sinus rhythm: electrical activity of the heart initiated by the sinoatrial node

ST segment: the part of an ECG that reflects the end of the QRS complex to the beginning of the T wave

T wave: the part of an ECG that reflects repolarization of the ventricles

TP interval: the part of an ECG that reflects the time between the end of the T wave and the beginning of the next P wave; used to identify the isoelectric line

U wave: the part of an ECG that may reflect Purkinje fiber repolarization; usually, it is not seen unless a patient's serum potassium level is low

It is essential for the heart to have a regular rate and rhythm to perform efficiently as a pump to circulate oxygenated blood and other life-sustaining nutrients to all of the body's tissues and organs (including the heart itself). With an irregular or erratic rhythm, the heart is considered to be arrhythmic (also called *dysrhythmic*). This is a potentially dangerous condition.

Nurses may encounter patients with arrhythmias in all health care settings, including primary care settings, skilled nursing facilities, rehabilitation settings, hospitals, and the home health care setting. Some arrhythmias are acute and others chronic; some require emergent interventions, while others may not. Because patients with arrhythmias are frequently encountered in many different types of settings, nurses must be able to identify and provide appropriate first-line treatment of arrhythmias.

ARRHYTHMIAS

Arrhythmias are disorders of the formation or conduction (or both) of the electrical impulse within the heart. These disorders can cause disturbances of the heart rate, the heart rhythm, or both. Arrhythmias may initially be evidenced by the hemodynamic effect they cause (e.g., a change in conduction may change the pumping action of the heart and cause decreased blood pressure), and are diagnosed by analyzing the electrocardiographic (ECG) waveform. Their treatment is based on the frequency and severity of symptoms produced. Arrhythmias are named according to the site of origin of the electrical impulse and the mechanism of formation or conduction involved.

For example, an impulse that originates in the sinoatrial (SA) node and at a slow rate is called *sinus bradycardia.*

Normal Electrical Conduction

The electrical impulse that stimulates and paces the cardiac muscle normally originates in the SA node, also called the *sinus node,* an area located near the superior vena cava in the right atrium. In the adult, the electrical impulse usually occurs at a rate of 60 to 100 times a minute. The electrical impulse quickly travels from the SA node through the atria to the atrioventricular (AV) node (see Fig. 22-1); this process is known as **conduction**. The electrical stimulation of the muscle cells of the atria causes them to contract. The structure of the AV node slows the electrical impulse, giving the atria time to contract and fill the ventricles with blood. This part of atrial contraction is frequently referred to as the atrial kick and accounts for nearly one third of the volume ejected during ventricular contraction (Fuster, Harrington, Narula, et al., 2017). The electrical impulse then travels very quickly through the bundle of His to the right and left bundle branches and the Purkinje fibers, located in the ventricular muscle.

The electrical stimulation is called **depolarization**, and the mechanical contraction is called *systole.* Electrical relaxation is called **repolarization**, and mechanical relaxation is called *diastole.* The process from sinus node electrical impulse generation through ventricular repolarization completes the electromechanical circuit, and the cycle begins again. (See Chapter 21 for a more complete explanation of cardiac function.)

Influences on Heart Rate and Contractility

The heart rate is influenced by the autonomic nervous system, which consists of sympathetic and parasympathetic fibers. Sympathetic nerve fibers (also referred to as adrenergic fibers) are attached to the heart and arteries as well as several other areas in the body. Stimulation of the sympathetic system results in positive **chronotropy** (increased heart rate), positive **dromotropy** (increased AV conduction), and positive **inotropy** (increased force of myocardial contraction). Sympathetic stimulation also constricts peripheral blood vessels, therefore increasing blood pressure. Parasympathetic nerve fibers are also attached to the heart and arteries. Parasympathetic stimulation reduces the heart rate (negative chronotropy), AV conduction (negative dromotropy), and the force of atrial myocardial contraction. The decreased sympathetic stimulation results in dilation of arteries, thereby lowering blood pressure.

Manipulation of the autonomic nervous system may increase or decrease the incidence of arrhythmias. Increased sympathetic stimulation (e.g., caused by exercise, anxiety, fever, or administration of catecholamines such as dopamine, aminophylline, or dobutamine) may increase the incidence of arrhythmias. Decreased sympathetic stimulation (e.g., with rest, anxiety reduction methods such as therapeutic communication or meditation, or administration of beta-adrenergic blocking agents) may decrease the incidence of arrhythmias.

The Electrocardiogram

The electrical impulse that travels through the heart can be viewed by means of electrocardiography, the end product of which is an **electrocardiogram (ECG)**. Each phase of the cardiac cycle is reflected by specific waveforms on the screen of a cardiac monitor or on a strip of ECG graph paper.

Obtaining an Electrocardiogram

An ECG is obtained by placing electrodes on the body at specific areas. Biomonitoring electrodes come in various shapes and sizes, but all have two components: (1) an adhesive substance that attaches to the skin to secure the electrode in place and (2) a substance that reduces the skin's electrical impedance, facilitating the transfer of ions from the tissue to electrons in the electrode, enhancing conductivity. Gently abrading the skin with a clean dry gauze pad or sandpaper edge of the electrode helps to expose the inner conductive layer of epidermis, which will reduce skin impedance. Although cleansing the skin with alcohol removes any oily residue from the skin, it also increases the skin's electrical impedance and hinders detection of the cardiac electrical signal. Washing the area with soap and water prior to electrode placement is recommended. If the amount of chest hair prevents the electrode from having good contact with the skin, the hair may need to be clipped (Sendelbach & Jepsen, 2018; see Chapter 21, Chart 21-5: Applying Electrodes). Poor electrode adhesion will cause significant **artifact** (distorted, irrelevant, and extraneous ECG waveforms), which may distort capturing an accurate ECG waveform.

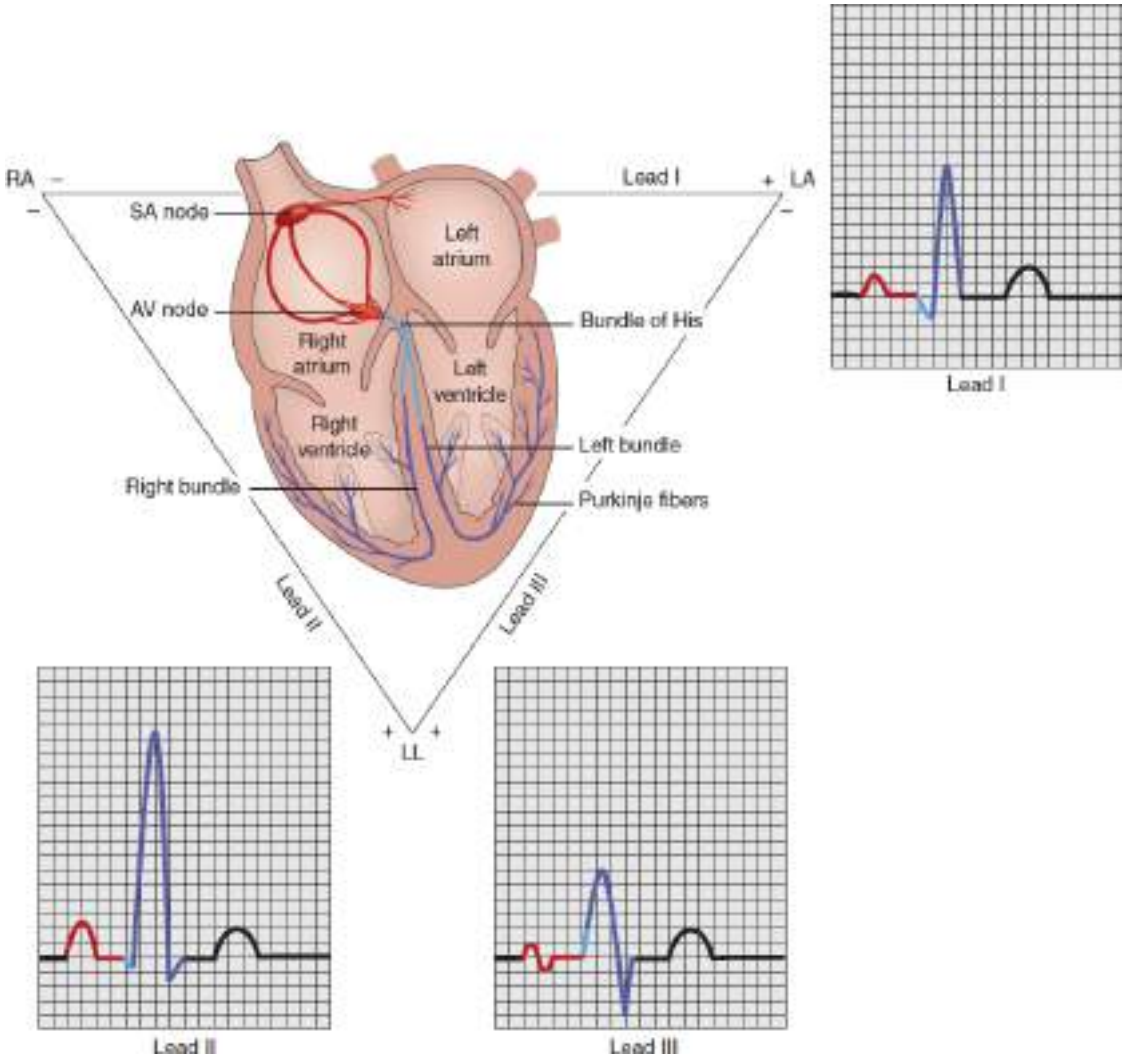

Figure 22-1 • Relationship of electrocardiographic (ECG) complex, lead system, and electrical impulse. The heart conducts electrical activity, which the ECG measures and shows. The configurations of electrical activity displayed on the ECG vary depending on the lead (or view) of the ECG and on the rhythm of the heart. Therefore, the configuration of a normal rhythm tracing from lead I will differ from the configuration of a normal rhythm tracing from lead II, lead II will differ from lead III, and so on. The same is true for abnormal rhythms and cardiac disorders. To make an accurate assessment of the heart's electrical activity or to identify where, when, and what abnormalities occur, the ECG needs to be evaluated from every lead, not just from lead II. Here the different areas of electrical activity are identified by color. RA, right arm; LA, left arm; SA, sinoatrial; AV, atrioventricular; LL, left leg.

The number and placement site of the electrodes depend on the type of ECG being obtained. Most continuous monitors use 2 to 5 electrodes, usually placed on the limbs and the chest. These electrodes create an imaginary line, called a *lead,* which serves as a reference point from which the electrical

activity is viewed. A lead is like an eye of a camera—it has a narrow peripheral field of vision, looking only at the electrical activity directly in front of it. Therefore, the ECG waveforms that appear on the ECG paper and cardiac monitor represent the electrical impulse in relation to the lead (see Fig. 22-1). A change in the waveform can be caused by a change in the electrical impulse (where it originates or how it is conducted) or by a change in the lead. Electrodes are attached to cable wires, which are connected to one of the following:

- An ECG machine placed at the patient's side for an immediate recording (standard 12-lead ECG)
- A cardiac monitor at the patient's bedside for continuous reading; this kind of monitoring, usually called *hardwire monitoring,* is used in intensive care units
- A small box that the patient carries and that continuously transmits the ECG information by radiowaves to a central monitor located elsewhere (called *telemetry*)
- A small, lightweight tape recorder–like machine (called *continuous ECG monitoring*, which might include a *Holter monitor* or a *patch monitor*) that the patient wears for a prescribed period of time and that continuously records the ECG, which is later viewed and analyzed with a scanner
- A very small device inserted under the skin or worn externally on a wrist band (called *intermittent monitoring* using a *looped recorder*) can perform ECG monitoring on demand whenever a patient is symptomatic (see Chapter 21 for further discussion of ECG monitoring systems)

A patient may undergo an electrophysiology study (EPS) in which electrodes are placed inside the heart in order to obtain an intracardiac ECG. This is used not only to diagnose the arrhythmia but also to determine the most effective treatment plan. However, because an EPS is invasive, it is performed in the hospital and may require that the patient be admitted (see later discussion).

During open heart surgery, temporary pacemaker wires may be lightly sutured to the epicardium and brought through the chest wall. These wires may be used not only for temporary pacing but also, when connected to the V lead cable, to obtain an atrial ECG, which can be helpful in the differential diagnosis of tachyarrhythmias (see Chapter 23 for further discussion).

The placement of electrodes for monitoring varies with the type of technology, the purpose of monitoring, and the protocols used in the health care facility. For a standard 12-lead ECG, 10 electrodes (6 on the chest and 4 on the limbs) are placed on the body (see Fig. 22-2). To prevent interference from the electrical activity of skeletal muscle, the limb electrodes are placed

on areas that are not bony and that do not have significant movement. The limb electrodes provide the first six leads: leads I, II, III, aVR (augmented voltage right arm), aVL (augmented voltage left arm), and aVF (augmented voltage left leg/foot). The 6 chest electrodes are applied to the chest at very specific areas. The chest electrodes provide the V or precordial leads, V_1 through V_6. To locate the fourth intercostal space and the placement of V_1, the sternal angle and then the sternal notch, which is about 1 or 2 inches below the sternal angle, are located. When the fingers are moved to the patient's immediate right, the second rib can be palpated. The second intercostal space is the indentation felt just below the second rib. Locating the specific intercostal space is critical for the correct placement of each chest electrode. Errors in diagnosis can occur if electrodes are incorrectly placed. Sometimes, when a patient in the hospital needs to be monitored more closely for ECG changes, the chest electrodes are left in place to ensure the same placement for follow-up 12-lead ECGs.

A standard 12-lead ECG reflects the electrical activity primarily in the left ventricle. Placement of additional electrodes for other leads may be needed to obtain more complete information. For example, in patients with suspected right-sided heart damage, right-sided precordial leads are required to evaluate the right ventricle (see Fig. 22-2).

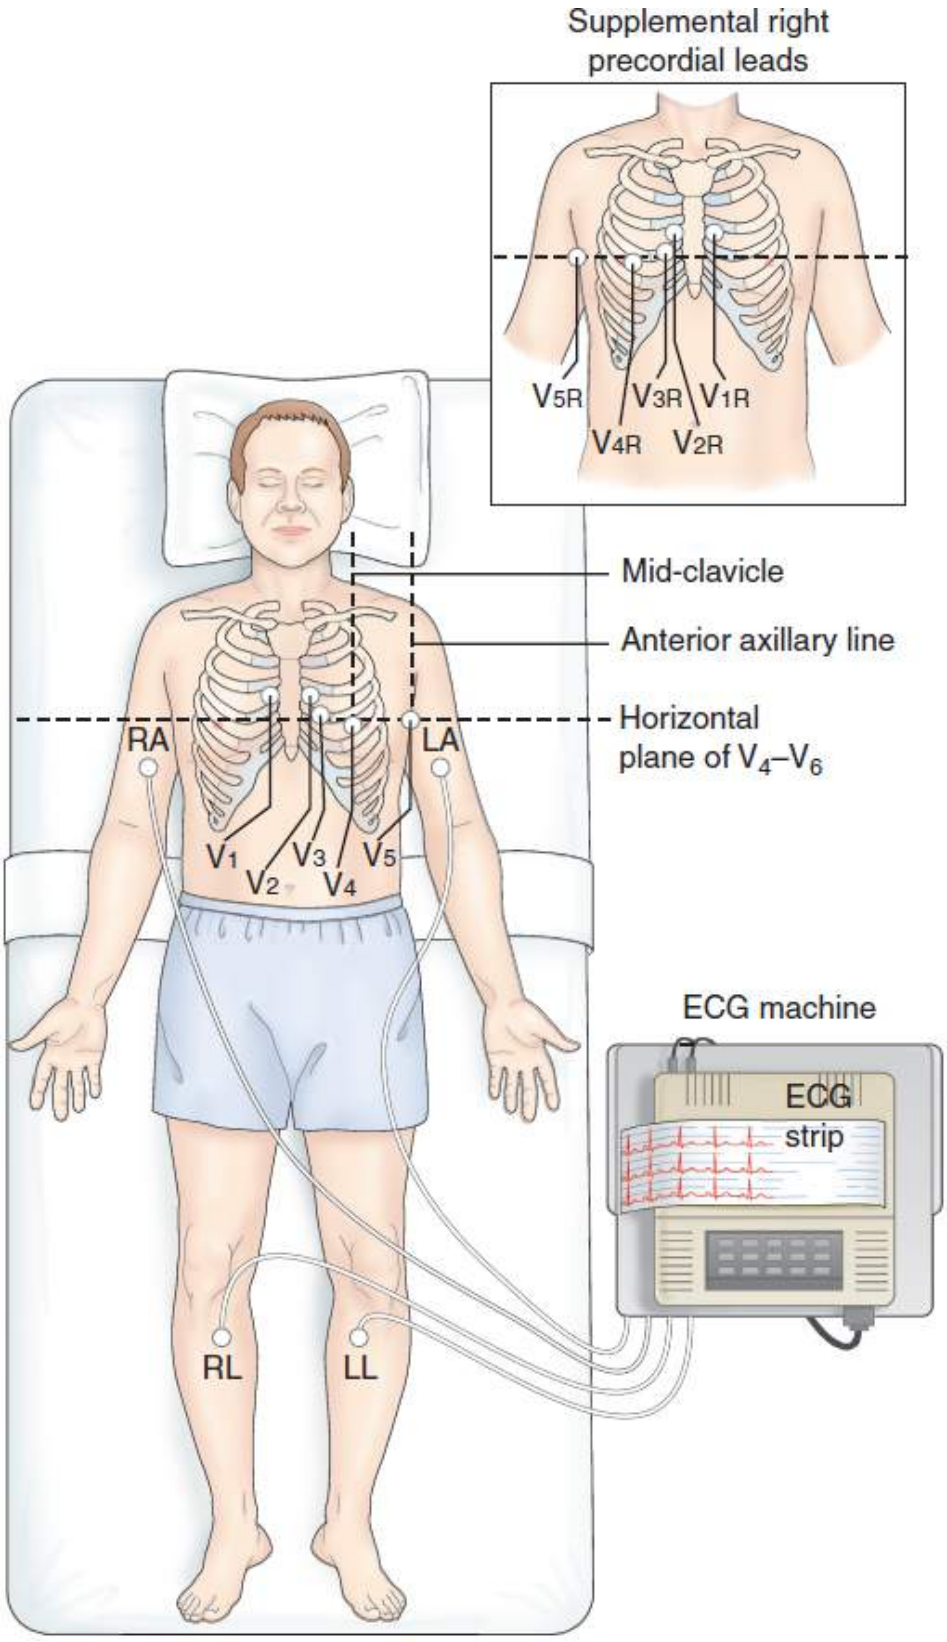

Figure 22-2 • ECG electrode placement. The standard left precordial leads are V_1—fourth intercostal space, right sternal border; V_2—fourth intercostal space, left sternal border; V_3—diagonally between V_2 and V_4; V_4—fifth intercostal space, left

midclavicular line; V_5—same level as V_4, anterior axillary line; V_6 (not illustrated)—same level as V_4 and V_5, midaxillary line. The right precordial leads, placed across the right side of the chest, are the mirror opposite of the left leads. RA, right arm; LA, left arm; RL, right leg; LL, left leg.

Components of the Electrocardiogram

The ECG waveform reflects the function of the heart's conduction system in relation to the specific lead. The ECG offers important information about the electrical activity of the heart and is useful in diagnosing arrhythmias. ECG waveforms are printed on graph paper that is divided by vertical and horizontal lines at standard intervals (see Fig. 22-3). Time and rate are measured on the horizontal axis of the graph, and amplitude or voltage is measured on the vertical axis. When an ECG waveform moves toward the top of the paper, it is called a *positive deflection.* When it moves toward the bottom of the paper, it is called a *negative deflection.* When reviewing an ECG, each waveform should be examined and compared with the others.

Waves, Complexes, and Intervals

The ECG is composed of waveforms (including the P wave, the QRS complex, the T wave, and possibly a U wave) and of segments and intervals (including the PR interval, the ST segment, and the QT interval) (see Fig. 22-3).

The **P wave** represents the electrical impulse starting in the SA node and spreading through the atria. Therefore, the P wave represents atrial depolarization. It is normally 2.5 mm or less in height and 0.11 seconds or less in duration.

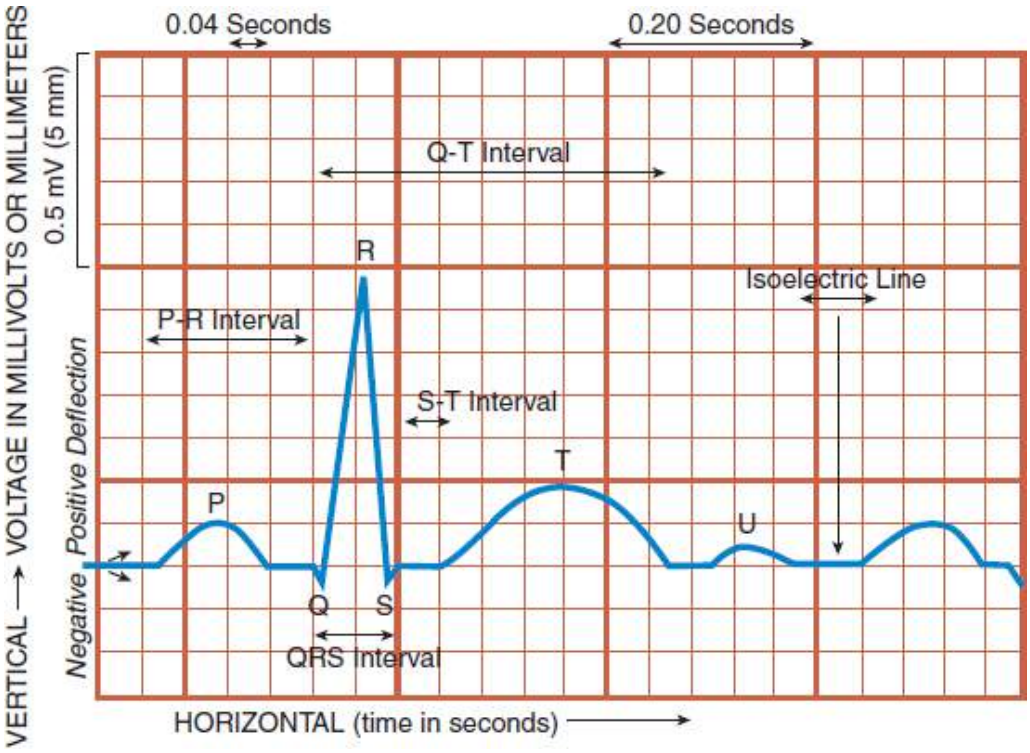

Figure 22-3 • ECG graph and commonly measured components. Each large box represents 0.20 seconds on the horizontal axis and 5 mm or 0.5 millivolt on the vertical axis. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-16). Philadelphia, PA: Wolters Kluwer.

The **QRS complex** represents ventricular depolarization. Not all QRS complexes have all three waveforms. The Q wave is the first negative deflection after the P wave. The Q wave is normally less than 0.04 seconds in duration and less than 25% of the R-wave amplitude. The R wave is the first positive deflection after the P wave, and the S wave is the first negative deflection after the R wave. When a wave is less than 5 mm in height, small letters (q, r, s) are used; when a wave is taller than 5 mm, capital letters (Q, R, S) are used to label the waves. The QRS complex is normally less than 0.12 seconds in duration.

The **T wave** represents ventricular repolarization (when the cells regain a negative charge; also called the *resting state*). It follows the QRS complex and is usually the same direction (deflection) as the QRS complex. Atrial repolarization also occurs but is not visible on the ECG because it occurs at the same time as ventricular depolarization (i.e., the QRS).

The **U wave** is thought to represent repolarization of the Purkinje fibers; although this wave is rare, it sometimes appears in patients with hypokalemia (low potassium levels), hypertension, or heart disease. If present, the U wave

follows the T wave and is usually smaller than the P wave. If larger in amplitude, it may be mistaken for an extra P wave.

The **PR interval** is measured from the beginning of the P wave to the beginning of the QRS complex and represents the time needed for sinus node stimulation, atrial depolarization, and conduction through the AV node before ventricular depolarization. In adults, the PR interval normally ranges from 0.12 to 0.20 seconds in duration.

The **ST segment,** which represents early ventricular repolarization, lasts from the end of the QRS complex to the beginning of the T wave. The beginning of the ST segment is usually identified by a change in the thickness or angle of the terminal portion of the QRS complex. The end of the ST segment may be more difficult to identify because it merges into the T wave. The ST segment is normally isoelectric (see later discussion of TP interval). It is analyzed to identify whether it is above or below the isoelectric line, which may be, among other signs and symptoms, a sign of cardiac ischemia (see Chapter 23).

The **QT interval**, which represents the total time for ventricular depolarization and repolarization, is measured from the beginning of the QRS complex to the end of the T wave. The QT interval varies with heart rate, gender, and age; therefore, the measured interval may be corrected (QT_c) for these variables through specific calculations. The QT_c may be automatically calculated by the ECG technology, or a nurse may manually calculate or use a resource that contains a chart of these calculations. The QT interval is usually 0.32 to 0.40 seconds in duration if the heart rate is 65 to 95 bpm. Many medications commonly given in the hospital can cause prolongation of the QT interval (QT_c), placing the patient at risk for a lethal ventricular arrhythmia called *torsades de pointes.*

The **TP interval** is measured from the end of the T wave to the beginning of the next P wave—an isoelectric period (see Fig. 22-3). When no electrical activity is detected, the line on the graph remains flat; this is called the *isoelectric line.* The ST segment is compared with the TP interval to detect ST segment changes. The PR segment is sometimes used to determine the isoelectric line. However, because the PR segment sometimes is altered due to ischemic conditions, the TP interval is the preferred reference for the isoelectric line.

The **PP interval** is measured from the beginning of one P wave to the beginning of the next P wave. The PP interval is used to determine atrial rate and rhythm. The **RR interval** is measured from one QRS complex to the next QRS complex. The RR interval is used to determine ventricular rate and rhythm (see later discussion).

Analyzing the Electrocardiogram Rhythm Strip

The ECG rhythm strip must be analyzed in a systematic manner to determine the patient's cardiac rate and rhythm, and to detect arrhythmias and conduction disorders, as well as evidence of myocardial ischemia, injury, and infarction.

Determining Heart Rate from the Electrocardiogram

Heart rate can be obtained from the ECG rhythm strip by several methods. A 1-minute rhythm strip contains 300 large boxes and 1500 small boxes. Therefore, an easy and accurate method of determining heart rate with a regular rhythm is to count the number of small boxes within an RR interval and divide 1500 by that number. If, for example, there are 10 small boxes between two R waves, the heart rate is 1500/10, or 150 bpm; if there are 25 small boxes, the heart rate is 1500/25, or 60 bpm (see Fig. 22-4).

An alternative but less accurate method for estimating heart rate, which is usually used when the rhythm is irregular, is to count the number of RR intervals in 6 seconds and multiply that number by 10. The top of the ECG paper is usually marked at 3-second intervals, which is 15 large boxes horizontally. The RR intervals are counted, rather than QRS complexes, because a computed heart rate based on the latter might be inaccurately high.

The same methods may be used for determining atrial rate, using the PP interval instead of the RR interval.

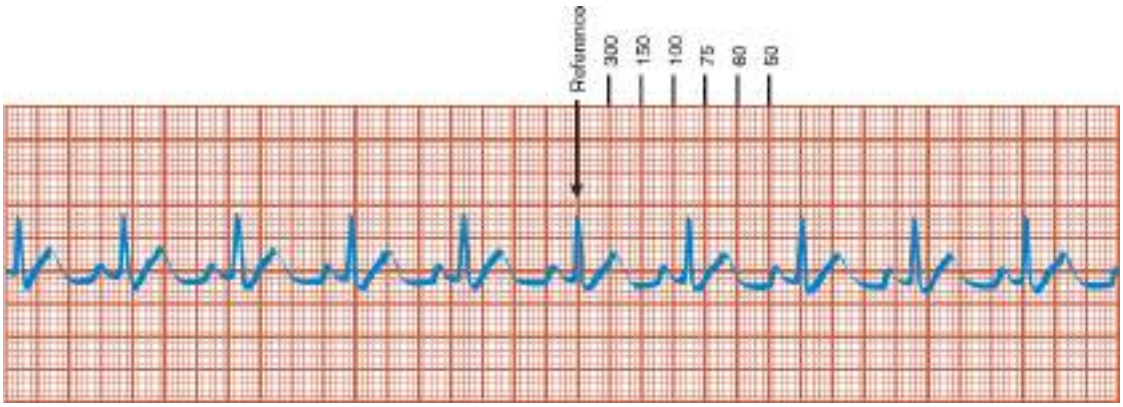

Figure 22-4 • Method for estimating heart rate. The number of small boxes in the RR interval is 17.5; divide this by 1500, and the heart rate is approximately 86 bpm. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-18 (bottom portion)). Philadelphia, PA: Wolters Kluwer.

