umbrella, sunblock, and a wide-brim hat. Give instructions to reapply sunblock after swimming and to limit time in direct sun. (See Chapter 18.)

Teaching patients how to find ways to adapt positively to SLE with normal growth and development as the goal will give them self-advocacy skills. Nurses should apply the principles of adjusting to a chronic illness that are discussed in Chapter 19.

NCLEX REVIEW QUESTIONS

1. The potential physiologic and psychologic effects of prolonged immobilization on a 9-year-old child who has experienced significant trauma in a motor vehicle crash include which of the following? Select all that apply.

A. Orthostatic intolerance
B. Deep vein thrombosis
C. Pressure ulcer formation
D. Pneumonia
E. Diarrhea
F. Kidney stones
G. Sense of euphoria and elation
H. Constipation

2. A 12-year-old who was in an ATV accident has a long-leg fiberglass cast on his left leg for a tibia-fibula fracture. He requests pain medication at 2:00 AM for pain he rates at a 10/10 on the Numeric Scale. The nurse brings the pain medication and notes that he has removed the pillows that kept his leg elevated. He complains of pain in the left foot, and she notes that there is 3+ edema in the exposed leg and foot and she is unable to slip a finger under the cast. The nurse's priority interventions in this situation should include:

A. Administer the pain medication and elevate the child's leg on the pillows
B. Elevate the leg on the pillows and follow up within 2 to 3 hours to see if the edema has decreased
C. Let the child know he cannot have any additional pain medication until 6:00 AM
D. Notify the surgeon of the findings immediately

3. Disordered eating patterns, which may be observed in the female athlete triad, may include which of the following? Select all that apply.
   - **A.** Use of diet pills and laxatives
   - **B.** Fasting
   - **C.** Binge eating
   - **D.** Restriction of certain foods
   - **E.** Inadequate caloric intake
   - **F.** Excessive vitamin consumption
4. Following the sudden death of a 14-year-old seemingly healthy basketball player, his parents ask the school administration to install an automatic external defibrillator (AED) in a central area of the athletic center. The school nurse is asked to participate in a meeting with the parents in which the administrators insist such a device is not necessary. The school nurse advocates by providing which information about AEDs and children?
   - **A.** An AED should be used only by health care persons trained in its use.
   - **B.** An AED provides too much of an energy shock dose for children under 12 years of age.
   - **C.** An AED can be effective in the resuscitation of a child or adolescent with a shockable rhythm.
   - **D.** An AED is more commonly used in adults who have heart attacks than in children with undiagnosed heart conditions.
5. A 2-day-old infant in the newborn nursery is diagnosed with developmental dysplasia of the hip, and treatment is started by the orthopedist. The nurse assists the parents by providing home care instructions that include:
   - **A.** Return to the orthopedist's office in 2 weeks to remove the hip spica cast
   - **B.** The infant's bilateral foot casts should be elevated on pillows as much as possible
   - **C.** Remove the Pavlik harness once a day for no more than 2 hours and inspect skin
   - **D.** Remove the Pavlik harness while the infant is awake to allow "tummy time"

Correct Answers
1. A, B, C, D, F, H
2. D
3. A, B, D, E
4. C
5. C

NEUROMUSCULAR DYSFUNCTION

Weakness or abnormal skeletal muscle function may represent a defect in the muscle itself or reflect a pathologic disorder at some point along the neural pathway from the cortex of the brain to the neuromuscular junction. Identifying the source of muscular dysfunction includes not only the testing of muscle function but also the systematic elimination of possible disorders of neural structures on which muscle function depends for its stimulus. In a few disorders muscle disease may be accompanied by a neural disorder.

Some clinical features are shared by muscle disease (**myopathy**), which differs in many ways from muscular dysfunction resulting from disorders of neuronal structures—brain, cranial nerve nuclei, long nerve tracts, anterior horn cells of the spinal cord, and peripheral nerves. Motor function is accomplished by means of the simple reflex arcs or by way of impulses transmitted from the cerebral cortex and other centers in the brain through the various nerve pathways of the central nervous system (CNS). The **upper motor neurons** consist of cells that lie in the cerebral cortex and fibers that traverse the brainstem and spinal cord to terminate at their synapses with the anterior horn cells. The **lower motor neurons** consist of the anterior horn cells, axons, and peripheral nerve branches. The motor unit consists of the lower motor neuron, the neuromuscular (or myoneural) junction, and the muscle fibers it supplies (Fig. 35-1). The upper motor neuronal pathways from the cerebrum to the lower motor neuron are described as (1) **pyramidal**—those whose fibers extend from the cortex, come together in the medulla, cross from one side to the other, then extend down the cord to synapse with anterior horn motor neurons; and (2) **extrapyramidal**—a complex network of motor neurons that comprise relays between motor areas of the cortex, basal ganglia, thalamus, cerebellum, and brainstem.

CLASSIFICATION AND DIAGNOSIS

The site of pathologic disturbance determines the type of muscular dysfunction. In general, upper motor neuron lesions produce weakness associated with spasticity, increased deep tendon reflexes, and abnormal superficial reflexes. The primary disorder of upper motor neuron dysfunction is cerebral palsy (CP). Lower motor neuron lesions interrupt the reflex arc, causing weakness and atrophy of the skeletal muscles involved with associated hypotonia or flaccidity, which eventually progress to atrophy with varying degrees of contracture deformity. A disorder of the extrapyramidal pathway and the cerebellum rarely produces muscle weakness.

Lower motor neuron involvement is usually symmetric (except that of poliomyelitis and single peripheral nerve

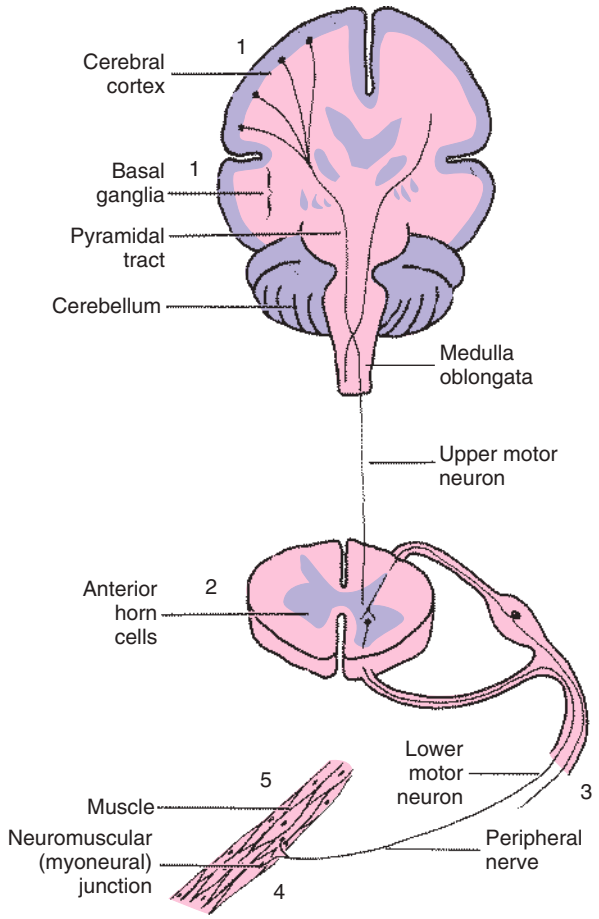

FIG. 35-1 Site of origin for neuromuscular disorders. *1,* Cerebral palsy; *2,* poliomyelitis, spinal muscular atrophy; *3,* mononeuropathies, polyneuropathies; *4,* myasthenia gravis, neurotoxic disorders; *5,* muscular dystrophies.

disease), whereas disorders of the pyramidal tract are more often asymmetric. Muscle wasting is characteristic of lower motor neuron lesions and more marked than in diseases of muscles. Deep tendon reflexes are briskly active in upper motor neuron disease, are diminished or absent in lower motor neuron disease, and depend on the progress of muscle degeneration in the myopathies.

These disorders can also be categorized according to onset: those in which there is acute onset of flaccid paralysis and those with more gradual onset and progressive degeneration. In most instances the sudden appearance of flaccid paralysis in a previously healthy child is due to an infectious process. Neurotoxins (e.g., botulism, tick paralysis, or heavy metal poisoning), pressure on the spinal cord from tumors or abscesses, and spinal cord injury (SCI) are less likely causes. Hereditary factors and metabolic disease are more often responsible for muscular weakness and atrophy of gradual onset.

Classification

The most useful classification of neuromuscular disorders is one that defines the site of origin of the pathologic lesion: the anterior horn cells of the spinal cord, the peripheral nerves, the neuromuscular junction, and the muscles.

Diseases of Anterior Horn Cells

Diseases and disorders that affect the anterior horn cells are the result of destruction or atrophy of the anterior horn of the spinal column along with the inability to transfer impulses from sensory neurons to motor neurons. Enteroviruses, which have a worldwide distribution, are prominent etiologic agents that selectively affect anterior horn cells. These include the nonpolioviruses, of which there are several types: human enterovirus A, B, C, and D, and the human parechoviruses 1 and 2 (Centers for Disease Control and Prevention, 2010). Inherited disorders, primarily the spinal muscular atrophies, cause degeneration of the anterior horn cells.

Neuropathies

Disorders affecting peripheral nerves may be **mononeuropathies**, which involve a single nerve and the muscles it innervates, or **polyneuropathies**, which involve multiple nerves and the muscles they supply. Neuropathies are caused by a number of hereditary diseases, traumatic injuries, infections, poisons, and (secondarily) some metabolic diseases. Polyneuropathy can be restricted to specific areas (as in diabetes mellitus). Some hereditary diseases involve skeletal muscles extensively. The distal limbs (feet and hands) are usually affected first, with gait disturbance and footdrop being early manifestations. The involvement gradually progresses proximally as the disorder becomes more severe.

In some polyneuropathies there is segmented or patchy loss of the myelin sheath of nerve fibers; in others the primary process appears to be progressive degeneration of nerve fibers. Examples of acute and chronic polyneuropathies are Guillain-Barré syndrome (infectious polyneuritis) and Charcot-Marie Tooth disease (peroneal muscular atrophy), respectively.

Neuromuscular Junction Disease

Disorders involving a neurohormonal deficiency interfere with transmission of nerve impulses to muscles at the neuromuscular junction. Normally nerve impulses are transmitted to skeletal muscles across the neuromuscular junction by acetylcholine. This is accomplished in three steps: (1) acetylcholine is released from vesicles in the terminal nerve endings; (2) it then diffuses across the junction and contacts receptor sites in the muscle membrane, stimulating the muscle to contract; and (3) it is removed by the action of cholinesterase. Interference at any of these three steps will block transmission of nerve impulses and prevent muscular contraction.

Several toxic substances act at the neuromuscular junction to inhibit nerve impulses to the skeletal muscles. Examples of toxins that prevent the release of acetylcholine are those that produce the paralysis of botulism and tick paralysis. Action at receptor sites is also blocked by the drug curare. Paralysis resulting from inhibition of cholinesterase release is caused by poisoning with organic phosphate insecticides.

Diseases of Muscles

Diseases of skeletal muscles can be inflammatory (such as polymyositis), the result of endocrine dysfunction (such as

hypothyroidism and hyperthyroidism), or the result of congenital defects (e.g., absence of muscle, periodic paralysis, and the various muscular dystrophies [MDs] and myotonias). Inflammation occurs in a number of infectious illnesses such as trichinosis, toxoplasmosis, and those caused by the enteroviruses (coxsackieviruses and echoviruses).

Diagnostic Tools

Several general diagnostic tools aid in differentiating diseases with similar manifestations. In addition, a number of more definitive tests are used to establish a specific diagnosis. The neurologic examination is a basic test that helps assess the extent of motor and sensory function.

The electromyogram (EMG) measures the electric potentials generated in individual muscles. A small metal disk is placed on the skin overlying the muscle to be tested, or a sterile needle electrode is inserted directly into the muscle. The electric activity generated in the skeletal muscles is measured at rest, with slight voluntary contraction, and with maximum contraction. The electric activity is amplified and displayed on a cathode ray oscilloscope. Needle electrodes are sensitive enough to pick up the activity of a single muscle fiber; thus this is usually the method of choice. However, the procedure is traumatic for children. It is often not useful because it requires cooperation. A topical anesthetic should be considered to decrease pain. Nerve conduction velocity, or the velocity of electric impulse conduction along motor or sensory nerves, is often measured in conjunction with the EMG. Certain diseases affect the peripheral nerves, prolonging the conduction time from the point of stimulation of the nerve to the muscle and increasing the duration of the evoked potential of the muscle.

Muscle biopsy may be used to confirm and classify muscle disorders. The vastus lateralis is the most commonly sampled muscle. Procedural sedation may be accomplished with a number of medications used singly or in combination: midazolam and morphine; ketamine and midazolam; pentobarbital; etomidate; inhaled nitrous oxide; or midazolam and fentanyl. (See Surgical Procedures, Chapter 23.) Serum enzyme measurements are helpful in diagnosing and monitoring the course of muscular disease, but these are used as adjuncts in the diagnosis of most neuromuscular diseases. The intracellular enzyme creatine (phosphokinase) kinase (CK) is present in muscle tissues, including cardiac muscle, and the brain. It is released in large amounts in some muscular diseases, such as MD. CK is not elevated in neurogenic disease. Genetic testing is becoming increasingly valuable in the diagnosis of many neuromuscular conditions and may make muscle biopsies less necessary. Because of the increasing complexities of choosing appropriate genetic tests, genetic counseling may be appropriate.

CEREBRAL PALSY

Cerebral palsy (CP) has been defined as a "group of permanent disorders of the development of movement and posture, causing activity limitation, that are attributed to nonprogressive disturbances that occurred in the developing fetal or infant brain" (Rosenbaum, Paneth, Leviton, et al, 2007). In addition to motor disorders, the condition often involves disturbances of sensation, perception, communication, cognition, and behavior; secondary musculoskeletal problems; and epilepsy (Rosenbaum, Paneth, Leviton, et al, 2007). The etiology, clinical features, and course vary and are characterized by abnormal muscle tone and coordination as the primary disturbances. It is the most common permanent physical disability of childhood, and the incidence is reported to range from 2.4 to 3.6 in 1000 live births in various studies in the United States (Hirtz, Thurman, Gwinn-Hardy, et al, 2007; Yeargin-Allsopp, Van Naarden Braun, Doernberg, et al, 2008). One systematic review and meta-analysis indicated a prevalence of 2.11 per 1000 live births, with the highest prevalence among infants born weighing 1000 grams to 1499 grams at birth; the prevalence of CP was higher among infants born prior to completion of 28 weeks' gestation (Oskoui, Coutinho, Dykeman, et al, 2013). In the 1960s the prevalence of CP rose approximately 20%, which most likely reflected the improved survival of extremely low-birth-weight (ELBW) and very low-birth-weight (VLBW) infants. However, in the past 2 decades there has been a decrease in the incidence of CP among ELBW and VLBW infants (Hack and Costello, 2008). The incidence is higher in males than females and more likely to occur in African Americans than in Caucasian or Hispanic children (Centers for Disease Control and Prevention, 2013).

Etiology

A variety of prenatal, perinatal, and postnatal factors contribute to the development of CP, singly or multifactorially (Box 35-1). The human brain undergoes development during the prenatal period and up to 2 years of age. A brain insult or injury occurring during this period may result in CP.

Although the prevalent traditional hypothesis has been that CP results from perinatal problems, especially birth asphyxia, it is now believed that CP results more often from existing *prenatal* brain abnormalities. However, the exact cause of these abnormalities remains unknown. It has been estimated that as many as 70% to 80% of the cases of CP are caused by unknown prenatal factors (Johnston, 2011; Krigger, 2006). Intrauterine exposure to maternal chorioamnionitis is associated with an increased risk of CP in infants of normal birth weight and preterm infants (Hermansen and Hermansen, 2006; Shatrov, Birch, Lam , et al, 2010); however, not all term infants exposed to chorioamnionitis develop CP.

In general, infants exposed to maternal and perinatal infections are at increased risk for the development of CP as a result of the effects on the developing brain. Although CP occurs in term births, preterm birth of ELBW and VLBW infants continues to be the single most important risk factor for CP. Still, in some cases no identifiable cause is determined. Periventricular leukomalacia and intracerebral hemorrhage in low-birth-weight infants are significant risk factors in the development of CP. Perinatal ischemic stroke is also associated with a later diagnosis of CP (Golomb, Saha, Garg, et al, 2007). One study found a higher risk for CP occurring among infants born at 42 weeks' gestation or later than among those born at 37 or 38 weeks' gestation (Moster, Wilcox, Vollset, et al, 2010). Additional factors that may contribute to the development of CP

BOX 35-1 ETIOLOGIC RISK FACTORS FOR CEREBRAL PALSY

Prenatal

Maternal

Diabetes mellitus or hyperthyroidism
Exposure to radiation or toxins
Malnutrition
Seizure disorder or cognitive impairment
Infections
Incompetent cervix
Bleeding
Polyhydramnios
Genetic abnormalities
Previous child with development disabilities
Previous premature birth
Previous fetal loss
Medication use (e.g., thyroid, estrogen, progesterone)
Inflammatory response
Severe proteinuria

Gestational

Chromosome abnormalities
Genetic syndromes
Teratogens
Rh incompatibility
Infections
Congenital malformations
Fetal development abnormalities
Problems in placental functioning
Inflammatory response

Labor and Delivery

Premature delivery
Prolonged rupture of membranes
Prolonged fetal heart rate depression
Abnormal presentation
Long labor
Preeclampsia
Asphyxia

Perinatal

Prematurity and associated problems
Sepsis and/or central nervous system infection
Seizures
Intraventricular hemorrhage
Periventricular leukomalacia
Meconium aspiration
Number of days on mechanical ventilation
Persistent pulmonary hypertension
Intrauterine growth restriction
Low birth weight
Perinatal stroke
Unknown

Childhood or Postnatal

Brain injury
Meningitis or encephalitis
Toxins
Traumatic brain injury
Infections
Stroke

Unknown

Unknown prenatal factors that contribute to the development of CP; possibly as many as 70% to 80% of CP (Krigger, 2006)

From Jackson PL, Vessey JA, Schapiro NA, editors: *Primary care of the child with a chronic illness,* ed 5, St. Louis, 2010, Mosby.

postnatally include bacterial meningitis, multiple births, viral encephalitis, motor vehicle accidents (MVCs), and child abuse (shaken baby syndrome [traumatic brain injury]). One study found that 10% to 15% of children with CP acquired the condition after birth from causes such as falls, motor vehicle crashes, and infections such as meningitis (Centers for Disease Control and Prevention, 2013). A significant percentage (15% to 60%) of children with CP also have epilepsy. In summary, as many as 80% of the total cases of CP may be linked to a perinatal or neonatal brain lesion or brain maldevelopment, regardless of the cause (Krageloh-Mann and Cans, 2009). A number of biochemical disorders may cause motor abnormalities often seen in CP and may be initially misdiagnosed as CP (Nehring, 2010).

Pathophysiology

It is difficult to establish a precise location of neurologic lesions on the basis of etiology or clinical signs because there is no characteristic pathologic picture. In some cases, there are gross malformations of the brain. In others, there may be evidence of vascular occlusion, atrophy, loss of neurons, and laminar degeneration that produce narrower gyri, wider sulci, and low brain weight. Anoxia appears to play the most significant role in the pathologic state of brain damage, which is often secondary to other causative mechanisms.

There are a few exceptions. In some cases, the manifestations or etiology is related to anatomic areas. For example, CP associated with preterm birth is usually spastic diplegia caused by hypoxic infarction or hemorrhage with periventricular leukomalacia in the area adjacent to the lateral ventricles. The athetoid (extrapyramidal) type of CP is most likely to be associated with birth asphyxia but can also be caused by kernicterus and metabolic genetic disorders such as mitochondrial disorders and glutaricaciduria (Johnston, 2011). Hemiplegic (hemiparetic) CP is often associated with a focal cerebral infarction (stroke) secondary to an intrauterine or perinatal thromboembolism, usually a result of maternal thrombosis or hereditary clotting disorder (Johnston, 2011). Cerebral hypoplasia and sometimes severe neonatal hypoglycemia are related to ataxic CP. Generalized cortical and cerebral atrophy often cause severe quadriparesis with cognitive impairment and microcephaly.

Clinical Classification

A revision of the Winter classification was proposed in 2005 to reflect the child's actual clinical problems and their severity, an

assessment of the child's physical and quality-of-life status across time, and long-term support needs (Bax, Goldstein, Rosenbaum, et al, 2005; Nehring, 2010). The proposed new definition has four major dimensions of classification (Bax, Goldstein, Rosenbaum, et al, 2005):

- **Motor abnormalities**—Nature and typology of the motor disorder; functional motor abilities
- **Associated impairments**—Seizures; hearing or vision impairment; attentional, behavioral, communicative, and/or cognitive deficits; oral motor and speech function
- **Anatomic and radiologic findings**—Anatomic distribution or parts of the body affected by motor impairments or limitations; radiologic findings sometimes including white matter lesions or brain anomaly noted on computed tomography (CT) or magnetic resonance imaging (MRI)
- **Causation and timing**—Identification of a clearly identified cause such as a postnatal event (e.g., meningitis, traumatic brain injury)

CP has four primary types of movement disorders: spastic, dyskinetic, ataxic, and mixed (Box 35-2) (Nehring, 2010). The most common clinical type, spastic CP (77.4 % reported by the Centers for Disease Control and Prevention, 2013), represents an upper motor neuron muscular weakness. The reflex arc is intact, and the characteristic physical signs are increased stretch reflexes, increased muscle tone, and (often) weakness. Early neurologic manifestations are usually generalized hypotonia or decreased tone that lasts for a few weeks or may extend for months or even as long as a year.

Clinical Manifestations

The alert observer may suspect CP when a child demonstrates some of the groups of manifestations in Box 35-3.

Delayed Gross Motor Development

Delayed gross motor development is a universal manifestation of CP. The child shows a delay in all motor accomplishments, and the discrepancy between motor ability and expected achievement tends to increase with successive developmental milestones as growth advances. It is especially significant if other developmental behaviors, such as language and personal-social achievement, are normal. Delayed development of the ability to balance may also slow the progression of milestones.

Abnormal Motor Performance

Neuromotor dysfunction is particularly evident in motor performance. An early sign is preferential unilateral hand use that may be apparent at approximately 6 months of age. Hand dominance does not normally develop until the preschool years. Abnormal crawling with propulsion by hand movements only and with lower extremities and hips hiked along, much like a "bunny hop," occurs in diplegia. Children with hemiplegia have an asymmetric crawl, using the unaffected arm and leg to propel themselves on either the buttocks or the abdomen. Spasticity may cause the child to stand or walk on the toes. Uncoordinated or involuntary movements are characteristic of dyskinetic CP, and facial grimacing and writhing movements of the tongue, fingers, and toes are signs of athetosis. Other significant signs of motor dysfunction are poor sucking and feeding difficulties, with persistent tongue thrust. Head staggering, tremor on reaching, and truncal ataxia are also common. Hand preference in the first 2 years of life is reported to be a sign of hemiplegic CP (Berker and Yalçin, 2008).

Alterations of Muscle Tone

Increased or decreased resistance to passive movements is a sign of abnormal muscle tone. The child may exhibit opisthotonic postures (exaggerated arching of the back) and may feel stiff on

BOX 35-2 CLINICAL CLASSIFICATION OF CEREBRAL PALSY

Spastic (Pyramidal)

- Characterized by persistent primitive reflexes, positive Babinski reflex, ankle clonus, exaggerated stretch reflexes, eventual development of contractures
- Seventy percent to 80% of all cases of cerebral palsy (CP)
- **Diplegia**—All extremities affected; lower more than upper (30% to 40% of spastic CP)
- **Tetraplegia**—All four extremities involved: legs and trunk, mouth, pharynx, and tongue (10% to 15% of spastic CP)
- **Triplegia**—Three limbs involved
- **Monoplegia**—Only one limb involved
- **Hemiplegia**—Motor dysfunction on one side of the body; upper extremity more affected than lower (20% to 30% of spastic CP)
- Hypertonicity with poor control of posture, balance, and coordinated motion
- Impairment of fine and gross motor skills

Dyskinetic (Nonspastic, Extrapyramidal)

- **Athetoid**—Chorea (involuntary, irregular, jerking movements); characterized by slow, wormlike, writhing movements that usually involve the extremities, trunk, neck, facial muscles, and tongue
- **Dystonic**—Slow, twisting movements of the trunk or extremities; abnormal posture
- Involvement of the pharyngeal, laryngeal, and oral muscles causing drooling and dysarthria (imperfect speech articulation)

Ataxic (Nonspastic, Extrapyramidal)

- Wide-based gait
- Rapid, repetitive movements performed poorly
- Disintegration of movements of the upper extremities when the child reaches for objects

Mixed Type

- Combination of spastic CP and dyskinetic CP
- May be labeled *mixed* when no specific motor pattern is dominant; however, this term losing favor to more precise descriptions of motor function and affected area of brain involved (Rosenbaum, Paneth, Leviton, et al, 2007)

Data from Nehring W: Cerebral palsy. In Allen PJ, Vessey JA, Schapiro NA (editors): *Primary care of the child with a chronic condition*, ed 5, St. Louis, 2010, Mosby; Jones MW, Morgan E, Shelton JE, et al: Cerebral palsy: introduction and diagnosis, part 1, *J Pediatr Health Care* 21(3):146-152, 2007; and National Institute of Neurologic Disorders and Stroke: *Cerebral palsy: hope through research*, 2006, available at www.ninds.nih.gov/disorders/cerebral_palsy/detail_cerebral_palsy.htm (accessed July 9, 2007).

BOX 35-3 CLINICAL MANIFESTATIONS OF CEREBRAL PALSY (AT TIME OF DIAGNOSIS)

Delayed Gross Motor Development
- A universal manifestation
- Delay in all motor accomplishments
- Increases as growth advances
- Delays more obvious as growth advances

Abnormal Motor Performance
- Very early preferential unilateral hand preference
- Abnormal and asymmetric crawl
- Standing or walking on toes
- Uncoordinated or involuntary movements
- Poor sucking
- Feeding difficulties
- Persistent tongue thrust

Alterations of Muscle Tone
- Increased or decreased resistance to passive movements
- Opisthotonic posturing (arching of back)
- Feels stiff on handling or dressing
- Difficulty in diapering
- Rigid and unbending at the hip and knee joints when pulled to sitting position (early sign)

Abnormal Postures
- Maintains hips higher than trunk in prone position with legs and arms flexed or drawn under the body
- Scissoring and extension of legs with feet plantar flexed in supine position
- Persistent infantile resting and sleeping position
- Arms abducted at shoulders
- Elbows flexed
- Hands fisted

Reflex Abnormalities
- Persistence of primitive infantile reflexes
- Obligatory tonic neck reflex at any age
- Nonpersistence beyond 6 months of age
- Persistence or hyperactivity of the Moro, plantar, and palmar grasp reflexes
- Hyperreflexia, ankle clonus, and stretch reflexes elicited in many muscle groups on fast, passive movements

Associated Disabilities*
- Altered learning and reasoning
- Seizures
- Impaired behavioral and interpersonal relationships
- Sensory impairment (vision, hearing)

From Nehring WM: Cerebral palsy. In Allen PJ, Vessey JA, Schapiro NA, editors: *Primary care of the child with a chronic condition,* ed 5, St. Louis, 2010, Mosby. Adapted from Jones MW, Morgan E, Shelton JE: Primary care of the child with cerebral palsy: a review of systems (part II), *J Pediatr Health Care* 21(4):226-237, 2007.
*May or may not be present.

handling or dressing. Also, there is difficulty in diapering because of spasticity of the hip adductor muscles and lower extremities. When pulled to a sitting position, the child may extend the entire body and be rigid and unbending at the hip and knee joints. This is an early sign of spasticity.

Abnormal Posture

Children with spastic CP assume abnormal postures at rest or when their position is changed. From an early age, a child lying in a prone position will maintain the hips higher than the trunk with the legs and arms flexed or drawn under the body. In the supine position spasticity is evident by scissoring (legs in crossed position; knees, hips, and ankles stiff) and extension of the legs, with the feet plantar flexed. This posture is exaggerated when the child is suspended vertically or when others try to make the child bear weight. Depending on the degree of impairment, spasticity may be mild or severe. A persistent infantile resting and sleeping posture (i.e., arms abducted at shoulders, elbows flexed, and hands fisted) is a sign of spasticity when it remains constant after 4 to 5 months of age. The hemiparetic child may rest with the affected arm adducted and held against the torso, with the elbow pronated and slightly flexed and the hand closed.

Reflex Abnormalities

Persistence of primitive reflexes is one of the earliest clues to CP (e.g., obligatory tonic neck reflex at any age or nonobligatory persistence beyond 6 months of age, and the persistence or even hyperactivity of the Moro, plantar, and palmar grasp reflexes). Hyperreflexia, ankle clonus, and stretch reflexes can be elicited from many muscle groups on fast passive movements (e.g., resistance to passive abduction when the hips are suddenly separated [adductor catch]).

Associated Disabilities and Problems

Some of the disabilities associated with CP are visual impairment, hearing impairment, behavioral problems, communication and speech difficulties, seizures, and intellectual impairment. Additional sensory deficits such as hypersensitivity, hyposensitivity, and balance difficulties may occur in children with CP (Nehring, 2010). According to data from the Centers for Disease Control and Prevention (2013) almost 7% of children with CP are also diagnosed with autism spectrum disorder.

Intellectual impairment is a concern, although children with CP have a wide range of intelligence, and 50% to 60% are within normal limits. Speech difficulties are often interpreted as a sign of cognitive impairment. Assessing the intelligence of a child with CP is often difficult because of the motor and sensory deficits. Tests carried out periodically over time should determine the degree of intelligence. Many persons with CP who have severely limiting physical involvement actually have the least intellectual impairment. As a group, children with athetosis and ataxia are intellectually superior to those with other types of CP. The incidence of severe or profound impairment is highest in rigid, atonic, and quadriparetic CP.

The manifestations of attention deficit hyperactivity disorder may occur in children with CP. The primary presenting symptoms are poor attention span, marked distractibility, hyperactive behavior, and defects of integration. (See Chapter 16.) Seizures are more likely to accompany postnatally acquired hemiplegia. They are an unusual finding in ataxia and diplegia. The most common types of seizures are generalized tonic-clonic seizures and minor motor types (Nehring, 2010).

Epilepsy is reported to occur in 41% of children with CP; epilepsy was especially common in nonambulatory children (Centers for Disease Control and Prevention, 2013).

Poor control of oral musculature may contribute to a number of problems. Abnormal posture and motor performance and alterations in muscle tone affect chewing, swallowing, and talking. Occupational and speech-language therapy interventions may be necessary to assist some children with feeding and speech. Coughing and choking, especially while eating, may predispose the child with CP to aspiration, which may not be readily apparent. Respiratory problems may result from and coexist with feeding difficulties in children with CP; respiratory symptoms observed during feedings include apnea, dyspnea, tachypnea, coughing and choking, and hypoxemia (Nehring, 2010). Many children with CP may also have gastroesophageal reflux.

Motor impairment associated with CP contributes to other problems. Children with CP who are nonambulatory have an increased risk of developing orthopedic complications such as unilateral or bilateral hip dislocations, scoliosis, and joint contractures resulting from unbalanced muscle tone. A variety of factors, including decreased mobility, decreased fluid intake, a fear of toileting, poor positioning on the toilet, and lack of fiber intake, may be responsible for constipation (Nehring, 2010). Stool softeners, laxatives, and a bowel management program may be required to prevent chronic constipation.

Increased incidence of dental caries results from improper dental hygiene, congenital enamel defects (hypoplasia of primary teeth), high carbohydrate intake and retention, dietary imbalance with poor nutritional intake, inadequate fluoride, and difficulty in mouth closure and drooling. Spastic or clonic movements can cause gagging or biting down on the toothbrush, thus interfering with cleaning techniques. Oral hypersensitivity is also common, which causes the child to resist dental hygiene. Malocclusion can occur in as many as 90% of these children. Gingivitis is secondary to inadequate dental hygiene and may be further complicated by the use of antiepileptic drugs (AEDs) such as phenytoin (Nehring, 2010).

Skin breakdown may occur with prolonged positioning, especially with underweight children with bony prominences and those who are unable to reposition themselves or who may have insensate areas of skin.

Nystagmus and amblyopia are common and may require surgery, corrective lenses, or both. Hearing impairment is also common in children with CP. Some loss is caused by sensorineural involvement. Affected infants may spend increased amounts of time lying flat. This predisposes them to otitis media, which may result in conductive hearing loss. (See Chapter 21.)

Diagnostic Evaluation

Infants at risk according to known etiologic factors associated with CP warrant careful assessment during early infancy to identify the signs of muscular dysfunction as early as possible. The neurologic examination and history are the primary modalities for diagnosis. Neuroimaging of the child with suspected brain abnormality and CP is now recommended for diagnostic assessment, with MRI being a strong predictor of CP when performed at term (corrected age); general movements assessment (GMA) also had a strong predictive value in children over 2 years of age and under 5 years of age (Bosanquet, Copeland, Ware, et al, 2013). Metabolic and genetic testing is recommended if no structural abnormality is identified by neuroimaging; laboratory tests are no longer recommended in the diagnostic process for CP.

Early recognition is made more difficult by the lack of reliable neonatal neurologic signs. However, the nurse should monitor infants with known etiologic risk factors and evaluate them closely in the first 2 years of life. Because cortical control of movement does not occur until later in infancy, motor impairment associated with voluntary control is usually not apparent until after 2 to 4 months of age at the earliest. More often the diagnosis cannot be confirmed until the age of 1 or 2 years because motor tone abnormalities may be indicative of another neuromuscular condition. In addition, some children who show signs consistent with CP before 2 years do not demonstrate such signs after 2 years (Nehring, 2010). However, there is no consensus regarding an age cutoff for the onset of symptoms.

Establishing a diagnosis may be easier with the persistence of primitive reflexes: either the asymmetric tonic neck reflex or persistent Moro reflex (beyond 4 months of age), and the crossed extensor reflex. The tonic neck reflex normally disappears between 4 and 6 months of age. An obligatory response is considered abnormal. This is elicited by turning the infant's head to one side and holding it there for 20 seconds. When a crying infant is unable to move from the asymmetric posturing of the tonic neck reflex, it is considered obligatory and an abnormal response. The crossed extensor reflex, which normally disappears by 4 months, is elicited by applying a noxious stimulus to the sole of one foot with the knee extended. Normally the contralateral foot responds with extensor, abduction, and then adduction movements. The possibility of CP is suggested if these reflexes occur after 4 months.

A number of assessment instruments are now available to evaluate muscle spasticity (Modified Ashworth Scale); functional independence in self-care, mobility, and cognition (Functional Independence Measure and WeeFIM [specific to children]); self-initiated movements over time (Gross Motor Function Measure); and capability and performance of functional activities in self-care, mobility, and social function (Pediatric Evaluation of Disability Inventory) (Krigger, 2006).

A thorough knowledge of normal variations of motor development is required for detecting abnormal progress, and a careful history is necessary to detect possible etiologic factors. Observe the child's spontaneous movements and behavior, including posture; attitude; and muscle size, function, and tone. Because children with CP often have sensory deficits, it is appropriate to evaluate the child for hearing and vision deficits.

Therapeutic Management: General Concepts

The goals of therapy for children with CP are early recognition and promotion of an optimum developmental course to enable affected children to attain their potential within the limits of their dysfunction. The disorder is permanent, and therapy is chiefly symptomatic and preventive.

The beneficial influences of a habilitation program on both child and family are based on recognizing the disability as early as possible and implementing treatment. Parents are essential to a treatment program. Consider their goals and desires, their cooperation, and their confidence in all aspects of management. With early diagnosis parents can begin to provide the sensorimotor experiences essential to cognitive development, since CNS structures depend on stimulation and use to attain and maintain their functional integrity.

The broad aims of therapy are to (1) establish locomotion, communication, and self-help; (2) gain optimum appearance and integration of motor functions; (3) correct associated defects as early and effectively as possible; (4) provide educational opportunities adapted to the individual child's needs and capabilities; and (5) promote socialization experiences with other affected and unaffected children. Each child is evaluated and managed on an individual basis. The plan of therapy may involve a variety of settings, facilities, and specially trained persons. The scope of the child's needs requires multidisciplinary planning and care coordination among professionals and the child's family (Box 35-4). The outcome for the child and family with CP is normalization and promotion of self-care activities that empower the child and family to achieve maximum potential.

Mobilizing Devices

Many children with CP wear ankle-foot orthoses (AFOs) (braces) and a variety of orthotics. Orthotics are molded to fit the feet and are worn inside the shoes. Devices are often used to help prevent or reduce deformity, increase the energy efficiency of gait, and control alignment. Some of the more commonly used mobility devices include wheeled scooter boards that allow children to propel themselves while the abdomen or total body is supported and the legs are positioned with wedges to prevent scissoring. Wheeled go-carts provide good sitting balance and serve as an early "wheelchair" experience for young children. Strollers can be equipped with custom seats for dependent mobilization. Special devices for independent mobilization that may or may not allow the upper extremities to remain free are particularly valuable for children with lower extremity involvement (Fig. 35-2). A number of wheelchairs can be customized to meet the needs and preferences of older children. (See Mobilization Devices, Chapter 34.)

Surgery

Surgical intervention is usually reserved for the child who does not respond to the more conservative measures such as orthotics, but it is also indicated for the child whose spasticity causes progressive deformities. Orthopedic surgery may be required to correct contracture or spastic deformities, to provide stability for an uncontrollable joint, to address bone malalignment (e.g., lever arm dysfunction), and to provide balanced muscle power. This includes tendon-lengthening procedures (especially heel-cord lengthening), release of spastic wrist flexor muscles, and correction of hip and adductor muscle spasticity or contracture to improve locomotion. Orthopedic surgery is generally not performed until after the child is 6 years of age (Nehring, 2010). Surgery is used primarily to improve function rather than for

BOX 35-4 THERAPEUTIC INTERVENTIONS FOR CEREBRAL PALSY

Interdisciplinary developmental and physical assessment with recommendations may include the following:

Physical Therapy

Orthotic Devices

Braces
Splints
Casting
Molded orthoses

Adaptive Equipment

Scooters, bicycles, and tricycles
Wheelchairs
Boards
Standing devices

Functional (Neuromuscular) Electrical Stimulation (in Combination with Dynamic Splinting)

Occupational Therapy

Adaptive Equipment

Utensils for functional use (e.g., eating, writing)
Switches
Computers

Speech-Language Therapy

Oral-motor skills
Adaptive communication techniques

Special Education

Early intervention programs
Specialized learning programs and support services in school
Socialization to promote self-concept development

Surgical Intervention

Orthopedic (e.g., tendon transfers, muscle lengthening, spinal deformities)
Neurologic (e.g., neurectomies)
Selective dorsal rhizotomy
Feeding (e.g., gastrostomy)
Dental

Medication Therapy

Medications to treat:

- Spasticity
- Pain
- Secondary conditions (e.g., seizure disorder, chronic constipation, urinary tract infections, gastroesophageal reflux)

Primary care for health supervision and acute childhood illnesses

Behavioral Therapy

Care Coordination

Care coordination of specialized services and community resources in collaboration with the child's family

Modified from Nehring WM: Cerebral palsy. In Jackson PL, Vessey JA, Schapiro NA, editors: *Primary care of the child with a chronic illness,* ed 5, St. Louis, 2010, Mosby.

FIG. 35-2 Child ambulating with use of assistive device.

cosmetic purposes and is followed by physical therapy. Surgery may also be performed to improve caloric intake, correct gastroesophageal reflux disease, prevent aspiration, and correct associated dental problems (Nehring, 2010).

Neurosurgical procedures are used only in selected cases. Selective dorsal rhizotomy has provided marked improvement in some children with CP (Nordmark, Josenby, Lagergren, et al, 2008). However, achieving the benefits from the surgery requires intensive physical therapy and family commitment. Because the procedure results in flaccid muscles, the child must relearn to sit, stand, and walk.

Medication

Intense pain may occur with muscle spasms in patients with CP. Children with CP may also experience pain as a result of painful procedures such as injection with botulinum toxin type A (Botox), surgical procedures intended to reduce contracture deformities, abdominal pain related to position and gastroesophageal reflux, and pain associated with physical therapy. Therefore, pain management is an important aspect of the care of the child with CP.

Pharmacologic agents given orally (dantrolene sodium [Dantrium], baclofen [Lioresal], and diazepam [Valium]) have had little effectiveness in improving muscle coordination in children with CP. However, they are effective in decreasing overall spasticity. The most common side effects of these agents include hepatotoxicity (dantrolene), drowsiness, fatigue, and muscle weakness. Less commonly, diaphoresis and constipation may occur with oral baclofen; other possible complications include hallucinations, mood changes, seizures, nausea, and urinary incontinence. Diazepam is used frequently but should be restricted to older children and adolescents.

Botulinum toxin A is also used to reduce spasticity in targeted muscles of the upper and lower extremities (Lukban, Rosales, and Dressler, 2009). Botulinum toxin A is injected into a selected muscle (commonly the quadriceps, gastrocnemius, or medial hamstrings), where it acts to inhibit the release of acetylcholine into a specific muscle group, thereby preventing muscle movement. When it is administered early in the course of the illness, this may prevent affected muscle contractures, particularly in lower extremities, thus avoiding surgical procedures with possible adverse effects. The goal is to allow stretching of the muscle as it relaxes and permits ambulation with an AFO. The major reported adverse effects of botulinum toxin A injection include pain at the injection site and a temporary weakness (Lukban, Rosales, and Dressler, 2009). Prime candidates for botulinum toxin A injections are children with spasticity confined to the lower extremities. The onset of action occurs within 24 to 72 hours, with a peak effect observed at 2 weeks and a duration of action of 3 to 6 months. Decreasing spasticity with botulinum toxin A may also result in less pain from spasms (Lundy, Doherty, and Fairhurst, 2009).

The neurosurgical and pharmacologic approach to managing the spasticity associated with CP involves the implantation of a pump to infuse baclofen directly into the intrathecal space surrounding the spinal cord to provide relief of spasticity. High doses of oral baclofen are associated with significant side effects, including drowsiness and confusion, yet are often unable to provide adequate relief of spasticity. Direct infusion of baclofen into the intrathecal space provides relief without as many side effects (Motta, Antonello, and Stignani, 2011). Intrathecal baclofen (ITB) is especially helpful in improving comfort (Morton, Gray, and Vloeberghs, 2011).

Patients may be screened before pump placement by the infusion of a "test dose" of intrathecal baclofen delivered via a lumbar puncture. Close monitoring for side effects (e.g., hypotonia, somnolence, seizures, nausea, vomiting, headache, and catheter- or pump-related problems) and relief of spasticity occurs for several hours after the infusion. If a positive effect occurs, the patient is considered a candidate for pump placement.

The pump is placed in the subcutaneous space of the midabdomen. An intrathecal catheter is tunneled from the lumbar area to the abdomen and connected to the pump. The pump is filled with baclofen and programmed to provide a set dose using a telemetry wand and a computer. The patient remains hospitalized for several days to adjust the dosage and ensure proper healing. Outpatient visits to refill the pump and make dosage adjustments occur about every 4 to 6 weeks, depending on the patient's response to the treatment. Benefits of intrathecal baclofen include fewer systemic side effects, dosage titration for maximizing effects, and reversibility of therapy with removal of the pump if so desired. Abrupt withdrawal of intrathecal baclofen, especially at high doses, may result in adverse effects such as rebound spasticity, pruritus, hyperthermia, rhabdomyolysis, disseminated intravascular coagulation, multiorgan failure, and death; in some cases intrathecal baclofen withdrawal may mimic sepsis. Treatment of withdrawal centers on reestablishing the medication dosage, with improvements observed within 1 to 2 hours. Hospitalization and surgery may be required for withdrawal as a result of pump or catheter failure.

AEDs such as carbamazepine (Tegretol), divalproex (valproate sodium and valproic acid; Depakote), oxcarbazepine (Trileptal), and lamotrigine (Lamictal) are prescribed routinely for children who have seizures. Gabapentin (Neurontin) has been used in adults with SCI to decrease spasticity with success. No studies are available on the effectiveness of the drug in children

with CP. The α_2-adrenergic agonists clonidine (Catapres) and tizanidine (Zanaflex) have been used to decrease spasticity in adults with SCI and multiple sclerosis; however, their use in children does not appear to have gained widespread acceptance in the United States. Oral tizanidine given in conjunction with botulinum type A has been reported to be more effective than oral baclofen and botulinum type A in one study of children with CP (Dai, Wasay, and Awan, 2008). Monitor all medications for maintenance of therapeutic levels and avoidance of subtherapeutic or toxic levels.

QUALITY PATIENT OUTCOMES

Seizures

- No physical injury as a result of seizure activity
- Prevention of seizure activity

Children with CP have been treated with a number of complementary and alternative medicine strategies, including Chinese herbs, acupuncture, growth hormone therapy, aquatic exercise, equine-assisted therapy, and hyperbaric oxygen (Nehring, 2010). Gasalberti (2006) reported some alternative therapies being used in children with disabilities that the practitioner may overlook during a health history but that may be beneficial to such children. These include pet therapy, massage, hippotherapy (horse riding), music, and color-light therapy. Other alternative therapies that may be used by families with children with disabilities include vitamins, prayer, meditation, hypnosis, and guided imagery.

Technical Aids

A wide variety of technical aids are available to improve the functioning of children with CP. These include electromechanical toys that employ the concept of biofeedback and operate from a head unit. The toy is manipulated only when the head and trunk are in correct alignment. Computerized toys and games can also enhance eye-hand coordination.

Microcomputers combined with voice synthesizers help children with speech difficulties to "speak." Smart phones and tablets with speech applications are appropriate for some children. These and other devices print messages onto screen monitors and paper. These devices have made it apparent that some children have been erroneously considered to be cognitively impaired. Microcomputers have also increased the possibilities for increased mobility via wheelchairs and specially designed mobilization devices.

Many other electronic devices allow independent functioning. Sensors can be activated and deactivated using a head-stick, a voluntary muscle such as the tongue, or any other voluntary muscle movement over which the child has control. (See Figs. 21-4 and 21-5.) The application of this technology makes it possible for older persons with CP to eventually function in their own apartments and can be extended into the workplace.

Associated Problems

Children with CP often have sensory deficits, which require the attention of appropriate specialists. Speech-language therapy involves the services of a speech-language pathologist (SLP) who may also assist with feeding problems. (See Chapter 21.) Dental care is especially important for children with CP and often is overlooked. Regular visits to the dentist and dental prophylaxis, including brushing, fluoride, and flossing (after several teeth are present), should begin as soon as the teeth erupt. This is especially important for children given phenytoin, who often develop gum hyperplasia. Additional problems common among children with CP include constipation caused by neurologic deficits and lack of exercise; poor bladder control and urinary retention; chronic respiratory tract infections and aspiration pneumonia, which occur as a result of gastroesophageal reflux, abnormal muscle tone, immobility, and altered positioning; and skin problems as a result of altered positioning, poor nutrition, and immobility. Hip dislocation occurs often in children with CP. Latex allergy has also been reported in children with CP (Nehring, 2010).

Therapeutic Management: Therapies, Education, Recreation

Physical Therapy

Physical therapy is one of the most commonly used treatment modalities in children with CP. In general, physical therapy is directed toward good skeletal alignment for the child with spasticity; training in purposeful acts, even in the face of involuntary motion, for the child with athetosis; and gait training and maximum development of proprioceptive sense for the child with ataxia.

An active therapy program involves the family, the physical therapist (PT), the occupational therapist (OT), and other members of the health care team. Developing a treatment program that can be carried out at home is of utmost importance. The major approach uses traditional types of therapeutic exercises that consist of stretching; passive, active, and resistive movements applied to specific muscle groups or joints to maintain or increase range of motion; strength; or endurance. Neuromuscular electrical stimulation (NMES) combined with dynamic splinting may benefit some children (Wright, Durham, Ewins, et al, 2012). No therapeutic approach is able to achieve spectacular changes in the ultimate outcome of motor disability. Early efforts focus on alleviating abnormal postures by positioning and range-of-motion exercises. Passive range-of-motion exercises, stretching, and elongation exercises are valuable at any age, even when the child is too young to cooperate. Some active extension can be performed when the child is old enough to cooperate, with passive motion applied to complete joint extension. Prevention of contracture deformity is a prime function of physical therapy. Seating and mobility are other key goals.

Functional and Adaptive Training (Occupational Therapy)

Training in manual skills and activities of daily living (ADLs) proceeds along developmental lines and according to the child's functional level. Sitting, balancing, crawling, and walking are encouraged at appropriate ages and are accompanied by

stimulation of protective extension and equilibrium reactions. Hand activities are begun early to improve motor function and provide the child with sensory experiences and information about the environment. As the child progresses from simple feeding and self-care activities, training is extended to include other tasks (e.g., cooking or use of keyboard or computer mouse) that are within the child's developmental and functional capabilities.

Incorporating play into the therapeutic program often requires great ingenuity and inventiveness from those involved in the child's care. Objects and toys are chosen to provide needed sensory input using a variety of shapes, forms, and textures. Nurses can help parents integrate therapy into play activities in natural ways.

Children with CP may need considerable help (and patience) in learning to feed and dress themselves and care for personal hygiene needs. A feeding program may be developed by an OT in conjunction with an SLP. Children should be fed in the normal eating position. When they have difficulty sucking and swallowing, it is tempting to hold them in a semireclining posture to make use of gravity flow. However, this method does not promote active swallowing, and the neck hyperextension may even interfere with swallowing. A more flexed sitting position, with the arms brought forward to decrease the tendency toward back and neck extension, is more natural during bottle- or spoon-feeding and encourages active swallowing.

Because jaw control is compromised, more normal control can be achieved if the feeder stabilizes the oral mechanism from the side or front of the face. When directed from the front, the middle finger of the nonfeeding hand is placed posterior to the bony portion of the chin, the thumb is placed below the bottom lip, and the index finger is placed parallel to the child's mandible (Fig. 35-3). Manual jaw control from the side assists with head control, correction of neck and trunk hyperextension, and jaw stabilization. The middle finger of the nonfeeding hand is placed posterior to the bony portion of the chin, the index finger is placed on the chin below the lower lip, and the thumb is placed obliquely across the cheek to provide lateral jaw stability (Fig. 35-4).

In all ADLs it is important to capitalize on the child's assets and compensate for liabilities. The level of expected independence is related to both gross and fine motor manipulation. Even when complete independence in a specific activity is not realistic, the child should learn any part of the task that he or she can master. However, motor function is not the sole purpose of learning to be as independent as possible. Any accomplishment promotes self-reliance and self-esteem for healthier personality development.

Speech Therapy

Speech training under the supervision of an SLP begins early, before the child learns poor habits of communication. Parents and others can help by following the directions of the speech therapist and by talking to the child slowly while using pictures or handling objects about which the adult is speaking. Feeding techniques such as forcing the child to use the lips and tongue in eating facilitate speech. An example of this technique is placing food at the side of the tongue, first one side and then the other, and making the child use the lips to take food from a spoon rather than placing it directly on the tongue. If severe dysarthria prevents articulate speech and the child has reasonable intelligence, the child learns nonverbal communication (e.g., sign language). (See Chapter 21.)

Education

As in all aspects of care, educational requirements are determined by the child's needs and potential. This includes the severity of the child's disease and the presence and degree of associated conditions that affect learning and participation, such as learning impairment, abnormal actions or behaviors, impaired vision or hearing, and seizures. Children with mild to moderate involvement are generally able to participate, for varying amounts of time, in regular classes. Resource rooms are available in most schools to provide more individualized attention to a child's particular needs. Integration of these children into regular classrooms should be the initial goal. Teachers' assistants often work one-on-one with children in both settings. A training program may be appropriate for those children who

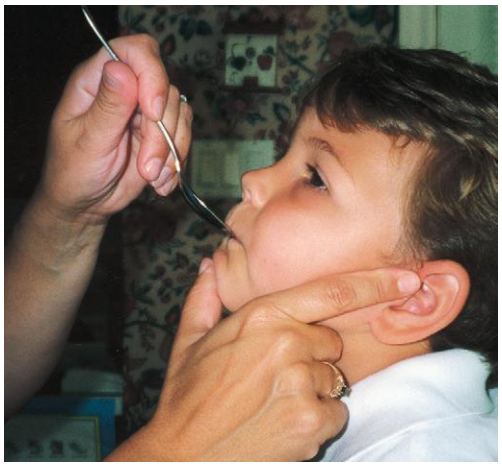

FIG. 35-3 Manual jaw control provided anteriorly.

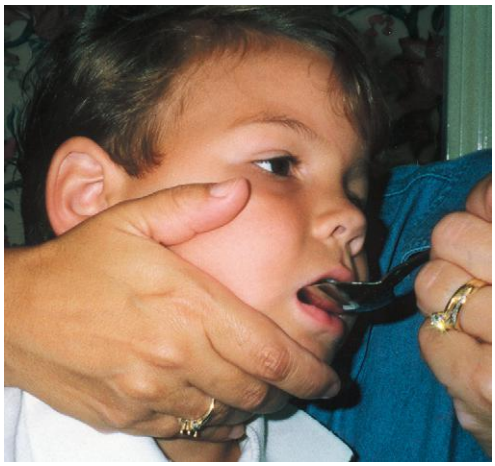

FIG. 35-4 Manual jaw control provided from the side.

are unable to benefit from formal education. Prevocational and vocational counseling and guidance are arranged at adolescence. Education is geared toward the child's assets at any phase or in any setting. Nurses should be aware of early intervention programs and provisions for special education and related services for children (see Box 21-3) and should support parents in their efforts to obtain appropriate educational services for the child.

Recreation

Recreational activities are also a necessary part of growing up. Recreational outlets and after-school activities should be an option for the child who is unable to participate in regular athletic and other peer activities. Some can compete in athletic and artistic endeavors, and many games and pastimes are suited to their capabilities. Sports, physical fitness, and recreation programs are encouraged for children with CP, and young children should be exposed to all physical activities available to children without disabilities. Individual sports such as the martial arts (e.g., Tae Kwon Do) in which groups are small and the emphasis is on discipline and balance are also enjoyable to many children with CP. Many states mandate adaptive physical education classes.

Numerous developmental centers have facilities for indoor and outdoor activities designed to appeal to children of all ages. If these are not available, they should be developed. However, such programs require adequate supervision to avoid any harmful effects. Recreational activities serve to stimulate children's interest and curiosity, help them adjust to their disability, improve their functional abilities, and build self-esteem. Competitive sports are also becoming increasingly available to children with disabilities and offer an added dimension to physical activities. For more information access the United Cerebral Palsy website (**www.ucp.org**) and go to the Sports and Leisure link.

Prognosis

The prognosis for the child with CP depends largely on the type and severity of the condition. Children with mild to moderate involvement (85%) have the capability of achieving ambulation between the ages of 2 and 7 years (Berker and Yalçin, 2008). If the child does not achieve independent ambulation by this time, chances are poor for ambulation and independence. Approximately 30% to 50% of individuals with CP have significant cognitive impairments, and an even higher percentage have mild cognitive and learning deficits (Green, Greenberg, and Hurwitz, 2003; Liptak and Accardo, 2004). Children with profound cognitive impairment have a higher mortality, and less than one half of those reach adulthood (O'Shea, 2008). However, many children with severe spastic tetraplegic CP have normal intelligence. Growth is affected in children with spastic tetraplegia, and many children remain below the 5th percentile for age and sex.

As children with CP become adults, about 30% remain in the home and are cared for by a parent or caregiver; 50% of individuals with spastic tetraplegia live in independent settings and function at appropriate social levels considering their disability (Green, Greenberg, and Hurwitz, 2003). Vocational rehabilitation and higher education are possible for adults with CP. Children with severe CP mobility impairment and feeding problems often succumb to respiratory tract infection in childhood. The few survival rate studies on children or adults with CP show that survival is influenced by existing comorbidities (Nehring, 2010). In general, the more medically fragile children are least likely to survive to adulthood (Westbom, Bergstrand, Wagner, et al, 2011).

QUALITY PATIENT OUTCOMES

Pain

- Acceptable pain threshold experienced as defined by patient or caregiver, or a pain score of 4 or less on Wong Baker Faces Pain Rating Scale

Nursing Care Management

Assessment

Nursing assessment includes risk identification of infants with etiologic factors that are associated with CP. Ongoing assessment of infants for abnormal muscle tone, inability to achieve developmental milestones, and persistence of neonatal reflexes alert the nurse to investigate further.

Reinforce Therapeutic Plan and Assist in Normalization

Because children are being treated at an earlier age, parents are participating at an earlier stage in treatment programs for their disabled child. They learn the proper handling and home care of young children with CP and need carefully programmed steps so that their expanded parental role can be melded into the established relationship. Close work with other multidisciplinary team members is essential. Nurses reinforce the therapeutic plan and assist the family in devising and modifying equipment and activities to continue the therapy program in the home. (See also Chapter 21.)

Some children have difficulty keeping their heads upright. Because of this, they can neither explore much of their environment nor process the information. Parents need to be complimented on their efforts to provide a stimulating environment for these children. These infants are at risk for delayed development in holding up their heads, righting their shoulders and trunks for stable posture, sitting, pulling, standing, and crawling. Most parents of children with impaired movements benefit from support and practical suggestions for feeding, moving, holding, and encouraging the infant to explore hands and feet and to play. Helping parents incorporate therapeutic suggestions into typical daily activities is an important normalizing strategy. (See Chapter 20 for a discussion of normalization.)

Although practical advice is important, the nurse, OT, or PT should offer suggestions at a pace that can be absorbed by the parents. Encourage the parents to define their concerns, acknowledge the concerns as genuine, and ask the parents what approaches they have tried and for how long. In this way the nurse is able to find out what works, what does not work, and what the parents would like to try next. Give the parents positive

feedback for their observations of the infant, the progress they note, and how they differentiate the child's needs.

Address Health Maintenance Needs

Because children with CP expend so much energy in their efforts to accomplish ADLs, more frequent rest periods should be arranged to avoid the fatigue that may aggravate their limited capabilities. Meeting the child's nutritional needs may be a challenge because of gastroesophageal reflux, feeding and swallowing difficulties, chronic constipation and subsequent anorexia, and absence or diminished ability to independently feed himself or herself (Jones, Morgan, and Shelton, 2007). As a result of being ELBW or VLBW in combination with these feeding problems, children with CP are at risk for failure to thrive, and the nurse must ensure an adequate caloric intake. Children with spasticity expend more energy and often require more energy intake than same-age counterparts to maintain adequate growth. Nutritional supplements such as high-calorie milk products (e.g., Pediasure) may be necessary to provide adequate caloric intake after the child has reached 1 year of age. Additional nutritional concerns include providing adequate intake of fruits and fiber to enhance gastrointestinal motility, routinely monitoring child's growth on a standardized growth chart, and avoiding overfeeding and obesity (Jones, Morgan, and Shelton, 2007).

Routine assessment of skin status is imperative in children with CP who are limited in movement or who must remain in assistive devices such as a wheelchair for a prolonged period. The overall nutritional status may also be a risk factor for skin breakdown. Care must be taken to ensure that adequate objective skin assessments are routinely performed. If skin breakdown does occur, consult a skin and wound specialist for treatment and further prevention.

Gastrostomy feedings may be necessary to supplement regular feedings and ensure adequate weight gain, particularly in children at risk for growth failure and chronic malnutrition, those with severe CP and subsequent oral feeding difficulties, and children whose well-being is affected by illness and decreased fluid or medication intake (Rogers, 2004). Oral feedings may be continued to maintain oral motor skills. Weight gain is perceived as an important measure of adequate oral feeding efficiency (Rogers, 2004).

Parents may need assistance and advice with medication administration through a gastrostomy tube to prevent clogging. Pills may be crushed and mixed with small amounts of water but not other liquids, such as formula or elixir medications, since these may act together to form a sludge that can interfere with gastrostomy tube function. When crushed pills or tablets are administered, flush the feeding tube with more water after instilling the dissolved pill in water. The pharmacist can provide information regarding crushed pills and tablets and elixirs, which should not be mixed together when administered via gastrostomy or nasogastric tube. A skin-level gastrostomy is particularly suited for the child with CP. (See also Gastrostomy Feeding, Chapter 23.)

Safety precautions are implemented, such as having children wear protective helmets if they are subject to falls or capable of injuring their heads on hard objects. Because the child with CP is at risk for altered proprioception and subsequent falls, parents should adapt the home and play environment to the child's particular needs to prevent bodily harm. Transportation of the child with motor problems and restricted mobility may be especially challenging for the family and child. Attention must be given to the child's safety when riding in a motor vehicle; a federally approved safety restraint should be used at all times. Lovette (2008) recommends that children with CP ride in a rear-facing position as long as possible because of their poor head, neck, and trunk control. This author also provides a list of options for special car restraint systems for children with CP, including several restraints that are suitable for children with a hip spica cast.

Appropriate immunizations should be administered to prevent childhood illnesses and protect against respiratory tract infections such as influenza. Depending on the level of involvement, dental problems may be more common in children with CP, which creates a need for meticulous attention to all aspects of dental care.

Support the Family

The nursing interventions that are probably most valuable to the family are support and help in coping with the emotional aspects of the chronic disorder, many of which are discussed in Chapter 20. Initially the parents need information and support in understanding the implications of the diagnosis and all the feelings it engenders. Later they need clarification regarding what they can expect from the child and from health care professionals. Educating families in the principles of family-centered care and parent-professional collaboration is essential. The family also may require help modifying the home environment for care of the child. Transportation to the practitioner's office and other health care agencies often requires special considerations.

Care management for the child and family with CP is an important nursing role. In many cases the family assumes complete care of the child and becomes quite adept at caring for her or his individual needs. The home health nurse or case manager has an important role in the support and encouragement of families who assume the primary care of a child with CP. Having a child with CP implies numerous problems of daily management and changes in family life, and the nurse can stress principles of normalization. (See Normalization, Chapter 20.)

The nurse can support the parents by acknowledging and addressing their concerns and frustrations and by noting and appreciating their problem-solving skills and their approaches to helping the child. Siblings of a child with a disability are also affected and may respond with overt or less evident behavioral problems. The family needs a relationship with nurses who can provide continued contact, support, and encouragement through the long process of habilitation.

Parents can also find help and support from parent groups, where they can share experiences, accomplishments, problems, and concerns while deriving comfort and practical information. For example, parents can understand from others what it is like

to have a child with CP. United Cerebral Palsy* has branches in most communities and provides a variety of services for children and families.

Care of the Hospitalized Child

CP is not a condition that requires hospitalization; therefore, when children with CP are hospitalized, they are usually admitted for an associated illness or for corrective surgery. To facilitate the care and management of hospitalized children with CP, the therapy program should be continued (insofar as their condition allows) while they are hospitalized. This should be incorporated into the multidisciplinary care plan, with every effort expended to make certain the ground that has been so laboriously gained is not lost. Encouraging the parent to room-in and actively participate in the child's care facilitates a continuation of the home therapy program and helps the child adjust to an unfamiliar environment. However, it is equally important to remember that a hospitalization may be the first time a parent can defer care to a nurse and not be the primary caregiver. This respite may be crucial to the parent's well-being. Respect the parent's preference in this regard (see Nursing Care Plan).

DEFECTS OF NEURAL TUBE CLOSURE

Abnormalities that come from the embryonic neural tube (**neural tube defects [NTDs]**) constitute the largest group of congenital anomalies with multifactorial inheritance. Normally the spinal cord and cauda equina are encased in a protective sheath of bone and meninges (Fig. 35-5, *A*). Failure of neural tube closure produces defects of varying degrees (Box 35-5). They may involve the entire length of the neural tube or may be restricted to a small area.

Etiology

Two of the defects, anencephaly and spina bifida (SB), occur in association with each other more often than would be expected by chance, suggesting a common origin. The CNS defects may alternate in siblings, which also tends to support the theory of a common origin. The incidence of SB is higher in girls than in boys, and it is more likely to occur in Hispanic (4.17 per 10,000 births) women than in Caucasians (3.22 per 10,000) or African-Americans (2.64 per 10,000) (Centers for Disease Control and Prevention, 2011). In the United States, rates of NTDs declined by as much as 23% between 1995 and 1996 and 2000. NTD rates decreased an additional 6.9% between 2000 and 2005, primarily among African-American mothers. One concern is that NTD rates have not decreased significantly among Hispanic and non-Hispanic Caucasian mothers since 1999 (Centers for Disease Control and Prevention, 2009). The decline in NTDs in the late 1990s has been attributed in large part to the addition of folic acid to cereal grain products (Centers for Disease Control and Prevention, 2011). In 2006 the rates for SB were estimated by the Centers for Disease Control and Prevention to be 3.05 per 10,000 live births, thus making this one of the most common birth defects in the United States (Matthews, 2009). Population-based studies have also witnessed a substantial decrease in NTDs since food fortification with folic acid and folic acid supplementation recommendations were made (Collins, Atkinson, Dean,

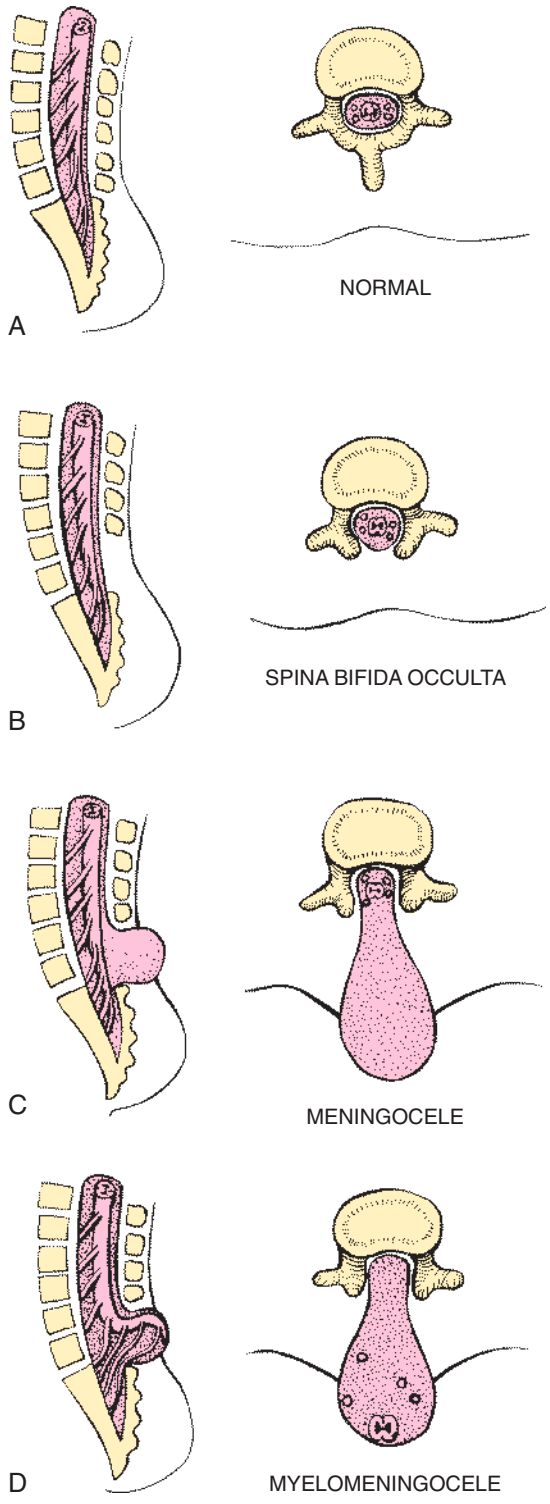

FIG. 35-5 **A** through **D,** Midline defects of osseous spine with varying degrees of neural herniations.

NURSING CARE PLAN

The Child with Cerebral Palsy

NURSING DIAGNOSIS	PATIENT OUTCOMES	NURSING INTERVENTIONS	RATIONALE
• Impaired Physical Mobility related to neuromuscular impairment **Child's/Family's defining characteristics** • (Subjective and Objective Data) • Postural instability during performance of routine activities of daily living • Limited ability to perform gross motor skills • Limited range of motion • Limited ability to perform fine motor skills • Gait changes • Movement-induced tremor • Persistence of primitive reflexes	• The infant or toddler will demonstrate active muscle movement. • The child will have adequate mobility to perform activities of daily living to maximum potential. **The following NOC concepts apply to these outcomes:** • Body Mechanics Performance • Ambulation: Wheelchair • Joint Movement: Elbow, Wrist, Neck, Knee, Hip, Ankle • Mobility	• Carry out and teach family to perform stretching exercises on affected muscles. • Use assistive devices such as wheelchair, ankle-foot orthoses (AFOs), and wrist splints. • Administer medications (specify) intended to decrease muscle spasticity. • Encourage and teach parent(s) to use jaw control during feedings. • Position child supright during feedings. • Encourage play exercises that involve joint movement and promote fine and gross motor skill acquisition and repetition. **The following NIC concepts apply to these interventions:** • Exercise Therapy: Joint Mobility • Exercise Promotion: Stretching • Self-Care Assistance	• To prevent muscle contractures • To increase mobility and prevent contractures • To minimize pain and decrease spasticity • To facilitate eating • To decrease chance of aspiration and facilitate mobilization of food and fluids through esophagus • To promote joint movement • To promote achievement of developmental milestones

• Risk for Injury related to mobility limitation, neuromuscular impairment, and perception and cognition impairment
Child's/Family's defining characteristics
• (Subjective and Objective Data)
• Physical factors: altered mobility
• Neuromuscular factors:
  • Limited perception of danger
  • Uncontrollable muscular movements
	• Child will remain injury free.
	• Home physical environment will be safe.
	The following NOC concepts apply to these outcomes:
	• Personal Safety Behavior
	• Falls Occurrence
		• Educate family regarding child's physical limitations that place him or her at greater risk for injury.
		• Instruct family in steps to avoid injury: padded furniture, lowered bed or side rails as appropriate, gates on stairs, avoidance of throw rugs, thick carpeting.
		• Position child in semiupright position after feedings.
		• Use jaw support as needed during feedings.
		• Use appropriate mobilization devices and ensure they are safe for child's age.
		• Encourage mobilization and play activities that stretch muscles.
		• Teach child which activities of daily living are safe and appropriate to perform without assistance of another person.
		The following NIC concepts apply to these interventions:
		• Risk Identification
		• Environmental Management: Safety
		• Surveillance: Safety
		• Physical Restraint
		• Parent Education: Childrearing, Family
			• To prevent accidental injury during mobilization
			• To promote family involvement in injury prevention
			• To prevent aspiration
			• To prevent choking
			• To prevent muscle contractures
			• To promote personal safety
			• To promote self-care

NURSING CARE PLAN—cont'd

The Child with Cerebral Palsy

NURSING DIAGNOSIS	PATIENT OUTCOMES	NURSING INTERVENTIONS	RATIONALE
• Pain (chronic) related to involuntary muscle movements (spasticity) and treatments for muscle spasticity **Child's/Family's defining characteristics** • (Subjective and Objective Data) • Observed evidence of guarded behavior, grimace, crying, restlessness • Atrophy of involved muscle group • Altered ability to continue previous activities	• Child's optimum comfort level will be maintained. **The following NOC concepts apply to these outcomes:** • Comfort Level • Pain: Disruptive Effects • Depression Level	• Administer medications to control spasticity (specify). • Perform stretching exercises after pain medication has been administered (60 minutes for oral medications). • Administer pain medications (specify) such as nonsteroidal anti-inflammatory drugs. • For treatments such as botulinum toxin A (Botox) injections, assist with administration of appropriate pain medications and monitoring child for pain sensation (specify). • For postoperative pain, administer pain medications on an around-the-clock schedule for 48 to 72 hours; use patient-controlled analgesia pump as child's cognitive and motor skills allow. • Use objective pain scale to assess pain level. • Encourage child to verbalize effects of pain on activities of daily living. • Use assistive devices such as AFOs and knee-ankle-foot orthoses. • Teach parent(s) and child appropriate positions to assume while sitting and recumbent to minimize effects of muscle spasticity. **The following NIC concepts apply to these interventions:** • Medication Administration • Analgesic Administration • Emotional Support • Splinting • Environmental Management: Comfort • Exercise Promotion	• To prevent muscle spasm pain • To control pain impulses during exercises • To minimize pain • To decrease pain of injection at site • To promote personal physical comfort • To provide objective measure of pain for intervention • To provide outlet for frustration related to chronic pain experience • To decrease muscle spasticity and contractures. • To promote self-care

et al, 2011). Increased use of prenatal diagnostic techniques and termination of pregnancies have also affected the overall incidence of NTDs.