Determining Heart Rhythm from the Electrocardiogram

The rhythm is often identified at the same time the rate is determined. Chart 22-1 provides an example of a method that can be used to analyze the patient's rhythm. The RR interval is used to determine ventricular rhythm and the PP interval to determine atrial rhythm. If the intervals are the same or if the difference between the intervals is less than 0.8 seconds throughout the strip, the rhythm is called *regular*. If the intervals are different, the rhythm is called *irregular*.

Once the rhythm has been analyzed, the findings are compared with and matched to the ECG criteria for arrhythmias to determine a diagnosis. It is important for the nurse not only to identify the arrhythmia, but also to assess the patient to determine the physiologic effect of the arrhythmia and identify possible causes. Treatment of an arrhythmia is based on clinical evaluation of the patient with identification of the arrhythmia's etiology and physiologic effect, not on its presence on ECG alone.

Chart 22-1

Interpreting Arrhythmias: Systematic Analysis of the Electrocardiogram

When examining an electrocardiogram (ECG) rhythm strip to learn more about a patient's arrhythmia:

1. Determine the ventricular rate.
2. Determine the ventricular rhythm.
3. Determine the QRS duration.
4. Determine whether the QRS duration is consistent throughout the strip. If not, identify other duration.
5. Identify the QRS shape; if not consistent, then identify other shapes.
6. Identify P waves; is there a P in front of every QRS?
7. Identify the P-wave shape; identify whether it is consistent or not.
8. Determine the atrial rate.
9. Determine the atrial rhythm.
10. Determine each PR interval.
11. Determine if the PR intervals are consistent, irregular but with a pattern to the irregularity, or just irregular.
12. Determine how many P waves for each QRS (P:QRS ratio).

In many cases, the nurse may use a checklist and document the findings next to the appropriate ECG criterion.

Most cardiac monitoring has functionality that includes the ability to continuously monitor the rhythm and alert health care personnel with an auditory and visual alarm when a clinically significant change in the rhythm occurs. However, a high rate of triggered, clinically insignificant alarms may lead to alarm fatigue, which has been linked to nurses ignoring, disabling, or

silencing alarms (Sendelbach & Jepsen, 2018)—putting patients at increased risk of adverse events.

Quality and Safety Nursing Alert

It is vital that the nurse assesses the cause(s) of a cardiac monitor's alarm and then adjusts the alarm default settings and individualizes the alarm parameter limits and levels. The assessment should also include an evaluation and discussion with the primary provider to validate that the patient needs to remain on continuous cardiac monitoring.

Normal Sinus Rhythm

Electrical conduction that begins in the SA node generates a **sinus rhythm.** Normal sinus rhythm occurs when the electrical impulse starts at a regular rate and rhythm in the SA node and travels through the normal conduction pathway. Normal sinus rhythm has the following characteristics (see Fig. 22-5):

Ventricular and atrial rate: 60 to 100 bpm in the adult
Ventricular and atrial rhythm: Regular
QRS shape and duration: Usually normal, but may be regularly abnormal
P wave: Normal and consistent shape; always in front of the QRS
PR interval: Consistent interval between 0.12 and 0.20 seconds
P:QRS ratio: 1:1

Normal sinus rhythm is generally indicative of good cardiovascular health. However, an increase of 10 bpm or more in the resting heart rate increases the risk for sudden cardiac death, atrial fibrillation, heart failure, coronary artery disease, stroke, and cardiovascular disease (Aune, Sen, ó'Hartaigh, et al., 2017).

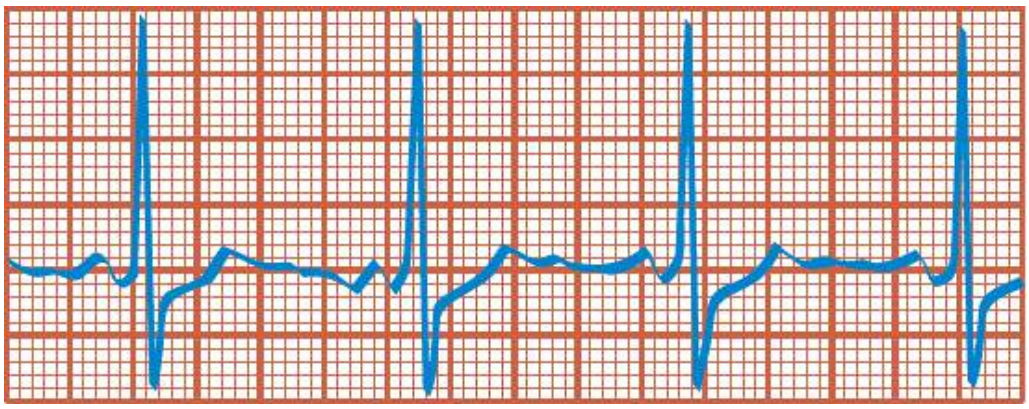

Figure 22-5 • Normal sinus rhythm. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-19A). Philadelphia, PA: Wolters Kluwer.

Types of Arrhythmias

Arrhythmias include sinus, atrial, junctional, and ventricular arrhythmias and their various subcategories, as well as conduction abnormalities.

Sinus Node Arrhythmias

Sinus node arrhythmias originate in the SA node; these include sinus bradycardia, sinus tachycardia, and sinus arrhythmia.

Sinus Bradycardia

Sinus bradycardia occurs when the SA node creates an impulse at a slower-than-normal rate. Causes include lower metabolic needs (e.g., sleep, athletic training, hypothyroidism), vagal stimulation (e.g., from vomiting, suctioning, severe pain), medications (e.g., calcium channel blockers [e.g., nifedipine, amiodarone], beta-blockers [e.g., metoprolol]), idiopathic sinus node dysfunction, increased intracranial pressure, and coronary artery disease, especially myocardial infarction (MI) of the inferior wall. Unstable and symptomatic bradycardia is frequently due to hypoxemia. Other possible causes include acute altered mental status (e.g., delirium) and acute decompensated heart failure (Fuster et al., 2017). Sinus bradycardia has the following characteristics (see Fig. 22-6):

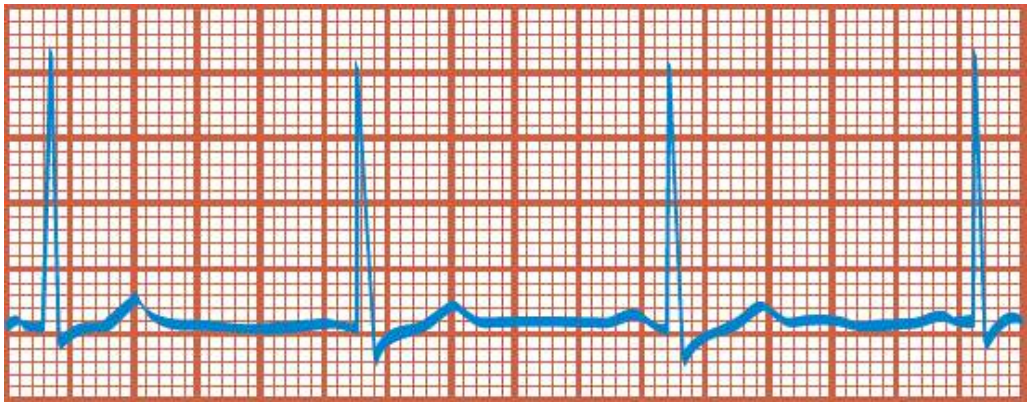

Figure 22-6 • Sinus bradycardia. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-19C). Philadelphia, PA: Wolters Kluwer.

Ventricular and atrial rate: Less than 60 bpm in the adult
Ventricular and atrial rhythm: Regular
QRS shape and duration: Usually normal, but may be regularly abnormal
P wave: Normal and consistent shape; always in front of the QRS
PR interval: Consistent interval between 0.12 and 0.20 seconds
P:QRS ratio: 1:1

All characteristics of sinus bradycardia are the same as those of normal sinus rhythm, except for the rate. The patient is assessed to determine the hemodynamic effect and the possible cause of the arrhythmia. If the decrease in heart rate results from stimulation of the vagus nerve, such as with bearing down during defecation or vomiting, attempts are made to prevent further vagal stimulation. If the bradycardia is caused by a medication such as a beta-blocker, the medication may be withheld. If the slow heart rate causes significant hemodynamic changes resulting in shortness of breath, acute alteration of mental status, angina, hypotension, ST-segment changes, or premature ventricular complexes (PVCs), treatment is directed toward increasing the heart rate. Slow heart rate may be due to sinus node dysfunction (previously known as *sick sinus syndrome*), which has a number of risk factors including increased body mass index, presence of right and left bundle branch block, history of a major cardiovascular event, increased age, and hypertension (Jackson, Rathakrishnan, Campbell, et al., 2017). *Tachy-brady syndrome* is the term used when bradycardia alternates with tachycardia.

Medical Management

Management depends on the cause and symptoms. Resolving the causative factors may be the only treatment needed. If the bradycardia produces signs and symptoms of clinical instability (e.g., acute alteration in mental status, chest discomfort, or hypotension), 0.5 mg of atropine may be given rapidly as

an intravenous (IV) bolus and repeated every 3 to 5 minutes until a maximum dosage of 3 mg is given. Rarely, if the bradycardia is unresponsive to atropine, emergency transcutaneous pacing can be instituted, or medications, such as dopamine, isoproterenol, or epinephrine, are given (Kusumoto, Schoenfeld, Barrett, et al., 2019; see later discussion).

Sinus Tachycardia

Sinus tachycardia occurs when the sinus node creates an impulse at a faster-than-normal rate. Causes may include the following:

- Physiologic or psychological stress (e.g., acute blood loss, anemia, shock, hypervolemia, hypovolemia, heart failure, pain, hypermetabolic states, fever, exercise, anxiety)
- Medications that stimulate the sympathetic response (e.g., catecholamines, aminophylline, atropine), stimulants (e.g., caffeine, nicotine), and illicit drugs (e.g., amphetamines, cocaine, ecstasy)
- Enhanced automaticity of the SA node and/or excessive sympathetic tone with reduced parasympathetic tone that is out of proportion to physiologic demands, a condition called *inappropriate sinus tachycardia*
- Autonomic dysfunction, which results in a type of sinus tachycardia referred to as postural orthostatic tachycardia syndrome (POTS). POTS is characterized by tachycardia without hypotension, and by presyncopal symptoms such as palpitations, lightheadedness, weakness, and blurred vision, which occur with sudden posture changes

Sinus tachycardia has the following characteristics (see Fig. 22-7):

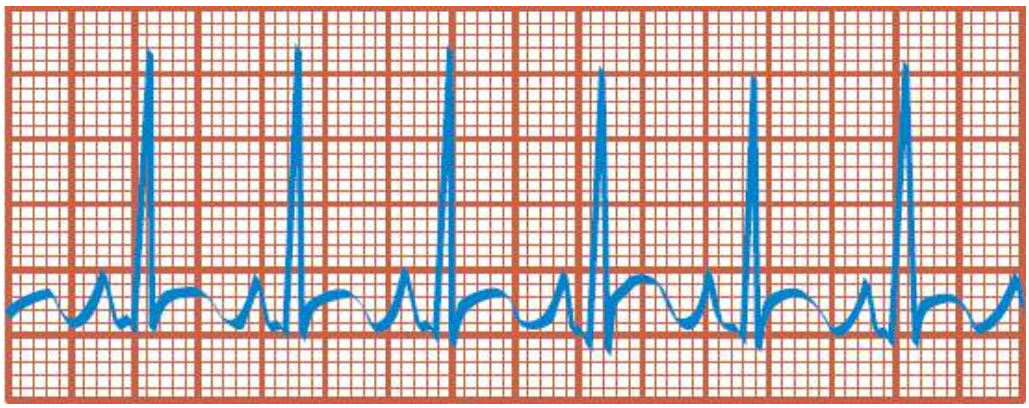

Figure 22-7 • Sinus tachycardia. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-19B). Philadelphia, PA: Wolters Kluwer.

Ventricular and atrial rate: Greater than 100 bpm in the adult, but usually less than 120 bpm

Ventricular and atrial rhythm: Regular

QRS shape and duration: Usually normal, but may be regularly abnormal

P wave: Normal and consistent shape; always in front of the QRS, but may be buried in the preceding T wave

PR interval: Consistent interval between 0.12 and 0.20 seconds

P:QRS ratio: 1:1

All aspects of sinus tachycardia are the same as those of normal sinus rhythm, except for the rate. Sinus tachycardia does not start or end suddenly (i.e., it is nonparoxysmal). As the heart rate increases, the diastolic filling time decreases, possibly resulting in reduced cardiac output and subsequent symptoms of syncope (fainting) and low blood pressure. If the rapid rate persists and the heart cannot compensate for the decreased ventricular filling, the patient may develop acute pulmonary edema.

Medical Management

Medical management of sinus tachycardia is determined by the severity of symptoms and directed at identifying and abolishing its cause. Vagal maneuvers, such as carotid sinus massage, gagging, bearing down against a closed glottis (as if having a bowel movement), forceful and sustained coughing, and applying a cold stimulus to the face (such as applying an ice-cold wet towel to the face), or administration of adenosine should be considered to interrupt the tachycardia. If the tachycardia is persistent and causing hemodynamic instability (e.g., acute alteration in mental status, chest discomfort, hypotension), synchronized **cardioversion** (i.e., electrical current given in synchrony with the patient's own QRS complex to stop an arrhythmia) is the treatment of choice, if vagal maneuvers and adenosine are unsuccessful or not feasible (see later discussion). IV beta-blockers (Class II antiarrhythmic) and calcium channel blockers (Class IV antiarrhythmic) (see Table 22-1) may also be considered in treating hemodynamically stable sinus tachycardia, although synchronized cardioversion may be used if medications are ineffective or contradicted (Page, Joglar, Caldwell, et al., 2016). Catheter ablation (see later discussion) of the SA node may be used in cases of persistent inappropriate sinus tachycardia unresponsive to other treatments. Treatment for POTS often involves a combination of approaches, with treatment targeted at the underlying problem. For example, patients with hypovolemia may be advised to increase their fluid and sodium intake, or use salt tablets if necessary.

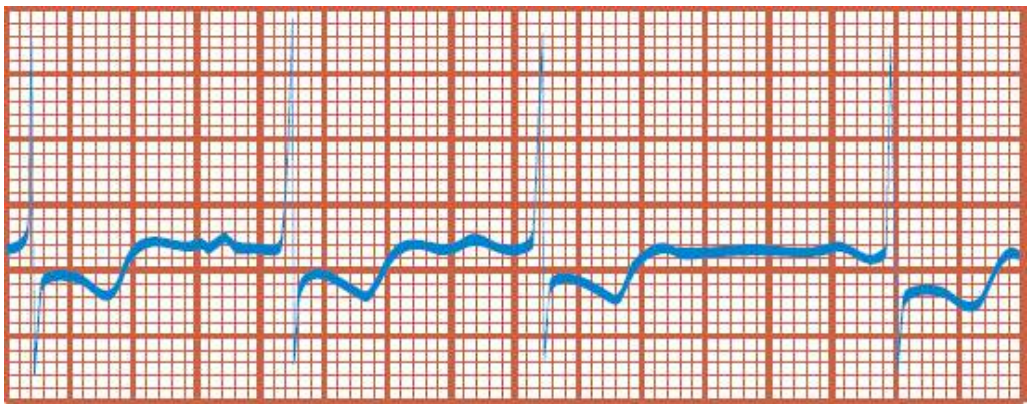

Figure 22-8 • Sinus arrhythmia. Note irregular RR and PP intervals. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-19D). Philadelphia, PA: Wolters Kluwer.

Sinus Arrhythmia

Sinus arrhythmia occurs when the sinus node creates an impulse at an irregular rhythm; the rate usually increases with inspiration and decreases with expiration. Nonrespiratory causes include heart disease and valvular disease, but these are rare. Sinus arrhythmia has the following characteristics (see Fig. 22-8):

Ventricular and atrial rate: 60 to 100 bpm in the adult
Ventricular and atrial rhythm: Irregular
QRS shape and duration: Usually normal, but may be regularly abnormal
P wave: Normal and consistent shape; always in front of the QRS
PR interval: Consistent interval between 0.12 and 0.20 seconds
P:QRS ratio: 1:1

Medical Management

Sinus arrhythmia does not cause any significant hemodynamic effect and therefore is not typically treated.

Atrial Arrhythmias

Atrial arrhythmias originate from foci within the atria and not the SA node. These include aberrancies such as premature atrial complexes (PACs) as well as atrial fibrillation and atrial flutter.

Premature Atrial Complex

A PAC is a single ECG complex that occurs when an electrical impulse starts in the atrium before the next normal impulse of the sinus node. The PAC may be caused by caffeine, alcohol, nicotine, stretched atrial myocardium (e.g., as

in hypervolemia), anxiety, hypokalemia (low potassium level), hypermetabolic states (e.g., with pregnancy), or atrial ischemia, injury, or infarction. PACs are often seen with sinus tachycardia. PACs have the following characteristics (see Fig. 22-9):

Ventricular and atrial rate: Depends on the underlying rhythm (e.g., sinus tachycardia)

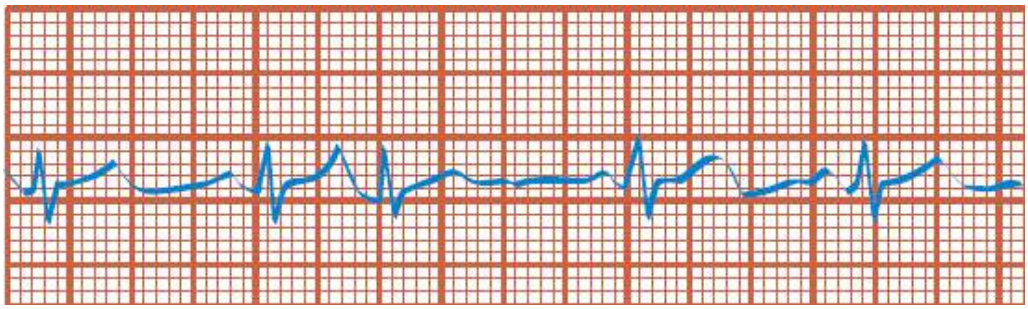

Figure 22-9 • Premature atrial complex (PAC). Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-22A). Philadelphia, PA: Wolters Kluwer.

TABLE 22-1 Summary of Antiarrhythmic Medications[a]

Class[b]	Action	Drug Names	Side Effects	Nursing Interventions
IA	Moderate depression of depolarization; prolongs repolarization Treats and prevents atrial and ventricular arrhythmias	quinidine, procainamide, disopyramide	Decreased cardiac contractility Prolonged QRS, QT Proarrhythmic Hypotension with IV administration Diarrhea with quinidine, constipation with disopyramide Cinchonism with quinidine Lupuslike syndrome with procainamide Anticholinergic effects: dry mouth, urinary hesitancy with disopyramide	Observe for HF. Monitor BP with IV administration. Monitor QRS duration for increase >50% from baseline. Monitor for prolonged QT. Monitor *N*-acetyl procainamide (NAPA) laboratory values during procainamide therapy. If given for atrial fibrillation, ensure that the patient has been pretreated with a medication to control AV conduction.
IB	Minimal depression of depolarization; shortened repolarization Treats ventricular arrhythmias	lidocaine, mexiletine	CNS changes (e.g., confusion, lethargy) Bradycardia GI distress Tremors	Monitor for CNS changes and tremors. Discuss with the primary provider decreasing lidocaine dose in older adult patients and patients with cardiac/liver dysfunction.
IC	Marked depression of depolarization; little effect on repolarization Treats atrial and ventricular arrhythmias	flecainide, propafenone	Proarrhythmic HF Dizziness, visual disturbances, dyspnea	Decrease dose with renal dysfunction and strict vegetarian diets. Avoid use in patients with structural heart disease (e.g., coronary artery disease and heart failure).
II	Decreases automaticity and conduction Treats atrial and ventricular arrhythmias	acebutolol[c], atenolol, bisoprolol/HCTZ, esmolol[c], labetalol, metoprolol, nadolol, propranolol[c], sotalol (also has class III actions)[c], timolol	Bradycardia, AV block Decreased contractility Bronchospasm Nausea Asymptomatic and symptomatic hypotension Masks hypoglycemia and thyrotoxicosis CNS disturbances (e.g., confusion, dizziness, fatigue, depression)	Monitor heart rate, PR interval, signs and symptoms of HF, especially in those also taking calcium channel blockers. Monitor blood glucose level in patients with type 2 diabetes. Caution the patient about abrupt withdrawal to avoid tachycardia, hypertension, and myocardial ischemia.
III	Prolongs repolarization Amiodarone treats and prevents ventricular and atrial arrhythmias, especially in patients with ventricular dysfunction. Dofetilide and ibutilide treat and prevent atrial arrhythmias.	amiodarone, dofetilide, chonadarone, ibutilide	Pulmonary toxicity (amiodarone) Corneal microdeposits (amiodarone) Photosensitivity (amiodarone) Bradycardia Hypotension, especially with IV administration Polymorphic ventricular arrhythmias (rare with amiodarone) Nausea and vomiting Potentiates digoxin (amiodarone) See beta-blockers above (sotalol).	Make sure that the patient is sent for baseline pulmonary function tests (amiodarone). Closely monitor the patient. Assess for contraindications prior to administration. Monitor QT duration. Continuous ECG monitoring with initiation of dofetilide and ibutilide. Monitor renal function.
IV	Blocks calcium channel Treats and prevents paroxysmal atrial arrhythmias[d]	verapamil, diltiazem	Bradycardia, AV blocks Hypotension with IV administration HF, peripheral edema Constipation, dizziness, headache, nausea	Monitor heart rate, PR interval. Monitor blood pressure closely with IV administration. Monitor for signs and symptoms of HF. Do not crush sustained-release medications.

[a]Based on Vaughan-Williams classification.
[b]There are other calcium channel blockers, but they are not approved or used for arrhythmias.
[c]Beta-blocker with labeled use for arrhythmias.
AV, atrioventricular; BP, blood pressure; CNS, central nervous system; ECG, electrocardiogram; GI, gastrointestinal; HCTZ, hydrochlorothiazide; HF, heart failure; IV, intravenous.
Adapted from the American Society of Health-System Pharmacists. (2019). AHFS drug information. Bethesda, MD: Author. Foster, V., Harrington, R. A., Narula, J., et al. (Eds.). (2017). Hurst's the heart (15th ed.). New York: McGraw-Hill. Al-Khatib, S. M., Stevenson, W. G., Ackerman, M. J., et al. (2018). 2017 AHA/ACC/HRS guideline for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death: A report of the American College of Cardiology/American Heart Association Task Force on clinical practice guidelines and the Heart Rhythm Society. *Circulation, 138*(13), e272–e391.

Ventricular and atrial rhythm: Irregular due to early P waves, creating a PP interval that is shorter than the others. This is sometimes followed by a longer-than-normal PP interval, but one that is less than twice the normal PP interval. This type of interval is called a *noncompensatory pause*

QRS shape and duration: The QRS that follows the early P wave is usually normal, but it may be abnormal (aberrantly conducted PAC). It may even be absent (blocked PAC)

P wave: An early and different P wave may be seen or may be hidden in the T wave; other P waves in the strip are consistent

PR interval: The early P wave has a shorter-than-normal PR interval, but still between 0.12 and 0.20 seconds

P:QRS ratio: Usually 1:1

PACs are common in normal hearts. The patient may say, "My heart skipped a beat." A pulse deficit (a difference between the apical and radial pulse rate) may exist.

Medical Management

If PACs are infrequent; no treatment is necessary. If they are frequent (more than six per minute), this may herald a worsening disease state or the onset of more serious arrhythmias, such as atrial fibrillation. Medical management is directed toward treating the underlying cause (e.g., reduction of caffeine intake, correction of hypokalemia).

Atrial Fibrillation

Atrial fibrillation is a very common arrhythmia; between 2.7 and 6.1 million Americans are living with atrial fibrillation (Centers for Disease Control and Prevention [CDC], 2017). Atrial fibrillation is a serious public health concern because it is associated with aging, and the older adult population is increasing in the United States (Chen, Chung, Allen, et al., 2018). Atrial fibrillation can result from diverse pathophysiologic etiologies and risks (see Chart 22-2).

Atrial fibrillation results from abnormal impulse formation that occurs when structural or electrophysiologic abnormalities alter the atrial tissue causing a rapid, disorganized, and uncoordinated twitching of the atrial musculature (January, Wann, Alpert, et al., 2014; January, Wann, Calkins, et al., 2019). Both the extrinsic (central) and intrinsic cardiac autonomic nervous systems (CANS) are thought to play an important role in the initiation and continuance of atrial fibrillation (Qin, Zeng, & Liu, 2019). Separate from the extrinsic (central) nervous system, which includes the brain and spinal cord, the CANS consists of a highly interconnected network of autonomic ganglia and nerve cell bodies embedded within the epicardium, largely within the atrial myocardium and great vessels (pulmonary veins). Hyperactive autonomic ganglia in the CANS are thought to play a critical role in atrial fibrillation, resulting in impulses that are initiated from the pulmonary veins and conducted through to the AV node. The ventricular rate of response depends on the conduction of atrial impulses through the AV node, presence of accessory electrical conduction pathways, and therapeutic effect of medications.

Lack of consistency in describing patterns or types of atrial fibrillation has led to the use of numerous labels, such as **paroxysmal** (i.e., sudden onset with

spontaneous termination), persistent, and permanent. The recommended classification system is noted in Chart 22-3. The use of the term "chronic atrial fibrillation" is no longer included in the classification system, due to a lack of consensus on what constitutes chronicity (January et al., 2014, 2019).

Chart 22-3

Atrial Fibrillation Classification System

Type	Description
Paroxysmal	Sudden onset with termination that occurs spontaneously or after an intervention; lasts ≤7 days, but may recur
Persistent	Continuous, lasting >7 days
Long-standing persistent	Continuous, lasting >12 months
Permanent	Persistent, but decision has been made not to restore or maintain sinus rhythm
Nonvalvular	Absence of moderate-to-severe mitral stenosis or mechanical heart valve

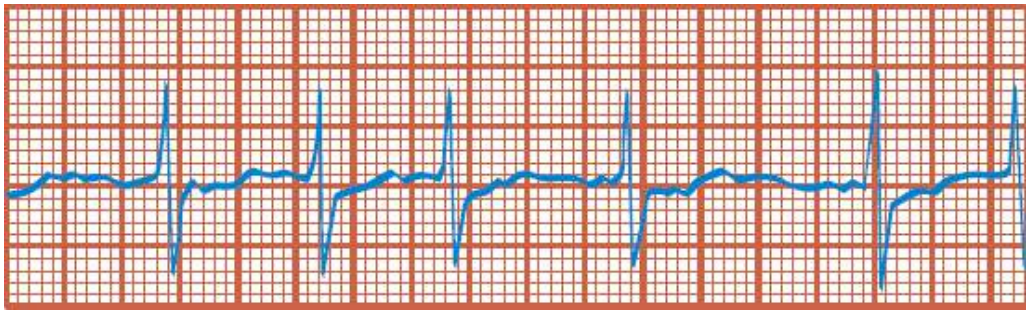

Figure 22-10 • Atrial fibrillation. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-22D). Philadelphia, PA: Wolters Kluwer.

Atrial fibrillation has the following characteristics (Fig. 22-10):

Ventricular and atrial rate: Atrial rate is 300 to 600 bpm; ventricular rate is usually 120 to 200 bpm in untreated atrial fibrillation

Ventricular and atrial rhythm: Highly irregular

QRS shape and duration: Usually normal, but may be abnormal

P wave: No discernible P waves; irregular undulating waves that vary in amplitude and shape are seen and referred to as fibrillatory or f waves

PR interval: Cannot be measured

P:QRS ratio: Many:1

Patients with atrial fibrillation are at increased risk of heart failure, myocardial ischemia, and embolic events such as stroke (January et al., 2014, 2019). A rapid and irregular ventricular response reduces the time for ventricular filling, resulting in a smaller stroke volume. Because atrial fibrillation causes a loss in AV synchrony (the atria and ventricles contract at different times), the atrial kick (the last part of diastole and ventricular filling, which accounts for 25% to 30% of the cardiac output) is also lost. As a consequence, although some patients with atrial fibrillation are asymptomatic, others experience palpitations and clinical manifestations of heart failure (e.g., shortness of breath, hypotension, dyspnea on exertion, fatigue; see Chapter 25). In addition, a high ventricular rate of response during atrial fibrillation (greater than 80 bpm) can eventually lead to mitral valve dysfunction, mitral regurgitation, intraventricular conduction delays, and dilated ventricular cardiomyopathy.

Patients with atrial fibrillation may exhibit a pulse deficit—a numeric difference between apical and radial pulse rates. The shorter time in diastole reduces the time available for coronary artery perfusion, thereby increasing the risk of myocardial ischemia with the onset of anginal symptoms (see Chapter 23). Decreasing the ventricular rate may avoid and correct these effects.