Most authorities believe that the primary defect in NTDs is a failure of neural tube closure during the embryo's early development (between the third and fourth week). However, evidence also implicates a multifactorial origin, including drugs, radiation, maternal malnutrition, chemicals, and possibly a genetic mutation in folate pathways in some cases, which may result in abnormal development (Kinsman and Johnston, 2011).

Additional factors predisposing the infant to NTDs include maternal obesity, previous NTD pregnancy, Hispanic ancestry, low folic acid intake, gestational diabetes, hot tub or sauna use, low maternal vitamin B_{12} status, and the use of antiepileptic drugs (e.g., valproic acid) in pregnancy (Agopian, Tinker, Lupo, et al, 2013). The degree of neurologic dysfunction depends on where the sac protrudes through the vertebrae, the anatomic level of the defect, and the amount of nerve tissue involved (Fig. 35-5). Most myelomeningoceles involve the lumbar or lumbosacral area.

The American Academy of Pediatrics (2007) recommends daily intake of folic acid for all women of childbearing age. The recommended 0.4-mg daily dose is supplied safely in many multivitamin preparations. Because the greatest risk factor is a

BOX 35-5 NEURAL TUBE DEFECTS

Cranioschisis—A skull defect through which various tissues protrude
Exencephaly—Brain totally exposed or extruded through an associated skull defect; fetus usually aborted
Anencephaly—If fetus with exencephaly survives, degeneration of the brain to a spongiform mass with no bony covering; incompatible with life usually beyond a few days
Encephalocele—Herniation of brain and meninges through a defect in the skull producing a fluid-filled sac
Rachischisis or spina bifida—Fissure in the spinal column that leaves the meninges and spinal cord exposed
Meningocele—Hernial protrusion of a saclike cyst of meninges filled with spinal fluid (see Fig. 35-5, *C*)
Myelomeningocele (meningomyelocele)—Hernial protrusion of a saclike cyst containing meninges, spinal fluid, and a portion of the spinal cord with its nerves (see Fig. 35-5, *D*)

previous pregnancy affected by NTDs, women in this category should increase their daily folic acid dose to 4 mg, under a practitioner's supervision, beginning at least 1 month before they plan a pregnancy and through the first trimester, since the neural tube closes about 1 month after conception. In 2009 the U.S. Preventive Services Task Force published a statement indicating there is ample evidence to support the recommendations for folic acid supplementation to decrease the incidence of NTDs (Wolff, Witkop, Miller, et al, 2009). In 1998 the U.S. Food and Drug Administration (FDA) authorized the fortification of cereal grains (including cornmeal, grits, and wheat flour) with folic acid. It remains important for all women of childbearing age to take a multivitamin with 0.4 mg folic acid daily (American Academy of Pediatrics, 2007). Sexually active females should be counseled regarding the risks of inadequate folate intake (Burke, Liptak, and Council on Children with Diasbilities, 2011).

The following discussion of NTDs is limited to the two most common types: anencephaly, a defect incompatible with life, and SB, in particular myelomeningocele, an abnormality that causes significant disability.

ANENCEPHALY

Anencephaly, the most serious NTD, is a congenital malformation in which both cerebral hemispheres are absent. The condition is incompatible with life, and many affected infants are stillborn. For those who survive, no specific treatment is available. The infants have a portion of the brainstem and are able to maintain vital functions (such as temperature regulation and cardiac and respiratory function) for a few hours to several weeks but eventually die of respiratory failure.

Traditionally these infants have been provided comfort measures, but with no effort at resuscitation. Ethical and moral questions are encountered regarding treatment and withdrawal of support systems (e.g., feedings) if the newborn survives the first few days of life, as well as use of the organs for donor transplants. During this time the family requires emotional support and counseling to cope with the birth of an infant with a fatal defect. Referral to neonatal palliative care or hospice should be made as soon as possible.

SPINA BIFIDA AND MYELODYSPLASIA

Myelodysplasia refers broadly to any malformation of the spinal canal and cord. Midline defects involving failure of the osseous (bony) spine to close are called **spina bifida**, the most common defect of the CNS. SB is categorized into two types: SB occulta and SB cystica.

SB occulta refers to a defect that is not visible externally. It occurs most commonly in the lumbosacral area (L5 and S1) (Fig. 35-5, *B*). Routine radiographic examinations indicate that the disorder may occur in as many as 10% to 30% of the general population. However, it may not be apparent unless there are associated cutaneous manifestations or neuromuscular disturbances. Superficial cutaneous indications include a skin depression or dimple (which may also mark the outlet of a dermal sinus tract that extends to the subarachnoid space); port-wine angiomatous nevi; dark tufts of hair; and soft, subcutaneous lipomas. These signs may be absent, appear singly, or be present in combination.

If associated neurologic involvement is present, the defect is known as occult spinal dysraphism. Fibrous bands and adhesions, an intraspinal **lipoma** (fatty tumor) or subcutaneous lipoma (lipomyelomeningocele), a dermoid or epidermoid cyst, diastematomyelia (spinal cord split in two), or a tethered cord can distort the spinal cord or roots. The usual cause is abnormal adhesion, or tethering, to a bony or fixed structure, resulting in traction on the spinal cord and cauda equina. (See Figs. 35-7 and 35-8 for areas innervated by specific spinal nerves.)

Neuromuscular disturbances usually consist of progressive or static changes in gait with foot weakness, foot deformity, or bowel and bladder sphincter disturbances. Some manifestations may not be evident until the child walks or is toilet trained.

Plain radiography is employed to disclose the precise bony defect in the symptomatic lesion and to establish the diagnosis in the suspected, nonsymptomatic occult variety. Magnetic resonance imaging (MRI) is the most sensitive tool for evaluating the defect. Computed tomography (CT), ultrasonography, and myelography are also used to differentiate between SB occulta and other spinal disorders.

SB cystica refers to a visible defect with an external saclike protrusion. The two major forms of SB cystica are meningocele, which encases meninges and spinal fluid but no neural elements (Fig. 35-5, *C*), and myelomeningocele (or meningomyelocele), which contains meninges, spinal fluid, and nerves (Fig. 35-5, *D*). Neurologic deficit is not associated with meningocele but occurs in varying, often serious, degrees in myelomeningocele.

MYELOMENINGOCELE (MENINGOMYELOCELE)

Myelomeningocele (MMC) develops during the first 28 days of pregnancy when the neural tube fails to close and fuse at some point along its length. It may be detected prenatally or at birth, accounts for 90% of spinal cord lesions, and may be located at any point along the spinal column. Usually the sac is

FIG. 35-6 **A,** Myelomeningocele with intact sac. **B,** Myelomeningocele with ruptured sac. (Courtesy Dr. Robert C. Dauser, Neurosurgery, Baylor College of Medicine, Houston, TX.)

encased in a fine membrane that is prone to tears through which cerebrospinal fluid (CSF) leaks. In other instances the sac may be covered by dura, meninges, or skin, in which case there is rapid and spontaneous epithelialization. The largest number (75%) of myelomeningoceles occur in the lumbar or lumbosacral area (Fig. 35-6). The location and magnitude of the defect determine the nature and extent of neurologic impairment. When the defect is below the second lumbar vertebra, the nerves of the cauda equina are involved, giving rise to symptoms such as flaccid, areflexic partial paralysis of the lower extremities and varying degrees of sensory deficit. Unlike a spinal cord injury, the degree of deficit is not necessarily uniform on both sides but may vary between extremities, depending on the compromise to specific nerves from malformation or tethering.

The anomaly most frequently associated with myelomeningocele is **hydrocephalus**; approximately 80% to 85% of children with SB develop hydrocephalus (Burke, Liptak, and Council on Children with Disabilities, 2011; Kinsman and Johnston, 2011). Although present at birth, hydrocephalus may not be apparent until shortly thereafter, or after the primary closure of the opening on the back. Careful monitoring of head circumference, fontanel tension, and ventricular size by head ultrasonography can indicate its presence. Hydrocephalus can occur because the NTD itself disrupts the flow of CSF (see p. 1493). In many cases Chiari malformation (type II) is responsible. Type II **Chiari malformation** (a downward herniation of the brain into the brainstem) is present, though asymptomatic, in many children with SB. It can, however, adversely affect respiratory function, causing episodic apnea. Other clinical symptoms of problematic Chiari malformation include stridor, hoarse cry from vocal cord paralysis, feeding difficulties, aspiration pneumonia, and, in older children, upper extremity spasticity. The appearance of such symptoms should not be taken for granted; immediate referral is required to prevent further neurologic deterioration.

Pathophysiology

The pathophysiology of SB is best understood when related to the normal formative stages of the nervous system. At approximately 20 days of gestation, a decided depression, the neural groove, appears in the dorsal ectoderm of the embryo. During the fourth week of gestation, the groove deepens rapidly, and its elevated margins develop laterally and fuse dorsally to form the neural tube. Neural tube formation begins in the cervical region near the center of the embryo and advances in both directions—caudally and cephalically—until by the end of the fourth week of gestation, the ends of the neural tube, the anterior and posterior neuropores, close.

Most experts believe the primary defect in neural tube malformations is a failure of neural tube closure. However, some evidence indicates that the defects are a result of splitting of the already closed neural tube as a result of an abnormal increase in cerebrospinal fluid (CSF) pressure during the first trimester.

There is evidence of a multifactorial etiology, including drugs, radiation, maternal malnutrition, chemicals, and possibly a genetic mutation in folate pathways in some cases, which may result in abnormal development. There is also evidence of a genetic component in the development of SB; myelomeningocele may occur in association with syndromes such as trisomy 18, PHAVER (limb **p**terygia, congenital **h**eart **a**nomalies, **v**ertebral defects, **e**ar anomalies, and **r**adial defects) syndrome, and Meckel-Gruber syndrome (Shaer, Chescheir, and Schulkin, 2007). The genetic predisposition is supported by evidence of the risk for recurrence after one affected child (3% to 4%) and

a 10% risk for recurrence with two previously affected children (Kinsman and Johnston, 2011).

The degree of neurologic dysfunction depends on where the sac protrudes through the vertebrae, the anatomic level of the defect, and the amount of nerve tissue involved. One classification designates the level of functional mobility in relationship to the anatomic level of the defect. For example, children with a high lumbar-thoracic defect may be able to walk short distances using long-leg braces and by early adolescence must use a wheelchair for mobility; children with a low lumbar defect can walk with short leg braces and forearm crutches (Liptak and Dosa, 2010). This classification system, however, does not describe genitourinary and bowel function. About 80% of patients with myelomeningocele develop a type II Chiari malformation (Kinsman and Johnston, 2011). There is some evidence that prolonged exposure of the MMC sac to amniotic fluid predisposes to the development of hindbrain herniation and Chiari II malformation (Adzick, 2013).

Clinical Manifestations

The manifestations of SB vary widely according to the degree of the spinal defect. The defect is readily apparent on inspection. The degree of neurologic dysfunction is directly related to the anatomic level of the defect and thus the nerves involved. Sensory disturbances usually parallel motor dysfunction. The upper level of sensory and motor impairment can be determined by observation of the infant's response to a pinprick over the legs and trunk. The infant responds to the sensory stimulus with limb movement, arousal, and crying. When withdrawal activity is used to determine the lowest level of spinal cord function, the response to pinprick should begin above the lesion.

Defective nerve supply to the bladder affects both sphincter and detrusor tone, which often causes constant dribbling of urine or produces overflow incontinence. This can often be mistaken for normal voiding patterns in the newborn. Some infants with SB, however, are able to void in a stream and achieve complete bladder emptying with each void.

Frequently the infant has poor anal sphincter tone and poor anal skin reflex, which result in lack of bowel control and sometimes rectal prolapse. Avoid taking rectal temperatures in affected infants. Because bowel sphincter function is frequently affected, the thermometer can cause irritation and rectal prolapse. If the defect is below the third sacral vertebra, the infant has no motor impairment but may have saddle anesthesia with bladder and anal sphincter paralysis.

Sometimes the denervation to the muscles of the lower extremities produces joint deformities in utero. These are primarily flexion or extension contractures, talipes valgus or varus contractures, kyphosis, lumbosacral scoliosis, and hip dislocations. The extent and severity of these associated orthopedic deformities again depend on the degree of nerve involvement. Most flexion deformities result from the pull of stronger, fully innervated muscles acting without the counterpull of their nonfunctioning paralyzed antagonists. Box 35-6 provides a summary of clinical manifestations of SB cystica and occulta.

BOX 35-6 CLINICAL MANIFESTATIONS OF SPINA BIFIDA

Spina Bifida Cystica

Sensory disturbances usually parallel to motor dysfunction

Below second lumbar vertebra:

- Flaccid, partial paralysis of lower extremities
- Varying degrees of sensory deficit
- Overflow incontinence with constant dribbling of urine
- Lack of bowel control
- Rectal prolapse (sometimes)

Below third sacral vertebra:

- No motor impairment
- Bladder and anal sphincter paralysis

Joint deformities (sometimes produced in utero):

- Talipes valgus or varus (foot) contractures
- Kyphosis
- Lumbosacral scoliosis
- Hip dislocation

Spina Bifida Occulta

Frequently no observable manifestations

May be associated with one or more cutaneous manifestations:

- Skin depression or dimple
- Port-wine angiomatous nevi
- Dark tufts of hair
- Soft, subcutaneous lipomas

May be neuromuscular disturbances:

- Progressive disturbance of gait with foot weakness
- Bowel and bladder sphincter disturbances

Diagnostic Evaluation

The diagnosis of SB is made on the basis of clinical manifestations (see Box 35-6) and examination of the meningeal sac (see Fig 35-6, *A*). Diagnostic measures used to evaluate the brain and spinal cord include MRI, ultrasonography, and CT. A neurologic evaluation will determine the extent of involvement of bowel and bladder function, as well as lower extremity neuromuscular involvement. Flaccid paralysis of the lower extremities is a common finding with absent deep tendon reflexes.

Prenatal Detection

It is possible to determine the presence of some major open NTDs prenatally. Ultrasonographic scanning of the uterus and elevated maternal concentrations of α-fetoprotein (AFP, or MS-AFP), a fetal-specific γ-$_1$-globulin, in amniotic fluid may indicate anencephaly or myelomeningocele. The optimum time for performing these diagnostic tests is between 16 and 18 weeks of gestation before AFP concentrations normally diminish and in sufficient time to permit a therapeutic abortion. It is recommended that such diagnostic procedures and genetic counseling be considered for all mothers who have borne an affected child, and testing is offered to all pregnant women (American College of Obstetrics and Gynecology, 2007). Chorionic villus sampling is also a method for prenatal diagnosis of NTDs; however, it carries certain risks (skeletal limb depletion) and is not recommended before 10 weeks of gestation (Simpson, Richards, and Otaño, 2012).

Therapeutic Management

Management of the child who has a myelomeningocele requires a multidisciplinary team approach involving the specialties of neurology, neurosurgery, pediatrics, urology, orthopedics, rehabilitation, physical therapy, occupational therapy, and social services, as well as intensive nursing care in a variety of specialty areas. The collaborative efforts of these specialists focus on:

- The myelomeningocele and the problems associated with the defect—hydrocephalus, paralysis, orthopedic deformities (e.g., developmental dysplasia of the hip, clubfoot), and genitourinary abnormalities
- Possible acquired problems that may or may not be associated, such as Chiari II malformation, meningitis, seizures, hypoxia, tethered cord, and hemorrhage
- Other abnormalities, such as cardiac or gastrointestinal (GI) malformations

Many hospitals have routine outpatient care by multidisciplinary teams to provide the complex follow-up care needed for children and families with myelodysplasia.

Many authorities believe that early closure, within the first 24 to 72 hours, offers the most favorable outcome. Surgical closure within the first 24 hours is recommended if the sac is leaking CSF (Kinsman and Johnston, 2011).

A variety of neurosurgical and plastic surgical procedures are used for skin closure without disturbing the neural elements or removing any portion of the sac. The objective is satisfactory skin coverage of the lesion and meticulous closure. Wide excision of the large membranous covering may damage functioning neural tissue.

Early surgical closure of the myelomeningocele sac through fetal surgery has been evaluated in relation to prevention of injury to the exposed spinal cord tissue and the improvement of neurologic and urologic outcomes in the affected child. The Management of Myelomeningocele Study, a clinical trial supported by the National Institutes of Health, found that prenatal surgery for myelomeningocele reduced the need for shunting (for hydrocephalus), evaluated at 12 months, and decreased the incidence of hindbrain herniation. In addition there was an improvement in mental and motor function scores at 30 months in the children who had prenatal surgery (compared with children who had postnatal surgery) (Adzick, Thom, Spong, et al, 2011). However, the surgery is not without risks to the fetus and mother, and premature delivery is common. Outcome data for urologic and bowel function, motor function, cognition, and spina bifida–associated outcomes are being gathered in the MOMS2 study, which is expected to end in late 2013 (Clinical Trials, 2013).

Initial Care

Care of the newborn involves preventing infection; performing a neurologic assessment, including observation for associated anomalies; and dealing with the impact of the anomaly on the family. Although meningoceles are repaired early, especially if the sac is in danger of rupturing, the philosophy regarding skin closure of myelomeningocele varies. Most authorities believe that early closure, within the first 24 to 72 hours, offers the most favorable outcome. Surgical closure within the first 24 hours is recommended if the sac is leaking CSF (Kinsman and Johnston, 2011). Early closure, preferably in the first 12 to 18 hours, not only prevents local infection and trauma to the exposed tissues but also avoids stretching other nerve roots (which may occur as the meningeal sac expands during the first hours after birth), thus preventing further motor impairment. Broad-spectrum antibiotics are initiated, and neurotoxic substances such as povidone-iodine are avoided at the malformation.

A variety of neurosurgical and plastic surgical procedures are employed for skin closure without disturbing the neural elements or removing any portion of the sac. The objective is satisfactory skin coverage of the lesion and meticulous closure. Wide excision of the large membranous covering may damage functioning neural tissue.

Associated problems are assessed and managed by appropriate surgical and supportive measures. Shunt procedures provide relief from imminent or progressive hydrocephalus (see Chapter 32). When diagnosed, ventriculitis, meningitis, and urinary tract infection are treated with vigorous antibiotic therapy and supportive measures. Surgical intervention for Chiari II malformation is indicated only when the child is symptomatic (i.e., high-pitched crowing cry, stridor, respiratory difficulties, apnea, failure to thrive, GER, oral-motor difficulties, upper extremity spasticity).

Improved surgical techniques do not alter the major physical disability and deformity or chronic urinary tract infections that affect the quality of life for these children. Superimposed on these physical problems are the disorder's effects on family life and finances and on school and hospital services.

Musculoskeletal Considerations

According to most orthopedists, musculoskeletal problems that will affect later locomotion should be evaluated early and treatment, where indicated, instituted without delay. Neurologic assessment determines the neurosegmental level of the lesion, spasticity and progressive paralysis, potential for deformity, and functional expectations. Orthopedic and musculoskeletal management includes preventing joint contractures, correcting the existing deformity, preventing or minimizing effects of motor and sensory deficits, preventing skin breakdown, and obtaining the best possible function of affected lower extremities. Common musculoskeletal problems requiring attention in SB include deformities of the knees, hips, feet, and spine; fractures and insensate skin further complicate orthopedic care. Other problems that may occur later include kyphosis and scoliosis (Lazzaretti and Pearson, 2010; Liptak and Dosa, 2010). About 50% of infants born with myelomeningocele will have clubfoot (Sandler, 2010). Because children with MMC often have decreased sensitivity in lower extremities, preventive skin care is important. A high percentage (60%) of children seen in a wound clinic for skin breakdown had myelomeningocele at birth (Samaniego, 2003).

The status of the neurologic deficit remains the most important factor in determining the child's ultimate functional

abilities; however, many children with lumbar and sacral myelomeningocele are able to achieve functional ambulation (Kinsman and Johnston, 2011). With technologic advances, a variety of lightweight orthoses, including braces, special "walking" devices, and custom-built wheelchairs, are available to provide mobility to children with spinal cord lesions (see also Chapter 34). Early in infancy, intervention with passive range-of-motion exercises, positioning, and stretching exercises may help decrease the incidence of muscle contractures. Corrective surgical procedures, when indicated, are best initiated at an early age so that the child will not lag significantly behind age-mates in developmental progress. The degree of lower extremity function guides decisions about whether orthopedic surgery will be needed.

Physical therapy and musculoskeletal management of children with myelomeningocele are continual processes to achieve optimum function and ambulation when possible. Problems such as type II Chiari malformation, hydrocephalus, and a tethered spinal cord can complicate expectations. A common complication is tethered cord syndrome in which there is a presumed traction injury to the distal spinal cord with subtle and progressive loss of neural function; this may occur any time but is more common during periods of rapid growth and can be precipitated by ventricular shunt failure (Burke, Liptak, and Council on Children with Disabilities, 2011).

Management of Genitourinary Function

Myelomeningocele is one of the most common causes of neuropathic (neurogenic) bladder dysfunction among children. Myelomeningocele affects approximately 1 in 1000 infants born in the United States, and as many as 90% experience subsequent voiding dysfunction. In infants the goal of treatment is to preserve renal function. In older children the goal is to preserve renal function and achieve optimum urinary continence. Urinary incontinence is a chronic, often debilitating, problem for the child. In addition, the neuropathic bladder may produce **urinary system distress**, characterized by symptomatic urinary tract infections, ureterohydronephrosis, vesicoureteral reflux, or renal insufficiency. The characteristics of bladder dysfunction in children vary according to the level of the neurologic lesion and the influence of bony growth and development of the spine. In addition, the presence of type II Chiari malformation and subsequent hydrocephalus has the potential to affect bladder function, although spinal influences predominate.

During infancy, urinary incontinence is normally physiologic, but urinary system distress may occur. Ongoing urologic monitoring is essential. Evidence is growing that early intervention, based on evaluation during the neonatal period and before complications occur, improves bladder function, reduces the subsequent risk of urinary system distress, and reduces the need for reconstructive surgery of the lower urinary tract. Ultrasonography of the bladder and ureters and routine urinalysis (and urine cultures when indicated) are used to detect urinary system distress before renal function is compromised. In addition, urodynamic testing is used to identify bladder dysfunction that predisposes the child to urinary system distress (Gray and Moore, 2009; Snodgrass and Gargollo, 2010). These conditions include high pressure detrusor hyperreflexia (reflex contractions of the detrusor muscle) with vesicosphincter dyssynergia (incoordination of detrusor and sphincter muscles), low bladder wall compliance (poor distensibility of the bladder wall causing increased intravesical pressures during urine filling and storage), or detrusor areflexia (absence of detrusor contractions caused by the spinal defect).

Infants may have one of several predominant neuropathic bladder disorders. Detrusor contractions associated with vesicosphincter dyssynergia are particularly common. Some infants are able to empty the bladder efficiently despite incoordination between the sphincter mechanism and detrusor, but the majority experience chronic residual urine, urinary tract infections, or more serious types of urinary system distress. A minority of infants have poor detrusor contraction strength or detrusor areflexia. This condition is particularly damaging to the urinary system when it coexists with low bladder wall compliance and an elevated detrusor leak point pressure. Low bladder wall compliance occurs when collagen or fibrosis causes stiffening of the bladder wall. This stiffened bladder wall raises intravesical pressures, obstructing the bladder, ureters, and, ultimately, the nephron. The impact of low bladder wall compliance is directly related to the influence of the bladder outlet. Among children with myelodysplasia, the urethral muscles are typically weakened, and collagen replaces much of the muscle tissue. As a result, the sphincter is fixed, so it neither closes efficiently to prevent urinary leakage nor opens well to allow urinary flow with a detrusor contraction. When the magnitude of the pressure required to drive urine across the abnormal sphincter is greater than 40 cm H_2O (the detrusor leak point pressure) and the compliance of the bladder wall is low (<10 cm H_2O), the risk of urinary system distress is high.

In contrast, a small number of infants experience effective detrusor contractions without vesicosphincter dyssynergia. Effective bladder evacuation is likely among this group, and the incidence of urinary system distress during the first year of life is low.

As the child grows, detrusor hyperreflexia is often replaced by deficient detrusor contraction strength and **stress urinary incontinence (SUI)** (leakage produced by physical exertion). The bladder wall is often poorly compliant (producing chronically elevated intravesical pressures), and the bladder outlet, while incompetent, obstructs the outflow of urine. When the detrusor leak point pressure exceeds 40 cm H_2O, the child is predisposed to chronic urinary leakage and urinary distress symptoms, including recurrent urinary tract infections and reflux. When the detrusor leak point pressure is lower than 40 cm H_2O, urinary leakage is more severe, although the risk of urinary system distress is lessened. Thus the child with more severe urinary incontinence is less predisposed than the "drier" child to serious urinary tract infections.

Infants with myelomeningocele and a neurogenic bladder who are not at risk for urinary system distress are managed by diaper containment and watchful waiting. The infant empties the bladder into a diaper, the urine is routinely monitored for

infection, and the upper urinary tracts are monitored for evidence of urinary system distress (dilation of the ureters, renal pelves, or collecting systems) via serial ultrasonography.

In contrast, children with evidence of urinary system distress, or those considered at risk based on early urodynamic testing, undergo **clean intermittent catheterization (CIC)**, typically in combination with an antispasmodic medication such as oxybutynin or propantheline (De Jong, Chrzan, Klijn, et al, 2008; Gray and Moore, 2009). Anticholinergic medications are prescribed because they reduce detrusor muscle tone and reduce bladder pressures during both urine filling and storage and during micturition. CIC is not intended to prevent spontaneous voiding. Instead, it ensures routine, regular bladder evacuation, further preventing deleterious elevation of intravesical pressures. Usually, the parents learn to catheterize the infant every 4 hours during the day and once each night. Follow-up evaluation, consisting of serial ultrasonography and urinalysis, is completed every 3 to 6 months as indicated.

Infants with significant urinary system distress and neuropathic bladder dysfunction at birth sometimes require temporary urinary diversion to ensure adequate urine outflow and prevent further damage to the upper urinary tracts. A vesicostomy is a relatively simple procedure wherein the anterior bladder wall is brought to the abdominal wall, creating a small stoma for urinary drainage. Urine is contained via a diaper, but double diapering or use of a larger diaper that can be placed higher on the abdomen is necessary for adequate urine containment. Meticulous skin care is necessary because the perineal skin is exposed to continuous urinary leakage.

Among older children the quest for continence typically begins with a CIC program. The parents learn the procedure and teach the child to self-catheterize as soon as possible, usually by 6 years of age (Gray and Moore, 2009). The child with detrusor hyperreflexia and dyssynergia often responds well to antispasmodic medications and CIC. In contrast, the child with poor bladder wall compliance and SUI often requires a combination of antispasmodic medications to reduce intravesical filling pressures and an asympathetic agonist (such as imipramine, pseudoephedrine, or phenylpropanolamine) to enhance sphincter competence. Unfortunately, the combination of medications and CIC is typically only partially effective, and more aggressive interventions are often required to render the neuropathic bladder both continent and free from its predisposition toward producing urinary system distress.

When the child cannot attain continence by conservative measures, surgery is considered. Augmentation enterocystoplasty (or gastrocystoplasty) is a surgical procedure that increases bladder capacity, reverses or halts the negative effects of the poorly compliant bladder wall, and reduces harmfully high bladder pressures caused by detrusor hyperreflexia with vesicosphincter dyssynergia. A detubularized segment of large or small bowel or a wedge of the fundus of the stomach has been used to successfully augment bladder capacity. The choice of segment varies according to the surgeon's preference and the status of the patient's urinary and GI systems. Large and small bowel segments produce significant volumes of mucus that may clog catheters used for CIC. Augmentation with the stomach produces less mucus, and its acidic secretions may reduce the urinary system's predisposition to infection. The bladder must be irrigated to decrease mucus within the bladder; this also decreases the possible complications of infection, stones, and bladder perforation.

Even though augmentation of the bladder may improve or resolve urinary leakage related to detrusor hyperreflexia or urinary system distress caused by low bladder wall compliance, the SUI produced by the abnormal sphincter mechanism typically persists. Several surgical procedures help correct this intrinsic sphincter deficiency. The Mitrofanoff procedure uses the appendix to provide an alternative route for intermittent catheterization. The appendix is removed from the colon and used to create a continent conduit between the abdominal wall and the bladder. The resulting stoma is relatively small and produces minimum mucus. The ureter may be used as an alternative to the appendix for some children. If the appendix is insufficient, a segment of tapered intestine, ileum, or colon may be used to create a conduit (Monti tube) (Gray and Moore, 2009). CIC through the easily accessible abdominal route fosters greater independence in children, especially in those unable to transfer from wheelchair to toilet to perform CIC.

When intrinsic sphincter deficiency produces only mild stress urinary leakage, the construction of a Mitrofanoff route alone may be sufficient to achieve continence between catheterization episodes. However, when SUI is more severe, a suburethral sling or suburethral collagen injection is used to alleviate intrinsic sphincter deficiency.

The suburethral sling is a slip of fascia or synthetic material that is placed below the proximal third of the urethra. The sling may be placed in a fashion that uses only slight tension to obstruct the urethra and prevent SUI. The sling may be used for both boys and girls, and the procedure can be completed at the same time the augmentation enterocystoplasty is constructed. After augmentation enterocystoplasty and placement of a suburethral sling, the patient can expect to evacuate the bladder by CIC of the appendiceal Mitrofanoff route (appendicovesicostomy) or the urethra if a Mitrofanoff route has not been constructed.

Suburethral injection of glutaraldehyde cross-linked (GAX) collagen also may be used to alleviate or prevent SUI caused by intrinsic sphincter deficiency. Collagen is used to bulk or expand the urethral tissue, promoting coaptation (approximation) of the mucosa. The collagen implant complements the urethra's ability to form a watertight seal, rather than obstructing the urethral lumen. Collagen may be injected using different approaches. Transurethral collagen is injected through the working channel of a cystoscope. Transperineal collagen is directed underneath the urethra using a needle inserted through the perineal skin. In this case the location of the urethra is confirmed by simultaneous cystoscopic visualization of the urethra. The antegrade approach requires creation of a suprapubic cystostomy tract. A flexible cystoscope is then inserted through the cystostomy tract, and collagen is injected into the proximal urethra. Multiple injections may be

required to achieve optimum continence. Subsequent injections may be required when the collagen is dissipated or resorbed by the body over a period of years. Botulinum toxin (Botox) can also be injected into the detrusor muscle to increase bladder capacity and decrease intravesicular pressures, but this measure is only temporary (Frimberger, Cheng, and Kropp, 2012).

The artificial urinary sphincter provides another alternative for the management of intrinsic sphincter deficiency in the child with myelomeningocele. The device consists of a urethral cuff, abdominal reservoir, and control pump. In the activated position, the cuff is filled, and the pressure of this cuff closes the urethral lumen. During micturition, the control pump is used to baffle fluid from the urethral cuff to the abdominal reservoir, opening the urethra for micturition or catheterization. However, because of the significant risk for infection, need for revision with growth, and mechanical failure, the popularity of the artificial urinary sphincter has declined.

Because of advances in neurogenic bladder management, adolescents and young adults with myelomeningocele and neurogenic bladder have been followed for up to 30 years without evidence of deterioration in renal function. Nevertheless, urinary and fecal incontinence are common, and these conditions lead to significant, and sometimes devastating, problems with growth and developmental tasks, including establishing independence and social and intimate relationships. This observation underscores the need to aggressively manage both continence and the threat of urinary system distress from an early age and to establish an expectation of social continence critical to providing these patients with the skills they need to thrive as adolescents and adults. Newborns with SB and normal urodynamics require close follow-up care during the first several years of life to prevent deterioration in urodynamic status as a result of neurologic deterioration.

Bowel Control

Some degree of fecal continence can be achieved in most children with myelomeningocele with diet modification, regular toilet habits, and prevention of constipation and impaction. It is frequently a lengthy process. Dietary fiber supplements (recommended age of child in years + 5 g/day), laxatives, suppositories, or enemas aid in producing regular evacuation. Older children and adolescents seeking more independence may attain bowel continence and higher quality of life after undergoing an **antegrade continence enema** (ACE) procedure (Doolin, 2006). In a procedure similar to the Mitrofanoff, the appendix or ileum is used to create a catheterizable channel with attachment of the proximal end to the colon. The distal end of the channel exits through a small abdominal stoma. Every 1 or 2 days, a catheter is passed through the stoma, allowing enema solution to be instilled directly into the colon. After administration of the enema solution, the child sits on the toilet for 30 to 60 minutes as stool is flushed out through the rectum. The frequency of enemas and volume of solution used to completely evacuate the bowel vary among individuals.

Prognosis

The early prognosis for the child with myelomeningocele depends on the neurologic deficit present at birth, including motor ability, bladder innervation, and associated neurologic anomalies. Early surgical repair of the spinal defect, antibiotic therapy to reduce the incidence of meningitis and ventriculitis, prevention of urinary system dysfunction, and early detection and correction of hydrocephalus have significantly increased the survival rate and quality of life in such children. Mortality rates are reported to be 10% to 15%, with many deaths occurring before the age of 4 years (Kinsman and Johnston, 2011). Many young adults with SB achieve partial independent living and gainful employment. Reports of survival rates vary, and many include adults who were born before medical advances and surgical techniques seen in the past 25 years. Coordinated care for adults with SB is essential; however, multidisciplinary adult care is often inadequate (Lazzaretti and Pearson, 2010). One of the factors associated with early death among adults with MMC is hydrocephalus and shunt failure (Mourtzinos and Stoffel, 2010). This chronic condition has an array of associated complications, including hydrocephalus and shunt malfunctions, tethered cord syndrome, scoliosis, Chiari II development, bowel and bladder management issues, latex allergy, and epilepsy. However, based on current medical knowledge and ethical considerations, aggressive, early management is favored for the child with myelomeningocele.

Prevention

The Centers for Disease Control and Prevention (2009) continues to affirm that 50% to 70% of NTDs can be prevented by daily consumption of 0.4 mg of folic acid by women of childbearing age. The data indicate that serum folate concentrations among women of childbearing age decreased 16% from 2003 to 2004 in all ethnic groups studied. Lowest serum folate levels were seen in non-Hispanic Caucasians in 2003 to 2004; however, overall serum folate levels remained below recommended levels in non-Hispanic African-Americans during all three periods studied (Centers for Disease Control and Prevention, 2007). These results indicate that nurses and other health care workers have an important task in disseminating information that may decrease the incidence of birth defects in children by promoting maternal consumption of folic acid.*

To ensure adequate daily intake of the recommended amount of folic acid, women must take a folic acid supplement, eat a fortified breakfast cereal containing 100% of the recommended dietary allowance of folic acid (e.g., Kellogg's Product 19, General

*Information is available from Centers for Disease Control and Prevention, National Center on Birth Defects and Developmental Disabilities, Division of Birth Defects and Developmental Disabilities, 1600 Clifton Road NE, MS E-86, Atlanta, GA 30333; 800-CDC-INFO; e-mail: cdcinfo@cdc.gov; **www.cdc.gov/ncbddd/folicacid**; and from the March of Dimes Resource Center, 1275 Mamaroneck Ave., White Plains, NY 10605; **www.marchofdimes.com**.

Mills Total, Multigrain Cheerios Plus), or increase their consumption of fortified foods (e.g., cereal, bread, rice, grits, pasta) and foods naturally rich in folate (e.g., green leafy vegetables and citrus fruits). For women who have had a previous pregnancy affected by NTDs, folic acid intake is increased to 4 mg/day under the supervision of a health care practitioner beginning 1 month before a planned pregnancy and continuing through the first trimester. Supplementation of 4 mg of folate should not be given solely in multivitamin preparations because of the risk for overdose of other vitamins. Drugs that affect folic acid metabolism and increase the risk for myelomeningocele should be avoided before pregnancy (if plans are to become pregnant in the near future) and during pregnancy; these include trimethoprim and the AEDs carbamazepine, phenytoin, phenobarbital, valproic acid, and primidone (Kinsman and Johnston, 2011).

Nursing Care Management

The basic needs of the infant with a myelomeningocele are essentially the same as for any newborn infant. (See Chapter 7.) Special needs related to the defect and potential complications are discussed in the following section. As the child matures, the problems increase and involve all aspects of daily living; therefore, care is directly related to the child's habilitation at each stage of development.

Assessment

At the time of delivery an examination is performed to assess the intactness of the membranous cyst. During transport to the nursery, make every effort to prevent trauma to this protective covering. In addition to the routine assessment of the newborn (see Chapter 7), assess the infant for the level of neurologic involvement. Note movement of extremities or skin response, especially an anal reflex that might provide clues to the degree of motor or sensory impairment.

Care of the Myelomeningocele Sac

The infant is usually placed in an incubator or radiant warmer so that temperature can be maintained without clothing or covers that might irritate the CNS lesion. When an overhead warmer is used, the dressings over the defect require more frequent moistening because of the dehydrating effect of the radiant heat. Before surgical closure, the myelomeningocele is kept from drying by the application of a sterile, moist, nonadherent dressing. The moistening solution is usually sterile normal saline. Dressings are changed frequently (every 2 to 4 hours), and the sac is closely inspected for leaks, abrasions, irritation, and signs of infection. The sac must be carefully cleansed if it becomes soiled or contaminated. Sometimes the sac ruptures during delivery or transport, and any opening in the sac greatly increases the risk of infection to the CNS (Fig. 35-6, *B*). When an overhead warmer is used, the dressings over the defect require more frequent moistening because of the drying effect of the radiant heat.

Positioning

One of the most important and challenging aspects of early care of the infant with myelomeningocele is positioning. Before surgery the infant remains in the prone position to minimize tension on the sac and the risk of trauma. The prone position allows for optimum positioning of the legs, especially in cases of associated hip dysplasia. A variety of aids, including diaper rolls, foam pads, or specially designed frames and appliances, are available to maintain the desired position.

The prone position affects other aspects of the infant's care. For example, in this position the infant is more difficult to keep clean, pressure areas are a constant threat, and feeding becomes a problem. The infant's head is turned to one side for feeding. Fortunately, most defects are repaired early, and the infant can be held for feeding and routine care soon after surgery. Physical therapy consultation may be necessary for difficult positioning problems. Speech-language pathologist consultation may be needed for difficulty with oral-motor skills that may indicate complications caused by a Chiari malformation.

General Care

Diapering the infant may be contraindicated until the defect has been repaired and healing is well advanced or epithelialization has taken place. The padding beneath the diaper area is changed as needed to keep the skin dry and free of irritation. When the nurse detects urinary retention (the bladder is still an abdominal organ in early infancy), CIC is employed. Because the bowel sphincter is frequently affected, there may be continual passage of stool, often misinterpreted as diarrhea, which is a constant irritant to the skin and a source of infection to the spinal lesion.

Areas of sensory and motor impairment are subject to skin breakdown and therefore require meticulous care. The infant may be placed on a pressure-reducing mattress or a mattress to prevent pressure on the knees and ankles. (See Skin Care, Chapter 9, and Maintaining Healthy Skin, Chapter 23.)

Gentle range-of-motion exercises are carried out to prevent contractures, and stretching of contractures is performed when indicated. However, these exercises may be restricted to the foot, ankle, and knee joint. When the hip joints are unstable, stretching against tight hip flexors or adductor muscles, which act much like bowstrings, may aggravate a tendency toward subluxation. A physical therapy consultation is often necessary to develop a multidisciplinary plan to prevent long-term complications.

Some infants with unrepaired myelomeningocele are unable to be held in the arms and cuddled as unaffected infants are, so their need for tactile stimulation is met by caressing, stroking, and other comfort measures. To facilitate handling and reduce parental anxiety, the infant can recline on a pillow placed in the parent's lap.

Ophthalmic complications may occur in children with SB and hydrocephalus. The appearance of a squint, other ocular motility, or papilledema usually denotes hydrocephalus and is reported. Ophthalmologic follow-up care, particularly in children with shunts, is generally included in the multidisciplinary care plan.

Postoperative Care

Postoperative care for the infant with myelomeningocele involves the same basic care as for any postsurgical infant:

monitoring vital signs, weight, and intake and output; maintaining body temperature; assessing and relieving pain; providing nourishment; and observing for signs of infection. The wound is managed according to the surgeon's directions, and general care is continued as preoperatively.

The prone position is maintained after operative closure, although many neurosurgeons allow a side-lying or partial side-lying position unless it aggravates a coexisting hip dysplasia or permits undesirable hip flexion. This offers an opportunity for position changes, which reduces the risk of pressure sores and facilitates feeding. Once the effects of anesthesia have subsided and the infant is alert, feedings may resume unless there are other anomalies or associated complications.

Nursing assessments are carried out for implementation of comfort measures in the postoperative period. The infant can be held upright against the body, taking care to avoid pressure on the operative site. In the case of an unusually large defect, skin grafting may be required for wound closure; the infant must then be kept prone postoperatively with as little movement as possible to prevent tension on the skin graft.

The nurse can assist in determining the extent of neuromuscular involvement. Note movement of the extremities or skin response, especially an anal reflex, that might provide clues to the degree of motor or sensory status. Measure head circumference daily (see Chapter 5), and examine the fontanels for signs of tension or bulging. The nurse is also alert to early signs of infection, such as elevated or decreased temperature (axillary), irritability, and lethargy, and to signs of increased intracranial pressure (ICP). Urinary catheterization may be needed for urine retention. Although it may not have been a problem preoperatively, swelling around the operative site may cause transient urine retention, which resolves in 2 to 5 days.

Family Support and Home Care

As soon as the parents are able to cope with the infant's condition, encourage them to become involved in care. They need to learn how to continue at home the care that has been initiated in the hospital: positioning, feeding, skin care, and range-of-motion exercises when appropriate. Parents also need to learn CIC technique when prescribed. The family needs to know the signs of complications and how to reach assistance when needed.

As the child grows and develops, parents need guidance to encourage and stimulate the infant to accomplish age-appropriate developmental tasks within the limits imposed by the disabilities. Upper limb movement can be stimulated early by placing the infant on the floor in a prone position with toys within reach. Activities that encourage body consciousness, such as rolling over and pulling to a sitting position, are encouraged at the appropriate times. Creeping and crawling help the child explore the environment. The parents may need help to modify appliances and activities normally expected of a growing child. A standing table, frame, or parapodium is helpful for a variety of activities, and it is best for the child to begin supported weight bearing and standing as close as possible to the expected time for standing to occur.

It is important for the family to understand the nature of sensory deficit in a child with a spinal defect. The child will be insensitive to pressure or other sources of tissue injury. Therefore, the family must be alert to hot or cold items that could cause thermal injury to tissues and remember to inspect the skin regularly for signs of pressure, especially over bony prominences. Because of sensory impairment, the child is unaware of bladder discomfort. Therefore, signs of urinary tract infections may go unnoticed. Urinary tract infection is often considered when the child becomes ill.

The long-range planning with and support of the parents and newborn begin in the hospital and extend throughout childhood and even into young adulthood. The life expectancy of children with SB extends well into adulthood; therefore, planning should involve long-term goals and plans for optimum function as an adult. Long-range planning goals should include a discussion of achievement of functional mobility, urinary continence, and as much bowel continence as physically possible. Discussion about aspects of adulthood such as having a mate, sexual relationships, and bearing and rearing children is important and should not be overlooked (Rowe and Jadhav, 2008). The unique service needs of adolescents with SB as they attempt to gain independence from family and establish a life of their own have not been adequately addressed in the literature (Sawyer and Macnee, 2010). Betz, Linroth, Butler, and colleagues (2010) interviewed young people with SB making the transition to adulthood. Some common themes that emerged among these young people were challenges in preparation for self-management, limited social relationships, awareness of their cognitive challenges, and the cost of independence. Advances in neurology, orthopedics, and urology have enabled adolescents to progress into adulthood with fewer deficits than observed in previous decades; one key factor is the recognition of subtle signs of neurologic deterioration and rapid intervention (Rowe and Jadhav, 2008).

Nurses assume an important role as a central member of the health team. As a coordinator, the nurse reviews information with the family, takes responsibility for family teaching, and acts as a liaison between inpatient and outpatient services. The child may require numerous hospitalizations over the years, and each one will be a source of stress to which the younger child is especially vulnerable.

Changes in functional ability, particularly in the lower extremities, bowel, or bladder, may indicate the presence of a tethered cord, one that is bound low or restricted in an abnormal position by scar tissue. These symptoms usually occur after a growth spurt and can best be detected with MRI. Tethering can be repaired surgically but, unfortunately, may recur.

Habilitation involves solving not only problems of self-help and locomotion but also the most distressing problem of incontinence, which threatens the child's social acceptability. Assistance in preparing the child and the school regarding the special needs of children with disabilities helps the parents provide a better initial adjustment to broader social experiences. A Life Course Model has been developed for patients, families, caregivers, teachers, and clinicians to facilitate, through a developmental approach, the care of the child and young person with

SB; this program has been made into a web-based tool that can be used to assist in the transition to adulthood (Dicianno, Fairman, Juengst, et al, 2010). Additional information regarding this program is available through the Spina Bifida Association's website at **www.sbpreparations.org**.

Numerous organizations and agencies offer assistance and support to children and families. The Spina Bifida Association* provides services and support for families of children with spinal lesions.

The multiple aspects of care of the child with a disability are discussed in Chapter 19. Complex problems associated with partial or complete lower extremity paralysis are discussed in this chapter and Chapter 34 and include bowel and bladder control; orthopedic appliances; and the observation and management of complications, especially urinary tract infections (see Chapter 25) and pressure necrosis (see Wounds, Chapter 16).

LATEX ALLERGY

Latex allergy, or latex hypersensitivity, was identified as being a serious health hazard when a report linked intraoperative anaphylaxis with latex in children with SB. Latex, a natural product derived from the rubber tree, is used in combination with other chemicals to give elasticity, strength, and durability to many products. Children with SB are at high risk for developing latex allergy because of repeated exposure to latex products during surgery and procedures. Therefore, such children should not be exposed to latex products from birth onward to minimize the occurrence of latex hypersensitivity. Allergic reactions range from urticaria, wheezing, watery eyes, and rashes to anaphylactic shock. More severe reactions tend to occur when latex comes in contact with mucous membranes, wet skin, the bloodstream, or an airway. There also can be cross-reactions to a number of foods (e.g., banana, avocado, kiwi, chestnut).

Allergic reactions to latex protein can also occur when the substance is transferred to food by food handlers wearing latex gloves, prompting several states to pass legislation that prohibits the use of latex gloves in food service. In addition to patients with SB, high-risk populations include patients with urogenital anomalies or multiple surgeries, as well as health care workers.

The most important goals are prevention of latex sensitivity and identification of children with a known hypersensitivity (see Nursing Care Guidelines box). High-risk and latex-allergic individuals must be managed in a **latex-free environment**. Take care that they do not come in direct or secondary contact with products or equipment containing latex at *any time* during medical treatment. Allergy testing can identify latex sensitivity with varying success. Skin prick testing and provocation testing carry the risk for allergic reaction or anaphylaxis. Several commercially available assays can be useful in confirming latex sensitivity. To date, none of these tests demonstrates complete diagnostic reliability, and they should not be the sole determinant of the presence or absence of an allergic response to latex.

Because children who have SB are prone to develop sensitivity to latex, reducing exposure from birth on may decrease the chance of allergy development. Nonlatex products lists are available to parents and health care workers; these products may be substituted for those containing latex. In the health care arena, it is important to use products with the lowest potential risk for sensitizing patients and staff members.*

The identification of those sensitive to latex is best accomplished through careful screening of all patients. During the health interview with the parent or child, ask *all* patients, not only those at risk, about sensitivity to latex. Be certain this is a routine part of all preoperative and preprocedural histories. Stress the importance of the allergy history to all personnel (e.g., phlebotomists, respiratory therapists). (See Guidelines box for questions related to latex allergy.) Children with latex hypersensitivity should carry some form of allergy identification, such as a MedicAlert bracelet. Education programs regarding latex hypersensitivity are aimed at those who care for high-risk groups, such as children with SB, and may include relatives, school nurses, teachers, child care workers, and babysitters. In addition to educating caregivers about the child's exposure to medical products that contain latex, nurses need to inform them of common nonmedical latex objects such as water toys, pacifiers, and plastic storage bags.† Items brought to the hospital, such as floral bouquets, should also be screened for latex toys and balloons. Parents should also receive literature explaining signs and symptoms of latex

NURSING CARE GUIDELINES

Identifying Latex Allergy

- Does your child have any symptoms, such as sneezing, coughing, rashes, or wheezing, when handling rubber products (e.g., balloons, tennis or Koosh balls, adhesive bandage strips) or when in contact with rubber hospital products, such as gloves or catheters?
- Has your child ever had an allergic reaction during surgery?
- Does your child have a history of rashes, asthma, or allergic reactions to medication or foods, especially milk, kiwi, bananas, or chestnuts?
- How would you identify or recognize an allergic reaction in your child?
- What would you do if an allergic reaction occurred?
- Has anyone ever discussed latex or rubber allergy or sensitivity with you?
- Has the child had any allergy testing?
- When did the child last come in contact with any type of rubber product? Were you present?

hypersensitivity and appropriate emergency treatment. (See Anaphylaxis, Chapter 24.)

HYPOTONIA

Decreased muscle tone may be observed in the neonatal period and is one of the most common presenting symptoms in neuromuscular disorders. Hypotonia in neonates born before 37 weeks may be due to neuromuscular immaturity or perinatal maternal medications. (See also Chapter 9.) Monitor such infants over time for neuromuscular tone and make further evaluation if physiologic immaturity is not determined to be a contributing factor. Hypotonia may also indicate a variety of systemic conditions. Common causes are cerebral trauma or perinatal hypoxia, but most neuromuscular disorders with hypotonia as the presenting symptom, especially Down syndrome and spinal muscular atrophy (SMA), are genetically determined. Additional conditions that may present in the neonatal period include inborn errors of metabolism such as glycogen storage disease; congenital and metabolic myopathies; cerebral dysgenesis such as lissencephaly; and congenital muscular dystrophies.

Clinical Manifestations

Hypotonia is marked by diminished muscle tone and weakness in both spontaneous and passive motion and reflex testing. The affected infant, when placed in a supine position, assumes a characteristic "frog-leg posture" or lies in some other unusual position at rest. Normally the neonate or infant who is held in horizontal suspension (i.e., with the examiner's hand supporting the infant under the chest) responds by slightly raising the head with the back relatively straight, the arms flexed and slightly abducted, and the knees partly flexed. The hypotonic infant droops over the supporting hand with head and extremities hanging loosely, resembling an inverted U. The muscles feel atrophied when palpated, and there is marked head lag when the infant is pulled to a sitting position. Poor sucking may be noted. *Floppy infant syndrome* was the term traditionally used to describe infants with hypotonia.

Diagnostic Evaluation

The infant with hypotonia presents a diagnostic challenge. The child's and family's history and the physical examination offer important clues to the general category of causes, such as central or motor neuron disorders. Laboratory diagnosis may include a CK level specific for skeletal muscle. Molecular deoxyribonucleic acid (DNA) analysis may eliminate the need for additional invasive tests when a definitive diagnosis is made for a hereditary myopathy or neuropathy (Sarnat, 2011). Nerve conduction velocity, electromyography (EMG), and muscle biopsy may be used in diagnostic testing. Accurate diagnosis is essential for appropriate treatment, genetic implications, and family counseling.

Therapeutic and Nursing Care Management

The management of an infant with hypotonia is determined by the cause of the hypotonia. It is a nursing responsibility to record and report findings that suggest hypotonia in an infant so that further evaluation can be carried out and therapeutic measures implemented if indicated.

SPINAL MUSCULAR ATROPHY TYPE 1 (WERDNIG-HOFFMANN DISEASE)

Spinal muscular atrophy (SMA) type 1 (Werdnig-Hoffmann disease) is a disorder characterized by progressive weakness and wasting of skeletal muscles caused by degeneration of anterior horn cells. It is inherited as an autosomal recessive trait and is the most common paralytic form of the **floppy infant syndrome (congenital hypotonia)**. The sites of the pathologic condition are the anterior horn cells of the spinal cord and the motor nuclei of the brainstem, but the primary effect is atrophy of skeletal muscles.

Clinical Manifestations

The age of onset is variable, but the earlier the onset, the more disseminated and severe the motor weakness. The disorder may be manifested early—often at birth—and almost always before 2 years of age; death may occur as a result of respiratory failure by age 2 years (Iannaccone and Burghes, 2002; Lunn and Wang, 2008).

The manifestations (Box 35-7) and prognosis are categorized according to the age of onset, severity of weakness, and clinical course; some children may fluctuate between exhibiting symptoms of types 1 and 2 or types 2 and 3 in regard to clinical function (Sarnat, 2011a). Some experts also categorize SMA according to the highest level of motor function (Lunn and Wang, 2008); type 1 includes "nonsitters," type 2 includes "sitters," and type 3 includes "walkers" (Iannaccone, 2007). A severe rare fetal form of SMA, classified as *type 0,* is reported to be quite lethal in the perinatal period; motor neuron degeneration may be noted as early as midgestation in type 0 (Sarnat, 2011a). Type 4 may present between 20 and 30 years of age and may be referred to as *proximal adult type SMA* (Prior, 2010).

Diagnostic Evaluation

The diagnosis is based on the molecular genetic marker for the *SMN* (survival motor neuron) gene, which is located on chromosome *5q13.* Prenatal diagnosis may be made by genetic analysis of circulating fetal cells in maternal blood or circulating fetal cells in amniotic fluid. The risk for subsequent affected offspring in carriers of the mutant gene or in families with known cases of SMA may also be evaluated genetically. Further diagnostic studies include muscle electromyography (EMG), which demonstrates a denervation pattern, and muscle biopsy; however, the genetic analysis has become the gold standard for diagnosis of the condition (Sarnat, 2011a).

Therapeutic Management

There is no cure for the disease, and treatment is symptomatic and preventive, primarily preventing joint contractures and treating orthopedic problems, the most serious of which is scoliosis. Hip subluxation and dislocation may also occur. Many children benefit from powered wheelchairs, lifts, special

BOX 35-7 CLINICAL MANIFESTATIONS OF SPINAL MUSCULAR ATROPHY

Type 1 (Werdnig-Hoffmann Disease)

Clinical manifestations within first few weeks or months of life
Onset within 6 months of life
Inactivity the most prominent feature
Infant lying in a frog-leg position with legs externally rotated, abducted, and flexed at knees
Generalized weakness
Absent deep tendon reflexes
Limited movements of shoulder and arm muscles
Active movement usually limited to fingers and toes
Diaphragmatic breathing with sternal retractions (diaphragmatic paralysis may occur)
Abnormal tongue movements (at rest)
Weak cry and cough
Poor suck reflex
Fatigues quickly during feedings (if breastfed, may lose weight before noticeable)
Failure to thrive (nutritional)
Alert facies
Normal sensation and intellect
Affected infants not able to sit alone, roll over, or walk
Early death possible from respiratory failure or infection

Type 2 (Intermediate Spinal Muscular Atrophy)

Onset before age 18 months
Early—Weakness confined to arms and legs
Later—Becomes generalized
Legs usually involved to greater extent than arms
Prominent pectus excavatum
Movements absent during complete relaxation or sleep
Some infants able to sit if placed in position, but few can ambulate
For most, life span varies from 7 months to 7 years, although many have normal life expectancy

Type 3 (Kugelberg-Welander Syndrome; Mild Spinal Muscular Atrophy)

Onset of symptoms after 18 months of age
Normal head control and ability to sit unassisted by 6 to 8 months of age
Thigh and hip muscles weak
Scoliosis common
Failure to walk a common presentation
In those who manage to walk:
- Waddling gait
- Genu recurvatum
- Protuberant abdomen
- Ambulation becoming increasingly difficult
- Confined to a wheelchair by second decade

Deep tendon reflexes may be present early but disappear

Type IV (Adult Spinal Muscular Atrophy)

Rare, adult-onset SMA usually in second or third decade of life; muscle weakness is first symptom.

NOTE: These classifications are general, but some research suggests there may be variations in life span and other characteristics (Iannaccone and Burghes, 2002; Lunn and Wang, 2008; Russman, 1996; Russman, Iannaccone, Buncher, et al, 1992).

pressure-adjustable mattresses, and accessible environmental controls. Muscle and joint contractures require careful attention and care to prevent further complications. Nutritional growth failure may occur in infants and toddlers as a result of poor feeding; supplemental gastrostomy feedings may be required to maintain adequate nutritional status and maintain weight gain. The use of lower extremity orthoses may assist with ambulation, but eventually, the child may be confined to a wheelchair as muscle atrophy progresses. Restrictive lung disease is the most serious complication of SMA (Iannaccone, 2007). Upper respiratory tract infections often occur and are treated with antibiotic therapy; they are the cause of death in many children. Rapid eye movement (REM)–related sleep-disordered breathing is common in children with SMA type 1; this progresses to sleep-disordered breathing during REM and non-REM sleep followed by respiratory failure, which often requires nocturnal noninvasive mechanical ventilation (Schroth, 2009). Noninvasive ventilation methods such as bilevel positive airway pressure (BiPAP) have decreased the morbidity and increased the survival rate of children with SMA types 1 and 2. Children with SMA type 1 who undergo tracheotomy and invasive ventilation often remain ventilator dependent for the rest of their lives; some families choose to withdraw support when invasive ventilation becomes necessary (Mercuri, Bertini, and Iannaccone, 2012). Palliative care is an important aspect of care for families of children with SMA type 1. A decreased ability to cough and clear secretions may be managed with airway clearance therapies such as the cough-assist machine and manual cough assistance. Guidelines for the standardization of respiratory care for patients with SMA have been published elsewhere (Schroth, 2009).

In addition to noninvasive respiratory support, some infants and children may benefit from tracheostomy and mechanical ventilation. If untreated, some infants may die of respiratory complications in infancy.

Associated medical conditions in survivors include gastroesophageal reflux, scoliosis, early-onset puberty, hip dysplasia, and recurrent oral candidiasis (Bach, 2007). A referral to pediatric palliative care may help the families of children with SMA make decisions about the benefits and burdens of treatment options.

A number of clinical trials are currently in progress with existing drugs (e.g., valproic acid, phenylbutyrate, creatine) aimed at increasing the SMN mRNA and thus decreasing muscle wasting (Lunn and Wang, 2008).

Nursing Care Management

An infant or a small child with progressive muscle weakness requires nursing care similar to that of an immobilized patient (see Chapter 34). However, the underlying goal of treatment should be to assist the child and family in dealing with the illness while progressing toward a life of normalization within the child's capabilities. Special attention should be directed to preventing muscle and joint contractures, promoting independence in performance of ADLs, and becoming incorporated into the mainstream of school when possible. In addition, parents need support and resources to be able to provide for the child and remain an intact family. Because children with neuromuscular

disease have abnormal breathing patterns that often contribute to early death, it is important to assess adequate oxygenation, especially during the sleep phase when shallow breathing occurs and hypoxemia may develop. Home pulse oximetry may be used to assess the child during sleep and provide noninvasive mechanical ventilation as necessary (Bush, Fraser, and Jardine, 2005; Young, Lowe, and Fitzgerald, 2007) (see Duchenne [Pseudohypertrophic] Muscular Dystrophy, p. 1665, for respiratory management). Supportive care also includes management of orthoses and other orthopedic equipment as required. Because children with SMA are intellectually normal, verbal, tactile, and auditory stimulation are important aspects of developmental care. Supporting them so they can see the activities around them and transporting them in appropriate equipment (e.g., wagon, power wheelchair) for a change of environment provide stimulation and a broader scope of contacts.

Children who are able to sit require proper support and attention to alignment to prevent deformities and other complications. Children who survive beyond infancy need attention to educational needs and opportunities for social interaction with other children. The parents of a child who is chronically ill require much support and encouragement* (see Chapter 19). Parents who have not sought genetic counseling should be encouraged to do so to evaluate further risk potential.

JUVENILE SPINAL MUSCULAR ATROPHY (KUGELBERG-WELANDER DISEASE)

Spinal muscular atrophy type 3 (Kugelberg-Welander disease) is a result of anterior horn cell and motor nerve degeneration. The disease is characterized by a pattern of muscular weakness similar to that of infantile SMA (see Box 35-7). Several modes of inheritance have been reported for the disease: autosomal recessive, autosomal dominant, and X-linked recessive.

The onset occurs from younger than 1 year of age into adulthood, with symptoms resembling group 3 infantile SMA. Proximal muscle weakness (especially of the lower limbs) and muscular atrophy are the predominant features. The disease runs a slowly progressive course. Some children lose the ability to walk 8 to 9 years after the onset of symptoms, but many can still walk after 30 years or more. One source notes that approximately one half of all children with SMA type 3 lose ambulation by age 14 years and may require a wheelchair when falls are more frequent (Mercuri, Bertini, and Iannaccone, 2012). Many affected persons have a normal life expectancy (Lunn and Wang, 2008).

Therapeutic and Nursing Care Management

The management is primarily symptomatic and supportive and is related to maintaining mobility as long as possible, preventing complications such as skin breakdown, optimizing and maintaining respiratory function, and providing support to the child and family. The discussion of family support in the section for Duchenne muscular dystrophy is also applicable to families of children with SMA.

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS), also known as *infectious polyneuritis,* is an uncommon acute demyelinating polyneuropathy with a progressive, usually ascending flaccid paralysis. The hallmark of GBS is acute peripheral motor weakness. The paralysis usually occurs approximately 10 days after a nonspecific viral infection; GBS has also been reported after administration of certain vaccines (e.g., rabies, influenza, polio, and meningococcal) (Sarnat, 2011b). Several subtypes of GBS include acute inflammatory demyelinating neuropathy, acute motor axonal neuropathy, acute motor sensory axonal neuropathy, and Miller Fisher syndrome. Children are less often affected than adults; among children, those between ages 4 and 10 years have higher susceptibility. The male-to-female ratio is reported to be 1.5 to 1. Two peak periods with an increased incidence of GBS have been identified: late adolescence and young adulthood.

Chronic inflammatory demyelinating polyradiculoneuropathies (CIDPs) are chronic types of GBS that recur intermittently or do not improve over a period of months to years (Sarnat, 2011b).The following discussion focuses on GBS.

Congenital GBS is rare, yet may occur in the neonatal period, and consists of hypotonia, weakness, and decreased or absent reflexes. Maternal neuromuscular disease may or may not be present. Diagnosis is established by the same criteria as in older children, but the symptoms gradually subside over the first few months of life and disappear by 12 months (Sarnat, 2011b).

Pathophysiology

Guillain-Barré syndrome is an immune-mediated disease often associated with a number of viral or bacterial infections or the administration of certain vaccines. It has been associated with infectious mononucleosis, measles, mumps, *Campylobacter jejuni* (gastroenteritis), cytomegalovirus, *Borrelia burgdorferi* (Lyme disease), Epstein-Barr virus, *Helicobacter pylori,* and *Mycoplasma* and *Pneumocystis* infections. Onset of GBS symptoms usually occurs within 10 days of the primary infection. Pathologic changes in spinal and cranial nerves consist of inflammation and edema with rapid, segmented demyelination and compression of nerve roots within the dural sheath. Nerve conduction is impaired, producing ascending partial or complete paralysis of muscles innervated by the involved nerves. GBS has three phases:

1. **Acute**—Phase starts when symptoms begin and continues until new symptoms stop appearing or deterioration ceases; it may last as long as 4 weeks.
2. **Plateau**—Symptoms remain constant without further deterioration; it may last from days to weeks.
3. **Recovery**—Patient begins to improve and progress to optimal recovery; it usually lasts a few weeks to months, depending on the deficits incurred by the illness.

Clinical Manifestations

A mild influenza-like illness or sore throat usually precedes the paralytic manifestations of GBS. The onset can be rapid, reaching peak activity within 24 hours, or there may be a gradual progression of symptoms over days or weeks. Neurologic symptoms initially involve muscle tenderness that sometimes is accompanied by paresthesia and cramps. Proximal muscle weakness progressing to paralysis usually occurs before distal weakness, and there is a tendency toward symmetric involvement. In most patients paralysis ascends from the lower extremities, often involving the muscles of the trunk and upper extremities and those supplied by cranial nerves. The seventh cranial (facial) nerve is often affected.

Tendon reflexes are depressed or absent, and paralysis is flaccid. Paralysis may involve facial, extraocular, labial, lingual, pharyngeal, and laryngeal muscles. Evidence of intercostal and phrenic nerve involvement includes breathlessness in vocalizations and shallow, irregular respirations. There may be variable degrees of sensory impairment. Most patients complain of muscle tenderness or sensitivity to slight pressure. Lower limb pain and back pain are common in children with GBS. Urinary incontinence or retention and constipation are often present. Abdominal pain and fatigue have also been reported in children with GBS (Lyons, 2008).

Autonomic nervous system disturbances may occur in children and adolescents with severe muscle involvement and respiratory muscle paralysis. These include orthostatic hypotension; hypertension; and vagal responses such as bradycardia, asystole, and heart block (Laskowski-Jones, 2007).

Diagnostic Evaluation

Diagnosis is based on the paralytic manifestations, CSF analysis, and EMG. Motor nerve conduction velocities are greatly reduced. Sensory nerve conduction time is often slowed. Cerebrospinal fluid analysis reveals an elevated protein concentration, and fewer than 10 WBCs/mm^3 and normal glucose level (Sarnat, 2011b). Other laboratory studies are usually noncontributory. The symmetric nature of the paralysis helps differentiate this disorder from spinal paralytic poliomyelitis, which usually affects sporadic muscles.

Therapeutic Management

Treatment of GBS is primarily supportive. In the acute phase, patients are hospitalized because respiratory and pharyngeal involvement may require assisted ventilation, sometimes with a temporary tracheostomy. Treatment modalities include aggressive ventilatory support in the event of respiratory compromise, intravenous (IV) administration of immunoglobulin (IVIG), and sometimes steroids; plasmapheresis and immunosuppressive drugs may also be used. Plasmapheresis has been shown to decrease the length of recovery in patients with severe GBS; however, it is expensive, and side effects include hypotension, fever, bleeding disorders, chills, urticaria, and bradycardia. Further evidence reports equal benefits to treatment of GBS with IVIG administration or plasmapheresis; both sped up recovery time in studies reviewed (Hughes and Cornblath, 2005). There is evidence, however, of significant improvement in children with high-dose IVIG therapy (vs. supportive treatment alone) (Hughes, Swan, and Van Doorn, 2012). IVIG is now recommended as the primary treatment of GBS when administered within 2 weeks of disease onset (Hughes, 2008). Corticosteroids alone do not decrease the symptoms or shorten the duration of the disease.

Additional medications that may be administered during the acute phase include a low-molecular-weight heparin to prevent deep vein thrombosis (DVT), a mild laxative or stool softener to prevent constipation, pain medication such as acetaminophen, and a histamine-antagonist to prevent stress ulcer formation. Chronic neuropathic pain after GBS may be treated with gabapentin, which is reported to be more effective than carbamazepine (Sarnat, 2011b).

Rehabilitation after the acute phase may involve physical therapy, occupational therapy, and speech therapy. Additional consideration should be given to problems of general weakness and retraining for toileting and feeding (Lyons, 2008).

Prognosis

Better outcomes are associated with younger age, no requirement for mechanical respiratory assistance, slower progression of disease, normal peripheral nerve function on EMG, and treatment with either IVIG or plasmapheresis. Recovery usually begins within 2 to 3 weeks, and most patients regain full muscle strength. The recovery of muscle strength progresses in the reverse order of onset of paralysis, with lower extremity strength being the last to recover. Poor prognosis with subsequent residual effects in children is reportedly associated with cranial nerve involvement, extensive disability at time of presentation, and intubation.

Most deaths associated with GBS are caused by respiratory failure; therefore, early diagnosis and access to respiratory support are especially important. The rate of recovery is usually related to the degree of involvement and may extend from a few weeks to months. The greater the degree of paralysis, the longer the recovery phase.

Nursing Care Management

Nursing care is primarily supportive and is the same as that required for children with immobilization and respiratory compromise. The emphasis of care is on close observation to assess the extent of paralysis and on prevention of complications, including aspiration, ventilator-associated pneumonia (VAP), atelectasis, DVT, pressure ulcer, fear and anxiety, autonomic dysfunction, and pain.

During the acute phase of the disease, the nurse should carefully observe the child's condition for possible difficulty in swallowing and respiratory involvement. The child's respiratory function is closely monitored, and oxygen source, appropriate-size insufflation bag and mask, endotracheal intubation and suctioning equipment, tracheotomy tray, and vasopressor drugs are kept available. Vital signs are monitored frequently, as well as neurologic signs and level of consciousness. For children who develop respiratory impairment, the care is the same as that for any child with respiratory distress requiring mechanical ventilation.