The erratic nature of atrial contraction, alterations in ventricular ejection, and atrial myocardial dysfunction promote the formation of thrombi, especially within the left atrium, increasing the risk of an embolic event. The origin of embolisms resulting in stroke for patients with nonvalvular atrial fibrillation is most often the left atrial appendage (LAA) (Schellinger, Tsivgoulis, Steiner, et al., 2018). A therapeutic approach to addressing the role of the LAA in atrial fibrillation, left atrial appendage occlusion (LAAO), is discussed later in this chapter.

Assessment and Diagnostic Findings

The clinical evaluation of atrial fibrillation should include a history and physical examination that identifies the onset and nature of signs and symptoms, including their frequency, duration and any precipitating factors, and any response to medications. Whether or not the patient has a known history of heart disease or other risks is identified (see Chart 22-2). A 12-lead ECG is performed to verify the atrial fibrillation rhythm, as well as to identify the presence (or absence) of left ventricular (LV) hypertrophy, bundle branch block, prior myocardial ischemia, or other arrhythmias. The RR, QRS, and QT intervals are analyzed to verify the effectiveness of any prescribed antiarrhythmic medications (January et al., 2014, 2019). A transesophageal echocardiogram (TEE) can identify the presence of valvular heart disease, provide information about LV and right ventricular (RV) size and function, RV

pressures (to identify pulmonary hypertension, which may exist concomitant with atrial fibrillation), LV hypertrophy, and presence of left atrial thrombi (January et al., 2014, 2019).

Blood tests to screen for diseases that are known risks for atrial fibrillation (see Chart 22-2), including thyroid, renal, and hepatic function, are assessed in the patient with a new onset of atrial fibrillation, as well as when the ventricular rate is difficult to control (January et al., 2014, 2019). Additional tests may include a chest x-ray (to evaluate pulmonary vasculature in a patient suspected of having pulmonary hypertension), exercise stress test (to exclude myocardial ischemia or reproduce exercise-induced atrial fibrillation), Holter or event monitoring (see Chapter 21), and an EPS (January et al., 2014, 2019; see later discussion).

Medical Management

Treatment of atrial fibrillation depends on the cause, pattern, and duration of the arrhythmia, the ventricular response rate, as well as the presence of structural or valvular heart disease and other cardiac conditions such as coronary artery disease or heart failure. Strategies for both rhythm control (i.e., conversion to sinus rhythm) and rate control are dependent on shared clinical decision making between the patient and primary provider. In some cases, atrial fibrillation spontaneously converts to sinus rhythm within 24 to 48 hours and without treatment. However, in instances where atrial fibrillation is concomitant with significant other morbid conditions (e.g., severe heart failure), the atrial fibrillation may be classified as "permanent," meaning that the patient and primary provider have made a joint decision to stop further attempts to restore or maintain sinus rhythm. Therefore, management of atrial fibrillation may not only be different in different patients, but it also may change over time for any one patient.

Medical management revolves around preventing embolic events such as stroke with anticoagulant medications, controlling the ventricular rate of response with antiarrhythmic agents, and treating the arrhythmia as indicated so that it is converted to a sinus rhythm (i.e., *cardioversion*).

Pharmacologic Therapy

Antithrombotic Medications. Antithrombotic drugs may include anticoagulants and antiplatelet drugs. Oral antithrombotic therapy is indicated for most patients with nonvalvular atrial fibrillation (e.g., absence of mechanical heart valve) because it reduces the risk of stroke (January et al., 2014, 2019). Atrial fibrillation guidelines recommend use of a scoring system to assist in assessment of stroke risk. Antithrombotic therapy is then selected based on risk factors outlined in the mnemonic CHA_2DS_2-VAS_C (see Chart 22-4) with each risk factor assigned points tallied for a total score that indicates an overall risk of stroke (January et al., 2014, 2019).

Chart 22-4

Stroke Risk Assessment for the Patient with Atrial Fibrillation: The CHA_2DS_2-VAS_C Scoring System

Risk Factor		Points
C	Congestive Heart Failure (left ventricular systolic dysfunction)	1
H	Hypertension (BP >130/80 mm Hg)	1
A_2	Age ≥75 years	2
D	Diabetes	1
S_2	Prior Stroke/TIA/Thromboembolism	2
V	Vascular disease (i.e., prior MI, PAD, or aortic plaque)	1
A	Age 65–74 years	1
S_c	Sex category (female gender)	1

MI, myocardial infarction; PAD, peripheral artery disease, TIA; transient ischemic attack.

Adapted from January, C. T., Wann, L. S., Alpert, J. S., et al. (2014). 2014 AHA/ACC/HRS guideline for the management of patients with atrial fibrillation: A report of the ACC/AHA Task Force on practice guidelines and the Heart Rhythm Society. *Circulation, 130*(23), e199–e267; January, C. T., Wann, L. S., Calkins, H., et al. (2019). 2019 AHA/ACC/HRS Focused Update of the 2014 AHA/ACC/HRS Guideline for the Management of Patients With Atrial Fibrillation: A Report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society in Collaboration With the Society of Thoracic Surgeons. *Circulation, 140*(2), e125–e151.

According to pharmacologic treatment guidelines (January et al., 2014, 2019):

- Patients with nonvalvular atrial fibrillation with a CHA_2DS_2-VAS_C score of zero may choose the option of no antithrombotic therapy.
- Patients with nonvalvular atrial fibrillation with a CHA_2DS_2-VAS_C score of one may choose no antithrombotic therapy, treatment with an oral anticoagulant, or aspirin.
- Patients with nonvalvular atrial fibrillation with a CHA_2DS_2-VAS_C score of 2 or higher for men and 3 or higher for women may choose warfarin, or a direct thrombin inhibitor (e.g., dabigatran), or a Factor Xa inhibitor (e.g., rivaroxaban, apixaban, edoxaban).

Patients with atrial fibrillation with valvular heart disease or bioprosthetic heart valves may be prescribed warfarin, or a direct-acting oral anticoagulant, or a Factor Xa inhibitor (Malik, Yandrapalli, Aronow, et al., 2019). For

patients with mechanical heart valves, warfarin is recommended (January et al., 2014, 2019). If immediate or short-term anticoagulation is necessary, the patient may be placed on IV or low–molecular-weight heparin until warfarin therapy can be started and the international normalized ratio (INR) level reaches a therapeutic range consistent with antithrombosis, usually defined as an INR between 2.0 and 3.0 (see Chapter 26 for further discussion).

Medication selection for all patients with atrial fibrillation depends upon stroke and bleeding risks as well as patient preferences and values (January et al., 2014, 2019). For instance, treatment with warfarin will require weekly INR testing during initiation of therapy, as well as ongoing monitoring (see Chapter 26 for further discussion). Home monitoring of therapy is an option for some patients. Direct-acting oral anticoagulants and Factor Xa inhibitors require baseline assessment of hemoglobin and hematocrit, as well as liver and renal function, along with INR. Advantages of these medications include fewer drug–drug interactions and dietary limitations, as well as the elimination of frequent INR testing.

Medications that Control the Heart Rate. A strategy to control the ventricular rate of response so that the resting heart rate is less than 80 bpm is recommended in order to manage symptoms of atrial fibrillation (January et al., 2014, 2019). To decrease the ventricular rate in patients with paroxysmal, persistent, or permanent atrial fibrillation, a beta-blocker (Class II antiarrhythmic, see Table 22-1) or non-dihydropyridine calcium channel blocker (Class IV antiarrhythmic, see Table 22-1) is generally recommended (January et al., 2014, 2019).

Medications that Convert the Heart Rhythm or Prevent Atrial Fibrillation. For patients with atrial fibrillation lasting 48 hours or longer, anticoagulation is recommended prior to attempts to restore sinus rhythm, which may be achieved through pharmacologic or electrical cardioversion (January et al., 2014, 2019). In the absence of therapeutic anticoagulation, TEE may be performed prior to cardioversion to identify left atrial thrombus formation, including in the LAA (January et al., 2014, 2019). If no thrombus is identified, cardioversion can proceed.

Medications that may be given to achieve pharmacologic cardioversion to sinus rhythm include flecainide, dofetilide, propafenone, amiodarone, and IV ibutilide (January et al., 2014, 2019). These medications are most effective if given within 7 days of the onset of atrial fibrillation. It is recommended that patients who were prescribed dofetilide be hospitalized so that the QT interval and renal function both may be monitored. Despite a degree of risk, dofetilide is a preferred medication because it is highly effective at converting atrial fibrillation to sinus rhythm, has fewer drug-to-drug interactions, and is better tolerated by patients than other medications. Some patients with recurrent atrial fibrillation may be prescribed flecainide to self-administer at home, an approach referred to as “pill in the pocket” (January et al., 2014, 2019).

Preoperative administration of beta-blockers (see Table 22-1) has resulted in a significant reduction in atrial fibrillation after cardiac surgery (Burrage, Low, Campbell, et al., 2019). Cholesterol-lowering drugs such as the HMG-CoA reductase inhibitors (also called statins; see Chapter 23, Table 23-1) may also be prescribed to prevent new-onset atrial fibrillation following cardiac surgery (Burrage et al., 2019).

If symptomatic, paroxysmal atrial fibrillation is refractory to at least one Class I or Class III antiarrhythmic medication (see Table 22-1), and rhythm control is desired, catheter ablation may be indicated (January et al., 2014, 2019; see later discussion).

Electrical Cardioversion for Atrial Fibrillation

Electrical cardioversion is indicated for patients with atrial fibrillation who are hemodynamically unstable (e.g., acute alteration in mental status, chest discomfort, hypotension) and do not respond to medications (January et al., 2014, 2019). Flecainide, propafenone, amiodarone, dofetilide, or sotalol may be given prior to cardioversion to enhance the success of cardioversion and maintain sinus rhythm (January et al., 2014, 2019).

Quality and Safety Nursing Alert

The patient with atrial fibrillation is at high risk for thrombus formation. When electrical cardioversion is indicated, the nurse may anticipate that a transesophageal echocardiogram may be performed to evaluate for possible atrial thrombi.

Because atrial function may be impaired for several weeks after cardioversion, antithrombotic therapy (e.g., warfarin) is indicated for at least 4 weeks after the procedure (January et al., 2014, 2019). Repeated attempts at electrical cardioversion may be made, following administration of an antiarrhythmic medication (see later discussion on Electrical Cardioversion).

Cardiac Rhythm Therapies

Atrial fibrillation that does not respond to medications or electrical cardioversion may be treated by cardiac rhythm therapies, including catheter ablation, maze or mini-maze procedure, or convergent procedure.

Catheter Ablation Therapy

Catheter **ablation** destroys specific cells that are the cause of a tachyarrhythmia. Catheter ablation is performed most often today for atrial fibrillation, although it may also be useful in treating atrioventricular nodal reentry tachycardia (AVNRT) and recurrent ventricular tachycardia (VT) (see later discussion of these arrhythmias).

Atrial fibrillation is associated with intrinsic cardiac autonomic nervous system activity to the pulmonary veins. Ablation involves a procedure similar to a cardiac catheterization (see Chapter 21); however, in this instance, a special catheter is advanced at or near the origin of the arrhythmia, where high-frequency, low-energy sound waves are passed through the catheter, causing thermal injury, localized cell destruction, and scarring. The tissue damage is more specific to the arrhythmic tissue, with less trauma to the surrounding cardiac tissue. Ablation may also be accomplished using a special catheter to apply extremely cold temperature to destroy selected cardiac cells, called *cryoablation*. The goal of each of these ablation procedures is to eliminate the arrhythmia, by preventing the ectopic activity arising from the pulmonary veins from reaching the atria, thereby stopping fibrillation (Weber, Sagerer-Gerhardt, & Heinze, 2017).

An EPS (see later discussion) may be performed to induce the arrhythmia prior to the catheter ablation. During the ablation procedure, defibrillation pads, an automatic blood pressure cuff, and a pulse oximeter are used. The patient is usually given moderate sedation (see Chapter 15) and IV heparin to reduce the risk of periprocedural thromboembolism. Immediately postablation, the patient is monitored for another 30 to 60 minutes and then retested to ensure that the arrhythmia does not recur. Successful ablation is achieved when the arrhythmia cannot be induced. Major risks of catheter ablation include pericardial effusion and tamponade, phrenic nerve injury, stroke, hematoma, retroperitoneal bleeding, pulmonary vein stenosis, and atrioesophageal fistulas (Canpolat, Kocyigit, & Aytemir, 2017).

Nursing Management. Postprocedural care on a step-down unit for the patient who has had ablation is similar to the nursing management of a patient who has had a cardiac catheterization (see Chapter 21); the patient is monitored closely to ensure recovery from sedation. Postprocedural nursing interventions include frequent monitoring for arrhythmias and for signs and symptoms of a stroke and vascular access site complications. Because of the prolonged time required for the procedure as well as the time needed in bed to obtain hemostasis at the vascular access site, it is not unusual for the patient to have back discomfort. In addition to administering any pain medications, the nurse may help to alleviate this pain by placing rolled towels under the patient's knees and waist.

Maze and Mini-Maze Procedures

The maze procedure is an open heart surgical procedure for refractory atrial fibrillation. Small transmural incisions are made throughout the atria. The resulting formation of scar tissue prevents reentry conduction of the aberrant electrical impulse. Because the procedure requires significant time and cardiopulmonary bypass, its use is reserved only for those patients undergoing cardiac surgery for another reason (e.g., coronary artery bypass; January et al.,

2014, 2019). Some patients may need a permanent pacemaker after this surgery because of subsequent injury to the SA node.

A modification of the maze procedure, minimally invasive maze surgery, or mini-maze, may be performed by making small incisions between the ribs, through which video-guided instruments are inserted. The pulmonary veins are encircled with surgical incisions within the left atrium. This surgery eliminates the need for opening the sternum, heart–lung bypass, and the use of cardioplegia (see Chapter 23 for further discussion of cardiac surgery). This results in a shorter recovery time and a lower risk of infection (January et al., 2014, 2019).

Convergent Procedure

The convergent procedure utilizes a hybrid approach to ablation, requiring the skills of both a cardiothoracic surgeon and an electrophysiologist, a cardiologist with specialized training. This procedure is associated with lower rates of arrhythmia recurrence than catheter ablation, but more complications within 30 days of the procedure (e.g., infections, bleeding) (Jan, Zizek, Gersak, et al., 2018). The surgeon creates a few small incisions in the abdomen so that a special catheter that allows visualization can be inserted through the diaphragm and toward the posterior wall of the heart. The surgeon performs ablation of the epicardial wall in the area around the pulmonary veins and the electrophysiologist performs ablation around the endocardial area of the pulmonary veins. Because of the incisions, the patient usually has a 3-day hospital length of stay (Elrod, 2014). The patient may experience mild dull chest pain caused by the resulting inflammation from the ablation that usually resolves within a few days (Elrod, 2014). This pain is usually alleviated by treatment with acetaminophen as needed. In addition, if the phrenic nerve was affected, the patient may experience shortness of breath that may take days to weeks to resolve (Elrod, 2014).

Left Atrial Appendage Occlusion

LAAO is an alternative to antithrombotic medications for stroke prevention in patients with nonvalvular atrial fibrillation (Masoudi, Calkins, Kavinsky, et al., 2015). As noted previously, the LAA is the area where the majority of stroke-causing blood clots form in patients with nonvalvular atrial fibrillation. However, concerns about the risk of long-term anticoagulant use and the risk of bleeding can complicate effective management (Ojo, Yandrapalli, Veseli, et al., 2020).

Candidates for LAAO include those patients with increased risk of stroke based on CHA_2DS_2-VAS_C scores of one or higher (see Chart 22-4) and those patients seeking a nonpharmacologic alternative to treatment (Masoudi et al., 2015). Commonly used is the WATCHMAN, a device typically inserted while the patient is under general anesthesia. Similar to a percutaneous coronary

intervention (PCI) procedure (see Chapter 23), a small incision is made in the femoral area and a catheter is then inserted that guides the device into position. The parachute-shaped device is threaded through to the opening of the LAA, sealing it off and preventing it from releasing clots (see Fig. 22-11).

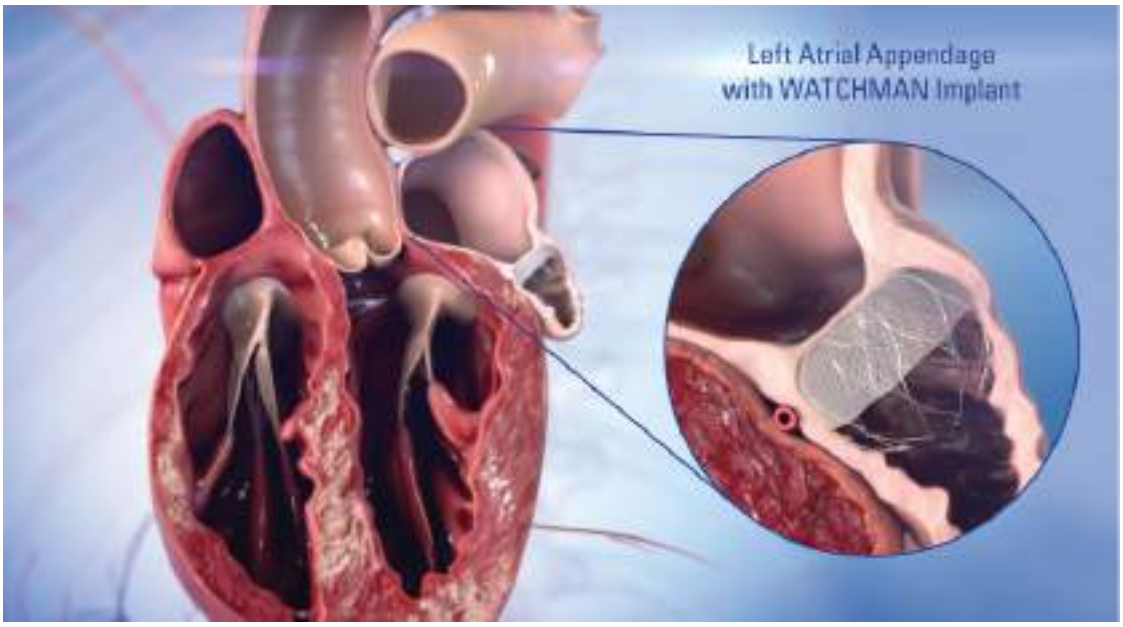

Figure 22-11 • The WATCHMAN device in place over the left atrial appendage. ©2021 Boston Scientific Corporation or its affiliates. All rights reserved.

Patients typically stay in the hospital overnight after placement of a WATCHMAN device. The nursing management of patients who received this device is similar to that of patients post cardiac catheterization (see Chapter 21). Patients are prescribed aspirin and warfarin post procedure; approximately 6 weeks post procedure, they should return to the cardiology clinic for a TEE to confirm that the device has effectively occluded the LAA. If LAAO has occurred, then the patient may stop taking warfarin and is prescribed clopidogrel, an antiplatelet medication. After 6 months, the patient may stop taking clopidogrel but must continue taking daily aspirin indefinitely (Carlson & Doshi, 2017).

Wolff-Parkinson-White Syndrome

In the patient with atrial fibrillation, if the QRS is wide and the ventricular rhythm is very fast and irregular, an accessory pathway should be suspected. An accessory pathway is typically congenital tissue between the atria, bundle of His, AV node, Purkinje fibers, or ventricular myocardium. This anomaly is known as Wolff-Parkinson-White (WPW) syndrome. Electrical cardioversion is the treatment of choice for atrial fibrillation in the presence of WPW syndrome that causes hemodynamic instability. Medications that block AV

conduction (e.g., digoxin, diltiazem, verapamil) should be avoided in WPW because they can increase the ventricular rate. If the patient is hemodynamically stable, procainamide, propafenone, flecainide, or amiodarone are recommended to restore sinus rhythm (January et al., 2014, 2019). Catheter ablation is performed for long-term management (see previous discussion).

Atrial Flutter

Atrial flutter occurs because of a conduction defect in the atrium and causes a rapid, regular atrial impulse at a rate between 250 and 400 bpm. Because the atrial rate is faster than the AV node can conduct, not all atrial impulses are conducted into the ventricle, causing a therapeutic block at the AV node. This is an important feature of this arrhythmia. If all atrial impulses were conducted to the ventricle, the ventricular rate would also be 250 to 400 bpm, which would result in ventricular fibrillation, a life-threatening arrhythmia. Atrial flutter risk factors mirror those for atrial fibrillation (Fuster et al., 2017; see Chart 22-2).

Atrial flutter has the following characteristics (see Fig. 22-12):

Ventricular and atrial rate: Atrial rate ranges between 250 and 400 bpm; ventricular rate usually ranges between 75 and 150 bpm

Ventricular and atrial rhythm: The atrial rhythm is regular; the ventricular rhythm is usually regular but may be irregular because of a change in the AV conduction

QRS shape and duration: Usually normal, but may be abnormal or absent

P wave: Saw-toothed shape; these waves are referred to as F waves

PR interval: Multiple F waves may make it difficult to determine the PR interval

P:QRS ratio: 2:1, 3:1, or 4:1

Medical Management

Atrial flutter can cause serious signs and symptoms, such as chest pain, shortness of breath, and low blood pressure. Medical management involves the use of vagal maneuvers (see previous discussion under Sinus Tachycardia) or a trial administration of adenosine, which causes sympathetic block and slowing of conduction through the AV node. This may terminate the tachycardia; optimally, it will facilitate visualization of flutter waves for diagnostic purposes. Adenosine is given IV by rapid administration, and immediately followed by a 20-mL saline flush and elevation of the arm with the IV line to promote rapid circulation of the medication.

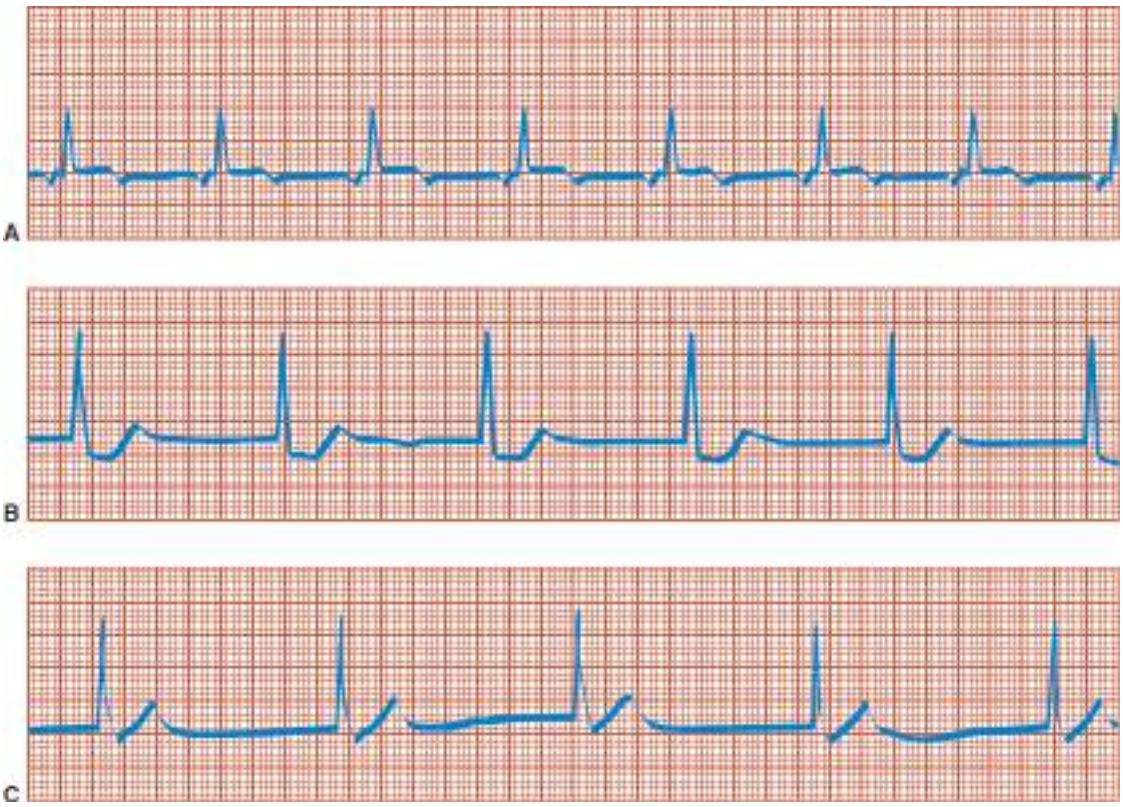

Figure 22-13 • Various types of junctional rhythms. **A.** Note that the inverted P wave appears before the normal QRS complex. **B.** Note that the inverted P wave is buried inside the QRS complex. **C.** Note that the inverted P wave follows the QRS complex. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-23A, B, and C). Philadelphia, PA: Wolters Kluwer.

Atrial flutter is treated with antithrombotic therapy, rate control, and rhythm control in the same manner as atrial fibrillation (January et al., 2014, 2019). Electrical cardioversion is often successful in converting atrial flutter to sinus rhythm (see later discussion).

Junctional Arrhythmias

Junctional arrhythmias originate within AV nodal tissue, and may include premature junctional complexes, junctional rhythms, nonparoxysmal junctional tachycardia, and AV nodal reentry tachycardia.

Premature Junctional Complex

A premature junctional complex is an impulse that starts in the AV nodal area before the next normal sinus impulse reaches the AV node. Premature junctional complexes are less common than PACs. Causes include digitalis toxicity, heart failure, and coronary artery disease. The ECG criteria for premature junctional complex are the same as for PACs, except for the P wave and the PR interval. The P wave may be absent, may follow the QRS, or may occur before the QRS but with a PR interval of less than 0.12 seconds. This arrhythmia rarely produces significant symptoms. Treatment for frequent premature junctional complexes is the same as for frequent PACs.

Junctional Rhythm

Junctional or idionodal rhythm occurs when the AV node, instead of the sinus node, becomes the pacemaker of the heart. When the sinus node slows (e.g., from increased vagal tone) or when the impulse cannot be conducted through the AV node (e.g., because of complete heart block), the AV node automatically discharges an impulse. Junctional rhythm not caused by complete heart block has the following characteristics (see Fig. 22-13):

Ventricular and atrial rate: Ventricular rate 40 to 60 bpm; atrial rate also 40 to 60 bpm if P waves are discernible

Ventricular and atrial rhythm: Regular

QRS shape and duration: Usually normal, but may be abnormal

P wave: May be absent, after the QRS complex, or before the QRS; may be inverted, especially in lead II

PR interval: If the P wave is in front of the QRS, the PR interval is less than 0.12 seconds

P:QRS ratio: 1:1 or 0:1

Medical Management

Junctional rhythm may produce signs and symptoms of reduced cardiac output. If this occurs, the treatment is the same as for sinus bradycardia. Emergency pacing may be needed (see later discussion under Pacemaker Therapy).

Nonparoxysmal Junctional Tachycardia

Junctional tachycardia is caused by enhanced automaticity in the junctional area, resulting in a rhythm similar to junctional rhythm, except at a rate of 70 to 120 bpm. Although this rhythm generally does not have any detrimental hemodynamic effect, it may indicate a serious underlying condition, such as digitalis toxicity, myocardial ischemia, hypokalemia, or chronic obstructive pulmonary disease.

Atrioventricular Nodal Reentry Tachycardia

AVNRT is a common arrhythmia that occurs when an impulse is conducted to an area in the AV node that causes the impulse to be rerouted back into the same area over and over again at a very fast rate. Each time the impulse is conducted through this area, it is also conducted down into the ventricles, causing a fast ventricular rate. AVNRT that has an abrupt onset and an abrupt cessation with a QRS of normal duration has frequently been called *paroxysmal atrial tachycardia (PAT)* and also *paroxysmal supraventricular tachycardia (PSVT)*. AVNRT also occurs when the duration of the QRS complex is 0.12 seconds or greater and a block in the bundle branch is known to be present. This arrhythmia may last for seconds or several hours. Factors associated with the development of AVNRT include caffeine, nicotine, hypoxemia, and stress. Underlying pathologies include coronary artery disease and cardiomyopathy; however, it occurs more often in females and not in association with underlying structural heart disease. AVNRT has the following characteristics (see Fig. 22-14):

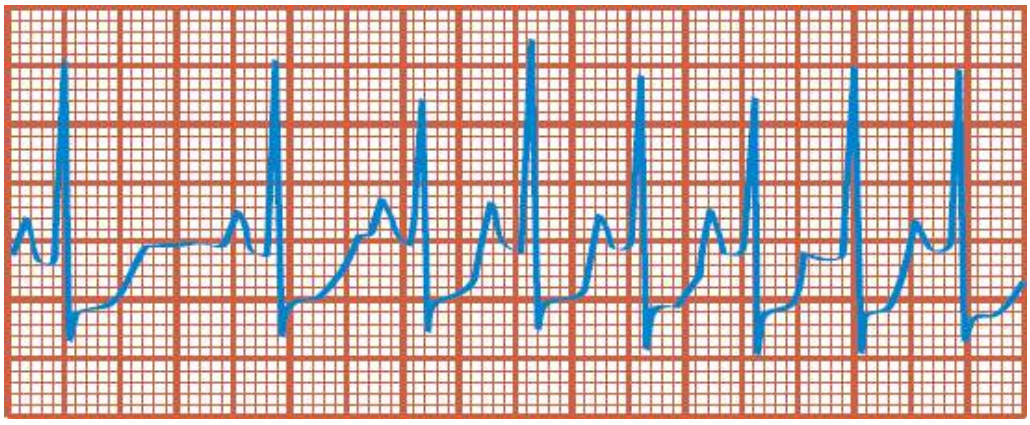

Figure 22-14 • Atrioventricular nodal reentry tachycardia (AVNRT), also called paroxysmal atrial tachycardia (PAT), and paroxysmal supraventricular tachycardia (PSVT). Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-22B). Philadelphia, PA: Wolters Kluwer.