Respiratory care, if intubation is required, requires close monitoring of oxygenation status (usually by pulse oximetry and sometimes arterial blood gases), maintenance of an open airway with suctioning, and postural changes to prevent pneumonia. Consideration should be given to preventing opportunistic infections such as VAP; meticulous oral care and hypopharynx suctioning, elevating the head of the bed 30 degrees, and strict asepsis with suctioning equipment (including catheters, a Yankauer device, or both) should be implemented to prevent VAP. Children with oral and pharyngeal involvement may be fed via a nasogastric or gastrostomy tube to ensure adequate feeding. It is also important to consider the possibility of stress ulcers in such patients and to administer a proton pump inhibitor. Immobilization, which occurs with GBS, decreases GI function; therefore, problems such as decreased gastric emptying, constipation, and feeding residuals require nursing assessment and appropriate collaborative interventions. Temporary urinary catheterization may be required; urinary retention is common, and appropriate assessment of urinary output is vital. Sensory impairment and paralysis in the lower extremities make the child susceptible to skin breakdown; therefore, attention should be given to meticulous skin care. Passive range-of-motion exercises and application of orthoses to prevent muscle contracture are important when paralysis is present. Prevention of DVT is accomplished with pneumatic compression (antiembolism) devices, administration of a low-molecular-weight heparin, and early mobilization and ambulation. Autonomic dysfunction may be life threatening; thus close monitoring of vital signs in the acute phase is essential.

A key to recovery in the child with GBS is the prevention of muscle and joint contractures, so passive range-of-motion exercises must be carried out routinely to maintain vital function. Although the child may have a generalized paralysis, cognitive function remains intact; therefore, it is important for nursing care to involve communication with the child or adolescent regarding procedures and treatments that may be frightening, especially if mechanical ventilation is required. Encourage parents to talk to the child and make eye and physical contact and to reassure the child during this phase of the illness.

Pain management is crucial in the care of children with GBS. Although neuromuscular impairment may make pain perception more difficult to accurately evaluate, objective pain scales should be used. Gabapentin and carbamazepine may be used to manage neuropathic pain in patients with GBS.

Physical therapy may be limited to passive range-of-motion exercises during the evolving phase of the disease. Later, as the disease stabilizes and recovery begins, an active physical therapy program is implemented to prevent contracture deformities and facilitate muscle recovery. This may include active exercise, gait training, and bracing.

Throughout the course of the illness, child and parent support are paramount. The usual rapidity of the paralysis and the long recovery period greatly tax the emotional reserves of all family members. The parents and child benefit from repeated reassurance that recovery is occurring and from realistic information regarding the possibility of permanent disability. In the event of a residual disability, the family needs assistance in accepting and adjusting to the loss of function. (See Chapter 19.) The GBS/CIDP Foundation International* is a nonprofit organization devoted to support, education, and research. It provides families with support from recovered persons, publishes informational literature and a newsletter, and maintains a list of health care practitioners experienced with the disease.

TETANUS

Tetanus, or lockjaw, is an acute, preventable, and sometimes fatal disease caused by an exotoxin produced by the anaerobic, spore-forming, gram-positive bacillus *Clostridium tetani*. It is characterized by painful muscular rigidity primarily involving the masseter and neck muscles. The development of tetanus has four requirements: (1) presence of tetanus spores or vegetative forms of the bacillus, (2) injury to the tissues, (3) wound conditions that encourage multiplication of the organism, and (4) a susceptible host.

Tetanus spores are found in soil, dust, and the intestinal tracts of humans and animals, especially herbivorous animals. The organisms are more prevalent in rural areas but are readily carried to urban areas by wind. They enter the body by way of wounds, particularly a puncture wound, burn, or crushed area. In the newborn, infection may occur through the umbilical cord, usually in situations in which infants are delivered in contaminated surroundings and the mother has not been properly immunized against tetanus. The disease has the greatest incidence during months in which persons are more involved in outdoor activities.

Prevention

Primary prevention is key and occurs through immunization and boosters (American Academy of Pediatrics, 2012). Once an injury has occurred, further preventive measures are based on the child's immune status and the nature of the injury. Specific prophylactic therapy after trauma is administration of either tetanus toxoid or tetanus antitoxin. A dose of tetanus toxoid is not necessary for clean, minor wounds in children who have completed the immunization series (see Chapter 10) or who have received a booster within the previous 10 years. Protective levels of antibody are maintained for at least 10 years. Therefore, antitoxin is not indicated for the fully immunized child. Children with more serious wounds (e.g., contaminated, puncture, crush, or burn wounds) are given a tetanus toxoid booster prophylactically as soon as possible after injury.

The unprotected or inadequately immunized child who sustains a "tetanus-prone" wound (including wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite) should receive tetanus immunoglobulin (TIG). Concurrent administration of both TIG and tetanus toxoid at separate sites is recommended both to provide protection and

*The Holly Building, 104½ Forrest Ave., Narberth, PA 19072; 610-667-0131, 866-224-3301; **www.gbs-cidp.org**.

to initiate the active immune process (American Academy of Pediatrics, 2012). Completion of active immunization is carried out according to the usual pattern. Proper surgical cleansing and débridement of contaminated wounds reduce the chance of infection.

Pathophysiology

When prevention efforts are not effective and conditions are favorable, the organisms multiply and form two exotoxins: (1) tetanospasmin, a potent toxin that affects the CNS to produce the clinical manifestations of the disease, and (2) tetanolysin, which appears to have no significance. The ideal conditions for growth of the organisms are devitalized tissues without access to air (e.g., puncture wounds); wounds that have not been washed or kept clean; and those that have crusted over, trapping pus beneath. The exotoxin appears to reach the CNS by way of either the neuron axons or the vascular system. The toxin becomes fixed on nerve cells of the brainstem and the anterior horn of the spinal cord. The toxin acts at the neuromuscular junction to produce muscular stiffness and to lower the threshold for reflex excitability.

The incubation period is 3 days to 3 weeks and averages 8 days. Most cases occur within 14 days; in neonates it is usually 5 to 14 days. Shorter incubation periods have been associated with more heavily contaminated wounds, more severe disease, and a worse prognosis (American Academy of Pediatrics, 2012).

Clinical Manifestations

There are several forms of the disease. Local tetanus is a less common but severe form characterized by persistent rigidity of muscles near the inoculation site, which may persist for weeks or months. Some cases resolve without sequelae. Neonatal tetanus results from contamination of the umbilical cord, which is rare in the United States but is common and often fatal in developing countries. The first symptom is difficulty in sucking, progressing to total inability to suck, excessive crying, irritability, and nuchal rigidity.

Generalized tetanus is the most common and dangerous form of the disease. The manner of onset varies, but the initial symptoms are usually a progressive stiffness and tenderness of the muscles in the neck and jaw. The characteristic difficulty in opening the mouth (**trismus**), which is caused by sustained contraction of the jaw-closing muscles, is evident early and gives the disease its common name, lockjaw. Spasm of facial muscles produces the so-called sardonic smile (**risus sardonicus**). Progressive involvement of the trunk muscles causes **opisthotonos** and a boardlike rigidity of abdominal and limb muscles. The patient has difficulty swallowing and is highly sensitive to external stimuli. The slightest noise, a gentle touch, or bright light triggers convulsive muscular contractions that last seconds to minutes. The paroxysmal contractions recur with increased frequency until they become almost continuous.

Mentation is unaffected; the patient remains alert, and pain and distress are reflected in a rapid pulse, sweating, and an anxious expression. Laryngospasm and tetany of respiratory muscles and accumulated secretions predispose the child to respiratory arrest, atelectasis, and pneumonia. Fever is usually absent or mild and generally indicates a poor prognosis. As the child recovers from the disease, the paroxysms become less frequent and gradually subside. Survival beyond 4 days usually indicates recovery, but complete recovery may take weeks.

Therapeutic Management

The unprotected or inadequately immunized child who sustains a "tetanus-prone" wound (as described earlier) should receive TIG. Concurrent administration of both TIG and tetanus toxoid at separate sites is recommended both to provide protection and to initiate the active immune process (American Academy of Pediatrics, 2012). After the individual has received primary tetanus immunization, antitoxin is believed to provide protection for at least 10 years and for a longer period after booster immunization (American Academy of Pediatrics, 2012). (See also Immunizations, Chapter 6.)

Antibiotic treatment with penicillin G (or erythromycin or tetracycline in older children with allergy to penicillin) is important in the management of tetanus as an adjunct against clostridia; metronidazole is a viable alternative (Arnon, 2011a).

Aggressive supportive care is necessary to treat tetanus in the acute phase. The acutely ill child is best treated in an intensive care facility, where close and constant observation and equipment for monitoring and respiratory support are readily available.

General supportive care is indicated, including maintaining adequate airway and fluid and electrolyte balance, providing pain management, and ensuring adequate caloric intake. Indwelling oral or nasogastric feedings may be required to maintain adequate fluid and caloric intake; continued laryngospasm may necessitate total parenteral nutrition or gastrostomy feeding. Severe or recurrent laryngospasm or excessive secretions may require advanced airway management such as endotracheal intubation; in some cases a tracheotomy may be performed to provide an adequate airway.

TIG therapy to neutralize toxins is the most specific therapy for tetanus. In countries where TIG is not available, equine tetanus antitoxin (not available in the United States) should be administered. Antibiotics are administered to control the proliferation of the vegetative forms of the organism at the site of infection. When the child recovers, active immunization should take place, since contraction of the disease does not confer a permanent immunity. Standard Precautions for the child with tetanus are recommended; isolation is not recommended.

Local care of the wound by surgical débridement and cleansing with an antiseptic solution helps reduce the number of proliferating organisms at the site of injury. The cleansing should be repeated several times during the first 48 hours. Deep, infected lacerations are usually exposed and débrided. Infiltration of the wound with TIG is no longer considered necessary (American Academy of Pediatrics, 2012).

Diazepam is the drug of choice for seizure control and muscle relaxation (Arnon, 2011a), but lorazepam (Ativan) may be used in some cases. Other AEDs may be administered as well. Intrathecal baclofen, magnesium sulfate, dantrolene sodium, and midazolam may also be used in the management of tetanus;

intrathecal baclofen may cause apnea and should only be used in the intensive care setting (Arnon, 2011a). Patients with severe tetanus and those who do not respond to other muscle relaxants may require the administration of a neuromuscular blocking agent, such as rocuronium or vecuronium. Because of their paralytic effect on respiratory muscles, use of these drugs requires mechanical ventilation with endotracheal intubation or tracheotomy and constant cardiopulmonary monitoring. Endotracheal tube insertion or tracheotomy is often indicated and should be performed before severe respiratory distress develops. Despite the absence of pain manifestation with these drugs, it is important to administer adequate analgesia. The administration of corticosteroids has met with success in some cases.

Nursing Care Management

The care of the child with tetanus requires supportive management with particular attention to airway and breathing. Respiratory status is carefully evaluated for any signs of distress, and appropriate emergency equipment is kept available at all times. The location, extent, and severity of muscle spasms are important nursing observations. Muscle relaxants, opioids, and sedatives that may be prescribed can also cause respiratory depression; therefore, the child should be assessed for excessive CNS depression. Attention to hydration and nutrition involves monitoring an IV infusion, monitoring nasogastric or gastrostomy feedings, and suctioning oropharyngeal secretions when indicated.

In caring for a child with tetanus during the acute phase, every effort should be made to control or eliminate stimulation from sound, light, and touch. Although a darkened room is ideal, sufficient light is essential so that the child can be carefully observed; light appears to be less irritating than vibratory or auditory stimuli. The infant or child is handled as little as possible, and extra effort is expended to avoid any sudden or loud noise to prevent seizures.

If a potent muscle relaxant such as vecuronium is used, the total paralysis makes oral communication impossible. The drug is not a sedative, however, and anxiety should be considered in children who are intubated. Therefore, all the child's needs must be anticipated and procedures carefully explained beforehand. Additional care is focused on preventing the complications associated with prolonged immobility, including decreased bowel and bladder tone and subsequent constipation, anorexia, DVT, pneumonia, and skin breakdown.

BOTULISM

Botulism is serious food poisoning that results from ingestion of the preformed toxin produced by the anaerobic bacillus *Clostridium botulinum*. Botulism toxin exerts its effect by inhibiting the release of acetylcholine at the neuromuscular junction, thereby impairing motor activity of the muscles innervated by the affected nerves. The disease has a wide variation in severity, from constipation to progressive sequential loss of neurologic function and respiratory failure. Human botulism is caused by neurotoxins A, B, E, and rarely F (American Academy of Pediatrics, 2012). Types A and B are the most common causes of infant botulism.

Several forms of botulism are recognized: food borne, infant, wound, man-made (for bioterrorism), and botulism from undetermined causes. This chapter only covers the first three forms.

Food-Borne Botulism

This classic form of the disease usually occurs in adults but may occur in children and adolescents. The most common source of the toxin is improperly sterilized home-canned foods. CNS symptoms appear abruptly approximately 12 to 36 hours after ingestion of contaminated food and may or may not be preceded by acute digestive disturbance. Early symptoms include blurred vision, diplopia, weakness, dizziness, difficulty talking and speaking, vomiting, and dysphagia. These are followed by descending paralysis and dyspnea. Progressive respiratory paralysis is life threatening.

Infant Botulism

Infant botulism, unlike the disease in older persons, is caused by ingestion of spores or vegetative cells of *C. botulinum* and the subsequent release of the toxin from organisms colonizing the gastrointestinal tract. *C. botulinum* types A and B are the most common causative strains of infant botulism. This form of botulism has become more prevalent than any other form. Many cases of infant botulism occur in breastfed infants who are being introduced to nonhuman milk substances (American Academy of Pediatrics, 2012). Cases of infant botulism are still being reported in Europe, where honey is commonly given to infants. There appears to be no common food or drug source of the organisms; however, the *C. botulinum* organisms have been found in honey. Botulism may occur in infants from 1 week to 12 months of age, with peak incidence between 2 and 4 months of age.

The severity of the disease varies widely, from mild constipation to progressive sequential loss of neurologic function and respiratory failure. The affected infant is usually well before the onset of symptoms. Constipation is a common presenting symptom, and almost all infants exhibit generalized weakness and a decrease in spontaneous movements. Deep tendon reflexes are usually diminished or absent. Cranial nerve deficits are common, as evidenced by loss of head control, difficulty in feeding, weak cry, and reduced gag reflex. SMA type 1 and metabolic disorders are often mistaken for infant botulism in the initial diagnostic phase because of the similarities in clinical manifestations of hypotonia, lethargy, and poor feeding (Arnon, 2011b). Presenting clinical signs also often mimic those of sepsis in young infants. Botulism toxin exerts its effect by inhibiting the release of acetylcholine at the myoneural junction, thereby impairing motor activity of muscles innervated by affected nerves.

Diagnosis and Therapeutic Management

The diagnosis is made on the basis of the clinical history, physical examination, and laboratory detection of the organism in the patient's stool and, less commonly, blood. However,

isolation of the organism may take several days; therefore, suspicion of botulism by clinical presentation should require emergency treatment (Arnon, 2011b). EMG may be helpful in establishing the diagnosis; however, results may be normal early in the course of the illness.

Treatment consists of immediate administration of botulism immune globulin intravenously (BIG-IV) (Arnon, 2011b) without delaying for laboratory diagnosis. Early administration of BIG-IV neutralizes the toxin and stops the progression of the disease. The human-derived botulism antitoxin (BIG-IV) has been evaluated and is now available nationwide for use only in infant botulism. Infants treated with BIG-IV usually have a shortened hospital stay from approximately 6 weeks to 2 weeks, reportedly as a result of decreased requirements for mechanical ventilation and intensive care (Arnon, 2011b). Approximately 50% of affected infants require intubation and mechanical ventilation; therefore, respiratory support is crucial, as is nutritional support because these infants are unable to feed. Trivalent equine botulinum antitoxin and bivalent antitoxin, used in adults and older children, are *not* administered to infants. Antibiotic therapy is not part of the management because the botulinum toxin is an intracellular molecule and antibiotics would not be effective; aminoglycosides in particular should not be administered because they may potentiate the blocking effects of the neurotoxin (Arnon, 2011b).

The prognosis is generally good if the patient is adequately treated, although recovery may be slow, requiring a few weeks after severe illness. Untreated patients may require a longer hospitalization.

! NURSING ALERT

Although the precise source of *C. botulinum* spores has not been identified as originating from honey in many cases of infant botulism in the United States, it is still recommended that honey not be given to infants younger than 12 months because the spores have been found in honey.

Nursing Care Management

Nursing responsibilities include observing, recognizing, and reporting signs of poor feeding, constipation, and muscle impairment in the infant with botulism and providing intensive nursing care when an infant is hospitalized. (See Nursing Care Management for the infant with SMA, p. 1642, and Nursing Care of High-Risk Newborns, Chapter 9.) Parental support and reassurance are important. Most infants recover when the disorder is recognized and BIG-IV therapy is implemented. Nursing care of the infant on mechanical ventilation requires observation of oxygenation status and vigilance for any complications (see Chapter 27). Parents should be aware that, during recovery, infants fatigue easily when muscular action is sustained. This has important implications for timing the resumption of feedings because of the risk of aspiration. They should also be advised that normal bowel activity may not return for several weeks. Therefore, a stool softener can be beneficial.

One cultural consideration that requires further parent education and anticipatory guidance is the use of honey pacifiers among mothers with small infants; there is evidence that honey pacifiers are still commonly used among many mothers to soothe their infants (Benjamins, Gourishankar, Yataco-Marquez, et al, 2013).

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is relatively uncommon in childhood. The incidence in children under 18 years is 1 per 1 million in North America (Cirillo, 2008). Juvenile MG appears to be identical to that seen in adults and usually has its onset after age 10 years, but it may appear as early as age 2 years. Girls are affected three times more often than boys. Juvenile and adult forms of the disease are autoimmune disorders associated with the attack of circulating antibodies on the acetylcholine receptors on the muscle end plate, which blocks their function.

Clinical Manifestations

The most common symptoms associated with MG are general paralysis of the optic muscles with ptosis and diplopia. Difficulty swallowing, chewing, and speaking are also prominent and are accompanied by varying degrees of weakness and paralysis of all skeletal muscles. The signs and symptoms are more pronounced in the late afternoon and evening. Rest can help relieve the symptoms, but exercise and stress worsen them. Some affected persons may have spontaneous remission of the symptoms with only mild residual ocular symptoms (Meriggioli and Sanders, 2012). Seizures are reported to occur in increasing frequency in children with MG (Meriggioli and Sanders, 2012).

Diagnostic Evaluation

The diagnosis is made on the basis of the characteristic distribution of muscle weakness and the progressive weakness on repeated or sustained muscular contraction. The definitive diagnosis is established on the basis of an EMG, which demonstrates a decrease in muscle potentials with repetitive nerve stimulation (Sarnat, 2011c). A clinical diagnosis may be established by observation of the response to the anticholinesterase drugs. IV administration of a small test dose of edrophonium (Tensilon) produces a beneficial effect in 1 minute, but the effect lasts less than 5 minutes. In infants and children under the age of 2 years prostigmine methylsulfate (Neostigmine) should be administered IM instead of Tensilon, because the latter may precipitate fatal cardiac arrhythmias in infants (Sarnat, 2011c). Electrophysiologic studies are helpful in diagnosis and help document transmission failure at the neuromuscular junction. Antibodies to human muscle acetylcholine are detected in the serum of almost one third of affected individuals. Thyroid profiles should also be obtained.

Therapeutic Management

Patients with mild MG may not require specific treatment. For others treatment consists of the administration of cholinesterase-inhibiting drugs, such as neostigmine (Prostigmin), given intramuscularly or as oral neostigmine bromide. Pyridostigmine (Mestinon) may be administered because it is considered less toxic, but a higher dose is required to achieve the same

results as neostigmine. The starting dosage of neostigmine is usually 0.04 mg/kg, administered intramuscularly every 4 to 6 hours; oral doses may be well tolerated (Sarnat, 2011c). The dosage is gradually increased until a satisfactory result is obtained. The child must be observed for signs of parasympathetic stimulation from overmedication. These signs include lacrimation, salivation, abdominal cramps, sweating, diarrhea, vomiting, bradycardia, and weakness of respiratory muscles. Long-term treatment with prednisone is effective in some patients. Thymectomy has been shown to be effective in achieving a cure in many children with MG (Castro, Derisavifard, Anderson, et al, 2013; Christison-Lagay, Dharia, Vajsar, et al, 2013). Other therapies directed at the immunologic mechanism include IVIG, long-term corticosteroid treatment, and plasmapheresis. Additional pharmacologic agents that may be used include azathioprine, methotrexate, cyclosporine A, tacrolimus, and rituximab (Gilhus, Owe, Hoff, et al, 2011). Thymectomy is not effective for familial and congenital forms of MG. The prognosis for juvenile MG is relatively good. However, the course of the disease is marked by fluctuating remissions and exacerbations.

DRUG ALERT

Neuromuscular-Blocking Agents

Avoid neuromuscular-blocking agents such as pancuronium or succinylcholine in patients with MG because they may induce paralysis that can last for weeks. Avoid aminoglycoside antibiotics such as gentamicin because they potentiate MG symptoms (Sarnat, 2011c).

Nursing Care Management

Children with MG often require ongoing medical and nursing supervision, especially in the early stages of diagnosis and treatment considerations. Parents and children with MG are educated regarding the symptoms of a **myasthenia crisis** (respiratory failure) so that appropriate therapy may be instituted before deterioration is acute. Infections should be treated aggressively, and yearly influenza vaccination is recommended. Respiratory viral infections are a common precipitating cause of a myasthenia crisis (Meriggioli and Sanders, 2012).

Counsel parents to promote a lifestyle that minimizes stress and maximizes relaxation. They should receive instruction in providing respiratory assistance until help arrives or the child can be transported to medical aid.

Neonatal Myasthenia Gravis

A transient form of MG occurs in approximately 10% to 20% of infants born to mothers with MG, who may not know they have the disease. The muscular weakness results from transplacentally acquired maternal acetylcholine receptor antibodies. These infants display generalized muscular weakness and hypotonia at birth with a depressed Moro reflex, ptosis, ineffective sucking and swallowing reflexes, and weak cry. Some infants may require short-term mechanical ventilation (Sarnat, 2011c). Symptoms may be evident within a few hours of birth, following a period of normal appearance after delivery. There is no evidence of neurologic damage. Cholinesterase inhibitors may be given on a short-term basis to improve feeding ability. Symptoms usually disappear within 2 to 3 weeks. Infants with transient neonatal MG regain strength once maternal antibodies clear the system, and they are not at increased risk of MG later in life (Cirillo, 2008; Sarnat, 2011c).

Congenital Myasthenia Gravis

Congenital MG is a rare familial abnormality of neuromuscular transmission that is not immunologically mediated. It appears indistinguishable from the transient form, but the mother usually does not have the disease. The disease persists throughout life, and more than one sibling may be affected, which suggests a genetic etiology. Gender distribution is equal. The disorder is relatively resistant to drug therapy, and the eyelid and extraocular muscles seem to be the muscles most severely affected.

The prognosis in congenital MG is usually good. Despite gradual worsening of symptoms with age, the life span is not affected significantly.

SPINAL CORD INJURIES

SCIs with major neurologic involvement are not a common cause of physical disability in children. However, many children with these injuries are admitted to major medical centers, and because of the increased survival rate as a result of improved management, nurses have an important role in the care of children with SCI.

The principles of management and nursing care of the child with a spinal cord lesion apply regardless of cause. In addition to care related to the immobilized child, as discussed in Chapter 34, children with damage to the spinal cord present additional problems—specifically, complications related to the neuropathology of the central and autonomic nervous systems. The extent of paralysis is determined by both neurologic and clinical assessment. Although the majority of children with SCI are paraplegic, some are tetraplegic (quadriplegic). Some children with tetraplegia are able to move only their face and neck muscles, whereas others are able to lift and bend their arms but are unable to perform fine hand movements. Almost every physiologic system is disrupted in a child with high-level tetraplegia. Not only are the central and peripheral nerves impaired, but there is also autonomic nervous system dysfunction. Vital structures such as blood vessels, lungs, bladder, and bowel are affected. Therefore, an understanding of neuromuscular physiology is essential to effectively care for the child with damage or injury to the spinal cord.

Essential Neuromuscular Physiology

The spinal cord extends from the medulla oblongata to the lower border of the first lumbar vertebra and contains millions of nerve fibers. However, because of its protected location, a considerable amount of direct trauma is required to cause injury. Posteriorly the cord is protected by the spinous processes, which are stabilized by related ligaments and muscles. It

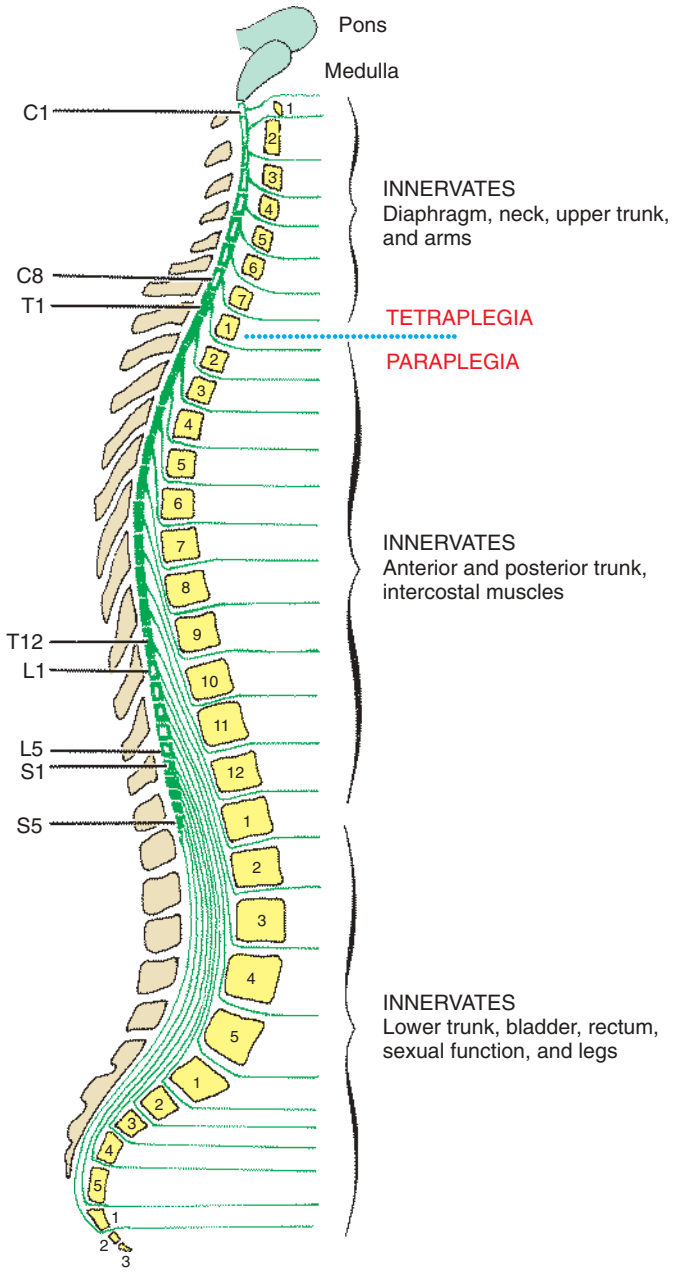

FIG. 35-7 Relationships of spinal cord segments and spinal nerves to vertebral bodies. Cervical nerves exit through intervertebral foramina above their respective vertebral bodies (seven cervical vertebrae and eight cervical nerves). Spinal cord ends at L1-L2 vertebral level.

is further protected by the spinal fluid, which surrounds it and absorbs some of the shock.

Spinal Nerves

The 31 nerves of the spinal cord are divided into five segments (Fig. 35-7). The cervical cord segments lie within the first seven vertebrae. The remaining cord segments—thoracic (12), lumbar (5), sacral (5), and coccygeal (1)—extend from the first thoracic vertebra to the lower level of the first lumbar vertebra. Therefore, the cord constituents do not anatomically match by number the 33 associated vertebrae. However, nerves that arise from the spinal cord exit from the spinal column at the numerically corresponding vertebrae. In describing injuries to the spinal cord, the highest point at which there is normal function is referred to in relation to the vertebra; for example, an intact cord at the sixth cervical vertebra is designated a C6 injury.

Certain areas of the curved vertebral column are less stable and more prone to damage from severe flexion and twisting. These sites are the cervical area and the junction of the thoracic and lumbar regions. The cervical vertebrae are fractured most often, and this high level of injury causes extensive paralysis and many associated neurologic problems (Table 35-1). Also, traumatic tearing or embolic occlusion of the arteries supplying these areas can markedly jeopardize the cord tissue. Impaired blood supply often produces severe neurologic deficit, which can extend to complete loss of cord function at the level of injury.

Cell bodies of interneurons and motor neurons within the spinal cord are identified as H-shaped gray matter surrounded by columns of white myelinated nerve fibers. Each column serves as a route for a specific type of impulse, such as touch, vibration, pain, and temperature (Fig. 35-8). Nerve pathways in the spinal cord transmit sensory and motor impulses between peripheral receptors and the brain, conduct impulses through the reflex arc, and convey sympathetic and parasympathetic nerve impulses from the brain to peripheral structures.

Sensory transmission begins when peripheral receptors pick up a wide variety of stimuli and transfer the impulses, by means of peripheral nerves, to the spinal nerves, where they make ganglionic connections and enter the cord posteriorly. At this point the impulses travel in two directions: across the interneuron connection and then to the motor neurons (reflex arc), or up the spinal cord to predetermined areas of the brain. Motor impulses are transmitted from the cerebral cortex to the medulla (where nerve tracts cross) and proceed down descending motor pathways to the desired level within the spinal cord. Here they connect with the anterior horn cells and are transmitted to the muscle fibers by means of the lower motor neurons to complete a meaningful movement.

A network of nerves that serves the major muscle groups constitutes a plexus. Total involvement of any one of these plexuses seriously impairs function to the areas it innervates. Box 35-8 describes the three major plexuses.

Upper Versus Lower Motor Neurons

Upper motor neurons extend from cerebral centers to cells in the spinal column; lower motor neurons consist of anterior horn cells and spinal and peripheral nerves. Motor fibers of the reflex arc are lower motor neurons. This is an important point because relative dominance of the CNS over reflex arcs suppresses some reflex responses. When the higher centers no longer exert an influence in SCI, spastic responses are observed in muscles innervated by the intact lower motor neurons. Most SCIs involve upper motor neurons; children born with spinal cord defects have primarily lower motor neuron deficits (see Fig. 35-7). Box 35-9 outlines manifestations of upper and lower motor neuron syndromes.

TABLE 35-1 FUNCTIONAL SIGNIFICANCE OF SPINAL CORD LESIONS

HIGHEST INTACT CORD SEGMENT	MUSCLE INNERVATION	FUNCTIONAL CAPACITY	FUNCTIONAL GOALS
Tetraplegia			
C1-C3	None below chin, including phrenic nerve to diaphragm	No voluntary control below chin Respiratory paralysis complete May cause bradycardia or tachycardia, vomiting	Mechanical ventilation; can be taught glossopharyngeal breathing to be used for short periods Electric wheelchair Adaptive equipment for special tasks in bed or wheelchair using mouth stick
C4	Intact sternocleidomastoid, trapezius, upper cervical paraspinal muscle	No voluntary function of upper extremities, trunk, or lower extremities All neck movements Mechanical ventilation dependent	Electric wheelchair Externally powered devices and adaptive equipment for special tasks in bed or wheelchair with mouth stick, such as turning pages, using computer Totally dependent for activities of daily living
C5	Partial deltoid, biceps, major muscles of rotator cuffs at shoulders Diaphragm	Abduction, flexion, and extension of arm Flexion and extension of forearm Unable to roll over or attain sitting position Abdominal respiration Poor respiratory reserve	Electric wheelchair Requires attendant to assist in moving and transfer to wheelchair Adaptive devices for self-feeding, grooming, using computer Vocational potential with adaptive devices
C6	Pectoralis major, serratus anterior, latissimus dorsi muscles Complete deltoid and brachioradialis muscles Partial triceps muscle	Significant increase in function over that with lesion at C5 level Adduction and medial rotation of arm Wrist extension Good elbow flexion	Cuff strapped to hand to permit use of implements for self-care and other activities Able to assist in dressing and transfer Hand rim extension to permit independence in wheelchair
C7	Triceps and finger flexion and extensor muscle Shoulder depressor muscles Still nerve disruption to intercostal muscles	With elbow stabilized in extension and intact shoulder depressor muscles, able to lift body weight Grasp and release still weak; dexterity lacking	Almost complete independence within limitations of wheelchair Requires some assistance in transfer and lower extremity dressing Hand splints helpful Can roll over in bed, sit up in bed, and eat independently Homebound employment possible; outside work usually not feasible
Paraplegia			
T1-T10	Full innervation of upper extremity muscles	Full use of upper extremities, including intrinsic muscles of hand Trunk balance poor—may have difficulty lifting trunk sufficiently to put on lower extremity clothing Considerable energy expenditure to put on long leg braces with extensive attachments	Completely wheelchair dependent Trunk balance benefits from training Able to drive automobile with hand controls May be braced for standing May hold job away from home Can manage adapted public transportation
T10-L2	Full abdominal and upper back muscle control	Good trunk balance Good respiratory reserve Can accomplish moderate hip hiking using external oblique and latissimus dorsi muscles	Ambulation with bilateral long braces using four-point or swing-through crutch gait Usually able to negotiate curbs Some able to use regular public transportation Few vocational limitations as long as does not require much walking or standing
L3-L4	Quadriceps muscle Partial gluteus and hamstring muscles	May have lumbar lordosis Floppy ankles	Ambulates well, often with short leg braces with or without cane Difficulty in getting out of wheelchair May never require wheelchair

BOX 35-8 THE THREE MAJOR PLEXUSES

Cervical plexus (C1-C4)—Innervates the neck and diaphragm
Brachial plexus (C4-T1)—Supplies the shoulders, chest, and arms
Lumbosacral plexus (L1-S4)—Transmits impulses to the lower trunk and legs

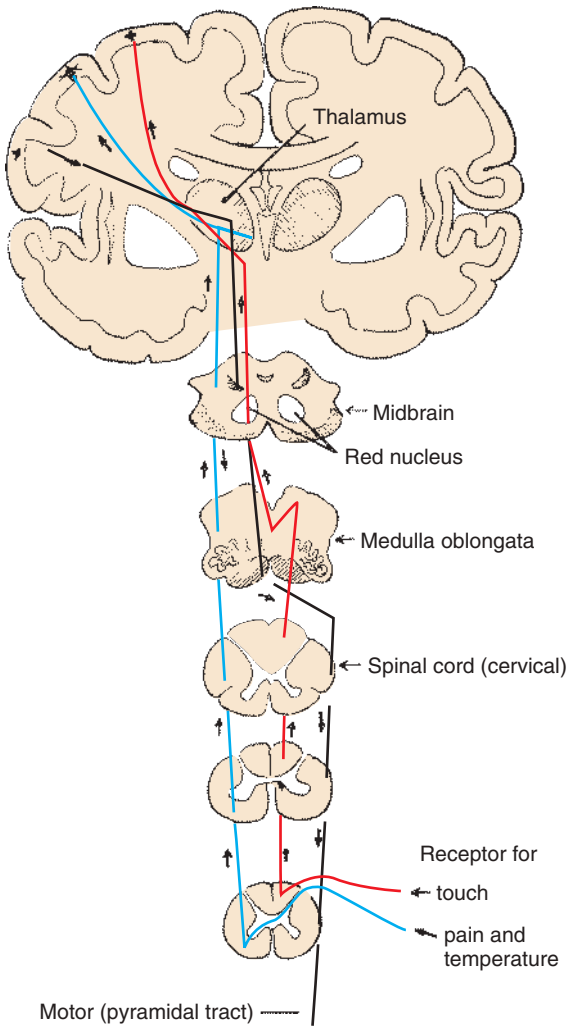

FIG. 35-8 Main motor and sensory pathways. Perception of touch, passive motion, position, and vibration is transmitted through posterior tract in spinal cord through medial lemniscus in brainstem to thalamus and through internal capsule to cortex (pathway is represented by *solid red line*). Pain and temperature sensations are transmitted through anterolateral tract and lateral lemniscus to thalamus, then through internal capsule to cortex *(blue line)*. Motor impulses are transmitted by pyramidal tract, descending from cerebral cortex, crossing in medulla to opposite side, and continuing to anterior horns of spinal cord *(black line)*. (From Conway BL: *Carini and Owens' neurological and neurosurgical nursing*, ed 7, St. Louis, 1978, Mosby.)