Ventricular and atrial rate: Atrial rate usually 150 to 250 bpm; ventricular rate usually 120 to 200 bpm

Ventricular and atrial rhythm: Regular; sudden onset and termination of the tachycardia

QRS shape and duration: Usually normal, but may be abnormal

P wave: Usually very difficult to discern

PR interval: If the P wave is in front of the QRS, the PR interval is less than 0.12 seconds

P:QRS ratio: 1:1, 2:1

Clinical symptoms vary with the rate and duration of the tachycardia and the patient's underlying condition. The tachycardia usually is of short duration, resulting only in palpitations. A fast rate may also reduce cardiac output, resulting in significant signs and symptoms such as restlessness, chest pain, shortness of breath, pallor, hypotension, and loss of consciousness.

Medical Management

Because AVNRT is generally a benign arrhythmia, the goal of medical management is to alleviate symptoms and improve quality of life. Patients who become significantly symptomatic and require emergency department visits to terminate the rhythm may want to initiate therapy immediately. However, those with minimum symptoms with an AVRNT that terminates spontaneously or with minimal treatment may choose just to be monitored and self-treat.

The aim of therapy is to break the reentry of the impulse. Catheter ablation is the initial treatment of choice and is used to eliminate the area that permits the rerouting of the impulse that causes the tachycardia (Katritsis, 2018; see previous discussion of Atrial Fibrillation: Catheter Ablation Therapy). Vagal maneuvers (see previous discussion under Sinus Tachycardia) may be used to interrupt AVNRT. These techniques increase parasympathetic stimulation, causing slower conduction through the AV node and blocking the reentry of the rerouted impulse. Some patients use some of these methods to terminate the episode on their own. Because of the risk of a cerebral embolic event, carotid sinus massage, which may be performed by physicians, is contraindicated in patients with carotid artery disease.

Pharmacologic Therapy

If the vagal maneuvers are ineffective, the patient may then receive a bolus of adenosine to correct the rhythm; this is usually effective in terminating AVNRT. Because the effect of adenosine is so short, AVNRT may recur; the first dose may be followed with two additional doses. If the vagal maneuvers and adenosine are ineffective, IV non-dihydropyridine calcium channel blockers (e.g., verapamil), IV beta-blockers or IV digoxin may be considered (Hafeez & Armstrong, 2019). If the patient is unstable or does not respond to the medications, electrical cardioversion is the treatment of choice (see later discussion).

If P waves cannot be identified, the rhythm may be called supraventricular tachycardia (SVT), or PSVT if it has an abrupt onset, until the underlying rhythm and resulting diagnosis is determined. SVT and PSVT indicate only that the rhythm is not VT. SVT could be atrial fibrillation, atrial flutter, or AVNRT, among others. Vagal maneuvers and adenosine may be used to convert the rhythm or at least slow conduction in the AV node to allow visualization of the P waves.

Ventricular Arrhythmias

Ventricular arrhythmias originate from foci within the ventricles; these may include premature ventricular complexes, VT, ventricular fibrillation, and idioventricular rhythms. Technically, ventricular asystole is characterized by an absence of rhythm formation.

Premature Ventricular Complex

A PVC is an impulse that starts in a ventricle and is conducted through the ventricles before the next normal sinus impulse. PVCs can occur in healthy people, especially with intake of caffeine, nicotine, or alcohol. PVCs may be caused by cardiac ischemia or infarction, increased workload on the heart (e.g., heart failure and tachycardia), digitalis toxicity, hypoxia, acidosis, or electrolyte imbalances, especially hypokalemia.

In a rhythm referred to as bigeminy, every other complex is a PVC. In trigeminy, every third complex is a PVC, and in quadrigeminy, every fourth complex is a PVC. PVCs have the following characteristics (see Fig. 22-15):

Ventricular and atrial rate: Depends on the underlying rhythm (e.g., sinus rhythm)

Ventricular and atrial rhythm: Irregular due to early QRS, creating one RR interval that is shorter than the others. The PP interval may be regular, indicating that the PVC did not depolarize the sinus node

QRS shape and duration: Duration is 0.12 seconds or longer; shape is bizarre and abnormal. When these bizarrely shaped, widened QRS complexes resemble each other, they are called unifocal. When they have at least two different morphologic appearances, they are called multifocal

P wave: Visibility of the P wave depends on the timing of the PVC; may be absent (hidden in the QRS or T wave) or in front of the QRS. If the P wave follows the QRS, the shape of the P wave may be different

PR interval: If the P wave is in front of the QRS, the PR interval is less than 0.12 seconds

P:QRS ratio: 0:1; 1:1

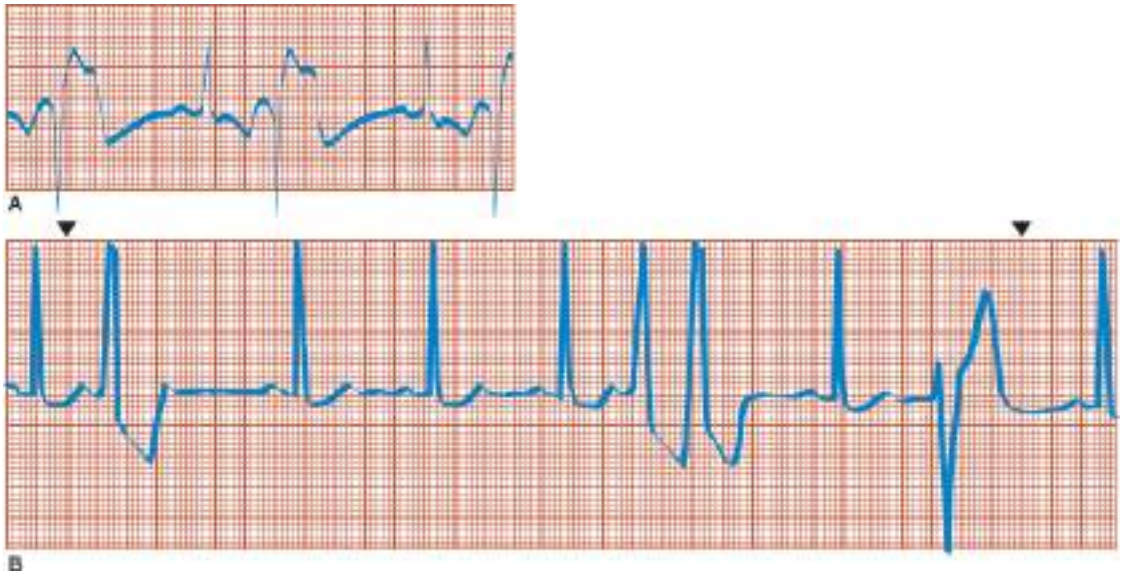

Figure 22-15 • Premature ventricular complexes (PVCs). **A.** Ventricular bigeminy that is unifocal; note that every other beat is a PVC, with the same morphologic appearance. **B.** Multifocal PVCs; note that there are at least two different appearing PVCs. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-25B and C). Philadelphia, PA: Wolters Kluwer.

The patient may feel nothing or may say that the heart "skipped a beat." The effect of a PVC depends on its timing in the cardiac cycle and how much blood was in the ventricles when they contracted. Initial treatment is aimed at correcting the cause.

Medical Management

PVCs are a common occurrence and may increase in frequency with age (Al-khatib, Stevenson, Ackerman, et al., 2018). PVCs that are frequent and persistent may be treated with amiodarone or beta-blockers, but long-term pharmacotherapy for PVCs is not usually indicated. PVCs are not considered a warning for ensuing VT. However, studies have shown an association of PVCs with adverse outcomes; therefore, patients may need to be evaluated for underlying causes (e.g., ischemic heart disease and LV dysfunction) (Al-khatib et al., 2018).

Unfolding Patient Stories: Kenneth Bronson • Part 2

Recall from Chapter 19 Kenneth Bronson, who came to the emergency department with difficulty breathing after a week of flu-like symptoms, productive cough, and high fever. He was diagnosed with a right lower lobe pneumonia. Sinus tachycardia with occasional unifocal premature ventricular contractions (PVCs) is seen on the cardiac monitor. What are potential causes for the tachycardia and PVCs that the nurse should investigate when considering his age of 27 years, symptoms experienced over the last week, and the clinical manifestations associated with his diagnosis?

Care for Kenneth and other patients in a realistic virtual environment: vSim (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Ventricular Tachycardia

VT is defined as three or more PVCs in a row, occurring at a rate exceeding 100 bpm. The causes are similar to those of PVC. Patients with larger MIs and lower ejection fractions are at higher risk of lethal VT. VT is an emergency because the patient is nearly always unresponsive and pulseless. VT has the following characteristics (see Fig. 22-16):

Ventricular and atrial rate: Ventricular rate is 100 to 200 bpm; atrial rate depends on the underlying rhythm (e.g., sinus rhythm)

Ventricular and atrial rhythm: Usually regular; atrial rhythm may also be regular

QRS shape and duration: Duration is 0.12 seconds or more; bizarre, abnormal shape

P wave: Very difficult to detect, so the atrial rate and rhythm may be indeterminable

PR interval: Very irregular, if P waves are seen

P:QRS ratio: Difficult to determine, but if P waves are apparent, there are usually more QRS complexes than P waves

The patient's tolerance or lack of tolerance for this rapid rhythm depends on the ventricular rate and severity of ventricular dysfunction.

Medical Management

Several factors determine the initial treatment, including the following: identifying the rhythm as monomorphic (having a consistent QRS shape and rate) or polymorphic (having varying QRS shapes and rhythms), determining

the existence of a prolonged QT interval before the initiation of VT, any comorbidities, and ascertaining the patient's heart function (normal or decreased). If the patient is stable, continuing the assessment, especially obtaining a 12-lead ECG, may be the only action necessary.

The patient may need antiarrhythmic medications, antitachycardia pacing, or direct cardioversion or defibrillation. Procainamide, amiodarone, sotalol, and lidocaine are all antiarrhythmic medications that may be considered based upon type of VT (e.g., monomorphic or polymorphic), clinical presentation, and patient comorbidities (e.g., impaired cardiac function, acute MI).

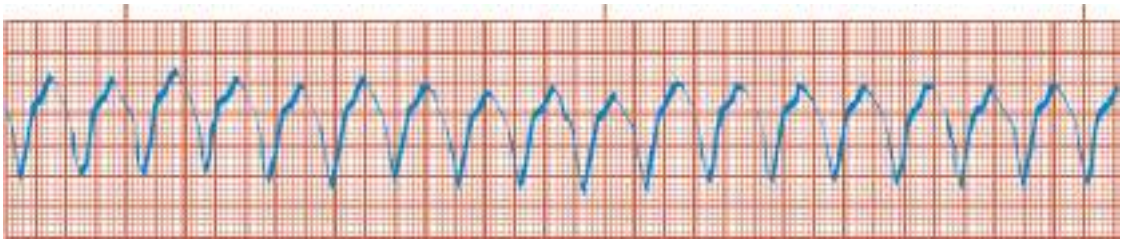

Figure 22-16 • Ventricular tachycardia. Reprinted with permission from Huff, J. (2002). *ECG Workout* (4th ed., p. 197). Philadelphia, PA: Lippincott, Williams & Wilkins.

Cardioversion is the treatment of choice for monophasic VT in a patient who is symptomatic. **Defibrillation**, which uses an electrical current given to stop the arrhythmia that is not set to synchronize with the patient's QRS complex, is the treatment of choice for pulseless VT. Any type of VT in a patient who is unconscious and without a pulse is treated in the same manner as ventricular fibrillation: immediate defibrillation is the action of choice (see later discussion on Cardioversion and Defibrillation).

For long-term management, patients with an ejection fraction less than 35% should be considered for an implantable cardioverter defibrillator (ICD) (see later discussion). Those with an ejection fraction greater than 35% may be managed with antiarrhythmic medication.

Torsades de pointes is a polymorphic VT preceded by a prolonged QT interval, which could be congenital or acquired. Common causes include central nervous system disease; certain medications (e.g., ciprofloxacin, erythromycin, haloperidol, lithium, methadone); or low levels of potassium, calcium, or magnesium. Congenital QT prolongation is another cause. Because this rhythm is likely to cause the patient to deteriorate and become pulseless, immediate treatment is required and includes correction of any electrolyte imbalance, such as administration of IV magnesium, and with IV isoproterenol or pacing if associated with bradycardia (Link, Berkow, Kudenchuk, et al., 2015; Soar, Donnino, Maconochie, et al., 2018).

Ventricular Fibrillation

The most common arrhythmia in patients with cardiac arrest is ventricular fibrillation, which is a rapid, disorganized ventricular rhythm that causes ineffective quivering of the ventricles. No atrial activity is seen on the ECG. The most common cause of ventricular fibrillation is coronary artery disease and resulting acute MI. Other causes include untreated or unsuccessfully treated VT, cardiomyopathy, valvular heart disease, several proarrhythmic medications, acid–base and electrolyte abnormalities, and electrical shock. Another cause is Brugada syndrome, in which the patient (frequently of Asian descent) has a structurally normal heart, few or no risk factors for coronary artery disease, and a family history of sudden cardiac death (Pappone & Santinelli, 2019). Ventricular fibrillation has the following characteristics (see Fig. 22-17):

Ventricular rate: Greater than 300 bpm

Ventricular rhythm: Extremely irregular, without a specific pattern

QRS shape and duration: Irregular, undulating waves with changing amplitudes. There are no recognizable QRS complexes

Medical Management

Ventricular fibrillation is always characterized by the absence of an audible heartbeat, a palpable pulse, and respirations. Because there is no coordinated cardiac activity, cardiac arrest and death are imminent if the arrhythmia is not corrected. Early defibrillation is critical to survival, with administration of immediate bystander cardiopulmonary resuscitation (CPR) until defibrillation is available. For refractory ventricular fibrillation, administration of amiodarone and epinephrine may facilitate the return of a spontaneous pulse after defibrillation (Link et al., 2015; see Chapter 25 for further discussion on interventions during Cardiac Arrest).

Idioventricular Rhythm

Idioventricular rhythm, also called *ventricular escape rhythm,* occurs when the impulse starts in the conduction system below the AV node. When the sinus node fails to create an impulse (e.g., from increased vagal tone) or when the impulse is created but cannot be conducted through the AV node (e.g., due to complete AV block), the Purkinje fibers automatically discharge an impulse. When idioventricular rhythm is not caused by AV block, it has the following characteristics (see Fig. 22-18):

Ventricular rate: Between 20 and 40 bpm; if the rate exceeds 40 bpm, the rhythm is known as accelerated idioventricular rhythm

Ventricular rhythm: Regular

QRS shape and duration: Bizarre, abnormal shape; duration is 0.12 seconds or more

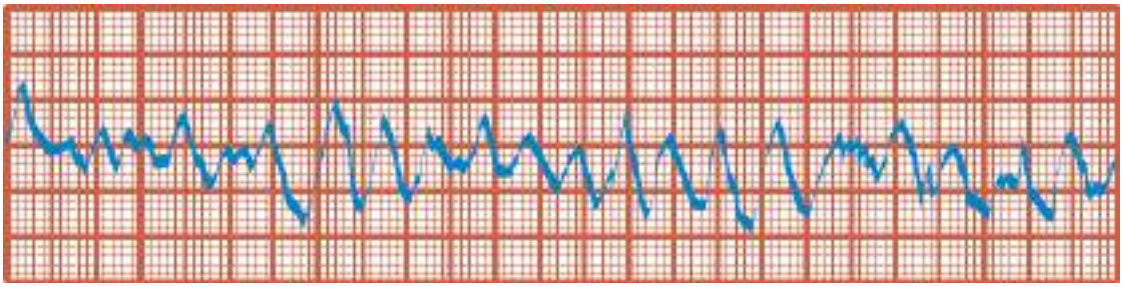

Figure 22-17 • Ventricular fibrillation. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical Care Nursing: A Holistic Approach* (11th ed., Fig. 17-27C). Philadelphia, PA: Wolters Kluwer.

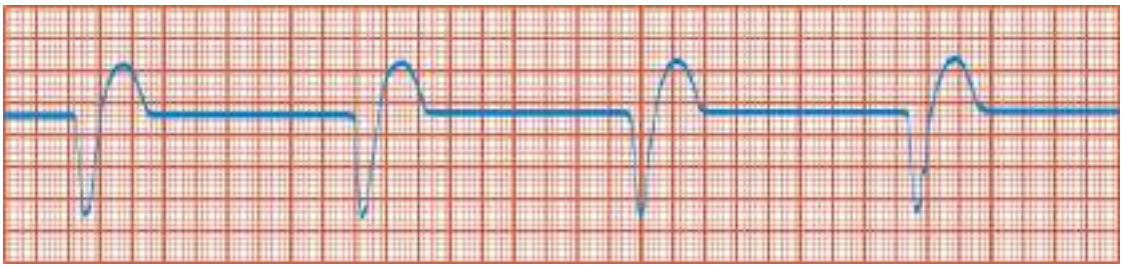

Figure 22-18 • Idioventricular rhythm.

Medical Management

Idioventricular rhythm commonly causes the patient to lose consciousness and experience other signs and symptoms of reduced cardiac output. In such cases, the treatment is the same as for asystole and pulseless electrical activity (PEA) (see Chapter 25) if the patient is in cardiac arrest or for bradycardia if the patient is not in cardiac arrest. Interventions include identifying the underlying cause; administering IV epinephrine, atropine, and vasopressor medications; and initiating emergency transcutaneous pacing. In some cases, idioventricular rhythm may cause no symptoms of reduced cardiac output.

Ventricular Asystole

Commonly called *flatline,* ventricular asystole is characterized by absent QRS complexes confirmed in two different leads, although P waves may be apparent for a short duration. There is no heartbeat, no palpable pulse, and no respiration. Without immediate treatment, ventricular asystole is fatal.

Medical Management

Ventricular asystole is treated the same as PEA, focusing on high-quality CPR with minimal interruptions and identifying underlying and contributing factors. The key to successful treatment is a rapid assessment to identify a possible cause, which is known as the Hs and Ts: hypoxia, hypovolemia, hydrogen ion (acid–base imbalance), hypo- or hyperglycemia, hypo- or hyperkalemia, hypothermia, trauma, toxins, tamponade (cardiac), tension pneumothorax, or thrombus (coronary or pulmonary) (Link et al., 2015). After the initiation of CPR, intubation and establishment of IV access are the next recommended actions, with no or minimal interruptions in chest compressions (see Chapter 25).

Conduction Abnormalities

When assessing the rhythm strip, the underlying rhythm is first identified (e.g., sinus rhythm, sinus arrhythmia). Then, the PR interval is assessed for the possibility of an AV block. AV blocks occur when the conduction of the impulse through the AV node or bundle of His area is decreased or stopped. These blocks can be caused by medications (e.g., digitalis, calcium channel blockers, beta-blockers), Lyme disease, myocardial ischemia and infarction, hypothyroidism, or activities that cause an increase in vagal tone (Kusumoto et al., 2019). If the AV block is caused by increased vagal tone (e.g., long-term athletic training, sleep, coughing, suctioning, pressure above the eyes or on large vessels, anal stimulation), it is commonly accompanied by sinus bradycardia. AV block may be temporary and resolve on its own, or it may be permanent and require permanent pacing.

The clinical signs and symptoms of a heart block vary with the resulting ventricular rate and the severity of any underlying disease processes. Whereas first-degree AV block rarely causes any hemodynamic effect, the other blocks may result in decreased heart rate, causing a decrease in perfusion to vital organs, such as the brain, heart, kidneys, lungs, and skin. A patient with third-degree AV block caused by digitalis toxicity may be stable; another patient with the same rhythm caused by acute MI may be unstable. Health care providers must always keep in mind the need to treat the patient, not the rhythm. The treatment is based on the hemodynamic effect of the rhythm.

First-Degree Atrioventricular Block

First-degree AV block occurs when all the atrial impulses are conducted through the AV node into the ventricles at a rate slower than normal. This conduction disorder has the following characteristics (see Fig. 22-19):

Ventricular and atrial rate: Depends on the underlying rhythm

Ventricular and atrial rhythm: Depends on the underlying rhythm

QRS shape and duration: Usually normal, but may be abnormal

P wave: In front of the QRS complex; shows sinus rhythm, regular shape

PR interval: Greater than 0.20 seconds; PR interval measurement is constant.

P:QRS ratio: 1:1

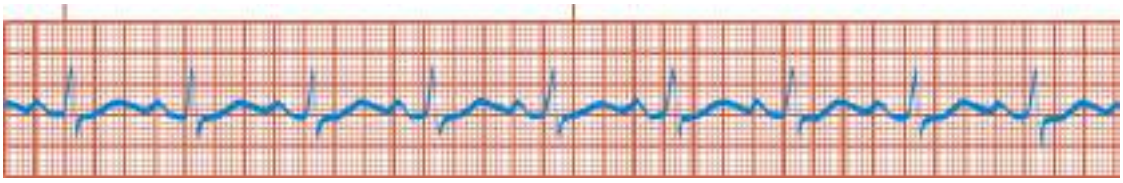

Figure 22-19 • First-degree atrioventricular block. Note that the PR interval is constant but greater than 0.20 seconds. Reprinted with permission from Huff, J. (2002). *ECG Workout* (4th ed., p. 150). Philadelphia, PA: Lippincott, Williams & Wilkins.

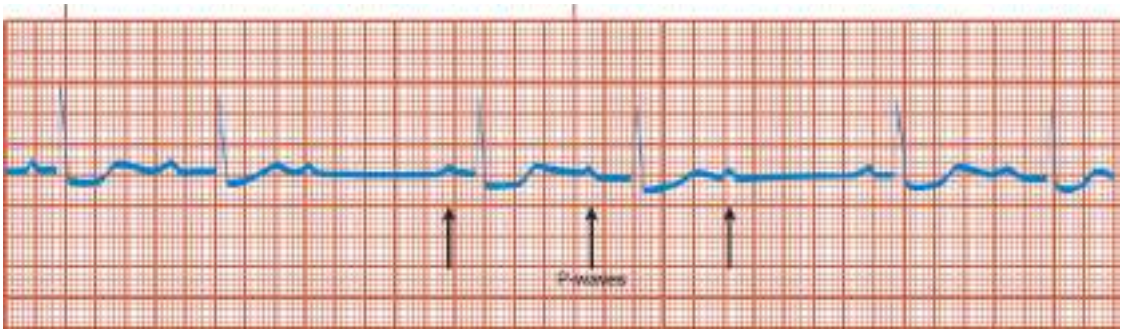

Figure 22-20 • Second-degree atrioventricular block, type I. Note progressively longer PR durations until there is a nonconducted P wave. Reprinted with permission from Huff, J. (2017). *ECG Workout: Exercises in Arrhythmia Interpretation* (7th ed., Fig. 8-20). Philadelphia, PA: Wolters Kluwer.

Second-Degree Atrioventricular Block, Type I (Wenckebach)

Second-degree AV block, type I, occurs when there is a repeating pattern in which all but one of a series of atrial impulses are conducted through the AV node into the ventricles (e.g., every four of five atrial impulses are conducted). Each atrial impulse takes a longer time for conduction than the one before, until one impulse is fully blocked. Because the AV node is not depolarized by the blocked atrial impulse, the AV node has time to fully repolarize so that the next atrial impulse can be conducted within the shortest amount of time. Second-degree AV block, type I, has the following characteristics (see Fig. 22-20):

Ventricular and atrial rate: Depends on the underlying rhythm, but the ventricular rate is lower than the atrial rate

Ventricular and atrial rhythm: The PP interval is regular if the patient has an underlying normal sinus rhythm; the RR interval characteristically reflects a pattern of change. Starting from the RR that is the longest, the RR interval gradually shortens until there is another long RR interval

QRS shape and duration: Usually normal, but may be abnormal

P wave: In front of the QRS complex; shape depends on underlying rhythm.

PR interval: The PR interval becomes longer with each succeeding ECG complex until there is a P wave not followed by a QRS. The changes in the PR interval are repeated between each "dropped" QRS, creating a pattern in the irregular PR interval measurements

P:QRS ratio: 3:2, 4:3, 5:4, and so forth

Second-Degree Atrioventricular Block, Type II

Second-degree AV block, type II, occurs when only some of the atrial impulses are conducted through the AV node into the ventricles. Second-degree AV block, type II, has the following characteristics (see Fig. 22-21):

Ventricular and atrial rate: Depends on the underlying rhythm, but the ventricular rate is lower than the atrial rate

Ventricular and atrial rhythm: The PP interval is regular if the patient has an underlying normal sinus rhythm. The RR interval is usually regular but may be irregular, depending on the P:QRS ratio

QRS shape and duration: Usually abnormal, but may be normal

P wave: In front of the QRS complex; shape depends on underlying rhythm

PR interval: The PR interval is constant for those P waves just before QRS complexes

P:QRS ratio: 2:1, 3:1, 4:1, 5:1, and so forth

Third-Degree Atrioventricular Block

Third-degree AV block occurs when no atrial impulse is conducted through the AV node into the ventricles. In third-degree AV block, two impulses stimulate the heart: one stimulates the ventricles, represented by the QRS complex, and one stimulates the atria, represented by the P wave. P waves may be seen, but the atrial electrical activity is not conducted down into the ventricles to initiate the QRS complex, the ventricular electrical activity. Having two impulses stimulate the heart results in a condition referred to as AV dissociation, which may also occur during VT. Complete block (third-degree AV block) has the following characteristics (see Fig. 22-22):

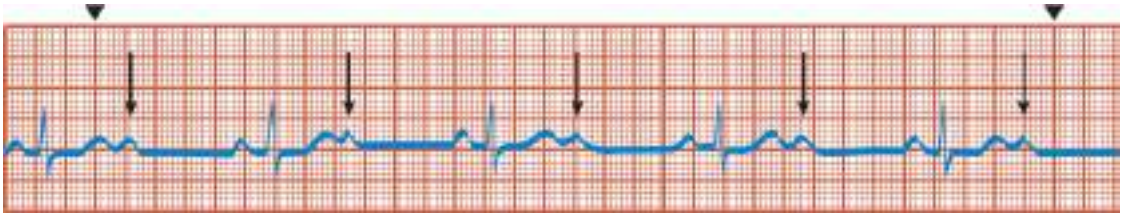

Figure 22-21 • Second-degree atrioventricular block, type II. Note constant PR interval and presence of more P waves than QRS complexes. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-29C). Philadelphia, PA: Wolters Kluwer.

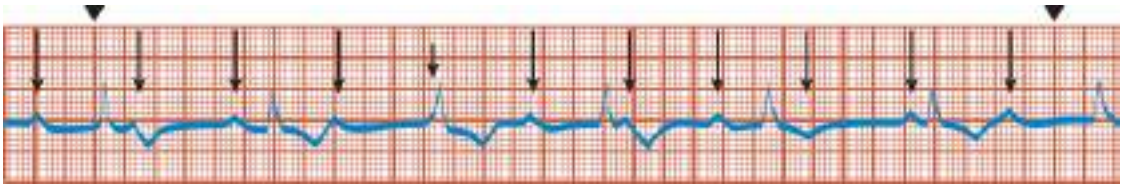

Figure 22-22 • Third-degree atrioventricular block; devoid relationship between P waves and QRS complexes. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 17-29D). Philadelphia, PA: Wolters Kluwer.

Ventricular and atrial rate: Depends on the escape rhythm (idionodal or idioventricular) and underlying atrial rhythm, but the ventricular rate is lower than the atrial rate

Ventricular and atrial rhythm: The PP interval is regular and the RR interval is regular, but the PP interval is not equal to the RR interval

QRS shape and duration: Depends on the escape rhythm; with junctional rhythm, QRS shape and duration are usually normal; with idioventricular rhythm, QRS shape and duration are usually abnormal

P wave: Depends on underlying rhythm

PR interval: Very irregular

P:QRS ratio: More P waves than QRS complexes

Medical Management of Conduction Abnormalities

Based on the cause of the AV block and the stability of the patient, treatment is directed toward increasing the heart rate to maintain a normal cardiac output. If the patient is stable and has no symptoms, no treatment may be indicated or it may simply consist of decreasing or eliminating the cause (e.g., withholding the medication or treatment). If the causal medication is necessary for treating other conditions and no effective alternative is available, pacemaker implantation may be indicated. The initial treatment of choice is an IV bolus of

atropine, although it is not effective in second-degree AV block, type II, or third-degree AV block. If the patient does not respond to atropine, has advanced AV block, or has had an acute MI, temporary transcutaneous pacing may be started. If the patient has no pulse, treatment is the same as for ventricular asystole (Link et al., 2015; Soar et al., 2018). A permanent pacemaker may be necessary if the block persists (see later discussion).

NURSING PROCESS

The Patient with an Arrhythmia

Assessment

Major areas of assessment include possible causes of the arrhythmia, contributing factors, and the arrhythmia's effect on the heart's ability to pump an adequate blood volume. When cardiac output is reduced, the amount of oxygen reaching the tissues and vital organs is diminished. This diminished oxygenation produces the signs and symptoms associated with arrhythmias. If these signs and symptoms are severe or if they occur frequently, the patient may experience significant distress and disruption of daily life.

A health history is obtained to identify any previous occurrences of decreased cardiac output, such as syncope, lightheadedness, dizziness, fatigue, chest discomfort, and palpitations. Possible causes of the arrhythmia (e.g., heart disease, chronic obstructive pulmonary disease) need to be identified. All medications, prescribed and over-the-counter (including herbs and nutritional supplements), as well as the route of administration, are reviewed. If a patient is taking an antiarrhythmic medication, assessment for treatment adherence, side effects, adverse reactions, and potential contraindications is necessary. For example, some medications (e.g., digoxin) can cause arrhythmias. Laboratory results are reviewed to assess levels of medications as well as factors that could contribute to the arrhythmia (e.g., anemia). A thorough psychosocial assessment is performed to identify the possible effects of the arrhythmia, the patient's perception and understanding of the arrhythmia and its treatment, and whether anxiety is a significant contributing factor.

The nurse conducts a physical assessment to confirm the data obtained from the history and to observe for signs of diminished cardiac output during the arrhythmic event, especially changes in level of consciousness. The nurse assesses the patient's skin, which may be pale and cool. Signs of fluid retention, such as neck vein distention and crackles and wheezes auscultated in the lungs, may be detected. The rate and rhythm of apical and peripheral pulses are also assessed, and any pulse deficit is noted. The nurse auscultates for extra heart sounds (especially S_3 and S_4) and for heart murmurs, measures blood pressure, and determines pulse pressures. A declining pulse pressure indicates reduced cardiac output. One assessment may not disclose significant changes in cardiac output; therefore, the nurse compares multiple assessment findings over time, especially those that occur with and without the arrhythmia.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include:

- Impaired cardiac output associated with inadequate ventricular filling or altered heart rate
- Anxiety associated with fear of the unknown outcome of altered health state
- Lack of knowledge about the arrhythmia and its treatment

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Cardiac arrest (see Chapter 25)
- Heart failure (see Chapter 25)
- Thromboembolic event, especially with atrial fibrillation (see Chapter 26)

Planning and Goals

The major goals for the patient may include eliminating or decreasing the occurrence of the arrhythmia (by decreasing contributory factors) to maintain cardiac output; verbalizing reduction in anxiety; verbalizing an understanding about the arrhythmia, tests used to diagnose the problem, and its treatment; and developing or maintaining self-management skills.

Nursing Interventions

Monitoring and Managing the Arrhythmia to Maintain Cardiac Output

The nurse evaluates the patient's blood pressure, pulse rate and rhythm, rate and depth of respirations, and breath sounds on an ongoing basis to determine the arrhythmia's hemodynamic effect. The nurse also asks the patient about possible symptoms of the arrhythmia (e.g., episodes of lightheadedness, dizziness, or fainting) as part of the ongoing assessment. If a patient with an arrhythmia is hospitalized, the nurse may obtain a 12-lead ECG, continuously monitor the patient, and analyze rhythm strips to track the arrhythmia.

Control of the occurrence or the effect of the arrhythmia, or both, is often achieved with antiarrhythmic medications. The nurse assesses and observes for the benefits and adverse effects of each medication. The nurse, in collaboration with the primary provider, also manages medication administration carefully so that a constant serum level of the medication is maintained. The nurse may also conduct a 6-minute walk test as prescribed, which is used to identify the patient's ventricular rate in response to exercise. The patient is asked to walk for 6 minutes, covering as much distance as possible (Chen, Chen, Lu, et al., 2018). The nurse monitors the patient for symptoms. At the end, the nurse records the distance covered and the pre- and postexercise heart rate as well as the patient's response.

The nurse assesses for factors that contribute to the arrhythmia (e.g., oxygen deficits, acid–base and electrolyte imbalances, caffeine, or

nonadherence to the medication regimen). The nurse also monitors for ECG changes (e.g., widening of the QRS, prolongation of the QT interval, increased heart rate) that increase the risk of an arrhythmic event.

Reducing Anxiety

When the patient experiences episodes of arrhythmia, the nurse stays with the patient and provides assurance of safety and security while maintaining a calm and reassuring attitude. This assists in reducing anxiety (reducing the sympathetic response) and fosters a trusting relationship with the patient. The nurse seeks the patient's view of the events and discusses the emotional response to the arrhythmia, encouraging verbalization of feelings and fears, providing supportive or empathetic statements, and assisting the patient to recognize feelings of anxiety, anger, or sadness. The nurse emphasizes successes with the patient to promote a sense of self-management of the arrhythmia. For example, if a patient is experiencing episodes of arrhythmia and a medication is given that begins to reduce the incidence of the arrhythmia, the nurse communicates that information to the patient and explores the patient's response to this information. In addition, the nurse can help the patient develop a system to identify possible causative, influencing, and alleviating factors (e.g., keeping a diary). The nursing goal is to maximize the patient's control and to make the episode less threatening.

Promoting Home, Community-based, and Transitional Care

Educating Patients About Self-Care. When educating patients about arrhythmias, the nurse first assesses the patient's understanding, clarifies misinformation, and then shares needed information in terms that are understandable and in a manner that is not frightening or threatening. The nurse clearly explains the etiology of the arrhythmia and treatment options to the patient and family. If necessary, the nurse explains the importance of maintaining therapeutic serum levels of antiarrhythmic medications so that the patient understands why medications should be taken regularly each day and the importance of regular blood testing. If the medication has the potential to alter the heart rate, the patient should be taught how to take their pulse before each dose and to notify the primary provider if the pulse is abnormal. In addition, the relationship between an arrhythmia and cardiac output is explained so that the patient recognizes symptoms of the arrhythmia and the rationale for the treatment regimen. If the patient is prescribed an anticoagulant medication, patient education points about taking anticoagulant medications are summarized in Chapter 26, Chart 26-10. The patient and family need to be educated about measures to take to decrease the risk of recurrence of the arrhythmia. If the patient has a potentially lethal arrhythmia, the nurse establishes with the

patient and family a plan of action to take in case of an emergency and, if appropriate, encourages a family member to obtain CPR training.

The patient and family should also be educated about potential risks of the arrhythmia and their signs and symptoms. For example, the patient with atrial fibrillation should be educated about the possibility of an embolic event.

Continuing and Transitional Care. A referral for home, community-based, or transitional care usually is not necessary for the patient with an arrhythmia unless the patient is hemodynamically unstable and has significant symptoms of decreased cardiac output. Home, community-based, or transitional care may be warranted if the patient has significant comorbidities, socioeconomic issues, or limited self-management skills that could increase the risk of nonadherence to the therapeutic regimen. A referral may also be indicated if the patient has had an electronic device implanted recently.

Evaluation

Expected patient outcomes may include:

1. Maintains cardiac output
   a. Demonstrates heart rate, blood pressure, respiratory rate, and level of consciousness within normal ranges
   b. Demonstrates no or decreased episodes of arrhythmia
2. Experiences reduced anxiety
   a. Expresses a positive attitude about living with the arrhythmia
   b. Expresses confidence in ability to take appropriate actions in an emergency
3. Expresses understanding of the arrhythmia and its treatment
   a. Explains the arrhythmia and its effects
   b. Describes the medication regimen and its rationale
   c. Explains the need to maintain a therapeutic serum level of the medication
   d. Describes a plan to eliminate or limit factors that contribute to the arrhythmia
   e. States actions to take in the event of an emergency

ADJUNCT MODALITIES AND MANAGEMENT

Arrhythmia treatments depend on whether the disorder is acute or chronic, as well as on the cause of the arrhythmia and its actual or potential hemodynamic effects.

Acute arrhythmias may be treated with medications or with external electrical therapy (emergency defibrillation, cardioversion, or pacing). Many antiarrhythmic medications are used to treat atrial and ventricular tachyarrhythmias (see Table 22-1). The choice of medication depends on the specific arrhythmia and its duration, the presence of structural heart disease (e.g., heart failure), and the patient's response to previous treatment. The nurse is responsible for monitoring and documenting the patient's responses to the medication and for ensuring that the patient has the knowledge and ability to manage the medication regimen.

If medications alone are ineffective in eliminating or decreasing the arrhythmia, certain adjunct mechanical therapies are available. The most common therapies are elective cardioversion and defibrillation for acute tachyarrhythmia, and implantable electronic devices for bradycardias (pacemakers) and chronic tachyarrhythmias (ICDs). Surgical treatments, although less common, are also available. The nurse is responsible for assessing the patient's understanding of and response to mechanical therapy, as well as the patient's self-management abilities. The nurse explains that the purpose of the device is to help the patient lead a life that is as active and productive as possible.

Cardioversion and Defibrillation

Cardioversion and defibrillation are used to treat tachyarrhythmias by delivering an electrical current that depolarizes a critical mass of myocardial cells. When the cells repolarize, the SA node is usually able to recapture its role as the heart's pacemaker.

Concept Mastery Alert

One major difference between cardioversion and defibrillation is the timing of the delivery of electrical current. In cardioversion, the delivery of the electrical current is synchronized with the patient's electrical events; in defibrillation, the delivery of the current is immediate and unsynchronized.

The same type of device, called a *defibrillator,* is used for both cardioversion and defibrillation. The electrical voltage required to defibrillate the heart is usually greater than that required for cardioversion and may cause more myocardial damage. Only biphasic types of defibrillators are now manufactured; these deliver an electrical charge from one paddle that then automatically redirects its charge back to the originating paddle. Because the delivery of the electrical charge varies among devices, the manufacturer's

recommended dose should be followed for the first and subsequent defibrillations (Link et al., 2015; Soar et al., 2018).

Figure 22-23 • Standard paddle placement for defibrillation.

The electrical current may be delivered externally through the skin with the use of paddles or with conductor pads. The paddles or pads may be placed on the front of the chest (standard placement) (see Fig. 22-23), or one pad may be placed on the front of the chest and the other pad placed under the patient's back just left of the spine (anteroposterior placement) (see Fig. 22-24).

Defibrillator multifunction conductor pads contain a conductive medium and are connected to the defibrillator to allow for hands-off defibrillation. This method reduces the risk of touching the patient during the procedure and increases electrical safety. Automated external defibrillators (AEDs), which are now found in many public areas, use this type of delivery for the electrical current.

Quality and Safety Nursing Alert

When using paddles, the appropriate conductant is applied between the paddles and the patient's skin. Any other type of conductant, such as ultrasound gel, should not be substituted.

Whether using pads or paddles, the nurse must observe two safety measures. First, good contact must be maintained between the pads or paddles and the patient's skin (with a conductive medium between them) to prevent electrical current from leaking through the air (arcing) when the defibrillator is

discharged. Second, no one is to be in contact with the patient or with anything that is touching the patient when the defibrillator is discharged, to minimize the chance that electrical current is conducted to anyone other than the patient. Chart 22-5 provides a review of nursing responsibility when a patient is cardioverted or defibrillated.

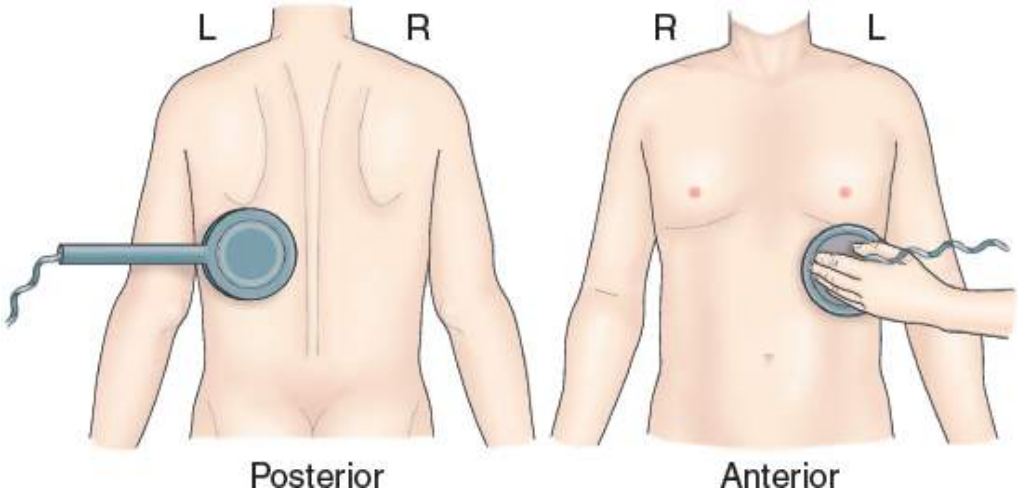

Figure 22-24 • Anteroposterior paddle placement for defibrillation.

Chart 22-5

Assisting with External Defibrillation or Cardioversion

When assisting with external defibrillation or cardioversion, the nurse should remember these key points:

- Multifunction conductor pads or paddles are used, with a conducting medium between the paddles and the skin in the proper locations. The conducting medium is available as a sheet, gel, or paste. Gels or pastes with poor electrical conductivity (e.g., ultrasound gel) should not be used.
- Paddles or pads should be placed so that they do not touch the patient's clothing or bed linen and are not near medication patches or in the direct flow of oxygen.
- Women with large breasts should have the left pad or paddle placed underneath or lateral to the left breast.
- During cardioversion, the monitor leads must be attached to the patient in order to set the defibrillator to the synchronized mode ("in sync"). If defibrillating, the defibrillator must *not* be in the synchronized mode (most machines default to the "not-sync" mode).
- When using paddles, 20–25 lb of pressure must be used in order to ensure good skin contact.
- When using a manual discharge device, it must not be charged until it is ready to shock; then thumbs and fingers must be kept off the discharge buttons until paddles or pads are on the chest and ready to deliver the electrical charge.
- When it is time to defibrillate, whomever is delivering the charge should announce, "charging to (number of joules)" prior to discharging.
- "Clear!" must be called three times before discharging: As "Clear" is called the first time, the discharger must visually check that they are not touching the patient, bed, or equipment; as "Clear" is called the second time, the discharger must visually check that no one else is touching the bed, the patient, or equipment, including the endotracheal tube or adjuncts; and as "Clear" is called the third time, the discharger must perform a final visual check to ensure that everyone is clear of the patient and anything touching the patient.
- The delivered energy and resulting rhythm are recorded.
- Cardiopulmonary resuscitation (CPR) is immediately resumed after the defibrillation charge is delivered, if appropriate, starting with chest compressions.
- If CPR is necessary, after five cycles (about 2 minutes) of CPR, the cardiac rhythm is checked again and another shock is delivered, if warranted. A vasoactive or antiarrhythmic medication is given as soon as possible after the rhythm check to facilitate a positive response to defibrillation.
- After the event is complete, the skin under the pads or paddles is inspected for burns; if any are detected, the primary provider or a wound care nurse is consulted about appropriate treatment.

- The defibrillator is plugged back into an outlet, and supplies are restocked as needed.

Electrical Cardioversion

Electrical cardioversion involves the delivery of a "timed" electrical current to terminate a tachyarrhythmia. In cardioversion, the defibrillator is set to synchronize with the ECG on a cardiac monitor so that the electrical impulse discharges during ventricular depolarization (QRS complex). The synchronization prevents the discharge from occurring during the vulnerable period of repolarization (T wave), which could result in VT or ventricular fibrillation. The ECG monitor connected to the external defibrillator usually displays a mark or line that indicates sensing of a QRS complex. Sometimes the lead and the electrodes must be changed for the monitor to recognize the patient's QRS complex. When the synchronizer is on, no electrical current is delivered if the defibrillator does not discern a QRS complex. Therefore, it is important to ensure that the patient is connected to the monitor and to select a lead (not "paddles") that has the most appropriate sensing of the QRS. Because there may be a short delay until recognition of the QRS, the discharge buttons of an external manual defibrillator must be held down until the shock has been delivered. In most monitors, the synchronization mode must be reactivated if the initial cardioversion was ineffective and another cardioversion is needed (i.e., the device defaults to unsynchronized defibrillation mode).

If the cardioversion is elective and the arrhythmia has lasted longer than 48 hours, anticoagulation for a few weeks before cardioversion may be indicated (January et al., 2014, 2019). Digoxin is usually withheld for 48 hours before cardioversion to ensure the resumption of sinus rhythm with normal conduction. The patient is instructed not to eat or drink for at least 4 hours before the procedure. Gel-covered paddles or conductor pads are positioned anteroposteriorly (front and back) for cardioversion. Before cardioversion, the patient receives moderate sedation IV as well as an analgesic medication or anesthesia. Respiration is then supported with supplemental oxygen delivered by a bag-valve mask device with suction equipment readily available. Although patients rarely require intubation, equipment is nearby in case it is needed. The amount of voltage used varies from 50 to 360 joules, depending

on the defibrillator's technology, the type and duration of the arrhythmia, and the size and hemodynamic status of the patient (Link et al., 2015; Soar et al., 2018).

Indications of a successful response are conversion to sinus rhythm, adequate peripheral pulses, and adequate blood pressure. Because of the sedation, airway patency must be maintained and the patient's state of consciousness assessed. Vital signs and oxygen saturation are monitored and recorded until the patient is stable and recovered from sedation and analgesic medications or anesthesia. ECG monitoring is required during and after cardioversion (Link et al., 2015; Soar et al., 2018).

Defibrillation

Defibrillation is used in emergency situations as the treatment of choice for ventricular fibrillation and pulseless VT, the most common cause of abrupt loss of cardiac function and sudden cardiac death. Defibrillation is not used for patients who are conscious or have a pulse. The energy setting for the initial and subsequent shocks using a monophasic defibrillator should be set at 360 joules (Link et al., 2015; Soar et al., 2018). The energy setting for the initial shock using a biphasic defibrillator may be set at 150 to 200 joules, with the same or an increasing dose with subsequent shocks (Link et al., 2015; Soar et al., 2018). The sooner defibrillation is used, the better the survival rate (Hedge & Gnugnoli, 2019). Several studies have demonstrated that early defibrillation performed by lay people in a community setting can increase the survival rate (Hedge & Gnugnoli, 2019). If immediate CPR is provided and defibrillation is performed within 5 minutes, more adults in ventricular fibrillation may survive with intact neurologic function (Link et al., 2015; Soar et al., 2018). The availability and the use of AEDs in public places can shorten the interval from collapse to rhythm recognition and defibrillation, which can significantly improve survival out of the hospital (Hedge & Gnugnoli, 2019).

Epinephrine is given after initial unsuccessful defibrillation to make it easier to convert the arrhythmia to a normal rhythm with the next defibrillation. This medication may also increase cerebral and coronary artery blood flow. Antiarrhythmic medications such as amiodarone, lidocaine, or magnesium may be given if ventricular arrhythmia persists (see Table 22-1). This treatment with continuous CPR, medication administration, and defibrillation continues until a stable rhythm resumes or until it is determined that the patient cannot be revived.

Electrophysiology Studies

An EPS is an invasive procedure used to evaluate and treat various chronic arrhythmias that have caused cardiac arrest or significant symptoms. It also is indicated for patients with symptoms that suggest an arrhythmia that has gone undetected and undiagnosed by other methods. Because an EPS is invasive, it is performed in the hospital and may require that the patient be admitted. An EPS is used to do the following:

- Identify the impulse formation and propagation through the cardiac electrical conduction system
- Assess the function or dysfunction of the SA and AV nodal areas
- Identify the location (called *mapping*) and mechanism of the arrhythmogenic foci (the exact site where the arrhythmia originates)
- Assess the effectiveness of antiarrhythmic medications and devices for the patient with an arrhythmia
- Treat certain arrhythmias through the destruction of the causative cells (ablation)

An EPS procedure is a type of cardiac catheterization that is performed in a specially equipped cardiac catheterization laboratory by an electrophysiologist, assisted by other EPS laboratory personnel. The patient is conscious but lightly sedated. Usually, one or more catheters are inserted into the groin, neck, or antecubital fossa. The electrodes are positioned within the heart at specific locations—for instance, in the right atrium near the sinus node, in the coronary sinus, near the tricuspid valve, and at the apex of the right ventricle. The number and placement of electrodes depend on the type of study being conducted. These electrodes allow the electrical signal to be recorded from within the heart (intracardiogram).

The electrodes also allow the electrophysiologist to introduce a pacing stimulus to the intracardiac area at a precisely timed interval and rate, thereby stimulating the area (programmed stimulation). An area of the heart may be paced at a rate much faster than the normal rate of **automaticity**, the rate at which impulses are spontaneously formed (e.g., in the sinus node). This allows the pacemaker to become an artificial focus of automaticity and to assume control (overdrive suppression). Then, the pacemaker is stopped suddenly, and the time it takes for the sinus node to resume control is assessed. A prolonged time indicates dysfunction of the sinus node.

One of the main purposes of programmed stimulation is to assess the ability of the area surrounding the electrode to cause a reentry arrhythmia. One or a series of premature impulses is delivered to an area in an attempt to cause the tachyarrhythmia. Because the precise location of the suspected area and the specific timing of the pacing needed are unknown, the electrophysiologist uses many different techniques to cause the arrhythmia during the study. If the arrhythmia can be reproduced by programmed stimulation, it is called *inducible.* Once an arrhythmia is induced, a treatment plan is determined and

implemented. If, on the follow-up EPS, the tachyarrhythmia cannot be induced, then the treatment is determined to be effective. Different medications may be given and combined with cardiac implantable electronic devices to determine the most effective treatment to suppress the arrhythmia.

Patient care, patient education, and associated complications of an EPS are similar to those associated with cardiac catheterization (see Chapter 21). The study is usually about 2 hours in length; however, if the electrophysiologist conducts not only a diagnostic procedure but also treatment, the study can take up to 6 hours. During the procedure, patients benefit from a calm, reassuring approach.

Patients who are to undergo an EPS may be anxious about the procedure and its outcome. A detailed discussion involving the patient, the family, and the electrophysiologist usually occurs to ensure that the patient can give informed consent and to reduce the patient's anxiety about the procedure. Before the procedure, the nurse educates the patient about the EPS and its usual duration, the environment where the procedure is performed, and what to expect. Although an EPS is not painful, it does cause discomfort and can be tiring. It may also cause feelings that were experienced when the arrhythmia occurred in the past. In addition, patients are educated about what will be expected of them (e.g., lying very still during the procedure, reporting symptoms or concerns).

The patient should also know that the arrhythmia may occur during the procedure. It often stops on its own; if it does not, treatment is given to restore the patient's normal rhythm. The arrhythmia may have to be terminated using cardioversion or defibrillation, but this is performed under more controlled circumstances than if performed in an emergency.

Postprocedural care is similar to that for cardiac catheterization, including restriction of activity to promote hemostasis at the insertion site (see Chapter 21). To identify any complications and to ensure healing, the patient's vital signs and the appearance of the insertion site are assessed frequently. Because an artery is not always used, there is a lower incidence of vascular complications than with other catheterization procedures (Zipes, Libby, Bonow, et al., 2018).

Pacemaker Therapy

A pacemaker is an electronic device that provides electrical stimuli to the heart muscle. Pacemakers are usually used when a patient has a permanent or temporary slower-than-normal impulse formation, or a symptomatic AV or ventricular conduction disturbance. They may also be used to control some tachyarrhythmias that do not respond to medication. Biventricular (both ventricles) pacing, also called **cardiac resynchronization therapy (CRT)**,

may be used to treat advanced heart failure. Pacemaker technology also may be used in conjunction with an ICD.

Pacemakers can be permanent or temporary. Temporary pacemakers are used to support patients until they improve or receive a permanent pacemaker (e.g., after acute MI or during open heart surgery). Temporary pacemakers are used only in hospital settings.

Pacemaker Design and Types

Pacemakers consist of two components: an electronic pulse generator and pacemaker electrodes, which are located on leads or wires. The generator contains the circuitry and batteries that determine the rate (measured in beats per minute) and the strength or output (measured in milliamperes [mA]) of the electrical stimulus delivered to the heart. The generator also has circuitry that can detect the intracardiac electrical activity to cause an appropriate response; this component of pacing is called *sensitivity* and is measured in millivolts (mV). Sensitivity is set at the level that the intracardiac electrical activity must exceed to be sensed by the device. Leads, which carry the impulse created by the generator to the heart, can be threaded by fluoroscopy through a major vein into the heart, usually the right atrium and ventricle (endocardial leads), or they can be lightly sutured onto the outside of the heart and brought through the chest wall during open heart surgery (epicardial wires). These epicardial pacemakers are typically temporary and are removed by a gentle tug a few days after surgery. The endocardial leads may be temporarily placed with catheters through a vein (usually the femoral, subclavian, or internal jugular vein [transvenous wires]), usually guided by fluoroscopy. The leads may also be part of a specialized pulmonary artery catheter (see Chapter 21). However, obtaining a pulmonary artery wedge pressure may cause the leads to move out of pacing position. The endocardial and epicardial wires are connected to a temporary generator, which is about the size of a cellular phone. The energy source for a temporary generator is a common household battery. Monitoring for pacemaker malfunctioning and battery failure is a nursing responsibility.

The endocardial leads also may be placed permanently, passed into the heart through the subclavian, axillary, or cephalic vein, and connected to a permanent generator. These types of pacemakers are sometimes also called transvenous pacemakers. Most current leads have a fixation mechanism (e.g., a screw) at the end of the lead that allows precise positioning and avoidance of dislodgement. The permanent generator, which often weighs less than 1 ounce and is the size of a pack of chewing gum, is usually implanted in a subcutaneous pocket created in the pectoral region, below the clavicle in men, or behind the breast in women (see Fig. 22-25). This procedure usually takes about 1 hour, and it is performed in a cardiac catheterization laboratory using a

local anesthetic and moderate sedation. Close monitoring of the respiratory status is needed until the patient is fully awake.

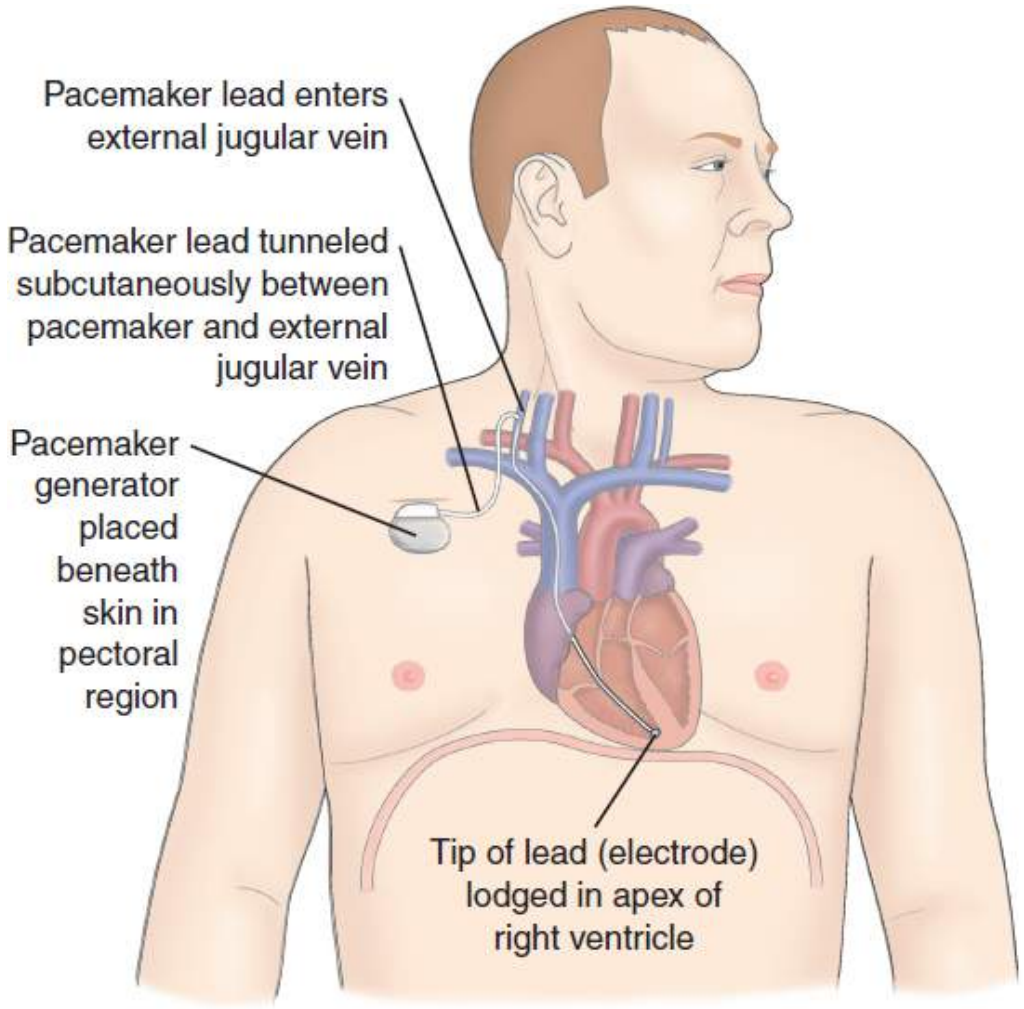

Figure 22-25 • Implanted transvenous pacing lead (with electrode) and pacemaker generator.