Effect on Sensory and Motor Tracts

Voluntary muscle control is lost after complete transection of the cord. In partial transection, function is altered to varying degrees depending on the areas innervated by involved nerves. The crossing of motor tracts at various levels makes it possible for an injured person to have motor paralysis in one leg but retain pain and temperature sensation in that leg, while the opposite leg retains its motor function but loses pain and temperature sensation.

Although a transected cord injury leads to sensory loss, it is not uncommon for the injured person to experience pain. For example, smooth or skeletal muscle spasms, destruction of the myelin sheath (impulses cross to adjacent nerves), and scar formation or irritation of nerve endings may cause pain. Pain suffered by a person with tetraplegia or paraplegia is often intensified because of loss of sensation in other parts. Severe and prolonged pain should be medically evaluated for a treatable pathologic condition.

BOX 35-9 DIFFERENCES IN CLINICAL MANIFESTATIONS BETWEEN UPPER AND LOWER MOTOR NEURON SYNDROMES

Upper Motor Neuron Syndrome
Spastic paralysis in muscle groups below lesion (intact reflex arcs below lesion)
Hyperreflexia with tendon reflexes exaggerated, Babinski reflex present
No wasting of muscle mass because of increased muscle tone
Flexion contractures and spasms of muscle groups below lesion level common
No skin or tissue changes

Lower Motor Neuron Syndrome
Flaccid paralysis caused by muscle atonia (reflex arcs permanently damaged)
Reflex with associated muscle response absent
Marked atrophy of atonic muscle
Fasciculations (local twitching of muscle groups) common
No flexor spasms
Loss of hair
Skin and tissue changes
Cornified nails

Effect on Autonomic System

Sympathetic and parasympathetic systems receive both excitatory and inhibitory stimuli from autonomic centers in the cerebral cortex, limbic system, and hypothalamus. The stimuli are transmitted by means of a feedback mechanism within the ascending fibers of the cord that normally controls descending input. Axons of the many CNS neurons synapse with autonomic preganglionic fibers and thus are able to alter their patterned responses. Box 35-10 describes the most significant effects of autonomic disruption.

Etiology

The most common cause of serious spinal cord damage in children is trauma involving motor vehicle crashes (including automobile-bicycle, all-terrain vehicles, and snowmobiles), sports injuries (especially from diving, trampoline activities, gymnastics, and football), birth trauma, and nonaccidental trauma. MVCs accounted for 56% of SCIs in children and adolescents, and falls and firearm injury caused 14% and 9% of SCIs. The children injured (SCI) in MVCs were not properly restrained in 67.7% of the cases (Vitale, Goss, Matsumoto, et al,

BOX 35-10 SIGNIFICANT EFFECTS OF AUTONOMIC DISRUPTION

- Decreased muscle tone and impairment of vasoconstrictive effects of sympathetic innervation cause venous pooling; diminished venous return to the heart; decreased cardiac output; and hypotension, especially orthostatic hypotension (orthostatic intolerance).
- Thermoregulatory disruption in the hypothalamus and skin receptors causes blood vessels to remain dilated during the initial stage, an inability to sweat in response to increased environmental temperature, and a possible rapid elevation in body temperature.
- Voluntary bowel and bladder function are lost because of damage to nerve fibers that innervate these organs.
- Altered sexual function (lack of erection, ejaculation, and orgasm) results from interference with numerous autonomic nerve fibers and plexuses.

2006). In the United States, football injuries accounted for a high percentage of sport-related injuries in adolescents, whereas in Canada, such injuries were associated with ice hockey (Mathison, Kadom, and Krug, 2008).

The increased use of recreational activities involving motorized vehicles such as jet water skis, all-terrain vehicles, and motorcycles has also increased the incidence of SCIs in children. Congenital defects of the spine such as myelomeningocele also may in some cases produce the effects of SCI (see p. 1631).

Transverse myelitis (inflammation of the spinal cord) may be caused by illness and has also been reported to develop from inadvertent intraarterial administration of long-acting penicillin injected into the buttocks. Damage can be extensive enough to result in paraplegia or even lower limb amputation.

In MVCs, most SCIs in children are a result of indirect trauma caused by sudden hyperflexion or hyperextension of the neck, often combined with a rotational force. Trauma to the spinal cord without evidence of vertebral fracture or dislocation (**SCI without radiographic abnormality**, or SCIWORA) is particularly likely to occur in an MVC when proper safety restraints are not used. An unrestrained child becomes a projectile during sudden deceleration and is subject to injury from contact with a variety of objects inside and outside the vehicle. Individuals who use only a lap seat belt restraint are at greater risk for SCI than those who use a combination lap and shoulder restraint. High cervical spine injuries have been reported in children younger than 2 years who are improperly restrained in forward-facing car seats. Infants who are improperly restrained in an infant car seat may experience cervical trauma in a car crash. Small children may also be severely injured by deploying front seat air bags.

Falling from heights occurs less often in children than in adults, but vertebral compression from blows to the head or buttocks can occur in water sports (diving and surfing), falls from horses, or other athletic activities. Birth injuries may occur in breech births from traction force on the spinal cord during birth of the head and shoulders. When shaken, infants commonly sustain cervical cord damage, as well as subdural hematoma and retinal hemorrhage; cognitive impairment and death may occur subsequent to the traumatic event. Infants have weak neck muscles, and during vigorous shaking, their large and heavy heads rapidly wobble back and forth. A significant number of adolescents receive SCIs secondary to gunshot wounds, stabbings, and other violent inflicted injury.

Because of the marked mobility of the neck, fracture or **subluxation** (partial dislocation) is the most common immediate cause of SCI, particularly in the lower cervical region. Although unusual in adults, SCI without fracture is common in children, whose spines are suppler, weaker, and more mobile than those of adults. Therefore, the force is more easily dissipated over a larger number of segments. In infants and small children younger than 5 years, upper cervical spine fractures and spinal compression are more common, but adolescents tend to have lower cervical and thoracolumbar fracture dislocations (Retake, 2011). Children who suffer SCI before puberty are reported to experience a higher incidence of musculoskeletal complications such as scoliosis and hip dislocation (Vogel, Betz, and Mulcahey, 2012).

Pathophysiology

The severity of the force, the mechanisms of the injury, and the degree of the individual's muscular relaxation at the time of the injury greatly influence the extent of the trauma. SCIs are classified as either *complete* or *incomplete*. In a complete injury, there is no motor or sensory function more than three segments below the neurologic level of the injury (Mathison, Kadom, and Krug, 2008). Incomplete lesions have several typical characteristics (Mathison, Kadom, and Krug, 2008):

- Central cord syndrome—Central gray matter destruction and preservation of peripheral tracts; tetraplegia with sacral sparing common; some motor recovery gained
- Anterior cord syndrome—Complete motor and sensory loss with trunk and lower extremity proprioception and sensation of pressure
- Posterior cord syndrome—Loss of sensation, pain, and proprioception with normal cord function, including motor function; able to move extremities but have difficulty controlling such movements
- Brown-Séquard syndrome—Unilateral cord lesion with a motor deficit on the opposite side of the body from the primary insult; absence of pain and temperature sensation on the opposite side from the injury
- Spinal cord concussion—Transient loss of neural function below the level of the acute spinal cord lesion, resulting in flaccid paralysis and loss of tendon, autonomic, and cutaneous reflex activity; may last hours to weeks

The American Spinal Injury Association (ASIA) (Kirschblum, Waring, Biering-Sorensen, et al, 2011) International Standards for Neurological Classification of Spinal Cord Injury worksheet was recently revised and published in the cited reference. The ASIA Impairment Scale (Box 35-11) combines motor and sensory function and is used to determine the severity of impairment from the injury (complete or incomplete). It may also be used to measure neurologic changes and functional goals for rehabilitation (Mathison, Kadom, and Krug, 2008).

The injury sustained can affect any of the spinal nerves, and the higher the injury, the more extensive the damage. The child

BOX 35-11 AMERICAN SPINAL INJURY ASSOCIATION IMPAIRMENT SCALE

A—Complete: No motor or sensory function is preserved in the sacral segments S4-S5.

B—Sensory Incomplete: Sensory but not motor function is preserved below the neurologic level and includes the sacral segments S4-S5, or deep anal pressure, AND no motor function is preserved more than 3 levels below the motor level on either side of the body.

C—Motor Incomplete: Motor function is preserved below the neurologic level*, and more than half of key muscle functions below the single neurologic level of injury have a muscle grade less than 3.

D—Motor Incomplete: Motor function is preserved below the neurologic level*, and at least half (or more) of key muscles below the neurologic level have a muscle grade of 3 or more.

E—Normal: If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

*For an individual to receive a grade of C or D, i.e., motor incomplete status, they must have either (1) voluntary anal sphincter contraction or (2) sacral sensory sparing with sparing of motor function more than 3 levels below the motor level for that side of the body. The Standards at this time allows even non-key muscle function more than 3 levels below the motor level to be used in determining motor incomplete status (AIS B versus C).

For further details and instructions see the online page at http://www.asia-spinalinjury.org/elearning/ISNCSCI_Exam_Sheet_r4.pdf (accessed March 24, 2014).

Used with permission, American Spinal Injury Association, 2011.

can be left with complete or partial paralysis of the lower extremities **(paraplegia)** or with damage at a higher level and without functional use of any of the four extremities **(tetraplegia)**. A high cervical cord injury that affects the phrenic nerve paralyzes the diaphragm and leaves the child dependent on mechanical ventilation.

A mild but equally frightening form of cord trauma is **spinal cord compression**, a temporary neural dysfunction without visible damage to the cord. Complete tetraplegia can result but initially may not be differentiated from serious cord injury.

Clinical Manifestations

It is often difficult to determine the extent and severity of damage at first. Immediate loss of function is caused by both anatomic and impaired physiologic function, and improved function may not be evident for weeks or even months. Manifestation of the initial response to acute SCI is flaccid paralysis below the level of the damage. This stage is often referred to as **spinal shock syndrome** and is caused by the sudden disruption of central and autonomic pathways. Local effects of cord edema and ischemia produce a physiologic transection with or without an anatomic severance. Most children with an SCI experience some spinal shock. Manifestations include the absence of reflexes at or below the cord lesion, with flaccidity or limpness of the involved muscles, loss of sensation and motor function, and autonomic dysfunction (i.e., symptoms of hypotension, low or high body temperature, loss of bladder and bowel control, and autonomic dysreflexia). It is estimated that 25% to 50% of children with SCI will have a delay in the onset of neurologic abnormalities ranging from 30 minutes to 4 days (Vogel, Betz, and Mulcahey, 2012).

Autonomic paralysis also affects thermoregulatory functions. Afferent impulses from temperature receptors in the skin are not integrated; therefore, the patient is subject to temperature increases or decreases in response to alterations in environmental temperature. Hyperthermia can result from excessive ambient temperature, such as too many covers.

Except in the situations previously mentioned, flaccid paralysis is replaced by spinal reflex activity and increasing spasticity or, in incomplete lesions, greater or lesser degree of neurologic recovery.

The paralytic nature of autonomic function is replaced by **autonomic dysreflexia**, especially when the lesions are above the midthoracic level. This autonomic phenomenon is caused by visceral distention or irritation, particularly of the bowel or bladder. Sensory impulses are triggered and travel to the cord lesion, where they are blocked, which causes activation of sympathetic reflex action with disturbed central inhibitory control. Excessive sympathetic activity is manifested by a flushing face, sweating forehead, pupillary constriction, marked hypertension, headache, and bradycardia. The precipitating stimulus may be merely a full bladder or rectum or other internal or external sensory input. It can be a catastrophic event unless the irritation is relieved.

Additional clinical findings of SCI may include numbness, tingling, or burning; priapism; weakness; and loss of bowel and bladder control (Hayes and Arriola, 2005).

Neurogenic shock occurs as a result of a disruption in the descending sympathetic pathways with loss of vasomotor tone and sympathetic innervations to the cardiovascular system (Hayes and Arriola, 2005). Hypotension, bradycardia, and peripheral vasodilation occur as a result of neurogenic shock.

Children with suspected SCI may have suffered multiple injuries (e.g., MVC); therefore, multiple clinical manifestations may occur that may mask those of an SCI.

In the final stage neurologic signs are stabilized in terms of loss and recovery of function. The major emphasis is on rehabilitation. A problem unique to injury in childhood is progressive spinal deformity usually not seen in adults or in adolescents near the end of the growth period. Scoliosis develops in the majority of children with high thoracic and cervical lesions and is almost certain to occur in children with tetraplegia whose injury occurred in infancy or early childhood.

Diagnostic Evaluation

A history of the injury provides valuable clues regarding the possible type of damage incurred and directions for further assessment without the risk of additional damage. A complete neurologic examination determines whether damage was incurred and, if so, the level and extent of any nerve impairment. A neurologic unit of the CNS is considered normal if reflex arcs are functioning, sensory tracts are intact when each dermatome is examined separately, and voluntary motor

response demonstrates an ability to move a body part against gravity on command.

Testing a reflex arc is accomplished by stimulating the peripheral receptors at a specific site, such as eliciting the patellar reflex. Symmetric testing is performed to determine unilateral or bilateral neurologic deficit. A sufficient number of reflexes are examined to test motor function thoroughly. The blunt end of a safety pin is used to assess pressure sensitivity, and the sharp point is used to elicit pain. Hot and cold water, a tuning fork, and cotton may also be used to determine specific sensory loss (e.g., temperature, vibration, and light touch).

The ASIA dermatome classification worksheet is used to determine the extent of neurologic damage (Fig. 35-9). Body surface zones, or **dermatomes**, accurately correspond to the spinal cord segment receiving the sensory input from the peripheral nerves in that zone. Systematically pinpricking the body surface in each zone determines intactness of sensory pathways. Fig. 35-9 illustrates the zones and the spinal cord segments they represent. The examiner tests for each specific sensory fiber in the dermatome areas in which neurologic deficit is suspected.

Matching cord level to vertebra is more difficult in infants and young children than it is in older children and adults because the sacral and several lower lumbar cord segments lie at a lower position, especially during the first 2 years of life. The spinal anatomy approaches adult configuration by the time the child reaches age 7 or 8 years; by late adolescence the conus medullaris has usually reached the level of L1.

Motor system evaluation includes observing gait if the child is able to walk; noting balance maintenance with the child's eyes open and closed; and noting the ability to lift, flex, and extend the arms and legs. Testing muscle strength with and without

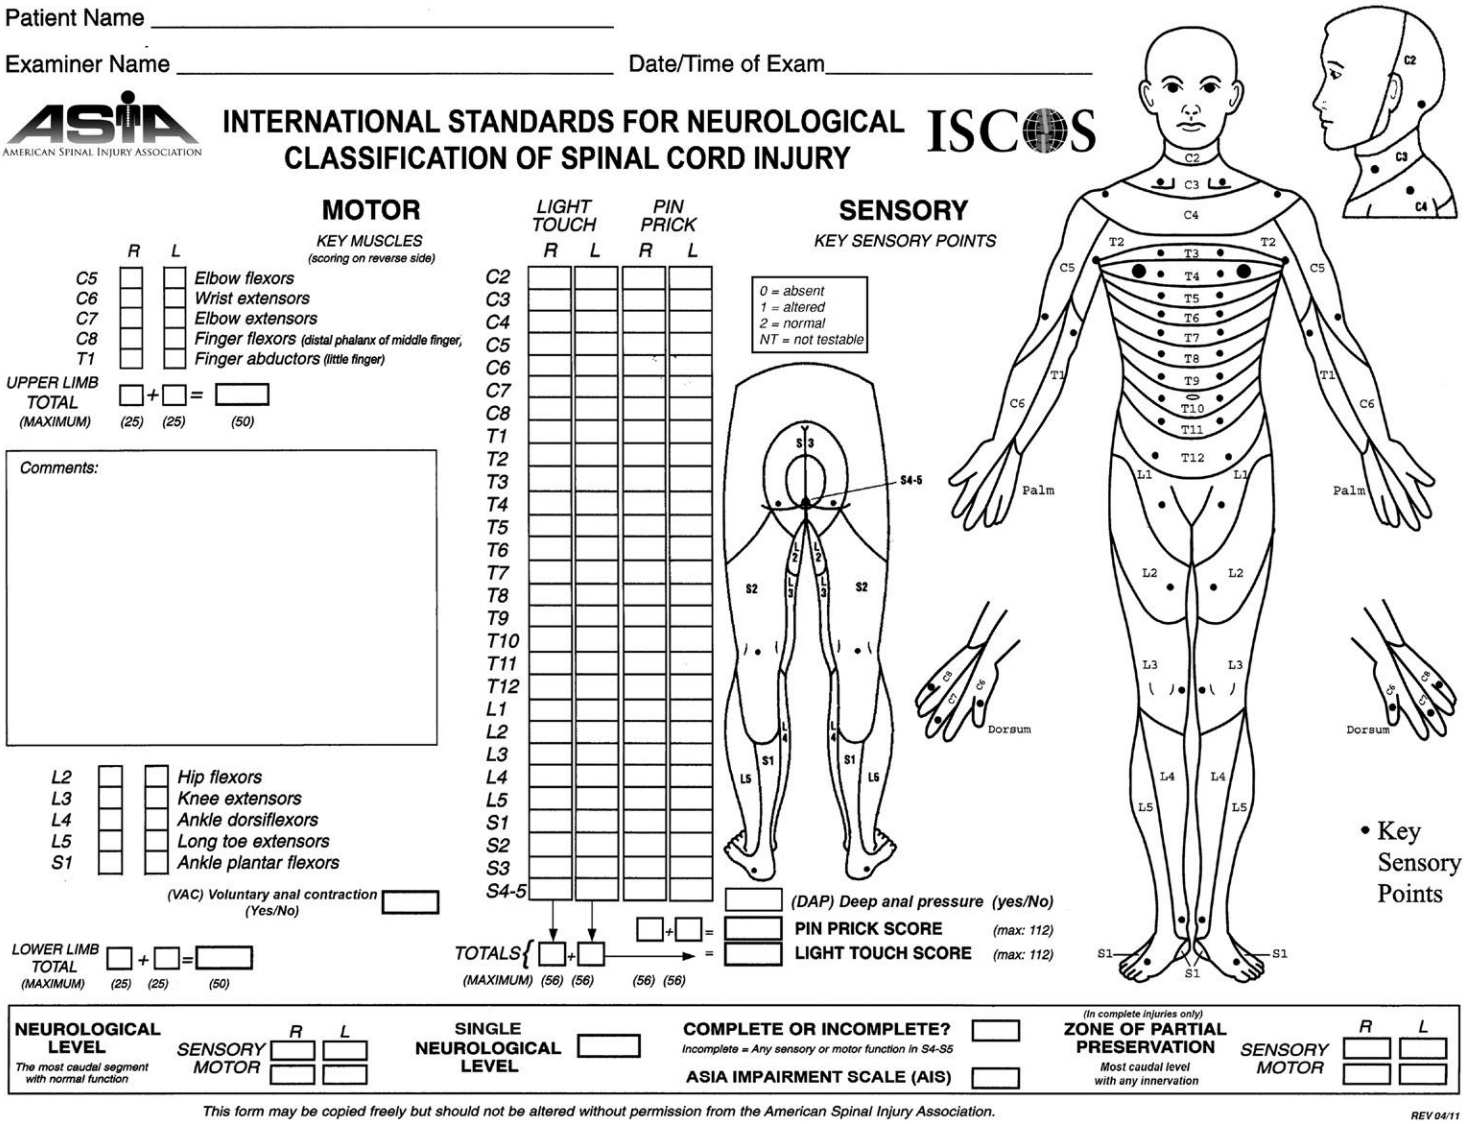

FIG. 35-9 ASIA classification of spinal cord injury. (Used with permission, American Spinal Injury Association, 2011.)

resistance and against gravity provides clues to the specific nature and degree of motor dysfunction. The number of muscles in any muscle group that remain completely intact in the upper extremities makes a marked difference in the individual's ability to provide self-care, especially at high injury levels. Hip movement is necessary for ambulation with braces and crutches.

The degree to which supportive aids are needed for ambulation is determined by the strength, stability, and movement of the pelvis, trunk, hip flexor muscles, and quadriceps muscles. A general guideline for determining the capacity for self-help is that a person with paraplegia who has function down to and including the quadriceps muscle or muscle function below the L3 level will have little difficulty in learning to walk with or without braces and crutches. It is especially vital that children with lumbar levels of injury be taught to walk functionally so that they are weight bearing at least part of the time; this minimizes the risk of osteoporosis and hypercalcemia. The functional significance of the spinal cord lesion level is given in Table 35-1.

If a CNS pathologic disorder is detected, a body system assessment is performed to determine the degree of autonomic impairment. Because the cord and CNS directly influence the function of the autonomic nerves, the specific sympathetically related organ systems are examined for skeletal muscle and vascular tone and body temperature regulation. For example, bladder and gastrointestinal functions have sympathetic and parasympathetic innervation and local reflexes.

CT and MRI scans are important for localizing the lesion, but the nature of the spine in childhood often creates difficulty in interpretation. Guidelines for diagnostic imaging of children with suspected SCI have been published elsewhere (Rozelle, Arabi, Dhall, et al, 2013). Small children often have no radiographic evidence of vertebral or spinal injury despite significant injuries ranging from complete transection with major hemorrhage to minor hemorrhage, edema, or normal neural findings. This condition, SCIWORA, is reported to occur in approximately 64% of children 5 years of age or younger and in 19% to 32% of older children with SCIs (Launay, Leet, and Sponseller, 2005; Mathison, Kadom, and Krug, 2008; Vogel, Betz, and Mulcahey, 2012). The younger the child, the more likely for SCIWORA to occur—up to 72% of children 5 and under (Schottler, Vogel, and Sturm, 2012). SCIWORA is also a common finding in very young children who are victims of abuse (primarily shaken baby syndrome) because of the elasticity and incomplete ossification of the vertebrae. SCIWORA is more common in children under the age of 8 years, and injury to the cervical spine is common. Diagnostic scans must be taken carefully and with sufficient help to prevent further damage to the spine.

Therapeutic Management

Initial care begins at the scene of the accident with proper immobilization of the cervical, thoracic, and lumbar spine. Immobilization should take into account the age and size of the child; smaller children have a larger head size, which may make effective immobilization on a rigid board difficult (Rozelle, Arabi, Dhall, et al, 2013). Because of the complexity of these injuries, it is usually recommended that these persons be transported to a spinal injury center for care by specially trained health care personnel as soon as possible after the injury for appropriate diagnostic evaluation and intervention.

The initial management of the child with a suspected SCI should begin with an assessment of the ABCs: **a**irway, **b**reathing, and **c**irculation. The airway should be opened using the jaw-thrust technique to minimize damage to the cervical spine. The child is monitored for cardiovascular instability, and measures are taken to support systemic blood pressure and maintain optimal cardiac output. Because MVCs and other trauma in children may involve internal organ damage and potential bleeding, abdominal distention and other signs are acted on immediately to prevent further systemic shock. After the child is stabilized and transported to a regional trauma center, a thorough evaluation of neurologic status and any other associated trauma is carried out by the multidisciplinary team. In the emergency department, spinal immobilization should be maintained until a thorough neurologic assessment is completed and spinal cord injury is ruled out; in children, this typically involves a CT scan and possibly an MRI. Additional interventions are discussed in the Nursing Care Management section. Assessment of neurologic status using the Glasgow Coma Scale (see Chapter 32) is important; a helpful assessment is represented in the mnemonic AVPU: ***a***lert; responds to ***v***erbal stimuli; responds to ***p***ainful stimuli; and ***u***nresponsive. A secondary assessment tool in the ED follows the mnemonic AMPLE: ***a***llergies, ***m***edications, ***p***ast medical history, ***l***ast meal or fluids, and ***e***nvironment and events leading to the incident (Avarello and Cantor, 2007).

The American Association of Neurological Surgeons and the Congress of Neurological Surgeons have published spinal cord injury management guidelines and standards of care for adult and pediatric patients with SCIs. Recently, evidence-based guidelines for the management of SCI in children were published (Rozelle, Arabi, Dhall, et al, 2013).

Intravenous methylprednisone may be started within the first 12 hours after the injury to decrease inflammation and minimize further injury; however, its use in small children is controversial. Studies of methyprednisone administration in adults with SCI have shown mixed results with experts recommending against its use in acute SCI (Hurlbert, Hadley, Walters, et al, 2013).

In children with upper motor neuron involvement, the spasticity that develops may require administration of an antispasmodic medication such as diazepam. Baclofen is considered the drug of choice for reducing muscle spasticity (Vogel, Betz, and Mulcahey, 2012). Gabapentin may be used to treat neuropathic pain (Hayes and Arriola, 2005). Botulinum toxin type A and α_2-adrenergic agonists may be used in older children with SCI to decrease muscle spasticity (see p. 1649).

A number of progressive rehabilitation modalities have been developed in recent years that have the potential for increasing the quality of life for children with SCI. One treatment is functional electrical stimulation (FES), also referred to as *functional neuromuscular stimulation* or *neuromuscular electrical stimulation.* With this treatment, an electrical stimulator is surgically

implanted under the skin in the abdomen and electrode leads are tunneled to paralyzed leg muscles, enabling the child to sit, stand, and walk with the aid of crutches, a walker, or other orthoses. The stimulator can also be used to elicit a voluntary grasp and release with the hand. Before the latter can be accomplished, a number of surgical tendon transfers may be required for elbow extension, wrist extension, and finger and thumb flexion. In addition, FES has therapeutic benefits, which include increased muscle strength, improved gait function, and increased cardiovascular fitness (Thrasher and Popovic, 2008). Tendon transfers have been shown to be successful in enhancing hand and arm function, increasing pinch force, and facilitating independence in ADLs (Hosalkar, Pandya, Hsu, et al, 2009). Restoration of hand and arm function enables children with SCI to perform self-catheterization and achieve greater independence in personal hygiene.

Exercise is considered an integral part of SCI rehabilitation; exercise may enhance neuroplasticity and decrease further muscle atrophy. Examples of exercise modalities in SCI patients include upper body strength training and hand cycling (Hosalkar, Pandya, Hsu, et al, 2009).

Administration of pharmacologic agents such as clonidine hydrochloride may improve ambulation in patients with partial SCIs, and exercise therapy through interactive locomotor training has helped some individuals with SCI regain ambulatory function.

A number of orthoses or ambulation aids such as crutches may still be necessary to achieve upright mobility, yet as robotic technology advances, so do the chances for improved mobilization in children with SCI. Mechanical or robotic orthoses may be used in conjunction with FES to enable ambulation in persons with SCI (To, Kirsch, Kobetic, et al, 2005). Gait training may be achieved with a number of different modalities, including a stationary cycle; however, no specific method has proved superior to the others. FES has also been effective in reducing complications from bladder and bowel incontinence and in assisting males in achieving penile erection. Ambulation is an important part of rehabilitation in SCI; retrospective studies found that ambulation was dependent on age at injury and extent of neurologic injury (as measured by ASIA motor scales). Age (younger) and lesser neurologic impairment are key predictors for ambulation (Vogel, Betz, and Mulcahey, 2012). Knee ankle foot orthosis (KAFO) and reciprocating gait orthosis (RGO) may also be used to assist with early rehabilitation and ambulation (Vogel, Betz, and Mulcahey, 2012). Additional detailed information regarding ambulation and orthotics for children have been published elsewhere (Calhoun, Schottler, and Vogel, 2013).

Surgical interventions for SCI include early cord decompression (decompression laminectomy) and cervical or thoracic fusion. Crutchfield, Vinke, or Gardner-Wells tongs and skeletal traction may be used for early cervical vertebral stabilization. A halo vest or Minerva jacket may be suited for ambulation after the acute phase. (See also Cervical Traction, Chapter 34.) After cervical spinal fusion, a hard cervical collar or sterno-occipital-mandibular immobilizer brace may be worn until the fusion is solidified. When SCI occurs in young children and preteens, scoliosis develops over time and often requires surgical consideration (Parent, Mac-Thiong, Roy-Beaudry, et al, 2011).

Prognosis

The ultimate outlook for spinal cord function after injury depends on the completeness of the cord transection, site of injury, complicating damage to the neuronal tissue, and success of treatment regimens aimed at recovery of lost muscle movement and ability. Healing of the injury and the return of neurologic function are related to two factors:

1. Although individual nerve fibers do regenerate, they do not necessarily reconnect or make synaptic connections with the distal portion of the severed fibers; the chance of numerous fibers reconnecting is highly unlikely.
2. The damage resulting from cord ischemia produces necrosis in the gray and white matter of the cord tissue, which does not regenerate if the axon cylinder is not intact.

In children the prognosis for recovery is considered better than in adults because children have rapid healing of bone and ligaments and increased potential for nervous system regeneration. Paraplegia is more common in children under 12 years, whereas older children and adolescents tend to have incomplete injuries (Mathison, Kadom, and Krug, 2008). Shavelle, DeVivo, Paculdo, and colleagues (2007) reported an increased likelihood of mortality among children less than 16 years of age who suffered an SCI in comparison to adults with similar injuries. Children with incomplete injuries (and who are not ventilator dependent) had a projected 83% chance of normal life expectancy, whereas those with high-level cervical injuries who are not ventilator dependent had a 50% chance of having a normal life expectancy. One study found that adults who had an SCI as children (less than 18 years of age at time of incident) had comparable or greater degrees of education in comparison to the general population of the same age (Vogel, Chlan, Zebracki, et al, 2011). The same study found lower employment rates for adults with pediatric-onset SCI, lower rates of independent living and independent driving, and lower rates of marriage in this select population.

In general, recovery of motor function in children with thoracic lesions is variable. Cervical injuries are also variable in the extent of damage. Incomplete lesions produce hemiplegia, whereas complete transection implies some involvement of all extremities—from partial use of the upper extremities to complete paralysis, including the need for some type of assisted ventilation. Lumbar injury may involve partial or complete loss of function in the lower extremities and bladder. With rapidly advancing surgical technology, use of microcomputers in medicine, and newer treatment modalities such as FES, there are increasing hope and evidence that functional mobility and independence can be restored in children with SCI.

QUALITY PATIENT OUTCOMES

Neurologic Impairment

- Neurologic status maintained or improved
- No further injuries

Nursing Care Management

The nursing care of the child affected by SCI is complex and challenging. A multidisciplinary SCI team is equipped to manage the acute phase of the injury, and some members, including the nurse, may follow the patient to eventual recovery. Nursing management is concerned with ensuring adequate initial stabilization of the entire spinal column with a rigid cervical collar with supportive blocks on a rigid backboard. The traumatic event causing the injury may or may not be recalled if the child lost consciousness; such events are extremely frightening to the child. The young child may also be frightened by the immobilization process and the inability to move extremities; therefore, it is important to reassure and comfort the child during this process.

During the acute phase of the injury it is imperative that airway patency be ensured, complications prevented, and function maintained. Evaluate the extent of the neurologic damage early to establish a baseline for neurologic function. Continual assessment of sensory and motor function should occur to prevent further deterioration of neurologic status as a result of spinal cord edema. The ASIA Impairment Scale can be used to assess neurologic function on a routine basis during the patient's recovery. Once the patient is admitted, further evaluation of his or her ability to perform ADLs and need for assistance during recovery can be made with the Functional Independence Measure scale.

Nursing care during the acute phase should also focus on frequent monitoring of neurologic signs to determine any changes in neurologic function that require further intervention (e.g., level of consciousness using the Glasgow Coma Scale). In addition to airway maintenance, the nurse monitors for changes in hemodynamic status that may require immediate medical attention. Neurogenic shock consists of hypotension, bradycardia, and vasodilation. Inotropic medications may be required to maintain adequate perfusion. Renal function is closely monitored by measuring urinary output and fluids administered. The child with a head injury may experience elevated intracranial pressure; therefore, changes in neurologic status are reported to the practitioner. Fluid restriction may be required if intracranial pressure is elevated, so fluid intake should be closely monitored.

The nursing care of the child with an SCI is, in most respects, the same as that of any immobilized child (see The Immobilized Child, Chapter 34). Additional aspects of care that should be addressed on an individual basis include hypercalcemia in adolescent boys, DVT, latex sensitization, pain, hypo- and hyperthermia, spasticity, autonomic dysreflexia, and sleep-disordered breathing (Vogel, Betz, and Mulcahey 2012).

Respiratory Care

The child with a high-level cervical injury (C3 and above) requires continuous ventilatory assistance. In most instances a tracheostomy is the method of choice for greater ease in clearing secretions and for less trauma to tissues during long-term ventilatory dependence. Patient-triggered synchronous intermittent mandatory ventilation (SIMV–assist/control mode) may be required to maintain adequate oxygenation. In an acute care center, respiratory therapy personnel are often responsible for establishing and maintaining the equipment, but the nurse must understand how it works and recognize mechanical malfunction and deviations from the prescribed rate and volume. In case of malfunction the nurse must be prepared to maintain respirations manually with a self-inflating bag-valve-mask device. In many home care situations the family is responsible for the care of ventilatory assistance devices; therefore, adequate family training and availability of the nurse (or durable medical equipment representative) for questions related to the equipment and evaluation of the child's breathing are essential. For some children, breathing pacemaker devices (phrenic nerve stimulators) are implanted to stimulate the phrenic nerve and produce diaphragmatic contractions and lung expansion without assisted ventilation.

Children with lesions below the C4 level are seldom ventilator dependent, but pulmonary vital capacity is significantly reduced. Position them for optimum chest expansion, and use a variety of breathing exercises and assistive devices to stimulate deep breathing. Chest physiotherapy is performed as needed to mobilize secretions, and flow-by oxygen may be needed occasionally. Regular monitoring of breath sounds to assess for adequate ventilation in all lung fields is part of routine care.

The cough reflex may be markedly diminished, which, combined with weak intercostal muscles, may mean the child has difficulty with secretions. Increasing the elastic qualities of the lung by breathing exercises, mechanical cough assist techniques, and incentive spirometry helps the child achieve a productive cough. (See discussion of airway management and airway clearance devices under Muscular Dystrophies: Therapeutic Management.)

Cardiovascular Care

Children with SCI may experience cardiovascular instability as a result of loss of vagal tone, vagal stimulation during procedures such as oral suctioning or insertion of a nasogastric tube, turning, and endotracheal suctioning. Close monitoring of heart rate and blood pressure is essential to detect any signs of decreased cardiac output. Pneumothorax may occur, resulting in a mediastinal shift and decreased cardiac output. Autonomic dysreflexia may occur and result in decreased cardiac output (see discussion later).

The child with loss of muscle tone and prolonged immobility may be at high risk for the development of DVT. In addition, major reparative surgery for associated injuries and spinal decompression place the child at risk for thrombus formation. DVT is prevented with the use of pneumatic compression devices and low-molecular-weight heparin during the acute phase of care. Fluid and electrolyte balance may be impaired as a result of trauma and associated injuries or decreased fluid intake during the recovery period. Fluid intake should be closely monitored, especially with regard to the development of pulmonary edema and intracranial pressure. The child may require nasogastric tube feedings due to anorexia and immobility.