Leadless pacemakers, a newer type of permanent pacemaker, are 90% smaller than transvenous pacemakers. They feature a self-contained, single-unit pulse generator and electrode that is inserted transvenously directly into the right ventricle (Groner & Grippe, 2019; Hayes, 2018).

Permanent pacemaker generators are insulated to protect against body moisture and warmth and have filters that protect them from electrical interference from most household devices, motors, and appliances. Lithium cells are most commonly used; they last approximately 5 to 15 years, depending on the type of pacemaker, how it is programmed, and how often it is used. Most pacemakers have an elective replacement indicator (ERI), which is a signal that indicates when the battery is approaching depletion. The pacemaker continues to function for several months after the appearance of ERI to ensure that there is adequate time for a battery replacement. Although

some batteries are rechargeable, most are not. Because the battery is permanently sealed in the pacemaker, the entire generator must be replaced. To replace a failing generator of a transvenous pacemaker, the leads are disconnected, the old generator is removed, and a new generator is reconnected to the existing leads and reimplanted in the already existing subcutaneous pocket. Sometimes the leads are also replaced. When leadless pacemaker batteries signal that they must be replaced, a new system is simply implanted and the old battery is then disabled (Groner & Grippe, 2019). Battery replacement of both systems is usually performed using a local anesthetic. The patient usually can be discharged from the hospital the day of the procedure.

If a patient suddenly develops a bradycardia, is symptomatic but has a pulse, and is unresponsive to atropine, emergency pacing may be started with transcutaneous pacing, which most defibrillators are now equipped to perform. Some AEDs are able to do both defibrillation and transcutaneous pacing. Large pacing ECG electrodes (sometimes the same conductive pads used for cardioversion and defibrillation) are placed on the patient's chest and back. The electrodes are connected to the defibrillator, which is the temporary pacemaker generator (see Fig. 22-26). Because the impulse must travel through the patient's skin and tissue before reaching the heart, transcutaneous pacing can cause significant discomfort (burning sensation and involuntary muscle contraction) and is intended to be used only in emergencies for short periods of time. This type of pacing necessitates hospitalization. If the patient is alert, sedation and analgesia may be given. After transcutaneous pacing, the skin under the electrode should be inspected for erythema and burns. Transcutaneous pacing is not indicated for pulseless bradycardia (Link et al., 2015; Soar et al., 2018).

Pacemaker Generator Functions

Because of the sophistication and wide use of pacemakers, a universal code has been adopted to provide a means of safe communication about their function. The coding is referred to as the NASPE-BPEG code because it is sanctioned by the North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group. The complete code consists of five letters; the fourth and fifth letters are used only with permanent pacemakers (Bernstein, Daubert, Fletcher, et al., 2002; Mulpuru, Madhavan, McLeod, et al., 2017; Tracy, Epstein, Darbar, et al., 2012; see Chart 22-6).

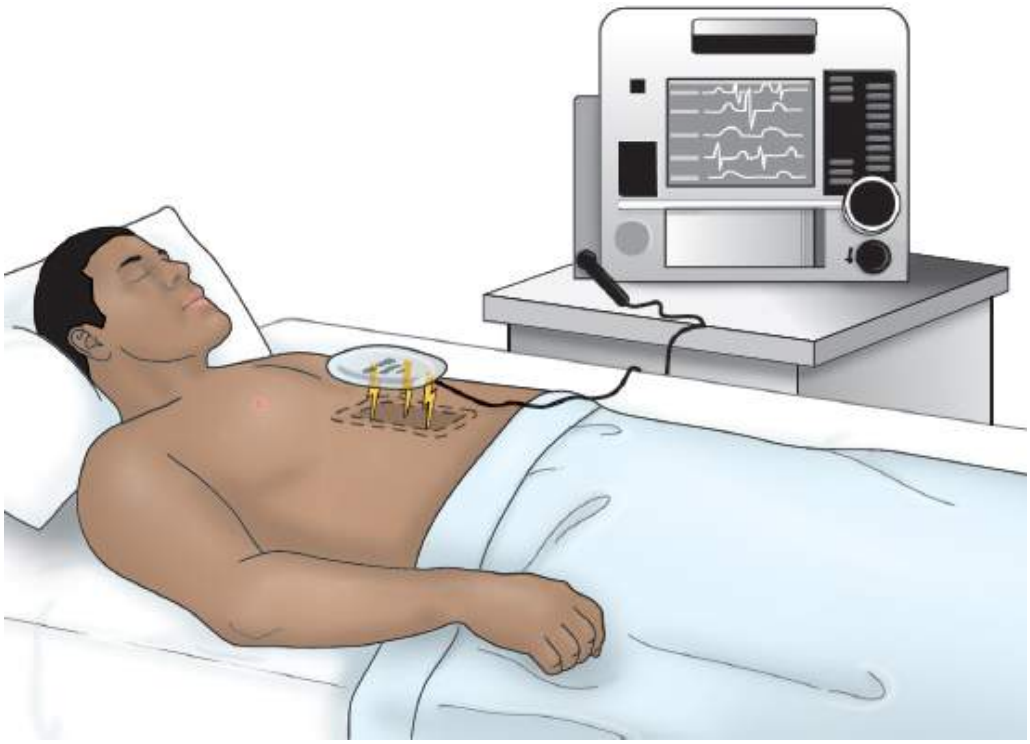

Figure 22-26 • Transcutaneous pacemaker with electrode pads connected to the anterior and posterior chest walls.

Chart 22-6

North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group Code (NASPE-BPEG Code) for Pacemaker Generator Function

- The first letter of the code identifies the chamber or chambers being paced (i.e., the chamber containing a pacing electrode). The letter characters for this code are A (atrium), V (ventricle), or D (dual, meaning both A and V).
- The second letter identifies the chamber or chambers being sensed by the pacemaker generator. Information from the electrode within the chamber is sent to the generator for interpretation and action by the generator. The letter characters are A (atrium), V (ventricle), D (dual), and O (indicating that the sensing function is turned off).
- The third letter of the code describes the type of response that will be made by the pacemaker to what is sensed. The letter characters used to describe this response are I (inhibited), T (triggered), D (dual—inhibited and triggered), and O (none). Inhibited response means that the response of the pacemaker is controlled by the activity of the patient's heart—that is, when the patient's heart beats, the pacemaker does not function, but when the heart does not beat, the pacemaker does function. In contrast, a triggered response means that the pacemaker responds (paces the heart) when it senses intrinsic heart activity.
- The fourth letter of the code is related to a permanent generator's ability to vary the heart rate. This ability is available in most current pacemakers. The possible letters are O, indicating no rate responsiveness, or R, indicating that the generator has rate modulation (i.e., the pacemaker has the ability to automatically adjust the pacing rate from moment to moment based on parameters, such as QT interval, physical activity, acid–base changes, body temperature, rate and depth of respirations, or oxygen saturation). A pacemaker with rate-responsive ability is capable of improving cardiac output during times of increased cardiac demand, such as exercise and decreasing the incidence of atrial fibrillation. All contemporary pacemakers have some type of sensor system that enables them to provide rate-adaptive pacing.
- The fifth letter of the code has two different indications: (1) that the permanent generator has multisite pacing capability with the letters A (atrium), V (ventricle), D (dual), and O (none); or (2) that the pacemaker has an antitachycardia function.
- Commonly, only the first three letters are used for a pacing code. An example of an NASPE-BPEG code is DVI:
  D: Both the atrium and the ventricle have a pacing electrode in place.
  V: The pacemaker is sensing the activity of the ventricle only.
  I: The pacemaker's stimulating effect is inhibited by ventricular activity—in other words, it does not create an impulse when the pacemaker

senses that the patient's ventricle is active.

Adapted from Bernstein, A. D., Daubert, J-C., Fletcher, R. D., et al. (2002). The revised NASPE/BPEG generic code for antibradycardia, adaptive-rate, and multisite pacing. Figure 22-27 • Pacemaker capture. **A.** Atrial pacemaker; note that each vertical pacemaker spike is followed by a P wave. **B.** Ventricular pacemaker; note that each vertical pacemaker spike is followed by a QRS complex. Reprinted with permission from Morton, G. M., & Fontaine, D. K. (2018). *Critical care nursing: A holistic approach* (11th ed., Fig. 18-34A and B). Philadelphia, PA: Wolters Kluwer.

The pacemaker paces the atrium and then the ventricle when no ventricular activity is sensed for a period of time (the time is individually programmed into the pacemaker for each patient). A straight vertical line usually can be seen on the ECG when pacing is initiated. The line that represents pacing is called a *pacemaker spike.* The appropriate ECG complex should immediately follow the pacing spike; therefore, a P wave should follow an atrial pacing spike (see Fig. 22-27A) and a QRS complex should follow a ventricular pacing spike (see Fig. 22-27B). Because the impulse starts in a different place than the patient's normal rhythm, the QRS complex or P wave that responds to pacing looks different from the patient's normal ECG complex. *Capture* is a term used to denote that the appropriate complex followed the pacing spike.

The type of pacemaker generator and the settings selected depend on the patient's arrhythmia, underlying cardiac function, and age. Pacemakers are

generally set to sense and respond to intrinsic activity, which is called *on-demand pacing*. If the pacemaker is set to pace but not to sense, it is called a *fixed* or *asynchronous pacemaker*; this is written in pacing code as AOO or VOO. The pacemaker paces at a constant rate, independent of the patient's intrinsic rhythm. VOO pacing may indicate battery failure.

VVI (V, paces the ventricle; V, senses ventricular activity; I, paces only if the ventricles do not depolarize) pacing causes loss of AV synchrony and atrial kick, which may cause a decrease in cardiac output and an increase in atrial distention and venous congestion. Pacemaker syndrome, causing symptoms such as chest discomfort, shortness of breath, fatigue, activity intolerance, and orthostatic hypotension, is most common with VVI pacing (Mulpuru et al., 2017; Tracy et al., 2012). Atrial pacing and dual-chamber (right atrial and RV) pacing have been found to reduce the incidence of atrial fibrillation, ventricular dysfunction, and heart failure (Mulpuru et al., 2017; Tracy et al., 2012).

Single-chamber atrial pacing (AAI) or dual-chamber pacing (DDD) is recommended over VVI in patients with sinus node dysfunction, the most common cause of bradycardias requiring a pacemaker, and a functioning AV node (Mulpuru et al., 2017; Tracy et al., 2012). AAI pacing ensures synchrony between atrial and ventricular stimulation (and therefore contraction), as long as the patient has no conduction disturbances in the AV node. Dual-chamber pacemakers are recommended as the treatment for patients with AV conduction disturbances (Mulpuru et al., 2017; Tracy et al., 2012).

Synchronized biventricular pacing, also called *cardiac resynchronization therapy (CRT),* is associated with improved mortality rates in patients with heart failure and in patients with left bundle branch block (Agrawal, 2018). Synchronized biventricular pacing features three leads: one for the right atrium; one for the right ventricle; and one for the left ventricle, usually placed in the left lateral wall. This therapy improves cardiac function, resulting in decreased heart failure symptoms and an improved quality of life. Biventricular pacing may be used with an ICD (Agrawal, 2018).

Complications of Pacemaker Use

Complications associated with pacemakers relate to their presence within the body and improper functioning (see Chart 22-7). In the initial hours after a temporary or permanent pacemaker is inserted, the most common complication is dislodgment of the pacing electrode. Minimizing patient activity can help prevent this complication. If a temporary electrode is in place, the extremity through which the catheter has been advanced is immobilized. With a permanent pacemaker, the patient is instructed initially to restrict activity on the side of the implantation.

Leadless pacemakers are associated with fewer complications than transvenous pacemakers, including fewer infections, hematomas, lead dislodgement, and lead fracture. However, they provide only single-chamber RV pacing and do not feature concomitant defibrillator capabilities, limiting their usefulness (Groner & Grippe, 2019; Hayes, 2018).

The ECG is monitored very carefully to detect pacemaker malfunction. Improper pacemaker function, which can arise from failure in one or more components of the pacing system, is outlined in Table 22-2. The following data should be noted on the patient's record: model of pacemaker, type of generator, date and time of insertion, location of pulse generator, stimulation threshold, and pacer settings (e.g., rate, energy output [mA], sensitivity [mV], and duration of interval between atrial and ventricular impulses [AV delay]). This information is important for identifying normal pacemaker function and diagnosing pacemaker malfunction.

Chart 22-7

Potential Complications from Insertion of a Pacemaker

- Local infection at the entry site of the leads for temporary pacing, or at the subcutaneous site for permanent generator placement. Prophylactic antibiotic and antibiotic irrigation of the subcutaneous pocket prior to generator placement has decreased the rate of infection to a minimal rate.
- Pneumothorax or hemothorax. The risk is reduced if cephalic vein cut down, contrast venography, or ultrasound guidance is utilized.
- Bleeding and hematoma at the lead entry sites for temporary pacing, or at the subcutaneous site for permanent generator placement. This usually can be managed with cold compresses and discontinuation of antiplatelet and antithrombotic medications.
- Ventricular ectopy and tachycardia from irritation of the ventricular wall by the endocardial electrode.
- Movement or dislocation of the lead placed transvenously (perforation of the myocardium).
- Phrenic nerve, diaphragmatic (hiccupping may be a sign), or skeletal muscle stimulation if the lead is dislocated or if the delivered energy (mA) is set high. The occurrence of this complication is avoided by testing during device implantation.
- Cardiac perforation resulting in pericardial effusion and, rarely, cardiac tamponade, which may occur at the time of implantation or months later. This condition can be recognized by the change in QRS complex morphology, diaphragmatic stimulation, or hemodynamic instability.
- Twiddler syndrome may occur when the patient manipulates the generator, causing lead dislodgement or fracture of the lead.
- Pacemaker syndrome (hemodynamic instability caused by ventricular pacing and the loss of AV synchrony).

A patient experiencing pacemaker malfunction may develop bradycardia as well as signs and symptoms of decreased cardiac output (e.g., diaphoresis, orthostatic hypotension, syncope). The degree to which these symptoms become apparent depends on the severity of the malfunction, the patient's level of dependency on the pacemaker, and the patient's underlying condition. Pacemaker malfunction is diagnosed by analyzing the ECG. Manipulating the electrodes, changing the generator's settings, or replacing the pacemaker generator or leads (or both) may be necessary.

TABLE 22-2 Assessing Pacemaker Malfunction

Problem	Possible Cause	Nursing Considerations
Loss of capture—complex does *not* follow pacing spike	Inadequate stimulus Lead dislodgement Lead wire fracture Catheter malposition Battery depletion Electronic insulation break Medication change Myocardial ischemia	Check security of all connections; increase milliamperage. Reposition extremity; turn patient to left side. Change battery. Change generator.
Undersensing—pacing spike occurs at preset interval despite the patient's intrinsic rhythm	Sensitivity too high Electrical interference (e.g., by a magnet) Faulty generator	Decrease sensitivity. Eliminate interference. Replace generator.
Oversensing—loss of pacing artifact; pacing does not occur at preset interval despite the lack of intrinsic rhythm	Sensitivity too low Electrical interference Battery depletion Change in medication	Increase sensitivity. Eliminate interference. Change battery.
Loss of pacing—total absence of pacing spikes	Oversensing Battery depletion Loose or disconnected wires Perforation	Change battery. Check security of all connections. Apply magnet over permanent generator. Obtain 12-lead ECG and portable chest x-ray. Assess for murmur. Contact physician.
Change in pacing QRS shape	Septal perforation	Obtain 12-lead ECG and portable chest x-ray. Assess for murmur. Contact physician.
Rhythmic diaphragmatic or chest wall twitching or hiccupping	Output too high Myocardial wall perforation	Decrease milliamperage. Turn pacer off. Contact physician at once. Monitor closely for decreased cardiac output.

ECG, electrocardiogram.

Adapted from Mulpuru, S. K., Madhavan, M., McLeod, C. J., et al. (2017). Cardiac pacemakers: Function, troubleshooting, and management: Part 1 of a 2-Part Series. *Journal of the American College of Cardiology*, *69*(2), 189–210.

Inhibition of permanent pacemakers or reversion to asynchronous fixed rate pacing can occur with exposure to strong electromagnetic fields (electromagnetic interference [EMI]). However, pacemaker technology allows patients to safely use most household electronic appliances and devices (e.g., microwave ovens, electric tools). Gas-powered engines should be turned off before working on them. Objects that contain magnets (e.g., the earpiece of a phone, large stereo speakers, jewelry) should not be near the generator for longer than a few seconds. Patients are advised to place digital cellular phones at least 6 to 12 inches away from (or on the side opposite of) the pacemaker generator and not to carry them in a shirt pocket. Large electromagnetic fields, such as those produced by magnetic resonance imaging (MRI), radio and television transmitter towers and lines, transmission power lines (not the distribution lines that bring electricity into a home), and electrical substations may cause EMI. Patients should be cautioned to avoid such situations or to simply move farther away from the area if they experience dizziness or a feeling of rapid or irregular heartbeats (palpitations). Welding and the use of a chain saw should be avoided. If such tools are used, precautionary steps such as limiting the welding current to a 60- to 130-ampere range or using electric rather than gasoline-powered chain saws are advised.

In addition, the metal of the pacemaker generator may trigger store and library antitheft devices as well as airport and building security alarms; however, these alarm systems generally do not interfere with the pacemaker function. Patients should walk through them quickly and avoid standing in or near these devices for prolonged periods of time. The handheld screening devices used in airports may interfere with the pacemaker. Patients should be advised to ask security personnel to perform a hand search instead of using the handheld screening device. Patients also should be educated to wear or carry medical identification to alert personnel to the presence of the pacemaker.

Pacemaker Surveillance

Remote monitoring technology is now routinely embedded in the pacemaker so that it replaces the need for frequent in-person follow-up cardiologist visits; this is also associated with improved survival (Costa, Yeung, Gilbert, et al., 2018). Remote monitoring systems in use include transtelephonic monitoring (use of an analog phone with transmission through a landline), inductive monitoring (use of a wand with transmission through a landline or a cellular connection), and remote wandless monitoring (use of wandless transmitter through radiofrequency) (Madhavan, Mulpuru, McLeod, et al., 2017). Remote monitoring allows pertinent information, such as ECG data, to be transmitted to the primary provider at the cardiology clinic. In addition, the pacemaker rate and other data concerning pacemaker function (e.g., generator setting, battery status, sensing function, lead integrity, pacing data, such as number of pacing

events) are obtained and evaluated by the cardiologist. This simplifies the diagnosis of a failing generator, reassures the patient, and improves management when the patient is physically remote from pacemaker testing facilities. A follow-up schedule is variable, and is dependent upon the patient's needs and the pacemaker in use; the system is setup for maintenance checks on an annual basis.

Implantable Cardioverter Defibrillator

The **implantable cardioverter defibrillator (ICD)** is an electronic device that detects and terminates life-threatening episodes of tachycardia or fibrillation, especially those that are ventricular in origin. Patients at high risk of VT or ventricular fibrillation and who would benefit from an ICD are those who have survived sudden cardiac death, which usually is caused by ventricular fibrillation, or have experienced spontaneous, symptomatic VT (syncope secondary to VT) not due to a reversible cause (called a *secondary prevention intervention*). Patients with coronary artery disease who are 40 days postacute MI with moderate to severe LV dysfunction (ejection fraction less than or equal to 35%) are at risk of sudden cardiac death and therefore an ICD is indicated (called a *primary prevention intervention*). An ICD implantation is also recommended in patients who have been diagnosed with nonischemic dilated cardiomyopathy for at least 9 months and have functional NYHA Class II or III heart failure (Wilkoff, Fauchier, Stiles, et al., 2015) (see Chapter 25, Table 25-1) (Al-khatib et al., 2018; Ganz, 2019).

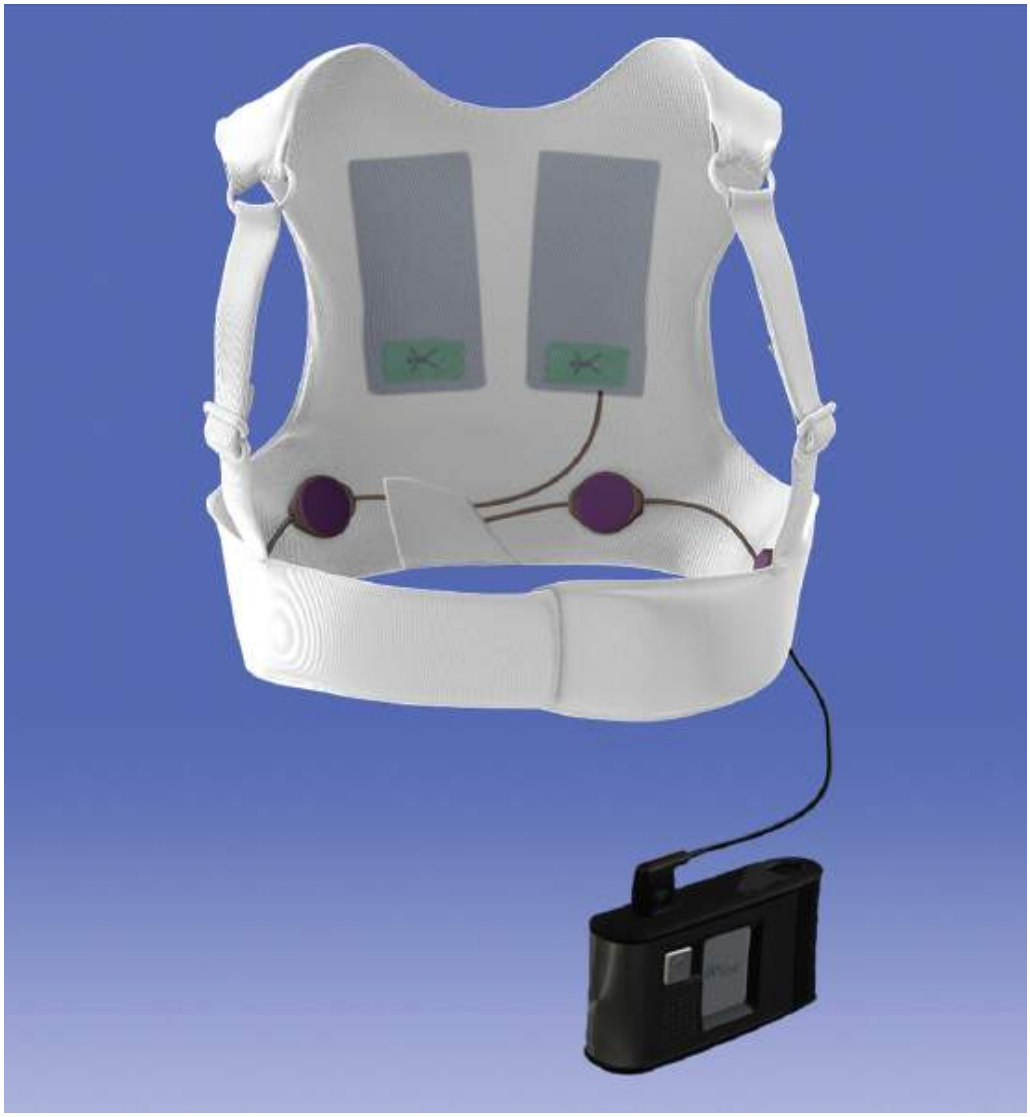

Figure 22-28 • The wearable cardioverter defibrillator vest. Courtesy of ZOLL LifeVest.

Because there may be a waiting period for ICD implantation, especially those postacute MI, patients who are at risk for sudden cardiac death may be prescribed a wearable vestlike automated defibrillator, which works just like an AED in that a shock is delivered less than a minute after a life-threatening rhythm is detected (National Heart, Lung, and Blood Institute [NHLBI], 2019; see Fig. 22-28). Prior to the delivery of the shock, the vest vibrates and issues an alarm to announce that a shock is imminent. The vest weighs about a pound, is worn under the patient's clothing, and is attached to a monitor with a battery that is worn in a holster or on a shoulder strap. The monitor automatically downloads information once a day, usually in the middle of the night. The vest must be worn at all times, even if the patient is admitted to the hospital and placed on an ECG monitor, and removed only when showering or bathing. The battery needs to be changed every day. Education is provided to

the patient by the device manufacturer. However, the nurse should assess the patient's understanding of the education provided and explore any issues that may prevent the patient from wearing it.

An ICD has a generator about the size of a pack of chewing gum that is implanted in a subcutaneous pocket, usually in the upper chest wall. An ICD also has at least an RV lead that is implanted transvenously and can sense intrinsic electrical activity and deliver an electrical impulse. The implantation procedure, postimplantation care, and length of hospital stay are much like those for insertion of a pacemaker (see Fig. 22-29).

ICDs are designed to respond to two criteria: a rate that exceeds a predetermined level and a change in the isoelectric line segments. When an arrhythmia occurs, rate sensors require a set duration of time to sense the arrhythmia. Then, the device automatically charges; after a second "look" confirms the arrhythmia, it delivers the programmed charge through the lead to the heart. The time from arrhythmia detection to electrical discharge depends on the charging time, which depends on the programmed energy level (Zipes et al., 2018). However, in an ICD that has the capability of providing atrial therapies, the device can be programmed to be activated by the patient, giving the patient time to activate the charge at a time and place of their choosing. The life of the lithium battery is about 9 years but varies depending on the use of the ICD. ICD surveillance is similar to that of the pacemaker; however, it includes stored endocardial ECGs as well as information about the number and frequency of shocks that have been delivered.

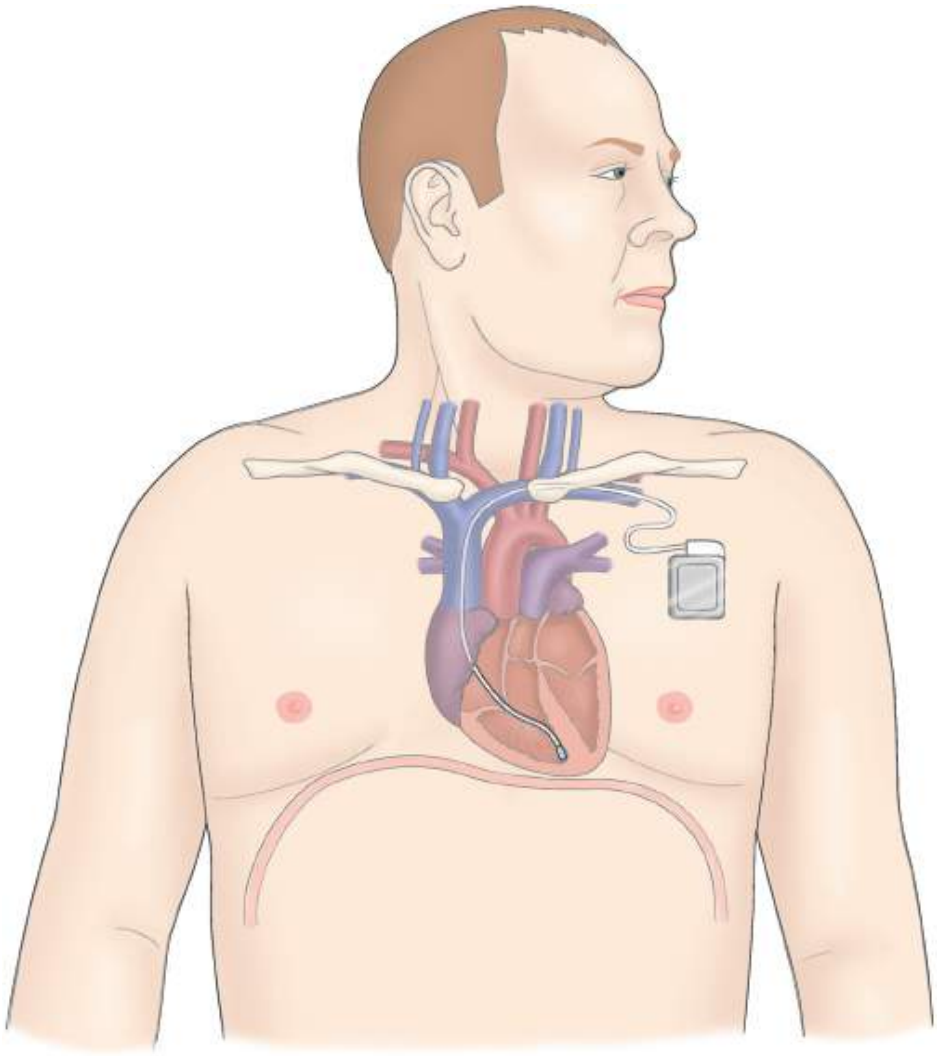

Figure 22-29 • The implantable cardioverter defibrillator consists of a generator and a sensing/pacing/defibrillating electrode.

Antiarrhythmic medication may be given with this technology to minimize the occurrence of a tachyarrhythmia and to reduce the frequency of ICD discharge.

Several types of devices are available. ICD, the generic name, is used as the abbreviation for these various devices. Each device offers a different delivery sequence, but all are capable of delivering high-energy (high-intensity) defibrillation to treat a tachycardia (atrial or ventricular).

Some ICDs can respond with (1) antitachycardia pacing, in which the device delivers electrical impulses at a fast rate in an attempt to disrupt the tachycardia, (2) low-energy (low-intensity) cardioversion, or (3) defibrillation; others may use all three techniques. Pacing is used to terminate tachycardias caused by a conduction disturbance called *reentry,* which is repetitive restimulation of the heart by the same impulse. An impulse or a series of impulses is delivered to the heart by the device at a fast rate to collide with and stop the heart's reentry conduction impulses, and therefore to stop the

tachycardia. Typically, ICDs also have pacemaker capability if the patient develops bradycardia, which sometimes occurs after treatment of the tachycardia. Usually, the mode is VVI.

The subcutaneous ICD is a more recently introduced therapeutic alternative to the conventional ICD. The main advantage to subcutaneous defibrillators is that the complications associated with vascular access are avoided. Patients without pacing indications, or antitachycardia pacing, or cardiac resynchronization are best candidates for this technology (Sideris, Archontakis, Gatzoulis, et al., 2017).

Which device is used and how it is programmed depend on the patient's arrhythmia(s). The device may be programmed differently for different arrhythmias (e.g., ventricular fibrillation, VT with a fast ventricular rate, and VT with a slow ventricular rate). As with pacemakers, there is an NASPE-BPEG code for communicating the functions of the ICDs (Bernstein et al., 2002; Wilkoff et al., 2015). The first letter represents the chamber or chambers shocked (O, none; A, atrium; V, ventricle; D, both atrium and ventricle). The second letter represents the chamber that can be antitachycardia paced (O, A, V, D, meaning the same as the first letter). The third letter indicates the method used by the generator to detect a tachycardia (E, electrogram; H, hemodynamics). The last letter represents the chambers that have antibradycardia pacing (O, A, V, D, meaning the same as the first and second letters of the ICD code).

Complications of ICD implantation are similar to those associated with pacemaker insertion. The primary potential complication is surgery-related infection; its risk increases with battery or lead replacement. A few complications are associated with the technical aspects of the equipment, like those of pacemakers, such as premature battery depletion and dislodged or fractured leads. Inappropriate delivery of ICD therapy, usually due to oversensing or atrial and sinus tachycardias with a rapid ventricular rate response, is the most frequent long-term complication. This requires reprogramming of the device.

Nursing Management

After a permanent electronic device (pacemaker or ICD) is inserted, the patient's heart rate and rhythm are monitored by ECG. The device's settings are noted and compared with the ECG recordings to assess the device's function. For example, pacemaker malfunction is detected by examining the pacemaker spike and its relationship to the surrounding ECG complexes. In addition, cardiac output and hemodynamic stability are assessed to identify the patient's response to pacing and the adequacy of pacing. The appearance or increasing frequency of arrhythmia is observed and reported to the primary provider. If the patient has an ICD implanted and develops VT or ventricular

fibrillation, the ECG should be recorded to note the time between the onset of the arrhythmia and the onset of the device's shock or antitachycardia pacing.

The incision site where the generator was implanted is observed for bleeding, hematoma formation, or infection, which may be evidenced by swelling, unusual tenderness, drainage, and increased warmth. The patient may complain of continuous throbbing or pain. These symptoms are reported to the primary provider.

A chest x-ray is usually taken after the procedure and prior to discharge to document the position of leads in addition to ensuring that the procedure did not cause a pneumothorax. It is necessary to assess the function of the device throughout its lifetime and especially after changes in the patient's medication regimen. For example, antiarrhythmic agents, beta-blockers, and diuretics may increase the pacing threshold, whereas corticosteroids and alpha-adrenergic agents may decrease the pacing threshold; the opposite effect occurs when the patient is taken off these medications.

The patient is also assessed for anxiety, depression, or anger, which may be symptoms of ineffective coping with the implantation. In addition, the level of knowledge and education needs of the patient and family and the history of adherence to the therapeutic regimen should be identified. It is especially important to include the family when providing education and support.

In the peri- and postoperative phases, the nurse carefully observes the patient's responses to the device and provides the patient and family with further education as needed. The nurse also assists the patient and family in addressing concerns and in making decisions about self-care and lifestyle changes necessitated by the arrhythmia and resulting device implantation.

Preventing Infection

The nurse changes the dressing as needed and inspects the insertion site for redness, swelling, soreness, or any unusual drainage. Any change in wound appearance, an increase in the patient's temperature, or an increase in the patient's white blood count should be reported to the primary provider.

Promoting Effective Coping

The patient treated with an electronic device experiences not only lifestyle and physical changes but also emotional changes (Palese, Cracina, Purino, et al., 2019; see Chart 22-8 Nursing Research Profile: Experiences of Patients Shocked by an Implantable Cardioverter Defibrillator). At different times during the healing process, the patient may feel angry, depressed, fearful, anxious, or a combination of these emotions. Although each patient uses individual coping strategies (e.g., humor, prayer, communication with a significant other) to manage emotional distress, some strategies may work better than others. Signs that may indicate ineffective coping include social

isolation, increased or prolonged irritability or depression, and difficulty in relationships.

To promote effective coping strategies, the nurse must recognize both the patient's and family's perceptions of the situation and their resulting emotional state and assist them to explore their reactions and feelings. Because of the unpredictable and possibly painful ICD discharge, patients with ICDs are most vulnerable to feelings of helplessness, leading to depression. The nurse can help the patient identify positive methods to deal with the actual or perceived limitations and manage any lifestyle changes needed. The nurse may help the patient identify changes (e.g., loss of ability to participate in contact sports), the emotional responses to the change (e.g., anger), and how the patient responds to that emotion (e.g., quickly becomes angry when talking with spouse). The nurse reassures the patient that these responses are normal and helps the patient identify realistic goals (e.g., develop interest in another activity) and develop a plan to attain these goals. The patient and family should be encouraged to talk about their experiences and emotions with each other and the health care team. The nurse may refer the patient and family to a hospital, community, or online support group. The nurse may also encourage the use of spiritual resources. Based on the patient's interest, the nurse also may educate the patient about easy-to-use stress reduction techniques (e.g., deep-breathing exercises, relaxation) to facilitate coping. Instructing the patient about the ICD may help the patient cope with changes that occur as a result of device implantation.

Chart 22-8 **NURSING RESEARCH PROFILE**

Experiences of Patients Shocked by an Implantable Cardioverter Defibrillator

Palese, A., Cracina, A., Purino, M., et al. (2019). The experiences of patients electrically shocked by an implantable cardioverter defibrillator: Findings from a descriptive qualitative study. *Nursing in Critical Care*. Retrieved on 7/9/2019 at: doi.org/10.1111/nicc.12424

Purpose

Insertion rates for implantable cardioverter defibrillators (ICDs) have steadily risen. ICDs may be surgically implanted as a secondary preventive measure for survivors of ventricular arrhythmias or sudden cardiac death and as primary prevention for patients with preexisting select cardiac conditions. The ICD is proven to be effective in lowering mortality rates in sudden cardiac death; however, little has been explored regarding the patients' experiences as lived before, during, and after shocks from an ICD.

Design

This study used a descriptive qualitative design. A convenience sample of adult patients with ICDs who reported at least one shock during their first follow-up visit post ICD implantation were eligible to participate. All patients were followed by a cardiology department in an academic hospital located in northern Italy. A total of 50 participants consented to enroll in this study. Each participant went through semi-structured face-to-face audiorecorded interviews. Content analysis methodology was used to analyze the data.

Findings

The content analysis revealed four themes*: feeling surprised versus feeling altered by the changes inside me; living an intense, monodimensional experience versus living a multidimensional storm experience*; *facing the event alone versus being supported*; and *living a drama versus being used to it*. Most participants reported that they received shocks in their homes or in other community-based settings, many with family members present, and that they then presented to their local emergency department. Most participants could not recall the moments preceding the shocks, but did report feeling vague physical symptoms.

Nursing Implications

Findings from this study suggest that ICD shocks can have a profound effect on patients' physical and emotional health. Nurses need to be vigilant to recognize patients' educational needs. Furthermore, nurses need to tailor appropriate, supportive interventions to improve patients' experiences living with an ICD. In particular, nurses can assist patients with ICDs in identifying pre-shock prodromal physical symptoms so that the ICD may be reprogrammed if indicated, or so that the doses of antiarrhythmic medications might be better titrated to prevent arrhythmias. Moreover, most

participants in this study received shocks outside the health care setting, and many of them were shocked in the presence of family members. Tailoring education programs to include significant others in identifying prodromal symptoms pre-shock and in seeking appropriate treatment post-shock may improve the quality of life of family members and patients with ICDs.

Promoting Home, Community-Based, and Transitional Care

After device insertion, the patient's hospital stay is typically short (e.g., may be 1 day or less), and follow-up in an outpatient clinic, office, or device clinic is common. The patient's anxiety and feelings of vulnerability may interfere with the ability to learn information provided. The nurse needs to include caregivers in the education and provide printed materials for use by the patient and caregiver. The nurse establishes priorities for learning with the patient and caregiver. Education includes the importance of periodic device monitoring, promoting safety, surgical site care, and avoiding EMI (see Chart 22-9). In addition, the educational plan should include information about activities that are safe and those that may be dangerous. The nurse discusses with the patient and family what they have to do when a shock is delivered. The nurse may facilitate CPR training for the family.

Chart 22-9 **HOME CARE CHECKLIST**

Educating the Patient with an Implantable Cardiac Device

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of device implantation on physiologic functioning, ADLs, IADLs, self-image and roles, relationships (including sexuality), and spirituality.
- State changes in lifestyle (e.g., diet, activity, mobility/driving restrictions) necessary to maintain health.
- State the name, dose, side effects, frequency, and schedule for all medications.
- For patients with pacemakers, check pulse daily. Report *immediately* any sudden slowing or increasing of the pulse rate. This may indicate pacemaker malfunction.
- Avoid infection at the insertion site of the device:
- Leave the incision uncovered and observe it daily for redness, increased swelling, and heat.
- Take temperature at same time each day; report any increase.
- Avoid wearing tight, restrictive clothing that may cause friction over the insertion site.
- Initially avoid soaking in the tub and lotion, creams, or powders in the area of the device.
- Adhere to activity restrictions:
- Restrict movement of arm until incision heals; do not raise arm above head for 2 wks.
- Avoid heavy lifting for a few weeks.
- Discuss safety of activities (e.g., driving) with a primary provider.
- Recognize that although it may take up to 2–3 wks to resume normal activities, physical activity does not usually have to be curtailed, with the exception of contact sports.
- Electromagnetic interference: Understand the importance of the following:
- Avoid large magnetic fields, such as those created by MRI, large motors, arc welding, and electrical substations. Magnetic fields may deactivate the device, negating its effect on an arrhythmia.
- At security gates at airports, government buildings, or other secured areas, show identification card and request a hand (not handheld device) search. Obtain and carry a letter from the primary provider about this requirement.
- Some electrical and small motor devices, as well as products that contain magnets (e.g., cellular phones), may interfere with the functioning of the cardiac device if the electrical device is placed very close to it. Avoid leaning directly over large electrical devices or motors, or ensure that contact is of brief duration; place cellular phone on opposite side of cardiac device.

- Household appliances (e.g., microwave ovens) should not cause any concern.
- Describe precautions and safety measures to be used:
- Describe what to do if symptoms occur, and notify the primary provider if any discharges seem unusual.
- Maintain a log that records discharges of an ICD. Record events that precipitate the sensation of shock. This provides important data for the primary provider to use in readjusting the medical regimen.
- Encourage family members to attend a cardiopulmonary resuscitation class.
- Call 911 for emergency assistance if feeling of dizziness occurs.
- Wear medical identification (e.g., MedicAlert) that includes primary provider information.
- Avoid frightening family or friends with unexpected shocks from an ICD, which will not harm them. Inform family and friends that in the event they are in contact with the patient when a shock is delivered, they may also feel the shock. It is especially important to warn sexual partners that this may occur.
- Carry medical identification with the primary provider's name, type and model number of the device, manufacturer's name, and hospital where device was inserted.
- Identify community resources for peer and caregiver/family support.
- Adhere to appointments for follow-up care that are scheduled to monitor the electronic performance of the cardiac device. This is especially important during the first month after implantation and near the end of the battery life. Remember to take the log of ICD discharges to review with the primary provider.
- Identify the need for health promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, instrumental activities of daily living; ICD, implantable cardioverter defibrillator.

CRITICAL THINKING EXERCISES

1 ebp Your uncle, who has a history of alcohol abuse, calls to tell you that his primary provider told him that he has atrial fibrillation. He says that he has been prescribed warfarin and that he really doesn't want to take it because he heard that it is an ingredient in "rat poison." What is the strength of the evidence that supports your uncle's continued adherence to warfarin therapy? What are the risks involved should he decide that he will not take this drug as prescribed?

2 pq You work as a staff nurse on a surgical gynecology unit. A 55-year-old woman assigned to your care is one day post total abdominal hysterectomy. On your initial rounds, the patient is resting comfortably in bed with moderate pain, heart rate of 65 bpm, blood pressure of 120/70 mm Hg, and respiratory rate of 20 breaths per minute. Four hours later, you enter the patient's room and she is sleeping with a heart rate of 98 bpm, blood pressure of 110/60 mm Hg, and respiratory rate of 16 breaths per minute. What are the possible causes of this increase in heart rate? What are your assessment priorities?

3 ipc It is the start of the 12-hour day shift on the cardiovascular unit where you work. A 45-year-old patient who was admitted last evening with a MI is now suddenly experiencing frequent PVCs and a four-beat run of ventricular tachycardia. The patient has remained hemodynamically stable during these episodes. You are preparing for the morning huddle with team members that include unlicensed assistive personnel and attending health care providers. How will you facilitate this interprofessional discussion concerning your patient's PVCs and ventricular tachycardia?

23 Management of Patients with Coronary Vascular Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the pathophysiology, clinical manifestations, and treatment of coronary vascular disorders including coronary atherosclerosis, angina pectoris, and myocardial infarction.
2. Use the nursing process as a framework for care of the patient with angina pectoris, with acute coronary syndrome, or who has undergone cardiac surgery.
3. Describe percutaneous coronary interventional and coronary artery revascularization procedures.
4. Identify the nursing care of a patient who has had a percutaneous coronary interventional procedure for treatment of coronary artery disease.

NURSING CONCEPT

Perfusion

GLOSSARY

acute coronary syndrome (ACS): signs and symptoms that indicate unstable angina or acute myocardial infarction

angina pectoris: chest pain brought about by myocardial ischemia

atheroma: fibrous cap composed of smooth muscle cells that forms over lipid deposits within arterial vessels and protrudes into the lumen of the vessel, narrowing the lumen and obstructing blood flow; also called *plaque*

atherosclerosis: abnormal accumulation of lipid deposits and fibrous tissue within arterial walls and the lumen

contractility: ability of the cardiac muscle to shorten in response to an electrical impulse

coronary artery bypass graft (CABG): a surgical procedure in which a blood vessel from another part of the body is grafted onto the occluded coronary artery below the occlusion in such a way that blood flow bypasses the blockage

high-density lipoprotein (HDL): a protein-bound lipid that transports cholesterol to the liver for excretion in the bile; composed of a higher proportion of protein to lipid than low-density lipoprotein; exerts a beneficial effect on the arterial wall

ischemia: insufficient tissue oxygenation

low-density lipoprotein (LDL): a protein-bound lipid that transports cholesterol to tissues in the body; composed of a lower proportion of protein to lipid than high-density lipoprotein; exerts a harmful effect on the arterial wall

metabolic syndrome: a cluster of metabolic abnormalities including insulin resistance, obesity, dyslipidemia, and hypertension that increase the risk of cardiovascular disease

myocardial infarction (MI): death of heart tissue caused by lack of oxygenated blood flow

percutaneous coronary intervention (PCI): a procedure in which a catheter is placed in a coronary artery, and one of several methods is employed to reduce blockage within the artery

percutaneous transluminal coronary angioplasty (PTCA): a type of percutaneous coronary intervention in which a balloon is inflated within a coronary artery to break an atheroma and open the vessel lumen, improving coronary artery blood flow

stent: a metal mesh that provides structural support to a coronary vessel, preventing its closure

sudden cardiac death: abrupt cessation of effective heart activity

thrombolytic: a pharmacologic agent that breaks down blood clots; alternatively referred to as a fibrinolytic

troponin: a cardiac muscle biomarker; measurement is used as an indicator of heart muscle injury

Cardiovascular disease is the leading cause of death in the United States for men and women of all racial and ethnic groups (Arnett, Blumenthal, Albert, et al., 2019).

Research related to the identification of and treatment for cardiovascular disease includes all segments of the population affected by cardiac conditions, including women, children, and people of diverse racial and ethnic backgrounds. The results of ongoing research are used by nurses to identify specific prevention and treatment strategies in these populations.

Coronary Artery Disease

Coronary artery disease (CAD) is the most prevalent type of cardiovascular disease in adults. For this reason, nurses must recognize various manifestations of coronary artery conditions and evidence-based methods for assessing, preventing, and treating these disorders.

Coronary Atherosclerosis

The most common cause of cardiovascular disease in the United States is **atherosclerosis**, an abnormal accumulation of lipid, or fatty substances, and fibrous tissue in the lining of arterial blood vessel walls. These substances block and narrow the coronary vessels in a way that reduces blood flow to the myocardium. Atherosclerosis involves a repetitious inflammatory response to injury of the artery wall and subsequent alteration in the structural and biochemical properties of the arterial walls. New information that relates to the development of atherosclerosis has increased the understanding of treatment and prevention of this progressive and potentially life-threatening process.

Pathophysiology

The inflammatory response involved with the development of atherosclerosis begins with injury to the vascular endothelium and progresses over many years (Norris, 2019). The injury may be initiated by smoking or tobacco use, hypertension, hyperlipidemia, and other factors. The endothelium undergoes changes and stops producing the normal antithrombotic and vasodilating agents. The presence of inflammation attracts inflammatory cells, such as macrophages. The macrophages ingest lipids, becoming "foam cells" that transport the lipids into the arterial wall. Some of the lipid is deposited on the arterial wall, forming fatty streaks. Activated macrophages also release biochemical substances that can further damage the endothelium by contributing to the oxidation of low-density lipoprotein (LDL). The oxidized LDL is toxic to the endothelial cells and fuels progression of the atherosclerotic process (Norris, 2019).

Following the transport of lipid into the arterial wall, smooth muscle cells proliferate and form a fibrous cap over a core filled with lipid and inflammatory infiltrate. These deposits, called **atheromas**, or plaques, protrude into the lumen of the vessel, narrowing it and obstructing blood flow (see Fig. 23-1). Plaque may be stable or unstable, depending on the degree of inflammation and thickness of the fibrous cap. If the fibrous cap over the plaque is thick and the lipid pool remains

relatively stable, it can resist the stress of blood flow and vessel movement. If the cap is thin and inflammation is ongoing, the lesion becomes what is called *vulnerable plaque.* At this point, the lipid core may grow, causing the fibrous plaque to rupture. A ruptured plaque attracts platelets and causes thrombus formation. A thrombus may then obstruct blood flow, leading to acute coronary syndrome (ACS), which may result in an acute **myocardial infarction (MI)**. When an MI occurs, a portion of the heart muscle no longer receives blood flow and becomes necrotic.

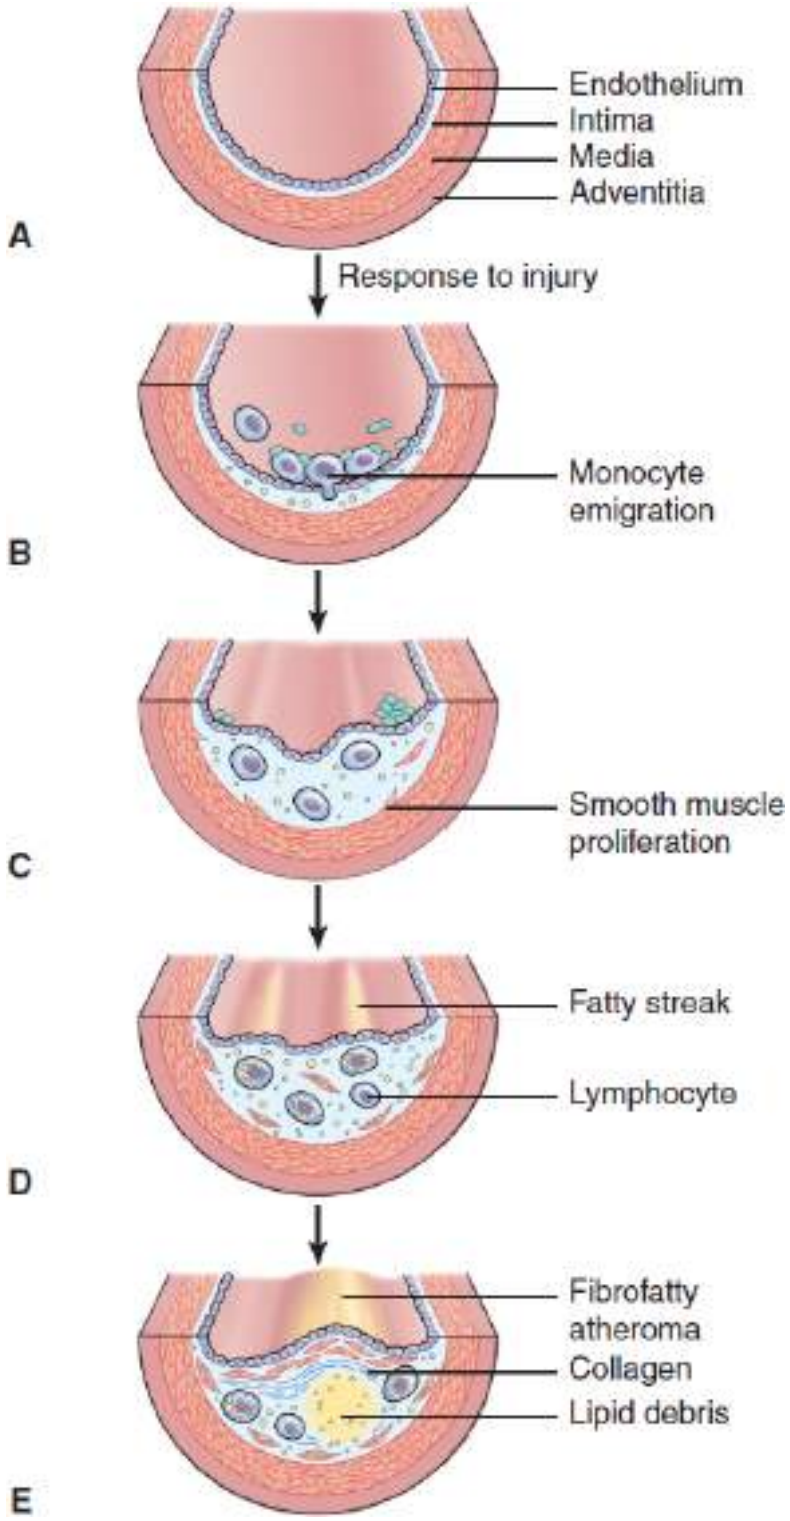

Figure 23-1 • **A, B.** Atherosclerosis begins as monocytes and lipids enter the intima of an injured vessel. Smooth muscle cells proliferate within the vessel wall (**C**), contributing to the development of fatty accumulations and atheroma (**D**). As the plaque enlarges, the vessel narrows and blood flow decreases (**E**). The plaque may rupture and a thrombus might form, obstructing blood flow.

The anatomic structure of the coronary arteries makes them particularly susceptible to atherosclerosis. As Figure 23-2 shows, the three major coronary arteries have multiple branches. Atherosclerotic lesions most often form where the vessels branch and with turbulent blood flow, suggesting a hemodynamic component is involved in their formation (Norris, 2019). Although heart disease is most often caused by atherosclerosis of the coronary arteries, other phenomena may also decrease blood flow to the heart. Examples include vasospasm (sudden constriction or narrowing) of a coronary artery and profound hypotension.

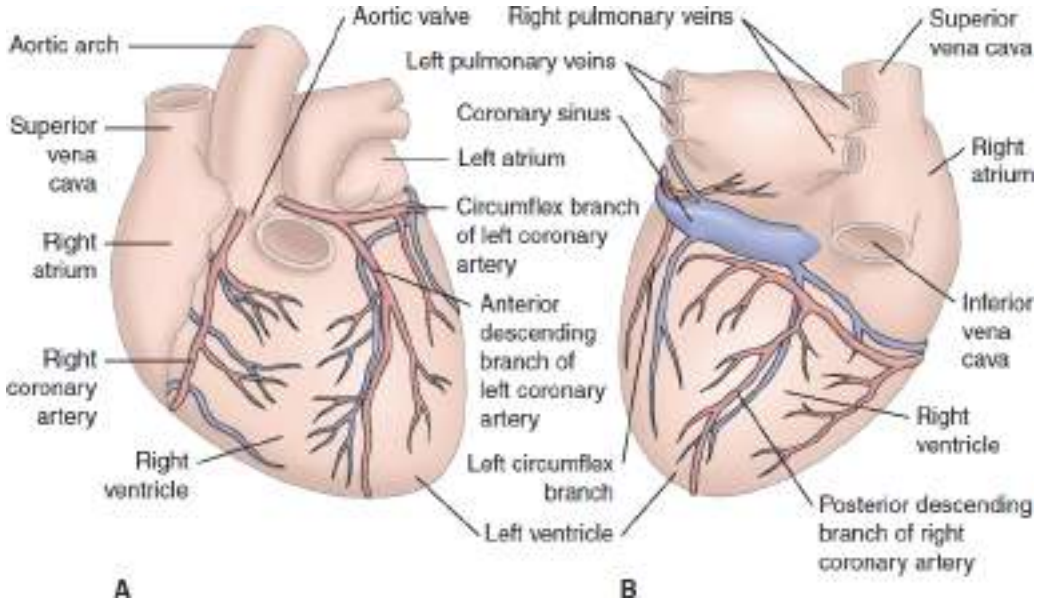

Figure 23-2 • The coronary arteries supply the heart muscle with oxygenated blood, adjusting the flow according to metabolic needs. **A.** Anterior view of the heart. **B.** Posterior view of heart.

Clinical Manifestations

CAD produces symptoms and complications according to the location and degree of narrowing of the arterial lumen, thrombus formation, and obstruction of blood flow to the myocardium. This impediment to blood flow is usually progressive, causing an inadequate blood supply that deprives the cardiac muscle cells of oxygen needed for their survival. The condition is known as **ischemia**. **Angina pectoris** refers to chest pain that is brought about by myocardial ischemia. Angina pectoris usually is caused by significant coronary atherosclerosis. If the decrease in blood supply is great enough, of long enough duration, or both, irreversible damage and death of myocardial cells may result. Over time, irreversibly damaged myocardium undergoes degeneration and is replaced by scar tissue, causing various degrees of myocardial dysfunction. Significant myocardial damage may result in persistently low cardiac output and heart failure where the heart cannot support the body's needs for blood. A decrease in blood supply from CAD may cause the heart to abruptly stop beating; this is known as **sudden cardiac death** (see Chapter 25 for further discussion on CPR).

The most common manifestation of myocardial ischemia is the onset of chest pain. However, the classic epidemiologic study of the people in Framingham,

Massachusetts, showed that nearly 15% of men and women who had coronary events, which included unstable angina, MIs, or sudden cardiac death events, were totally asymptomatic prior to the coronary event (Kannel, 1986). Patients with myocardial ischemia may present to an emergency department (ED) or clinic with a variety of symptoms other than chest pain. Some complain of epigastric distress and pain that radiates to the jaw or left arm. Patients who are older or have a history of diabetes or heart failure may report shortness of breath. Many women have been found to have atypical symptoms, including indigestion, nausea, palpitations, and numbness (Davis, 2017). Prodromal symptoms may occur (e.g., angina a few hours to days before the acute episode), or a major cardiac event may be the first indication of coronary atherosclerosis.

Risk Factors

Epidemiologic studies point to several factors that increase the probability that a person will develop heart disease. Major risk factors are listed in Chart 23-1. Although many people with CAD have one or more risk factors, some do not have classic risk factors. Elevated **low-density lipoprotein (LDL)**, also known as bad cholesterol, is a well-known risk factor and the primary target of cholesterol-lowering therapy. People at the highest risk for having a cardiac event are those with known CAD or those with diabetes, peripheral arterial disease, abdominal aortic aneurysm, or carotid artery disease. The latter diseases are referred to as CAD risk equivalents, because patients with these diseases have the same risk for a cardiac event as patients with CAD. The likelihood of having a cardiac event is also affected by factors, such as age, gender, systolic blood pressure, smoking history, level of total cholesterol, and level of **high-density lipoprotein (HDL)**, also known as good cholesterol. The Framingham Risk Calculator is a tool commonly used to estimate the risk for having a cardiac event within the next 10 years (Grundy, Stone, Bailey, et al., 2018). This tool is designed for adults 20 years and older. The calculation is performed using the individual's risk factor data, including age, gender, total cholesterol, HDL, smoking status, systolic blood pressure, and need for antihypertensive medication.