Temperature Regulation

Temperature is often poorly regulated in children with SCI; therefore, body temperature must be monitored closely for fluctuations. In small children hypothermia may occur relative to large body surface and inability to mount an appropriate metabolic response to the initial injury, so close attention should be given to preserving body temperature. Response to environmental temperature changes may be slow or absent, and the ability to dissipate heat through the process of shivering may be compromised.

During the spinal shock stage the dilated capillaries conducting body heat to the subcutaneous tissues cause heat loss. Without the capacity to sweat, the body retains heat in hot weather. An elevated temperature that cannot be corrected by environmental measures should be evaluated to rule out urinary or upper respiratory tract infection. However, excessive perspiration observed in sentient areas usually indicates an elevated ambient temperature.

Skin Care

Children with SCI have unique needs in relation to skin care. Because of decreased sensation and impaired mobility, they depend on others to assess and assist in the management of intact skin. Skin care practices are the same as those for any child who is immobilized. A skin score scale such as the Braden Q Scale can objectively evaluate risks for skin breakdown and skin conditions (Noonan, Quigley, and Curley, 2011). Keep an alternating-pressure mattress or other pressure relief/reduction device underneath the child, and inspect the skin thoroughly at least twice a day for signs of pressure, especially over bony prominences. Prevention of skin breakdown is much easier than treatment. A number of factors contribute to the risk of skin breakdown in these children: decreased sensation, inadequate nutrition, muscle spasticity, impaired peripheral circulation, diaphoresis, mechanical shearing from assistive devices, and improper positioning. (See Maintaining Healthy Skin, Chapter 23.)

The areas most likely to be affected are the sacrum, scapulae, heels, and occiput when the child is supine; the trochanters and the lateral aspect of the ankles, heels, and knees when the child is in a side-lying position; and the ischial tuberosities when the child is sitting. The pressure wound may begin in deeper tissues and be visible on the surface only at a later stage. Therefore, areas that feel firm, irregular, or warm or that appear to be only slightly reddened require careful evaluation. (See Wounds, Chapter 16.) Keeping the skin clean and dry is particularly important in these children, especially those who are incontinent of urine or stool or those who have significant diaphoresis. When there is any evidence of skin breakdown, treatment to prevent further breakdown is implemented promptly. When orthotic devices such as AFOs and braces are used, skin care and vigilance for pressure areas are also important in the prevention of pressure ulcers. Prolonged use of wheelchairs without special sacral protection may also lead to skin ulceration.

The child who is heavily sedated or who is being given muscle paralytics should receive appropriate eye care to prevent corneal damage (e.g., artificial tears, ointment, and impermeable eye shield). Additional nursing care may involve the administration of histamine blockers and proton pump inhibitors to prevent stress ulcers by reducing the secretion of hydrochloric acid.

Physical Therapy

An important consideration for the child with SCI is achievement of mobility and ambulation. A developmental approach should be considered in the rehabilitation phase (Calhoun, Schottler, and Vogel, 2013). Range-of-motion, passive, and active exercises are carried out under the guidance of a physical therapist.

Unless there are contraindications, exercises during the period of immobilization are aimed at maintaining and increasing the strength of the child's intact musculature. Upper extremity strengthening is especially important to the paraplegic child, who must rely on these muscle groups for turning, transferring, dressing, parallel bar walking, gait training, and other activities. Children are usually eager to use their muscles and respond to interesting and innovative activities.

Neurogenic Bladder

When the bladder is denervated, as in the acute stage of spinal shock syndrome or after lower motor neuron damage, the bladder wall is flaccid. Lack of muscle tone inhibits the bladder's ability to respond to changes in passive pressure, causing overdistention. Therefore, it is important to prevent distention by periodic emptying, even though there may be dribbling between emptying.

In contrast, an upper motor neuron lesion causes increased bladder tone and contractions that often include the urinary sphincter. Thus, although the bladder empties periodically by reflex action, complete emptying is prevented, resulting in urinary retention and ureteral reflux. Administration of an anticholinergic drug such as dicyclomine (Bentyl) relaxes bladder musculature and promotes increased bladder capacity and more adequate emptying. Intervals of urination depend on many factors, including patterns of fluid intake and perspiration.

In school-age children and adolescents, achieving bladder and bowel continence is a significant developmental issue related to self-esteem and perception of self in relation to peers. Therefore, it is imperative to consider options that best meet the child's physiologic and emotional needs.

Surgical options for children with neurogenic bladder include the creation of a urinary stoma, made possible by removing the appendix and creating a urinary diversion from the bladder to the exterior, usually the umbilicus, thus making self-catheterization more private, especially with the recovery of hand and elbow movement (with tendon transfers). Other options include surgical bladder augmentation to increase capacity and FES to restore micturition on command without a urinary catheter (Merenda and Hickey, 2005).

Emptying the bladder by clean intermittent catheterization (CIC) is also an option for children with SCI; older children who are functionally capable can learn to perform self-catheterization. Encourage the child to adhere to a schedule for

CIC and to maintain a regular pattern of fluid intake throughout the day; they should avoid large intakes of fluid without considering the need for more frequent CIC. Caffeinated beverages and other caffeinated foods are used sparingly to avoid bladder overdistention with increased urine formation (Francis, 2007). Latex catheters should be avoided to prevent the development of latex allergy (if it is not already present). Bladder-training programs usually begin with intermittent bladder emptying at regular intervals that are gradually increased. (See Management of Genitourinary Function under Myelomeningocele [Meningomyelocele], p. 1635.) The Credé method (applying suprapubic pressure) for emptying the bladder may be used by some individuals with SCI, but this may result in high intravesical pressures, causing further bladder complications (Francis, 2007).

Urinary tract infections are common due to urinary stasis. A regular schedule of CIC may help prevent such infections. Encourage the child to increase fluid intake by approximately 240 ml/day and use CIC every 3 to 4 hours.

Maintenance of bladder dynamics and control of urinary tract infections are of utmost importance. Pyelonephritis and renal failure are the most significant causes of death in long-standing paraplegia.

Bowel Training

The loss of bowel function is considered to be one of the most stressful events when quality-of-life issues are considered in persons with SCI; however, successful bowel training is easier to institute than bladder management. The aim is to control defecation until an appropriate time and place are found. Merenda and Hickey (2005) propose four components in a successful bowel management program: desired stool consistency (i.e., a soft stool), a regular evacuation pattern, upright positioning for planned evacuation, and motivation and commitment from the child and family.

A diet with sufficient fiber (age in years plus 5 grams is recommended) for adequate stool bulk and insertion of a glycerin or bisacodyl (Dulcolax) suppository at a convenient time, either morning or evening, are often all that are necessary to induce a bowel movement within a short time. The probability of an accident between times diminishes once the bowel is completely evacuated. The key to adequate bowel training is to maintain consistency in the time of day for evacuation. Stool softeners, such as docusate sodium (Colace) and senna (Senokot), may be prescribed, and manual anal stimulation may help initiate evacuation, especially in spastic paraplegia. Sometimes an oral laxative such as bisacodyl may be necessary. Once an appropriate regimen is established, little modification is required.

One surgical option is the antegrade continence enema (ACE), which involves the creation of a stoma whereby colonic washouts may be performed with the child sitting on the toilet. FES has also been used successfully in some children with SCI to achieve bowel training.

Autonomic Dysreflexia

Children with high-level lesions are susceptible to the development of autonomic dysreflexia, which requires prompt action to prevent encephalopathy and shock. Clinical manifestations of autonomic dysreflexia include an increase in systemic blood pressure, headache, bradycardia, profuse diaphoresis, cardiac arrhythmias, flushing, piloerection, blurred vision, nasal congestion, anxiety, spots on the visual field, or absent or minimum symptoms. A quick assessment may rule out other causes, such as orthostatic intolerance. After that, vital signs, including blood pressure, are taken while the bladder is checked for distention (the usual precipitating cause). The bladder is drained slowly; if this does not relieve symptoms, any tight clothing is loosened, and the bowel is checked for the pressure of impacted feces.

Other potential causes of autonomic dysreflexia in SCI children include bowel impaction and abdominal distention, pressure ulcers, tight clothing, burns, DVT, menses, trauma, fractures, pregnancy, labor, surgery or invasive procedures, any painful stimulus, and hyperthermia (Vogel, Betz, and Mulcahey, 2012). If removal of the causative agent is unsuccessful in controlling the syndrome, IV administration of an antihypertensive drug is indicated, followed by oral maintenance doses. Antispasmodics may also be administered.

Remobilization

As soon as the condition warrants, the child is moved from a reclining to an upright position. Cardiovascular deconditioning and impaired autonomic responses below the level of injury will cause pooling of blood in the extremities (because of peripheral vasodilation); a drop in blood pressure; and a feeling of lightheadedness, dizziness, or fainting on sudden assumption of an upright posture, often referred to as **orthostatic intolerance**. Therefore, an upright position must be accomplished gradually by first placing the child (who is secured by passive restraint) on a head-up tilt table. The table is slowly elevated from a horizontal to a 30-degree semireclining position. This is performed twice daily for 20 to 30 minutes, with the angle gradually increased until the vertical angle is reached.

During the procedure the vital signs are monitored, and the child's behavior is observed for subjective symptoms of syncope. The pooling of blood is reduced by using elastic antiembolism stockings and sequential pneumatic compression devices, which consist of inflatable sleeves that fit on the legs and compress the leg muscles for cyclic emptying and filling of leg veins. The process of achieving an upright posture may require several weeks. After tolerance is achieved, the child will be ready to begin using a wheelchair. Getting the child up should be accomplished slowly by gradually elevating the bed over 20 to 30 minutes before placing the child in the wheelchair and then gradually lowering the legs after the child has been in the chair a short time.

All adaptive devices help children increase their mobility, function, and endurance. The child with some lower extremity function progresses to parallel bars and then to a walker. The child with tetraplegia learns to use a wheelchair—among the most valuable aids available to the child with an SCI. The wheelchair should be selected carefully in relation to where it will be used, the architectural barriers, and the child's functional capacity. For lower extremity paralysis, the wheelchair described on p. 1566 is applicable. For children with severe upper extremity

paralysis, a variety of motorized wheelchairs are used; however, the more complex they are, the greater their cost, weight, and tendency to break down. Wheelchair tolerance is gained over time and is accompanied by measures to prevent orthostatic hypotension and pressure sores.

A variety of orthoses and other appliances can be adapted for use by many children. The primary purpose of lower extremity bracing in the child with an SCI is for ambulation, although correction of deformities may be attempted. However, the efficacy is limited because of the tendency to develop pressure lesions over insensate areas. The higher the lesion, the more support required, with the accompanying difficulties of getting into the orthosis and the greater energy expended in using the appliance. The energy required in walking with crutches and braces is two to four times greater than that required for normal walking.

Children, with their natural and overwhelming desire for mobility, usually attain or even surpass the maximum expectation in ambulation. However, as they approach adulthood, the increasing weight and energy cost usually cause them to resort to predominant use of the wheelchair for mobility and the pursuit of more intellectual and vocational interests. Wheelchair mobility has the advantages of requiring no more energy than normal walking and allowing the person with paraplegia to maintain the speed of other pedestrians on level ground.

Physical Rehabilitation

The process of physical rehabilitation usually begins once the child is medically stable and associated problems have been managed. The major aims of physical rehabilitation are to prepare the child and family to achieve normalization and resume life at home and in the community. Additional goals of rehabilitation in children with SCI are to promote independence in mobility and self-care skills, academic achievement, independent living, and employment (Box 35-12).

Members of the multidisciplinary rehabilitation team cooperate with one another and the family to identify the child's needs and to plan realistic interventions. Integration of activities is coordinated by one team member, most often a specialist in physical medicine and rehabilitation. Members of the team attempt to achieve their collaborative goals through mutual trust, good communication, professional respect, and sincere interest in the child and family. Training in the rehabilitation center promotes maximum achievement commensurate with each child's physical capacities (Fig. 35-10). Instruction for home routine is stressed and includes all the precautions and management implemented in the acute care center (e.g., skin care, nutrition, bladder and bowel training, gait training) and an exercise program.

Inpatient physical rehabilitation of children with tetraplegia takes approximately 2 to 4 months; children with paraplegia can achieve these goals in 1 to 3 months but require constant vigilance to avoid complications. Emotional adjustments take longer, especially in older children and adolescents. In most children the outlook is favorable unless the life-threatening consequences of urinary pathologic condition are severe or the emotional adjustment is poor.

BOX 35-12 GOALS OF REHABILITATION FOR THE CHILD WITH A SPINAL CORD INJURY

- Maximizing motor function and minimizing the disabling effects of the pathologic condition
- Assisting the child and family in setting realistic goals for the child, learning to be good problem solvers, and using the child's assets
- Helping the child to cope with the stigma of being different and to build a positive self-image

Psychosocial Rehabilitation

Early-acquired or congenital disability is usually more readily accepted by children than paralysis that appears later in childhood. Rehabilitation efforts should include not only the child's emotional responses but also those of the persons closest to the child. Intensive education is important so that family members understand the nature of the disability, the therapeutic regimen, and complications and are able to provide the physical and emotional support the child needs.

As with any disability, treat children as normally as possible and encourage them in developmental tasks at the age at which they would typically be expected to acquire abilities and perform activities. However, the goals must be realistic, and children should not be forced beyond their capabilities. Vogel, Betz, and Mulcahey (2012) emphasize the need for children and adolescents with SCI to assume responsibility for their own care. When this is not physically possible, they should direct others in their care. Encouraging self-care is important in the emotional and physical rehabilitation of the child or adolescent with SCI.

Severe depression can be emotionally and intellectually immobilizing, but it indicates that the child is no longer hiding behind denial. In rehabilitation it is desirable for the child to

FIG. 35-10 Training in a rehabilitation facility can promote achievement and encourage the child to strive to reach his maximum physical abilities. (Courtesy E. Jacob, Texas Children's Hospital, Houston.)

begin to express negative feelings toward the situation because these feelings, redirected by efforts of the rehabilitation team, are the ones that will motivate the child toward learning a new way of life. Anxiety and depression in young children and adolescents with SCI are associated with a poorer quality of life (Anderson, Kelly, Klaas, et al, 2009).

The responses to loss are discussed in Chapter 19. The multiple problems related to altered self-image, especially in older children and adolescents, are discussed in relation to children with disabilities in Chapter 21. Children with severe disabilities need to alter certain concepts about self and social roles. If they perceive adults as persons with complete control over their bodies and the ability to do what they want when they want, they will need to develop a more realistic definition of interdependent adult living.

The needs of young children and adolescents who are permanently disabled must be reevaluated periodically by the total rehabilitation team, including the children and their families. Vocational rehabilitation is important for helping these adolescents find meaningful work activities and enroll in formal educational programs as desired.

The outlook for children and adolescents with SCI is increasingly favorable for integration into society. Increased awareness of the needs of persons with disabilities has removed many structural and occupational barriers. The success of a rehabilitation program is judged not by how well children and adolescents manage within the rehabilitation setting but by how well they function on the outside. In addition to agencies that offer assistance to children with disabilities in general, some agencies provide specific assistance to paralyzed persons, including children.*

Sexuality

Issues related to loss of sexual function also apply to adolescents with debilitating neuromuscular diseases such as Duchenne muscular dystrophy (DMD) and SMA. The problems of self-image are particularly significant when children with SCI reach puberty, especially if the disability was acquired during early adolescence. Sexual development and awareness and changing perceptions of body image are prominent aspects of adolescence; a loss that affects these areas is often devastating. Development of secondary sexual characteristics does not seem to be altered by SCIs, and it is now believed that with comprehensive rehabilitation, motivated young people can look forward to successful participation in marital and family activities.

In females, if the injury occurs after the onset of menstruation, there is usually a temporary cessation and irregularity in menstrual flow, but menstruation resumes in the majority of cases. Ovulation and conception are possible, but only about 50% of females experience vaginal or clitoral orgasms, although they can learn to use other erogenous zones for a sexual experience. This is important to emphasize in sex education, since many females have the misconception that they are unable to conceive because they lack sensation. FES may help some women with SCI achieve orgasm. Education is important because the pregnant paraplegic or tetraplegic patient may be unaware that she is in labor, and those with a high-level injury are subject to autonomic dysreflexia during labor.

More attention has been focused on rehabilitating male sexual function (erection and ejaculation) than female sexual function until the last two decades. A number of pharmacologic (prostaglandin E_1) and mechanical devices (e.g., penile implants, vacuum pump devices) now make it possible for males to participate in sexual intercourse and produce offspring, provided that fertility has not been affected by associated complications. Penile injections with vasoactive substances (prostaglandin E_1) are reported to be effective in 90% of men (DeForge, Blackmer, Garritty, et al, 2006). However, sildenafil (Viagra) is now considered the treatment of choice for the sexually active male. Adolescents with SCI should be counseled regarding condom use and the symptoms of latex allergy.

As soon as adolescent males become aware of their functional loss, they will be concerned about sexual capacities, regardless of the type of sexual activities experienced before the SCI. The health care professional should take the initiative in discussing sexuality with adolescents and their families. Parents of younger children may want to know about their children's sexual and reproductive potential. As their interest and understanding increase, adolescents need to know the specifics of physiology, the prognosis, and sexual techniques related to their particular problems. The practitioner should provide them with information about what can be expected regarding erection, ejaculation, and other sexual experiences.

A knowledgeable rehabilitation team is valuable to adolescents as they experience concerns regarding loss as a sexual being. This is especially true in paraplegia or tetraplegia. Most sexual counseling for adolescents with SCI focuses on developing the idea that sex means different things to different people. Most rehabilitation teams have an active counseling program to help adolescents learn intimacy and how to function sexually within their limitations. Through individual and group counseling they gain new attitudes concerning sexuality and experiences exclusive or inclusive of intercourse. Guidelines for sexual and reproductive health care of persons with SCI are published elsewhere (Consortium for Spinal Cord Medicine, 2010).

Transition to Adulthood

With the ultimate goal of making an effective transition to adulthood, adolescents with SCI often face challenges similar to others with chronic and debilitating conditions. Issues such as housing, education, personal assistance care, transportation, medical care, and specialized medical care must be addressed in a coordinated transition program (Vogel, Betz, and Mulcahey, 2012). The concepts of care coordination for children and adolescents requiring home care also apply to adolescents making the transition to adulthood, since different health care

services may be needed or requirements may change for benefits for those no longer dependent on parents.

MUSCULAR DYSFUNCTION

JUVENILE DERMATOMYOSITIS

Juvenile dermatomyositis (JDM) is a relatively rare systemic autoimmune vasculopathy that often occurs after a triggering event such as infection with group A β-hemolytic streptococci, enterovirus (coxsackievirus B), or parvovirus B19. An environmental trigger such as excessive sun exposure has also been proposed in some children. In children one of the human leukocyte antigens (DQA1*0501, B8, DRB*0301, or DQA1*0301) is present on chromosome 6 and may be associated with increased susceptibility to the disease (Feldman, Rider, Reed, et al, 2008; Robinson and Reed, 2011). Caucasian girls are twice as likely to be affected as boys. The peak age at onset is between 4 and 10 years of age. Children with onset before age 7 may experience milder symptoms.

The diagnosis is often established through the following clinical presentations: bilateral symmetric proximal weakness; a characteristic heliotropic rash of the eyelids; Gottron papules on the knuckles, knees, and elbows; Gottron sign; elevated serum enzymes (aldolase, creatine kinase, aspartase aminotransferase, and lactate dehydrogenase); altered EMG; and abnormal muscle biopsy. An atraumatic alternative to muscle biopsy is an MRI. Nailfold capillaroscopy shows decreased capillary density and presence of disease activity and may be used to diagnose the condition (Feldman, Rider, Reed, et al, 2008).

For approximately half of affected children, the disease is acute and progresses rapidly. Children under 6 years of age often are seen initially with fever and signs of an upper respiratory tract illness. There is proximal limb and trunk muscle weakness and loss of reflexes. Consequently, the child may not be able to rise from the floor to a standing position without walking the hands up the legs (Gower sign). The disease often affects the neck muscles, and the child may have difficulty lifting the head or supporting it in an upright position. Muscles tend to be stiff and sore. A generalized vasculitis of small arteries and capillaries is one prominent feature of the disease. Masseter involvement with atrophy may occur, which makes it difficult to chew food during the active stage of the disease. Soft palate dysfunction may make speech difficult and interfere with breathing. Distal muscle strength and reflex responses remain unaffected. JDM is characterized by a red erythematous rash over the malar areas and nose and a violet discoloration of the eyelids. The skin over extensor muscle surfaces may be erythematous, scaly, and atopic. Calcium deposits (calcinosis) develop in muscle tissues as the disease progresses. Dystrophic calcifications may develop over areas exposed to pressure, including the elbows, knees, digits, and buttocks. These lesions may result in skin ulceration with subsequent infection, pain, and functional disability from joint contractures. The vasculitis may cause gastrointestinal, renal, cardiac, and ophthalmologic symptoms as the disease progresses. A common problem in JDM is aspiration pneumonia, and measures should be taken to ensure the child has an adequate airway at all times. Additional pulmonary involvement includes interstitial lung disease, so pulmonary function testing should be part of the medical management. There is evidence that adults with pediatric-onset JDM may develop cardiac problems such as heart failure. If the child has difficulty feeding, a gastrostomy may be used to supplement caloric intake until the drug regimen controls the symptoms.

JDM responds to high-dose oral corticosteroid therapy and methotrexate; in some children high-dose intermittent intravenous methylprednisone may be required. All children with JDM should use a sunscreen to protect against ultraviolet A and B rays. Vitamin D and adequate dietary intake of calcium are also recommended to increase and maintain bone density and minimize osteopenia (Feldman, Rider, Reed, et al, 2008; Huber, 2012). IVIG has been effective in some children who were intolerant of high-dose corticosteroids. Other treatments that have been effective in adult myositis and in isolated cases of JDM include hydroxychloroquine, systemic tacrolimus, etanercept or infliximab, rituximab, and cyclosporin (Feldman, Rider, Reed, et al, 2008).

Physical therapy is essential to prevent contracture deformity and to rebuild muscle strength. Meticulous skin care is an important nursing consideration in the care of these patients.

Although the prognosis for survival has steadily improved, JDM remains a serious chronic illness. Death can occur in the acute phase as a result of myocarditis, progressive unresponsive myositis, perforation of the bowel, or, occasionally, lung involvement. The current mortality rate is approximately 1% (Robinson and Reed, 2011).

MUSCULAR DYSTROPHIES

The MDs constitute the largest and most important single group of muscle diseases of childhood (Table 35-2). They have a genetic origin in which there is gradual, progressive degeneration of muscle fibers, and they are characterized by progressive weakness and wasting of symmetric groups of skeletal muscles, with increasing disability and deformity. In all forms of MD there is insidious loss of strength, but each differs in regard to the muscle groups affected, age of onset, rate of progression, and inheritance patterns.

The basic defect in MD is still being clarified but appears to be caused by a metabolic disturbance unrelated to the nervous system. Initial sites of muscle involvement are illustrated in Fig. 35-11.

Treatment of the MDs consists mainly of providing supportive measures (including physical therapy; orthopedic procedures to minimize deformity; and ventilatory support, including airway clearance techniques) and assisting the affected child in meeting the demands of daily living.

Facioscapulohumeral (Landouzy-Dejerine) muscular dystrophy is inherited as an autosomal dominant disorder with onset in early adolescence. It is characterized by difficulty in raising the arms over the head, lack of facial mobility, and a forward slope of the shoulders. The progression is slow, and the life span is usually unaffected.

TABLE 35-2 CHARACTERISTICS OF MAJOR MUSCULAR DYSTROPHIES

PRIMARY MYOPATHY AND INHERITANCE PATTERN	AGE OF ONSET	INITIAL MANIFESTATIONS	PROGRESSION	THERAPY
Duchenne X-linked recessive, sporadic	Early childhood; ages 3-5 yr	Lordosis Waddling gait Frequent falls Toe walking Difficulty in rising from floor and climbing stairs Fat deposits replace wasted gastrocnemius muscles	Rapid Ultimately involves all voluntary muscles Death usually occurs at ages 15-30 yr	Supportive Physical therapy to prevent disuse atrophy of unaffected muscles
Becker X-linked recessive, sporadic	>7 yr of age	Same as Duchenne	Much slower progression than Duchenne	Same as Duchenne
Myotonic MD Autosomal dominant Second most common MD in United States and Europe	Early infancy, except for severe congenital form	Facial wasting and hypotonia	Progressive muscle wasting into adolescence and adulthood; affects multiple organs	Treatment of cardiac, ocular, endocrine, and GI complications
Limb-girdle Autosomal recessive (usually, but 16 genetic forms are recognized and some are autosomal dominant)	Late childhood or adolescence; >8 yr of age	Weakness of proximal muscles of both pelvic and shoulder girdles	Variable but usually slow Most become incapacitated within 20 yr of onset; in some, disability may remain slight	Supportive Physical therapy to prevent disuse atrophy of unaffected muscles
Facioscapulohumeral (Landouzy-Dejerine) Autosomal dominant	Early adolescence; >8 yr of age	Lack of facial mobility Difficulty raising arms over head Forward slope of shoulders	Very slow May be intervals with no progression Considerable disability in time, but life span unaffected	Supportive

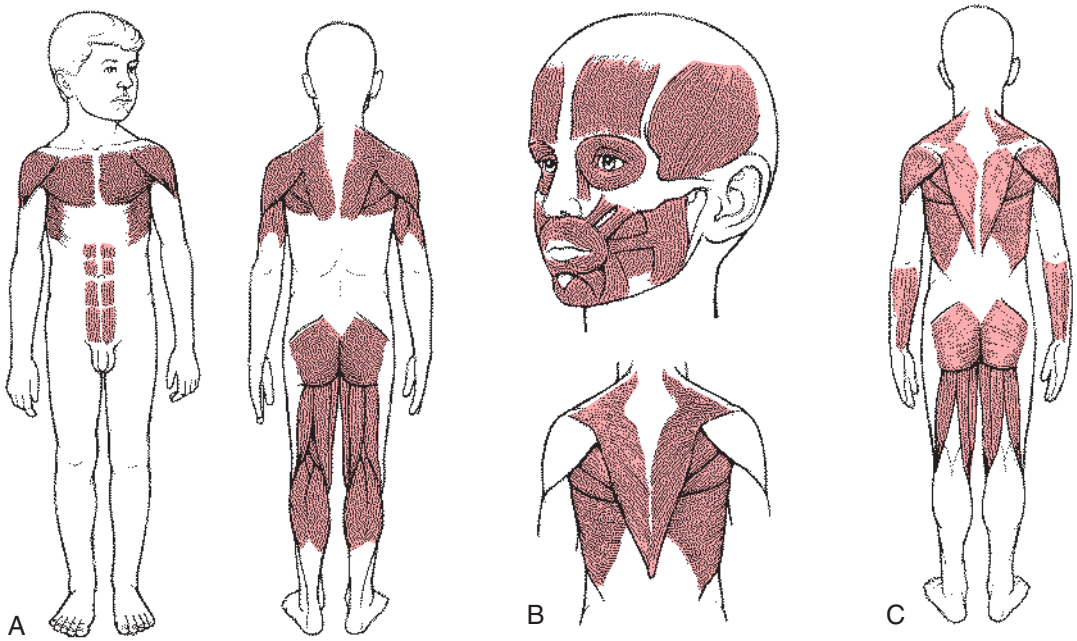

FIG. 35-11 Initial muscle groups involved in muscular dystrophies. **A,** Pseudohypertrophic (Duchenne). **B,** Facioscapulohumeral. **C,** Limb-girdle.

Limb-girdle muscular dystrophy (LGMD) is a heterogenous group of disorders with autosomal dominant and recessive inheritance whose clinical manifestations often appear in later childhood, adolescence, or early adulthood with variable but usually slow progression (Quan, 2011). All types of LGMD are characterized by weakness of proximal muscles of the pelvic and shoulder girdles. Other forms of MD include myotonic dystrophy, scapulohumeral MD (Emery-Dreifuss MD), fascioscapulohumeral MD (Landouzy-Dejerine disease), and congenital MD; these forms consist of subtypes of MD and are discussed at length elsewhere (see Sarnat, 2011d). Duchenne muscular dystrophy is discussed in the following section.

DUCHENNE MUSCULAR DYSTROPHY

DMD is the most severe and most common MD of childhood. It is inherited as an X-linked recessive trait, and the single-gene defect is located on the short arm of the X chromosome. DMD has a high mutation rate, with a negative family history in approximately 65% to 75% of all cases; therefore, genetic counseling is an important aspect of the care of the family. Approximately 30% of DMD patients are *new* mutations and the mother is *not* the carrier (Sarnat, 2011d).

As in all X-linked disorders, males are affected almost exclusively. The female carrier may have an elevated serum CK, but muscle weakness is usually not a problem; however, about 10% of female carriers develop cardiomyopathy (Manzur, Kinali, and Muntoni, 2008). In rare instances a female may be identified with DMD disease yet with muscular weakness that is milder than in boys (Sarnat, 2011d). The incidence is approximately 1 in 3600 male births for the Duchenne form and approximately 1 in 30,000 live births for the Becker type, a milder variant (Sarnat, 2007; 2011d). Box 35-13 describes the characteristics of DMD.

At the genetic level, both DMD and Becker MD result from mutations of the gene that encodes dystrophin, a protein product in skeletal muscle. Dystrophin is absent from the muscle of children with DMD and is reduced or abnormal in children with Becker MD. The absence of dystrophin leads to a number of problems in muscle, including muscle fiber degeneration. A deficiency of dystrophin isoforms in brain tissue causes cognitive and intellectual impairment (Manzur, Kinali, and Muntoni, 2008). Children with Becker MD have a later onset of symptoms, which are usually not as severe as those seen in DMD. There is a strong correlation between the clinical severity of these disorders and the type of genetic mutation and dystrophin protein alterations. Survival has increased with newer ventilation technologies, and median age is reported as high as 27 years in those being ventilated; types of ventilation used were not described in the report (Rall and Grimm, 2012).

BOX 35-13 CHARACTERISTICS OF DUCHENNE MUSCULAR DYSTROPHY

- Early onset, usually between 3 and 5 years of age
- Progressive muscular weakness, wasting, and contractures
- Calf muscle hypertrophy in most patients
- Loss of independent ambulation by 9 to 12 years of age
- Slowly progressive, generalized weakness during adolescence
- Relentless progression until death from respiratory or cardiac failure

Clinical Manifestations

Most children with DMD reach the appropriate developmental milestones early in life, although they may have mild, subtle delays. Evidence of muscle weakness usually appears during the third to seventh year, although there may have been a history of delay in motor development, particularly walking. Difficulties in running, riding a bicycle, and climbing stairs are usually the first symptoms noted. Later, abnormal gait on a level surface becomes apparent. In the early years, rapid developmental gains may mask the progression of the disease. Questioning the parents may reveal that the child has difficulty in rising from a sitting or supine position. Occasionally the parents notice enlarged calves.

Typically, affected boys have a waddling gait and lordosis, fall frequently, and develop a characteristic manner of rising from a squatting or sitting position on the floor (Gower sign) (Fig. 35-12). Lordosis occurs as a result of weakened pelvic muscles, and the waddling gait is a result of weakness in the gluteus medius and maximus muscles (Battista, 2010). Muscles, especially in the calves, thighs, and upper arms, become enlarged from fatty infiltration and feel unusually firm or woody on palpation. The term *pseudohypertrophy* is derived from this muscular enlargement. Profound muscular atrophy occurs in the later stages; contractures and deformities involving large and small joints are common complications as the disease progresses. Ambulation usually becomes impossible by 12 years of age. The loss of mobilization further increases the spectrum of complications, which may include osteoporosis, fractures, constipation, skin breakdown, and psychosocial and behavioral problems. Atrophy of facial, oropharyngeal, and respiratory muscles does not occur until the advanced stage of the disease. Ultimately the disease process involves the diaphragm and auxiliary muscles of respiration, and cardiomegaly is common.

Mild to moderate mental impairment is commonly associated with MD. The mean intelligence quotient (IQ) is approximately 20 points below normal, and frank mental deficit is present in 20% to 30% of these children. Verbal IQ is markedly low in males with DMD, and emotional disturbance is more common than in other children with disabilities; however, children with DMD should be involved in early learning programs and eventually moved into regular classrooms as much as possible.

Complications

The major complications of MD include contractures, scoliosis, disuse atrophy, infections, obesity, and respiratory and cardiopulmonary problems. Contracture deformities of the hips, knees, and ankles occur from early selective muscle involvement and often exaggerate the weakness. Passive range-of-motion exercises, stretching, and active exercises under the supervision

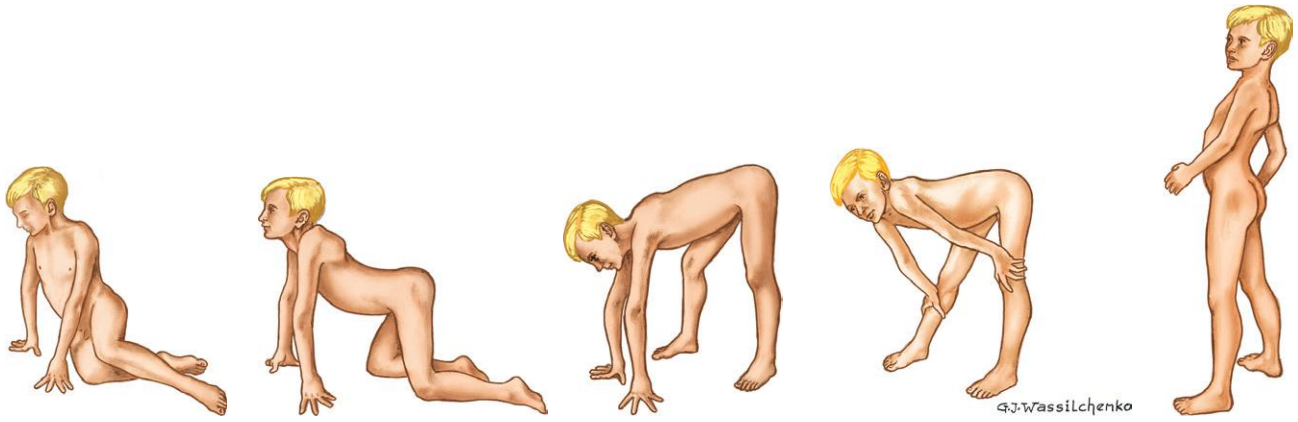

FIG. 35-12 Child with Duchenne muscular dystrophy attains standing posture by kneeling, then gradually pushing his torso upright (with knees straight) by "walking" his hands up his legs (Gower sign). Note marked lordosis in upright position.

of a PT are effective in treating reducible contractures. Nonreducible contractures require wedge casting or surgical reduction. Scoliosis caused by muscle imbalance is common in children who lose ambulatory capability and tends to progress even when the child becomes dependent on a wheelchair. Bracing with an orthosis may be required, but in many cases spinal fusion surgery is performed to prevent complications associated with cardiac and pulmonary restriction.

Atrophy of disuse from prolonged inactivity occurs readily when children are immobilized or confined to bed with illness, injury, or surgery. To minimize this complication, physical therapy should begin if bed rest extends beyond a few days. To maintain muscle strength, a daily goal for well children with moderate disability should be at least 3 hours of ambulation.

Pulmonary infections become increasingly frequent as the dystrophic process produces a progressive decrease in pulmonary vital capacity as a result of weakness of the primary, secondary, and associated muscles of respiration. Consequently, even minor upper respiratory tract infections may become serious in these children. The eventual cause of death is usually respiratory tract infection or cardiac failure; however, much progress has been made in providing ventilatory methods to prolong and maintain quality of life. Prompt and vigorous antibiotic therapy, supplemented by postural drainage and aggressive airway clearance methods, is effective. Because of the respiratory musculature weakness, these children are unable to cough effectively and secretions collect easily.

Obesity is a common complication that contributes to premature loss of ambulation. Children who have restricted opportunities for physical activity and who suffer from boredom easily consume calories in excess of their needs. This may be compounded by overfeeding by well-meaning family and friends. Proper dietary intake and a diversified recreational program help reduce the likelihood of obesity and enable children to maintain ambulation and functional independence for a longer time.

Cardiac manifestations are usually late events but may occur in ambulatory children. The most significant of these, cardiac failure, is difficult to correct in advanced cases, but treatment with digoxin and diuretics is often beneficial in the early stages of the disease.

Diagnostic Evaluation

MD is suspected on the basis of clinical manifestations (see Box 35-13) and confirmed by molecular genetic detection of deficient dystrophin by DNA analysis from peripheral blood or in muscle tissue obtained by biopsy. The diagnosis of DMD is primarily established by blood polymerase chain reaction (PCR) for the dystrophin gene mutation (Sarnat, 2011d). Diagnostic techniques such as multiplex PCR have made it possible to diagnose 98% of the DMD mutations. Prenatal diagnosis is also possible as early as 12 weeks of gestation. However, ethical questions exist regarding diagnosing a condition in the fetus when no treatment exists.

Serum enzyme measurement, muscle biopsy, and EMG may also be used in establishing the diagnosis. Serum CK levels are extremely high in the first 2 years of life, before the onset of clinical weakness. If the child demonstrates the usual characteristics, has a positive family history for DMD, and the PCR is positive, the muscle biopsy may be deferred.

Muscle biopsy reveals degeneration of muscle fibers, with fibrosis and fatty tissue replacement. EMG readings show a decrease in amplitude and duration of motor unit potentials.

Therapeutic Management

Currently no curative treatment exists for childhood MD. Increased muscle bulk and muscle power have been reported after a course of corticosteroids. Several clinical trials demonstrated increased muscle strength and improved performance and pulmonary function, with significant decrease in the progression of weakness, when prednisone was administered for 6 months to 2 years (Manzur, Kuntzer, Pike, et al, 2008). Corticosteroid administration also prolonged ambulation, preserved respiratory function, and decreased the incidence of scoliosis and cardiomyopathy (Manzur, Kinali, and Muntoni, 2008). Major side effects in these studies included weight gain

and a cushingoid facial appearance. The American Academy of Neurology has published a practice parameter for the administration of corticosteroids in the treatment of DMD (Moxley, Ashwal, Pandya, et al, 2005).

Maintaining optimum function in all muscles for as long as possible is the primary goal; secondary is the prevention of contractures. In general, children who remain as active as possible are able to avoid wheelchair confinement for a longer time. Maintenance of function often includes stretching exercises, strength and muscle training, breathing exercises and use of incentive spirometry to increase and maintain vital lung capacity, airway clearance, range-of-motion exercises, surgery to release contracture deformities, bracing, and performance of ADLs. Knee-ankle-foot orthoses have been shown to prolong ambulation for 18 to 24 months beyond the termination of independent ambulation. Serial casting of ankles has proven more effective than surgical release of Achilles tendons in many children with DMD to prevent contractures (Manzur, Kinali, and Muntoni, 2008).

Parents should always be involved in making decisions about the child's care, and teaching regarding home safety and prevention of falls is important as well. Also encourage parents to have the child keep follow-up appointments for medical care and physical and occupational therapy. Because respiratory tract infections are most troublesome in these children, encourage regular influenza and pneumococcal vaccines and avoidance of contact with persons with respiratory tract infections as much as possible. Baseline pulmonary function testing, electrocardiograms, and echocardiograms are also recommended.

Eventually, respiratory and cardiac problems become the central focus of the debilitating illness. Referral to Palliative Care may help the family evaluate the benefits and burdens of various treatments. The child and parents should be involved in discussion of long-term ventilation options. Cardiac and respiratory assessment during wake-sleep cycles is imperative. Children with neuromuscular disease eventually develop abnormal breathing patterns, particularly during rapid-eye-movement sleep, and hypoxia occurs as a result of inadequate oxygenation. The sleep-disordered breathing of DMD results in symptoms such as frequent night awakenings, morning headache, and daytime sleepiness. Polysomnography should be performed once daytime symptoms of sleep-disordered breathing occur. Noninvasive positive pressure ventilation should be considered in such children to prevent further hypoventilation and cardiorespiratory deterioration (Culebras, 2008). Respiratory care for children with neuromuscular conditions such as SMA and DMD may involve the use of noninvasive ventilation with BiPAP on a temporary or full-time basis, mechanically assisted coughing (MAC), or tracheostomy and relief of airway obstruction with coughing and suctioning devices; the tracheostomy, however, is associated with more complications (Simonds, 2006; Young, Lowe, and Fitzgerald, 2007). Home pulse oximetry may be used to monitor oxygenation during sleep or to aid in decision making regarding the use of MAC to clear the airways. A polysomnogram may be used to evaluate the effectiveness of supplemental oxygen and noninvasive ventilation devices.

Several devices are available for children with neuromuscular disease to assist in clearing the airway when the cough reflex is ineffective or diminished. The *mechanical cough in-exsufflator* (MIE) (also referred to as cough assist) has been found to be safe and effective in the daily management of respiratory function (Kravitz, 2009; Miske, Hickey, Kolb, et al, 2004). The MIE delivers positive inspiratory pressures at a set rate, followed by negative pressure exsufflation coordinated with the patient's own breathing rhythm. The exsufflation is designed to mimic a cough reflex so mucus can be effectively cleared. Airway suctioning after exsufflation is accomplished as necessary to clear the airways. In children the MIE device may be connected directly to a tracheostomy or used with a mouthpiece or face mask. Boitano's (2009) article provides a variety of equipment options, including various masks that can be used to deliver noninvasive positive pressure.

Manual cough-assisting techniques include glossopharyngeal breathing or air stacking (frog breathing); the abdominal thrust, which is similar to the Heimlich maneuver (Kravitz, 2009); and manual hyperinflation with a self-inflating resuscitation bag (without oxygen) and a mouthpiece. Hyperinflation may be used in conjunction with abdominal thrusts to improve peak cough flows (Boitano, 2009).

The use of routine chest physiotherapy for DMD has not been adequately evaluated for its effectiveness in clearing the airway of mucus except when there is focal atelectasis and mucus plugging the airways (Kravitz, 2009).

Survival in individuals with DMD may be prolonged several years with the use of noninvasive ventilation and airway clearance devices such as cough assist as alternatives to tracheotomy and airway suctioning (Simonds, 2006). The American Thoracic Society (2004) has published extensive guidelines for respiratory monitoring and care of children and adults with DMD. See Finder's (2009) article for an elaboration on the 2004 American Thoracic Society statement.

The American Academy of Pediatrics (2005) recommends an extensive cardiac evaluation of the child diagnosed with either DMD or Becker MD. Patients with neuromuscular conditions may not have the typical signs and symptoms of cardiac dysfunction. Therefore, symptoms such as weight loss, nausea and vomiting, cough, increased fatigue on performance of ADLs, and orthopnea should be carefully evaluated to detect early signs of cardiomyopathy.

Research evaluating a number of treatments for DMD is in progress. These include clinical trials with glutamine and creatine monohydrate to preserve muscle strength; utrophin, a protein that is similar to dystrophin and that in large quantities may counteract the effects of the dystrophin deficiency (Chakkalakal, Thompson, Parks, et al, 2005; Miura and Jardin, 2006); and the enzyme CT GalNAc transferase, which blocks muscle wasting in mice. Oral albuterol administered daily for 12 weeks increased lean body mass and decreased fat mass in a group of 14 ambulatory boys with Becker and DMD; however, overall muscle strength improvement was not observed (Skura, Fowler, Wetzel, et al, 2008).

Genetic counseling is recommended for parents, sisters, and maternal aunts and their daughters. (See Chapter 3.) Long-term

care, end-of-life care, and palliative care options are issues that the health care team must discuss with the child and family affected by MD (Finder, 2009). Professional counseling is necessary in some cases to allow frank discussion of these issues, and referrals should be made as appropriate (Finder, Birnkrant, Carl, et al, 2004). (See Chapter 21.)

Guidelines for the standardization of diagnosis and therapeutic management of DMD have been published elsewhere (Bushby, Finkel, Birnkrant, et al, 2010).

Nursing Care Management

The care and management of a child with MD involve the combined efforts of a multidisciplinary health care team. Nurses can help clarify the roles of these health care professionals to family and others. The major emphasis of nursing care is to assist the child and family in coping with the progressive, incapacitating, and fatal nature of the disease; to help design a program that will afford a greater degree of independence and reduce the predictable and preventable disabilities associated with the disorder; and to help the child and family deal constructively with the limitations the disease imposes on their daily lives. Because of advances in technology, children with MD may live into early adulthood; therefore, the goals of care should also involve decisions regarding quality of life, achievement of independence, and transition to adulthood.

Working closely with other team members, nurses assist the family in developing the child's self-help skills to give the child the satisfaction of being as independent as possible for as long as possible. It is tempting for parents to overprotect their affected children. Children derive pleasure and build self-esteem from performing actions that visibly please their parents. Therefore, parents must be helped to develop a balance between limiting the child's activity because of muscular weakness and allowing the child to accomplish things alone. This requires continual evaluation of the child's capabilities, which are often difficult to assess. Most children with MD instinctively recognize the need to be as independent as possible and strive to do so.

Practical difficulties faced by families are the physical limitations of housing, transportation, and mobility. Housing accommodations must be made so the wheelchair-bound child can be mobile in the home setting. Transportation in a car restraint seat adapted for the child with weakened neck and back musculature will be necessary, and eventually a wheelchair-accessible vehicle will be required. Discuss diet, nutritional needs, and nutrition modification according to the needs of the individual child and family. Nutritional needs decrease once the child becomes wheelchair bound, and dietary modifications should be made in conjunction with a pediatric dietitian to ensure the child is receiving an adequate amount of the necessary nutrients to maintain bone health and prevent constipation.

Parents' social activities may be restricted, and the family's activities must be continually modified to meet the needs of the affected child. (See Chapter 21.) When the child becomes increasingly incapacitated, the family may consider home care to provide the care needed. The nurse as case manager can assist the family in making this difficult transition. Unless the child is severely incapacitated, he or she should also be involved in the decisions regarding such care. Nurses can assist with decision making by exploring all available options and resources and supporting the child and family in the decision.

Each child's therapy program is tailored to individual needs and capabilities, and family members should be active participants. Parents often need assistance with the physical therapy program and education regarding a home regimen of exercises and activity. Many parents erroneously believe that by exerting sufficient effort, the child can overcome the weakness and prevent progression of the disease process. They should also be advised to notify the nurse or other designated person when the child becomes even temporarily bedridden so that the exercise program can be modified and continued during this time.

Children with MD tend to become socially isolated as their physical condition deteriorates to the point that they can no longer keep up with friends and classmates. Their physical capabilities diminish, and their dependency increases at the age at which most children are expanding their range of interests and relationships. To gain peer associations, they often learn and employ behaviors that bring them the rewards of other children's company. These friends are often children who have been rejected by more able-bodied classmates.

Older boys with MD may also need psychiatric or psychologic counseling to deal with issues such as depression, anger, and quality of life. Parents need encouragement to become involved in support groups, since there is evidence that adequate social support from family, community, and other parents is crucial to appropriate coping in families with children with chronic illness.

Regardless of the success of the program and how well the family adapts to the disorder, superimposed on the physical and emotional problems associated with the child's long-term disability is the constant specter of the disease's ultimate outcome. These families encounter all the manifestations of the child with a chronic and fatal illness. (See Chapter 23.)

Nurses are especially valuable health care professionals as they come to know the family and the family's challenges. Nurses can be alert to the problems and needs of the families and make necessary referrals when supplementary services are indicated. The Muscular Dystrophy Association–USA* has branches in most communities to provide assistance to families that have a member with MD.

NCLEX REVIEW QUESTIONS

1. The most common complication that should be anticipated and observed for in an infant with myelomeningocele after surgical repair of the defect is:
   - **A.** Urinary stress
   - **B.** Chiari malformation
   - **C.** Hydrocephalus
   - **D.** Latex allergy
2. A 14-year-old male with a spinal cord injury is placed on a standing table and suddenly begins to sweat profusely and complain of a headache. The nurse takes a set of vital signs and notes a significant increase in systolic blood pressure and a heart rate of 50 bpm. The most helpful intervention in this situation would be for the nurse to:
   - **A.** Place the adolescent back in his wheelchair and take him to his room
   - **B.** Palpate the bladder for distention
   - **C.** Administer a routine analgesic for his headache and discontinue the therapy
   - **D.** Place the standing table in a horizontal position and allow the adolescent to rest for a few minutes
3. The primary risk factor for the development of cerebral palsy is:
   - **A.** Maternal chorioamnionitis
   - **B.** Premature birth
   - **C.** Birth asphyxia
   - **D.** Intraventricular hemorrhage
4. Urinary system distress (neurogenic bladder) in children with spina bifida is managed by:
   - **A.** DDAVP (1-deamino-8-D-arginine vasopressin)
   - **B.** Clean intermittent catheterization
   - **C.** Continuous urinary catheterization
   - **D.** Mitrofanoff procedure
5. Which of these statements accurately describes Duchenne muscular dystrophy? Select all that apply.
   - **A.** The absence of dystrophin leads to muscle fiber degeneration.
   - **B.** DMD is inherited as an X-linked recessive trait.
   - **C.** Cognitive and intellectual impairment are rare in children with DMD.
   - **D.** Affected children have a waddling gait and lordosis and fall frequently.
   - **E.** Ambulation usually becomes impossible by 12 years of age, and affected children are confined to a wheelchair.
   - **F.** Affected children must be hospitalized when ambulation becomes impossible.

Correct Answers

1. C
2. B
3. B
4. B
5. A, B, D, E

APPENDIX

A

Growth Measurements

BODY MASS INDEX FORMULA

English Formula

$$\text{BMI} = [\text{Weight in pounds} \div \text{Height in inches} \div \text{Height in inches}] \times 703$$

Fractions and ounces must be entered as decimal values.

FRACTION	OUNCES	DECIMAL
1/8	2	0.125
1/4	4	0.25
3/8	6	0.375
1/2	8	0.5
5/8	10	0.625
3/4	12	0.75
7/8	14	0.875

Example: A 33-lb, 4-oz child is 37 5/8 inches tall.

$$[(33.25 \text{ lb} \div 37.625 \text{ in}) \div 37.625 \text{ in}] \times 703 = 16.5$$

Metric Formula

$$\text{BMI} = \text{Weight in kilograms} \div [\text{Height in meters}]^2$$

or

$$\text{BMI} = [(\text{Weight in kilograms} \div \text{Height in cm}) \div \text{Height in cm}] \times 10{,}000$$

Example: A 16.9-kg child is 105.2 cm tall.

$$[(16.9 \text{ kg} \div 105.2 \text{ cm}) \div 105.2 \text{ cm}] \times 10{,}000 = 15.3$$

From Kuczmarski RJ, Ogden CL, Grummer-Strawn LM, and others: *CDC growth charts: United States: advance data from vital and health statistics,* no 314, Hyattsville, Md, June 8, 2000, National Center for Health Statistics; retrieved from www.cdc.gov/nchs/about/major/nhanes/growthcharts/fullreport.htm.

French		Pas mal	Un petit peu mal	Un peri plus mal	Encore plus mal	Très mal	Très mal
Italian		Non fa male	Fa male un poco	Fa male un po di piu	Fa male ancora di piu	Fa molto male	Fa maggior-mente male
Portuguese		Não doi	Doi um pouco	Doi um pouco mais	Doi muito	Doi muito mais	Doi o máximo
Bosnian		Ne boli	Boli samo malo	Boli malo više	Boli još više	Boli puno	Boli najviše
Vietnamese		Không dau	Hôi dau	Dau hôn chút	Dau nhiêu hôn	Dau thât nhiêu	Dau qúa dô
Chinese†		無痛	微痛	較痛	更痛	很痛	劇痛
Greek		Δεν Ποναϊ	Ποναϊ Λιγο	Ποναϊ Λιγο Πιο Πολν	Ποναϊ Πολν	Ποναϊ Πιο Πολν	Ποναϊ Παρα Πολν
Romanian		No doare	Doare puţin	Doare un pic mai mult	Doare şi mai mult	Doare foarte tare	Doare cel mai mult

Brief Word Instructions (Above)

Point to each face using the words to describe the pain intensity. Ask person to choose face that best describes own pain and record the appropriate number. Rating scale can be used with people 3 years and older.

NOTE: In a study of 148 children ages 4 to 5 years, there were no differences in pain scores when children used the original or brief word instructions. (In Wong D, Baker C: *Reference manual for the Wong-Baker FACES Pain Rating Scale,* Duarte, Calif, 1998, City of Hope Mayday Pain Resource Center; retrieved from http://evolve.elsevier.com/Wong/essentials.)

*__Wong-Baker FACES Pain Rating Scale:__ Available at no charge from The Purdue Frederick Company, 100 Connecticut Ave., Norwalk, CT 06850-3590; www.partnersagainstpain.com. Spanish and Portuguese translations by Ellen Johnsen; French translation from Wong DL: *Soins infirmiers pediatrie*, Quebec, 2002, Editions Etudes Vivantes, Groupe Educalivres, Inc.; Italian translation by Madeline Mitchko; Bosnian transla- tion by Barbara Bogomolov; Vietnamese translation by Yen B. Isle; Chinese translation by Hung-Shen Lin; Greek translation by Nicholas Mamalis; Romanian translation by Bogdan R. Dinu.

Original Instructions

English. Explain to the person that each face is for a person who feels happy because he has no pain (hurt) or sad because he has some or a lot of pain. **Face 0** is very happy because he doesn't hurt at all. **Face 1** hurts just a little bit. **Face 2** hurts a little more. **Face 3** hurts even more. **Face 4** hurts a whole lot. **Face 5** hurts as much as you can imagine, although you don't have to be crying to feel this bad. Ask the person to choose the face that best describes how he or she is feeling.

Rating scale is recommended for persons ages 3 years and older.

Spanish. Expliquele a la persona que cada cara representa una persona que se siente feliz porque no tiene dolor o triste porque siente un poco o mucho dolor. **Cara 0** se siente muy feliz porque no tiene dolor. **Cara 1** tiene un poco de dolor. **Cara 2** tiene un poquito más de dolor. **Cara 3** tiene más dolor. **Cara 4** tiene mucho dolor. **Cara 5** tiene el dolor más fuerte que usted pueda imaginar, aunque usted no tiene que estar llorando para sentirse asi de mal. Pidale a la persona que escoja la cara que mejor describe su proprio dolor.

Esta escala se puede usar con personas de tres años de edad o más.

French. Expliquez à la personne que chaque visage représent une personne qui est heureux parce qu'elle n'a pas point du mal ou triste parce qu'elle a un peu ou beaucoup du mal. **Visage 0** est trés heureux parce qu'elle n'a pas point du mal. **Visage 1** a un petit peu de mal. **Visage 2** a plus du mal. **Visage 3** a encore plus du mal. **Visage 4** a beaucoup du mal. **Visage 5** a autant mal que vous pouvez imaginer, bien que ces mauvais sentiments ne finissent pas nécessairement a vous faire pleurer. Demandez à la personne de choisir le visage qui convient le mieux avec ses sentiments.

Ces evaluations sont recommendés pour des personnes de trois ans et davantage.

Italian. Spiegare a la persona che ogni facien è per una persona che si sente felice perchè non tiene dolore oppure triste perchè ha poco o molto dolore. **Faccia O** è molto felice perchè non tiene dolore. **Faccia 1** tiene poco dolore. **Faccia 2** tiene un po più di dolore. **Faccia 3** tiene più dolore. **Faccia 4** tiene molto dolore. **Faccia 5** tiene molto dolore che non puoi immaginare però non devi piangere per tenere dolore. Domandi ala persona di scegliere quale faccia meglio descrive come si sente.

Grado scale è raccomandata a la persona di tre anni in sù.

Portuguese. Explique a pessoa que cada face representa uma pessoa que está feliz porque não têm dor, ou triste por ter um pouco ou muita dor. **Face 0** está muito feliz porque não têm nenhuma dor. **Face 1** têm apenas um pouco de dor. **Face 2** têm um pouco mais de dor. **Face 3** têm ainda mais dor. **Face 4** têm muita dor. **Face 5** têm uma dor máxima, apesar de que nem sempre provoca o choro. Peça a pessoa que escolhe a face que melhor descreve como ele se sente.

Esta escala é aplicável a pessoas de tres anos de idade ou mais.

Romanian. Explicati copilului că fiecare desen (figură) corespunde unei persoane care este veselă, pentru ca nu are nici o durere, sau unei persoane care este tristă, pentru că are dureri. **Figura 0** este foarte fericită pentru că nu are nici o durere. **Figura 1** arată că doare doar un pic. **Figura 2** arată că doare ceva mai mult. **Figura 3** arată că doare şi mai mult. **Figura 4** arată că doare foarte tare. **Figura 5** arată că doare atât de tare cât se poate imagina, chiar dacă nu este însotita neapărat de lacrimi. Cereti copilului (persoanei) să indice figura care exprimă cel mai bine cum se simte el.

Scala de evaluare a durerii este recomandată pentru copiii în vârstùă de trei ani şi peste.

Bosnian. Objasnite osobi da je svako lice namjenjeno za osobu koja se osjeća sretnom jer ne osjeća bol ili tužnom jer osjeća malo ili puno boli. **Lice 0** je sretno jer ne osjeća nikakvu bol. **Lice 1** osjeća samo malu bol. **Lice 2** osjeća malo više boli. **Lice 3** osjeća još veću bol. **Lice 4** osjeća puno boli. **Lice 5** osjeća onoliku bol koju je moguće zamisliti, što ne znači da osoba koja osjeća tu bol mora plakati. Upitajte osobu da izabere lice koje najbolje opisuju kako se osjeća. Skala procijene bola se preporu ćuje za osobe starosti 3 godine ili više.

Upirati prstom na svako lice objašnjavajući rijećima intensitet boli. Pitajte dijete da izabere lice koje najbolje opisuje njihovu bol i zabiljezue odgovarajući broj.

German. Erläutern Sie dem Kind, daß jedes Gesicht zu einer Person gehört, die froh darüber ist, keine Schmerzen zu haben, oder die sehr traurig ist, weil sie mäßige bis starke Schmerzen hat. **Gesicht 0** ist sehr froh, weil es keine Schmerzen hat. **Gesicht 1** sagt, es tut ein bißchen weh. **Gesicht 2** hat ein bißchen mehr Schmerzen. **Gesicht 3** sagt, es tut noch mehr weh, und **Gesicht 4,** es tut ziemlich weh. **Gesicht 5** leidet unter so starken Schmerzen, wie Du Dir nur vorstellen kannst, auch wenn dabei nicht unbedingt Tränen fließen müssen. Bitten Sie das Kind, das Gesicht auszuwählen, das seinem Empfinden am besten entspricht.

Empfohlen für Kinder ab drei Jahren.

Vietnamese

Xin cắt nghĩa cho mối người, từng khuôn mặt của một người cảm thấy vui vẽ tại vì không có sự đau đớn hoặc, buồn vì có chút ít hay rất nhiều sự đau đớn.

Cái **mặt** với **số 0** thì rất là vui tại vì mặt ấy không có sự đau đớn. **Mặt số 1** chỉ đau một chút thôi. **Mặt số 2** hơi đau hơn một chút nữa. **Mặt số 3** đau hơn chút nữa. **Mặt số 4** đau thật nhiều. **Mặt số 5** đau không thể tưởng tượng, mặc dù người ta không cần phải khóc mới cảm thấy được sự buồn khổ như thế.

Bạn hỏi từng người tự chọn khuôn mặt nào diễn tả được sự đau đớn của chính mình.

Japanese

3歳以上の患者に望ましい。それぞれの顔は、患者の痛み(pain, hurt)がないのでご機嫌な感じ、または、ある程度の痛み・沢山の痛みがあるので悲しい感じを表現していることを説明して下さい。0＝痛みがまったくないから、とても幸せな顔をしている、1＝ほんの少し痛い、2＝もう少し痛い、3＝もっと痛い、4＝とっても痛い、5＝痛くて涙を流す必要はないけれども、これ以上の痛みは考えられないほど痛い。今、どのように感じているか最もよく表わしている顔を選ぶよう、患者に求めて下さい。

Chinese

解釋給人聽用每張臉譜來代表著一個人的感覺是因為沒有疼痛〔傷痛〕而感快樂或是因為些許疼痛或者是許多疼痛而感傷心。第零張臉是很快樂的因為他一點也不覺得疼痛。第一張臉只痛一丁點兒。第二張臉又痛多了一些。第三張臉痛得更多了。第四張臉是非常痛了。第五張臉是為人們所能想像到的劇痛即使感到這樣難過，卻不一定哭出來。請這人選擇出最能代表他現在感覺的一張臉譜。此量表適用於三歲以上的人。

APPENDIX C

Spanish–English Translations

ENGLISH PHRASE	SPANISH PHRASE
PHYSICAL EXAMINATION	
Open your mouth	Abre la boca
Breathe deeply	Respira profundo
Turn over	Volteate
Hoarse	Ronco
Rash or skin lesion produced by insect bite	Rozadura o una lesión en la piel producida por una picadura de insecto
Rash	Roncha, salpullido, rozadura
Ringworm	Tiña
To tighten (grip)	Apretar
To loosen	Relajar, aflojar
Bruise	Moretón
Skin "spot" (like a blanching)	Mancha
Snore, stertor	Roncar
Snoring sound	Ronquido
Swollen	Hinchado
SYMPTOMS	
I would like to know if you have (or have had):	Quisiera saber si tienes (o has tenido):
Cough	Tos
Runny nose	Moquera
Fever	Fiebre o calentura
Vomiting or nausea	Vómito o náusea
Diarrhea	Diarrea
Constipation	Estreñimiento
Pain	Dolor
Allergic reaction	Reacción alérgica
Seizure	Convulsión
Sore throat	Dolor de garganta
Diaper dermatitis	Dermatitis por el pañal
Dizzy	Mareado(a)
HISTORY	
Are you sleeping well?	¿Estás durmiendo bien?
Have you had any trauma?	¿Has tenido algún trastorno o algún trauma?
Have you had any hemorrhage or loss of blood?	¿Has tenido una hemorragia o pérdida de sangre?
Problems during pregnancy or delivery?	¿Problemas en el embarazo o parto?
Born at term or premature?	¿Nació a tiempo o fue prematuro?
Did he get better after the treatment or the medicine given?	¿Mejoró después del tratamiento o después de haberle dado la medicina?
How many times did (he/she) urinate today?	¿Cuántas veces orinó hoy?
How many wet diapers has (he/she) had?	¿Cuántos pañales ha mojado?
How many dirty diapers?	¿Cuántos pañales sucios?
Where does it hurt?	¿Dónde te duele?
When did it start?	¿Cuándo empezó?
Does (he/she) have any allergies to medicine or food?	¿Él (ella) tiene alergia a alguna medicina o comida?
Up-to-date	Al día
Contagious	Contagioso
Stool (various terms)	Excremento, heces, popo
Has (she/he) had any chronic illnesses?	¿Él (ella) ha tenido alguna enfermedad crónica?
How many times did he/she vomit today?	¿Cuántas veces vomitó hoy?
Wheezing or adventitious sounds (in lungs)	Pillido o ruidos en los pulmones
Nasal secretions	Secreción nasal
Stuffy nose	Bloqueo nasal
Breathing problems	Dificultad para respirar
Thick discharge	Flujo grueso
Wound	Herida
Blood pressure	Presión arterial
Temperature	Temperatura
Fever	Calentura, fiebre
Pulse	Pulso
Heartbeat	Latido del corazón
Airway	Vía respiratoria
Vital signs	Signos vitals
SPECIFIC CONDITIONS	
Flu	Gripa
Croup	Crup
Bronchitis	Bronquitis
Burn	Quemadura
Rash or dermatitis	Erupción o rozadura
Pneumonia	Neumonía

ENGLISH PHRASE	SPANISH PHRASE
Pertussis	Tos ferina
Measles	Sarampión
Mumps	Paperas
Chickenpox	Varicela
Rubella	Rubéola
Polio	Polio
Tetanus	Tétano
Vomiting	Vómito
Diarrhea	Diarrea
Asthma	Asma
Mucous	Moco
Seizures	Convulsións
Drainage	Drenaje
Immunization	Vacuna
Poison ivy	Hiedra venenosa
Bacterial infection	Infección bacterial
Viral infection	Infección viral
Diaper dermatitis	Dermatitis por causa del pañal
Rash or skin lesion produced by insect bite	Rozadura o lesión de la piel hecha por una picadura de insecto
Ulcer (as in mouth ulcers or chancre sores)	Úlceras o llagas en la boca
Gastritis	Gastritis, agruras
Constipation	Estreñimiento
Home remedies	Tratamientos caseros
Fracture	Fractura
Intensive care	Cuidado intensivo
Immunizations	Vacunas
Animal bite	Mordida de animal
Menstrual period	Menstruación, período
Birth control	Anticonceptivo

EQUIPMENT

Tube; can also mean nasogastric tube or urinary catheter or any tube that has to be inserted into body (MicKey button, gastrostomy)	Sonda, catéter urinario, tubo que se introduce en el cuerpo
Gown	Bata
Suction	Succión
Sheet	Sábana
Diaper	Pañal
Bulb syringe	Saca mocos
Clothes, clothing	Ropa
Splint or cast	Férula o yeso
Dressing, bandage	Bendaje, gaza
Infusion pump	Máquina para infusion
Tape	Cinta
Teaspoon	Cucharadita
Cup (as in small medicine cup or drinking cup)	Taza
Syringe	Jeringa
Pill	Pastilla, píldora
Needle	Aguja
Antibiotic	Antibiótico
Cotton swab	Algodón
Pacifier	Chupón
Bottle, as in baby bottle or medicine bottle	Biberón
Juice	Jugo
Milk	Leche

BODY PARTS

Bone	Hueso
Blood	Sangre
Tongue	Lengua
Head	Cabeza
Arm	Brazo
Finger	Dedo
Leg	Pierna
Neck	Cuello
Elbow	Codo
Foot	Pie
Ear	Oreja
Nose	Nariz
Mouth	Boca
Bladder	Vejiga
Back	Espalda
Chest	Pecho
Spleen	Bazo
Gallbladder	Vesícula

PAIN MANAGEMENT

Do you have any pain …?	¿Tienes dolor …?
Headache	De cabeza
Stomachache	De estómago
Backache	De espalda
Chest pain	En el pecho
In the arm	En el brazo
In the legs	En las piernas
In the mouth	En la boca
In the eyes	En los ojos
In the bladder	En la vejiga
How many hours, days, months, years have you had pain …?	¿Por cuántos (cuántas) horas, días, meses, años has tenido dolor …?
Please show me where it hurts	Muéstreme dónde te duele, por favor.
What medicine are you taking for pain?	¿Qué medicina estás tomando para el dolor?
What medicine have you taken for pain?	¿Qué medicina has tomado para el dolor?
Calm down	Cálmate
This won't hurt	Esto no te va a doler

PROCEDURES

Injection	Inyección
Lumbar puncture	Punción lumbar
Oral hydration solution (e.g., Pedialyte)	Suero oral o por la boca
Intravenous fluids	Suero intravenoso o por la vena
Start an intravenous line	Vamos a ponerle suero intravenoso o por la vena
Normal saline drops	Gotas de solución salina
Humidity	Humedad
Vaporizer	Vaporizador de aire
Breathing treatment	Tratamiento para la respiración
Humidity in the bathroom with a hot shower running	El vapor en el baño de la regadera o ducha de agua caliente
Stool sample	Muestra de heces (popo) excremento

Continued

ENGLISH PHRASE	SPANISH PHRASE
We need to take some blood to see what exactly (illness) (he/she) has	Tenemos que tomar una muestra de sangre para saber con seguridad lo que el o ella tiene o padece
The results of your blood test show …	Los resultados de la sangre muestran …
The most important thing is to decrease the fever with Tylenol or Motrin	Lo más importante es reducir la fiebre con Tylenol o Motrin
We will have to catheterize (him/her)	Tendremos que ponerle una sonda en la vejiga
Topical treatment	Tratamiento tópico
To suture	Suturar
A suture	Sutura
To swab (as in "swab the mouth" or "to place a cream on …")	Untar
He/she should take lots of clear liquids	Debe tomar bastantes líquidos claros
To nurse, breastfeed	Amamantar
To burp	Eructar
X-ray	Radiografía
Computed tomography scan	Tomografía
Nasal drops	Gotas nasales
Put ice on it	Póngale hielo

MISCELLANEOUS PHRASES

He/she will need to be hospitalized for treatment (observation)	Tendrá que ser hospitalizado(a) para darle tratamiento (ser observado[a])
We need a urine specimen in this cup	Necesitamos su muestra de orina en esta taza
Take him/her to the primary doctor tomorrow	Llévelo mañana a su doctor principal o de cabecera
He/she's very sick	Está muy enfermo(a)

Word association game, 98
Word-Graphic Rating Scale, 155t-156t
Work as adolescent social environment, 667
Work of breathing, 1135t
Working mothers, 32
World Health Organization (WHO)
  child growth standards of, 456, 457b
  oral rehydration solution of, 1063t
Wound(s), 610-612
  acute, 610
  burn. *See* Burn wound(s).
  chronic, 610
  classification of, 610
  defined, 610
  general management of, 616-617, 616b, 629f
  general therapeutic management of, 612-615
    dressings in, 612-613, 614t
    systemic therapy in, 615
    topical therapy in, 613-615, 614b-615b
  home care and family support for, 617-618, 618b
  relief of symptoms due to, 617
  types of, 610

Wound healing
factors that influence, 612, 613t
mechanism of, 611
by primary intention, 611-612, 612f
process of, 610-612
for epidermal injuries, 610-611, 611f
for injuries to deeper tissues, 611
by secondary intention, 612, 612f
by tertiary intention, 612, 612f
types of, 611-612, 612f
Wound hygiene for burns, 980, 980f-981f
Wound sepsis with burns, 976, 976b
Wrist restraints, 906f
Wristdrop due to immobilization, 1551
Written communication, 99
Wryneck, 125, 1585
of infants, 478
of newborn, 254t-258t, 298

X

X inactivation, 48
Xenograft, porcine, 982, 982f
Xeroderma pigmentosum, 58t-62t
Xiphoid process, 135, 135f
Xiphoid retractions, 371, 371f
X-linked inheritance. *See* Sex-linked inheritance.
X-linked lymphopenic agammaglobulinemia, 1373

Y

Yawn reflex, 264t
Yeast infection, vulvovaginal, 703-704, 703t
Yellow jacket stings, 627-630, 628t-629t
Yersinia enterocolitis, 1059t-1061t
Yoga for dysmenorrhea, 695, 696f
Yolk sack tumors, 1420
Youth Risk Behavior Surveillance System, 717

Z

Zollinger-Ellison syndrome, 1089
Zone of coagulation, 972b, 972f
Zone of hyperemia, 972b, 972f
Zone of injury in burns, 972, 972b, 972f
Zone of necrosis, 972b, 972f
Zone of stasis, 972b, 972f
Zoster, 219, 229t
Zygote, 48