In addition, a cluster of metabolic abnormalities known as **metabolic syndrome** has emerged as a major risk factor for cardiovascular disease (Grundy et al., 2018). A diagnosis of this syndrome is made when a patient has three of the following five risk factors:

- Enlarged waist circumference (greater than 35.4 inches in males, greater than 31.4 inches in females)
- Elevated triglycerides (greater than or equal to 175 mg/dL, or currently on drug treatment for elevated triglycerides)
- Reduced HDL (less than 40 mg/dL in males, less than 50 mg/dL in females, or currently on drug treatment for reduced HDL)
- Hypertension (systolic blood pressure greater than or equal to 130 mm Hg and/or diastolic blood pressure greater than or equal to 80 mm Hg on an average of two to three measurements obtained on two to three separate occasions, or currently on antihypertensive drug treatment for a history of hypertension)

Chart 23-1 RISK FACTORS

Coronary Artery Disease

A nonmodifiable risk factor is a circumstance over which a person has no control. A modifiable risk factor is one over which a person may exercise control, such as by changing a lifestyle or personal habit or by using medication. A risk factor may operate independently or in tandem with other risk factors. The more risk factors a person has, the greater the likelihood of coronary artery disease (CAD). Those at risk are advised to seek regular medical examinations and to engage in heart-healthy behavior (a deliberate effort to reduce the number and extent of risks).

Nonmodifiable Risk Factors

Family history of CAD (first-degree relative with cardiovascular disease at 55 years of age or younger for men and at 65 years of age or younger for women)
Increasing age (more than 45 years for men; more than 55 years for women)
Gender (men develop CAD at an earlier age than women)
Race (higher incidence of heart disease in African Americans than in Caucasians)
History of premature menopause (before age 40) and history of pregnancy-associated disorders such as preeclampsia
Primary hypercholesterolemia (a genetic condition resulting in elevated LDL)

Modifiable Risk Factors

Hyperlipidemia
Tobacco use
Hypertension
Diabetes
Metabolic syndrome
Obesity
Physical inactivity
Chronic inflammatory conditions (e.g., rheumatoid arthritis, lupus, HIV/AIDS)
Chronic kidney disease

Adapted from Arnett, D. K., Blumenthal, R. S., Albert, M. A., et al. (2019). ACC/AHA Guideline on the Primary Prevention of Cardiovascular Disease. *Journal of the American College of Cardiology, 74*(10), e177–e232.

- Elevated fasting glucose (greater than or equal to 100 mg/dL on two separate occasions, or current drug treatment for elevated glucose)

Many people with type 2 diabetes fit this clinical picture. Theories suggest that in patients with obesity, excessive adipose tissue may secrete mediators that lead to metabolic changes. Adipokines (adipose tissue cytokines), free fatty acids, and other substances are known to modify insulin action and contribute to atherogenic changes in the cardiovascular system (see Fig. 23-3).

C-reactive protein (CRP) is known to be an inflammatory marker for cardiovascular risk, including acute coronary events and stroke. The liver produces CRP in response to a stimulus such as tissue injury, and high levels of this protein may occur in people with diabetes and those who are likely to have an acute coronary event (Norris, 2019). To determine overall cardiovascular risk, clinicians may view high sensitivity C-reactive protein (hs-CRP) test results together with other screening tools such as measurements of lipid levels.

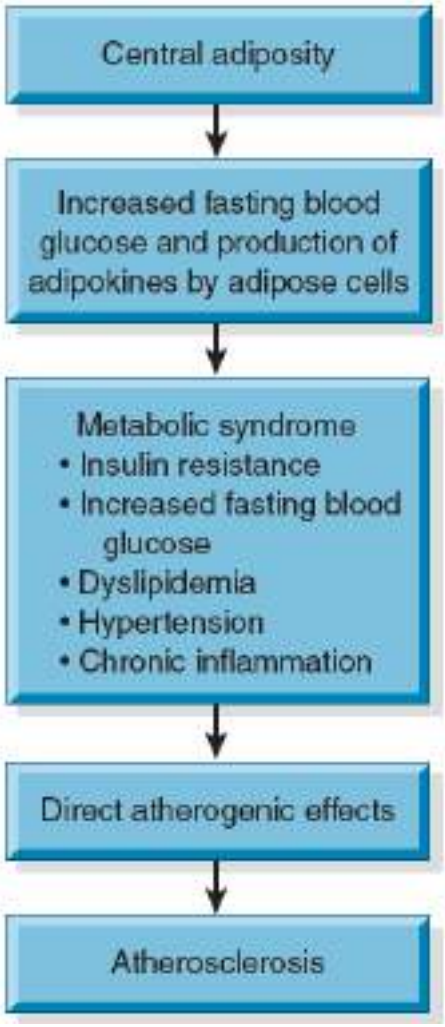

Figure 23-3 • Pathophysiology of cardiovascular disease in metabolic syndrome. Central adiposity plays a major role in the development of metabolic syndrome. Adipokines released from fat cells along with other hormones and metabolites are thought to contribute to the development of metabolic abnormalities. The eventual effect of these processes is the promotion of atherosclerosis.

Prevention

Four modifiable risk factors—cholesterol abnormalities, tobacco use, hypertension, and diabetes—are established risk factors for CAD and its complications. As a result, they receive much attention in health promotion programs.

Controlling Cholesterol Abnormalities

The association of a high blood cholesterol level with heart disease is well established, and the metabolism of fats is known to be an important contributor to the development of heart disease. Fats, which are insoluble in water, are encased in

water-soluble lipoproteins that allow them to be transported within the circulatory system. The various lipoproteins are categorized by their protein content, which is measured in density. The density increases when more protein is present. Four elements of fat metabolism—total cholesterol, LDL, HDL, and triglycerides—are known to affect the development of heart disease. Cholesterol is processed by the gastrointestinal (GI) tract into lipoprotein globules called *chylomicrons*. These are reprocessed by the liver as lipoproteins (see Fig. 23-4). This is a physiologic process necessary for the formation of lipoprotein-based cell membranes and other important metabolic processes. When an excess of LDL is produced, LDL particles adhere to receptors in the arterial endothelium. Here, macrophages ingest them, contributing to plaque formation.

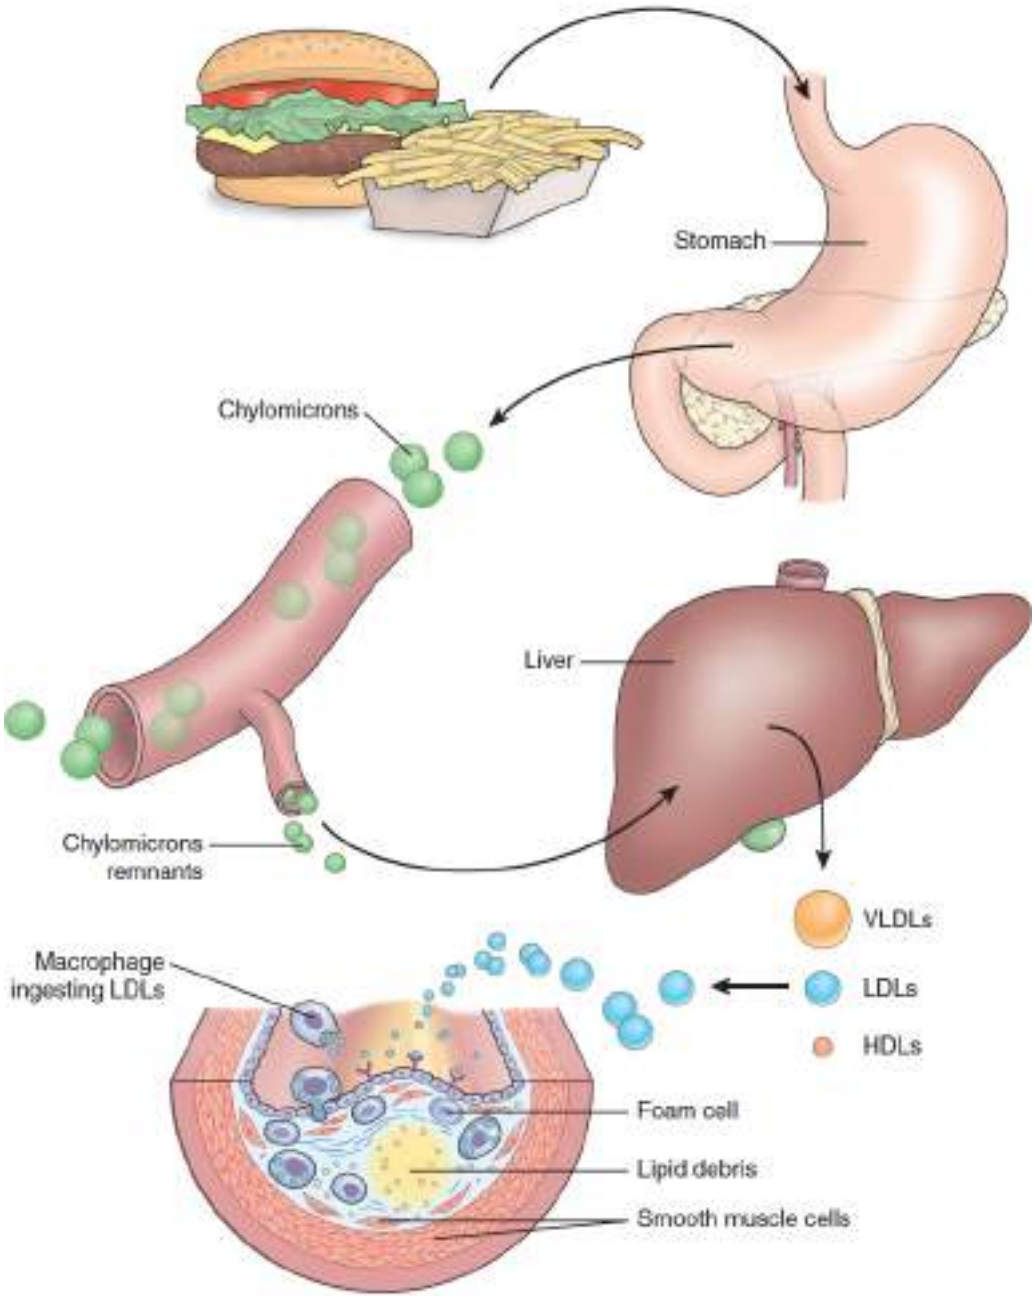

Figure 23-4 • Lipoproteins and the development of atherosclerosis. As dietary cholesterol and saturated fat are processed by the gastrointestinal tract, chylomicrons enter the blood. They are broken down into chylomicron remnants in the capillaries. The liver processes them into lipoproteins. When these are released into the circulation, excess low-density lipoproteins (LDLs) adhere to receptors on the intimal wall. Macrophages also ingest LDLs and transport them into the vessel wall, beginning the process of plaque formation. HDLs, high-density lipoproteins; VLDLs, very–low-density lipoproteins.

The American College of Cardiology and the American Heart Association (ACC/AHA) have developed clinical practice guidelines on the treatment of blood cholesterol to reduce cardiovascular risk in adults (Grundy et al., 2018). These guidelines address primary prevention (preventing the occurrence of CAD) and secondary prevention (preventing the progression of CAD). All adults 20 years and older should have a fasting lipid profile (total cholesterol, LDL, HDL, and triglycerides) performed at least once every 5 years, and more often if the profile is abnormal. Patients who have had an acute event (e.g., MI), a percutaneous coronary intervention (PCI), or a coronary artery bypass graft (CABG) require assessment of their LDL cholesterol level within a few months of the event or procedure, because LDL levels may be low immediately after the acute event or procedure. Subsequently, lipids should be monitored every 4 to 12 weeks until the desired level is achieved and then every 3 to 12 months as needed (Grundy et al., 2018). A fasting lipid profile should demonstrate the following values (Stone, Robinson, Lichtenstein, et al., 2014):

- LDL cholesterol less than 100 mg/dL (less than 70 mg/dL for very high risk patients)
- Total cholesterol less than 200 mg/dL
- HDL cholesterol greater than 40 mg/dL for males and greater than 50 mg/dL for females
- Triglyceride less than 150 mg/dL

LDL is the target of current therapy because of its strong association with advancing CAD. The total cholesterol level is also a clear predictor of coronary events. HDL is known as good cholesterol because it transports other lipoproteins such as LDL to the liver, where they can be degraded and excreted. Because of this, a high HDL level is a strong negative risk factor for heart disease (i.e., it protects against heart disease).

Triglyceride is made up of fatty acids and is transported through the blood by a lipoprotein. Although an elevated triglyceride level (more than 200 mg/dL) may be genetic in origin, it also can be caused by obesity, physical inactivity, excessive alcohol intake, high-carbohydrate diets, diabetes, kidney disease, and certain medications, such as oral contraceptives and corticosteroids.

Concept Mastery Alert

It is important to remember the different types of cholesterol and the role of each as a risk factor for heart disease. HDL is the “good cholesterol,” and higher levels are better; LDL is the “bad cholesterol,” and lower levels are better.

Dietary Measures

Adults who need to lower LDL (and blood pressure) should consider the AHA’s diet recommendations or the Mediterranean diet, which are reported to reduce mortality from cardiovascular disease (Franquesa, Pujol-Busquets, García-Fernández, et al., 2019). Both eating plans provide similar key elements: an emphasis on plant foods (fruits, vegetables, whole-grain breads or other forms of cereals, beans, nuts, and seeds), minimally processed foods, seasonally fresh foods, inclusion of fish, and minimal intake of red meat. Individuals needing to lower LDL and blood pressure

should also limit the intake of sweets and sugar sweetened beverages (Arnett et al., 2019). Adopting a strict vegetarian diet can significantly reduce blood lipids, blood glucose, body mass index, and blood pressure; however, this type of intensive dietary program may not be acceptable to all patients who need to modify risk factors. Referral to a dietitian can help patients in following a diet that is appropriate.

Many resources are available to assist people in controlling their cholesterol levels. The National Heart, Lung, and Blood Institute (NHLBI) and its National Cholesterol Education Program (NCEP), the AHA, and the American Diabetes Association (ADA), as well as CAD support groups and reliable Internet sources, are a few examples of the available resources (see Resources section at the end of this chapter). Cookbooks and recipes that include the nutritional contents of foods can be included as resources for patients. Dietary control has been made easier because food manufacturers are required to provide nutritional data on product labels. The label information of interest to a person attempting to eat a heart-healthy diet is as follows: serving size (expressed in household measures), amount of total fat per serving, amount of saturated fat and trans fat per serving, amount of cholesterol per serving, and amount of fiber per serving.

Physical Activity

Management of an elevated triglyceride level focuses on weight reduction and increased physical activity. Regular, moderate physical activity increases HDL levels and reduces triglyceride levels, decreasing the incidence of coronary events and reducing overall mortality risk. The goal for most adults is to engage in moderate-intensity aerobic activity of at least 150 minutes per week or vigorous-intensity aerobic activity of at least 75 minutes per week, or an equivalent combination (Arnett et al., 2019). In addition, adults should engage in muscle-strengthening activities on 2 or more days each week that work all major muscle groups. The nurse helps the patient to set realistic goals for physical activity. For example, inactive patients can start with activity that lasts 3 minutes, such as parking farther from a building to increase daily walking time. Patients should be instructed to engage in an activity or variety of activities that interest them to maintain motivation. They should also be taught to exercise to an intensity that does not preclude their ability to talk; if they cannot have a conversation while exercising, they should slow down or switch to a less intensive activity. When the weather is hot and humid, patients should exercise during the early morning, or indoors, and wear loose-fitting clothing. When the weather is cold, they should layer clothing and wear a hat. Patients should stop any activity if chest pain, unexpected shortness of breath, dizziness, lightheadedness, or nausea occurs.

Medications

If diet alone cannot normalize serum cholesterol levels, medications can have a synergistic effect with the prescribed diet and control cholesterol levels (see Table 23-1). Lipid-lowering medications can reduce CAD mortality in patients with elevated lipid levels and in at-risk patients with normal lipid levels (Grundy et al., 2018). The various types of lipid-lowering agents affect the lipid components somewhat differently; these types include 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) (or statins), fibric acids (or fibrates), bile acid sequestrants (or resins),

cholesterol absorption inhibitors, and proprotein convertase subtilisin-kexin type 9 (PCSK9) agents. Because of their high cost, PCSK9 agents are prescribed on a limited basis, but may be considered for those at high cardiovascular risk or who have familial hypercholesterolemia (Grundy et al., 2018).

Before starting statin therapy, the provider and patient should discuss risk factors, adherence to a healthy lifestyle, benefits of risk-reduction, the potential of adverse effects and drug–drug interactions, as well as patient preferences for an individualized treatment plan (Grundy et al., 2018).

Promoting Cessation of Tobacco Use

Tobacco use contributes to the development and severity of CAD in at least three ways:

- Nicotinic acid in tobacco triggers the release of catecholamines, which raise the heart rate and blood pressure (Frandsen & Pennington, 2021). Nicotinic acid can also cause the coronary arteries to constrict. These effects lead to an increased risk of CAD and sudden cardiac death.
- Tobacco use can increase the oxidation of LDL, damaging the vascular endothelium (Lee, Ong, Zhou, et al., 2019). This increases platelet adhesion and leads to a higher probability of thrombus formation.
- Inhalation of smoke increases the blood carbon monoxide level and decreases the supply of oxygen to the myocardium (Frandsen & Pennington, 2021). Hemoglobin, the oxygen-carrying component of blood, combines more readily with carbon monoxide than with oxygen. Myocardial ischemia and reduced contractility can result.

TABLE 23-1 Select Medications that Affect Lipoprotein Metabolism

Medications	Therapeutic Effects	Considerations
HMG-CoA Reductase Inhibitors (Statins)		
Atorvastatin Simvastatin Rosuvastatin	↓ Total cholesterol ↓ LDL ↑ HDL ↓ TGs Inhibit enzyme involved in lipid synthesis (HMG-CoA) Favorable effects on vascular endothelium, including anti-inflammatory and antithrombotic effects	Frequently given as initial therapy for significantly elevated cholesterol and LDL levels Myalgia and arthralgia are common adverse effects Myopathy and possible rhabdomyolysis are potential serious effects Monitor liver function tests Contraindicated in liver disease Check for drug interactions Indication for use now includes ACS and stroke Administer in evening
Fibric Acids (Fibrates)		
Fenofibrate Gemfibrozil	↑ HDL ↓ TGs ↓ Synthesis of TGs and other lipids	Adverse effects include diarrhea, flatulence, rash, myalgia Serious adverse effects include pancreatitis, hepatotoxicity, and rhabdomyolysis Contraindicated in severe kidney and liver disease Use with caution in patients who are also taking statins
Bile Acid Sequestrants		
Cholestyramine Colestipol Colesevelam	↓ LDL Slight ↑ HDL Oxidize cholesterol into bile acids, which ↓ fat absorption	Most often used as adjunct therapy when statins alone have not been effective in controlling lipid levels Side effects include constipation, abdominal pain, GI bleeding May decrease absorption of other drugs Taken before meals
Cholesterol Absorption Inhibitor		
Ezetimibe	↓ LDL Inhibits absorption of cholesterol in small intestine	Better tolerated than bile acid sequestrants Used in combination with other agents, such as statins Side effects include abdominal pain, arthralgia, myalgia Contraindicated in liver disease
Proprotein Convertase Subtilisin-Kexin Type 9 (PCSK9) Agents		
Alirocumab Evolocumab	Prolongs receptor activity to promote clearance of cholesterol ↓ LDL ↓ risk of MI and stroke ↓ need for stent or CABG	Only administered by subcutaneous injection via a pen device, one or two times per month as prescribed Side effects include rhinitis, sore throat, flulike symptoms, muscle pain, diarrhea, and redness, pain, or bruising at injection site

↓ decrease, ↑ increase; ACS, acute coronary syndrome; CABG, coronary artery bypass graft; GI, gastrointestinal; HDL, high-density lipoprotein; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low-density lipoprotein; MI, myocardial infarction; TGs, triglycerides.

Adapted from Frandsen, G., & Pennington, S. S. (2021). *Abrams' clinical drug therapy: Rationales for nursing practice* (12th ed.). Philadelphia, PA: Wolters Kluwer Health.

A person at increased risk for heart disease is encouraged to stop tobacco use through any means possible: educational programs, counseling, consistent motivation and reinforcement messages, support groups, and medications. Some people have found complementary therapies (e.g., acupuncture, guided imagery, hypnosis) to be helpful. People who stop smoking reduce their risk of heart disease within the first year, and the risk continues to decline as long as they refrain from smoking (Benjamin, Muntner, Alonso, et al., 2019).

The use of medications such as the nicotine patch, nicotine lozenges, nicotine gum, varenicline, or bupropion may assist with stopping the use of tobacco (Barua, Rigotti, Benowitz, et al., 2018). Products containing nicotine have some of the same effects as smoking: catecholamine release (increasing heart rate and blood pressure) and increased platelet adhesion. These medications should be used for a short time and at the lowest effective doses.

Exposure to others' smoke (passive or secondhand smoke) increases the risk for CAD by 25% to 30% and for stroke by 20% to 30% (Benjamin et al., 2019). Other forms of tobacco use are becoming increasingly common today. Use of electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars has increased, particularly among adolescents and young adults. Specifically, e-cigarette use, which entails inhalation of a vaporized liquid that includes nicotine, solvents, and flavoring ("vaping"), has risen significantly in these groups. Use of cigarillos and other mass market cigars, hookahs, and water pipes are also on the rise. Short-term exposure to water pipe smoking is associated with an increase in systolic blood pressure and heart rate, but long-term effects remain unclear. The cardiovascular risks associated with e-cigarette use are not yet known (Benjamin et al., 2019).

Managing Hypertension

Hypertension is defined as systolic blood pressure measurements of greater than 130 mm Hg and/or diastolic blood pressure levels greater than 80 mm Hg. A single reading is not adequate to make a diagnosis. Averaging two or three measurements obtained on two to three different occasions will provide a more accurate measurement (Whelton, Carey, Aronow, et al., 2018). The risk of cardiovascular disease increases as blood pressure increases, and current guidelines support treating hypertension with a goal of keeping the blood pressure under 130/80 for all adults (Whelton et al., 2018). Long-standing elevated blood pressure may result in increased stiffness of the vessel walls, leading to vessel injury and a resulting inflammatory response within the intima. Inflammatory mediators then lead to the release of growth-promoting factors that cause vessel hypertrophy and hyperresponsiveness. These changes result in acceleration and aggravation of atherosclerosis. Hypertension also increases the work of the left ventricle, which must pump harder to eject blood

into the arteries. Over time, the increased workload causes the heart to enlarge and thicken (i.e., hypertrophy) and may eventually lead to heart failure.

Early detection of high blood pressure and adherence to a therapeutic regimen can prevent the serious consequences associated with untreated elevated blood pressure, including CAD. Intensive management of hypertension lowers the risk of cardiovascular events, including heart attack and stroke, and lowers the risk of death (Whelton et al., 2018; see Chapter 27 for a detailed discussion of hypertension).

Controlling Diabetes

Diabetes is known to accelerate the development of heart disease. Hyperglycemia fosters dyslipidemia, increased platelet aggregation, and altered red blood cell function, which can lead to thrombus formation. These metabolic alterations may impair endothelial cell–dependent vasodilation and smooth muscle function, promoting the development of atherosclerosis. Treatment with insulin, metformin, and other therapeutic interventions that lower plasma glucose levels can lead to improved endothelial function and patient outcomes. See Chapter 46 for a detailed discussion of diabetes.

Gender

Heart disease has long been recognized as a cause of morbidity and mortality in men, but it has not always been as readily recognized in women. Cardiovascular events in women occur an average of 10 years later in life than they do in men (Wada, Miyauchi, & Daida, 2019). Women tend to have a higher incidence of complications from cardiovascular disease and a higher mortality. In addition, women tend to not recognize the symptoms of CAD as early as men, and they wait longer to report their symptoms and seek medical assistance (Wada et al., 2019).

The age difference between women and men who were newly diagnosed with CAD was traditionally thought to be related to estrogen. Menopause is now recognized as a milestone in the aging process, during which risk factors tend to accumulate. Cardiovascular disease may be well developed by the time of menopause, and although hormone therapy (HT) (formerly referred to as hormone replacement therapy) for menopausal women was once promoted as preventive therapy for CAD, research does not support HT as an effective means of prevention. HT decreases menopausal symptoms and the risk of osteoporosis-related bone fractures; however, it also has been associated with an increased incidence of CAD, breast cancer, deep vein thrombosis, stroke, and pulmonary embolism. Current guidelines do not recommend HT for primary or secondary prevention of CAD (Wada et al., 2019; see Chapter 21 for further discussion).

In the past, women who possibly had coronary vascular events were less likely than men to be referred for coronary artery diagnostic procedures such as heart catheterization or treatment with invasive interventions (e.g., PCI). However, as a result of better education of health care professionals and the general public, gender differences now have less influence on diagnosis and treatment (Wada et al., 2019).

Unfolding Patient Stories: Carl Shapiro • Part 1

Carl Shapiro, who has a family history of atherosclerotic cardiovascular disease, is diagnosed with hypertension and hyperlipidemia during a routine visit to his primary provider. He is overweight, smokes a half pack of cigarettes per day, and describes his job as stressful. What questions can the nurse ask Carl Shapiro to help develop a plan for patient education? What topics are important for the nurse to address, and how can the information be presented? (Carl Shapiro's story continues in Chapter 67.)

Care for Carl and other patients in a realistic virtual environment: vSim (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Angina Pectoris

Angina pectoris is a clinical syndrome usually characterized by episodes or paroxysms of pain or pressure in the anterior chest. The cause is insufficient coronary blood flow, resulting in a decreased oxygen supply when there is increased myocardial demand for oxygen in response to physical exertion or emotional stress. In other words, the need for oxygen exceeds the supply.

Pathophysiology

Angina is usually caused by atherosclerotic disease and most often is associated with a significant obstruction of at least one major coronary artery. Normally, the myocardium extracts a large amount of oxygen from the coronary circulation to meet its continuous demands. When demand increases, flow through the coronary arteries needs to be increased. When there is a blockage in a coronary artery, flow cannot be increased and ischemia results. The types of angina are listed in Chart 23-2. Several factors are associated with typical anginal pain:

- Physical exertion, which precipitates an attack by increasing myocardial oxygen demand
- Exposure to cold, which causes vasoconstriction and elevated blood pressure, with increased oxygen demand
- Eating a heavy meal, which increases the blood flow to the mesenteric area for digestion, thereby reducing the blood supply available to the heart muscle; in a severely compromised heart, shunting of blood for digestion can be sufficient to induce anginal pain

Chart 23-2

Types of Angina

- **Stable angina:** predictable and consistent pain that occurs on exertion and is relieved by rest and/or nitroglycerin
- **Unstable angina** (also called *preinfarction angina* or *crescendo angina*): symptoms increase in frequency and severity; may not be relieved with rest or nitroglycerin
- **Intractable or refractory angina:** severe incapacitating chest pain
- **Variant angina** (also called *Prinzmetal's angina*): pain at rest with reversible ST-segment elevation; thought to be caused by coronary artery vasospasm
- **Silent ischemia:** objective evidence of ischemia (such as electrocardiographic changes with a stress test), but patient reports no pain

- Stress or any emotion-provoking situation, causing the release of catecholamines, which increases blood pressure, heart rate, and myocardial workload

Unstable angina is not closely associated with these listed factors. It may occur at rest (see later discussion).

Clinical Manifestations

Ischemia of the heart muscle may produce pain or other symptoms, varying from mild indigestion to a choking or heavy sensation in the upper chest. The severity ranges from discomfort to agonizing pain. The pain may be accompanied by severe apprehension and a feeling of impending death. It is often felt deep in the chest behind the sternum (retrosternal area). Typically, the pain or discomfort is poorly localized and may radiate to the neck, jaw, shoulders, and inner aspects of the upper arms, usually the left arm. The patient often feels tightness or a heavy choking or strangling sensation that has a viselike, insistent quality. The patient with diabetes may not have severe pain with angina because autonomic neuropathy can blunt nociceptor transmission, dulling the perception of pain (Norris, 2019).

A feeling of weakness or numbness in the arms, wrists, and hands, as well as shortness of breath, pallor, diaphoresis, dizziness or lightheadedness, and nausea and vomiting, may accompany the pain. An important characteristic of angina is that it subsides with rest or administration of nitroglycerin. In many patients, anginal symptoms follow a stable, predictable pattern.

Unstable angina is characterized by attacks that increase in frequency and severity and are not relieved by rest and administration of nitroglycerin. Patients with unstable angina require medical intervention.

Gerontologic Considerations

The older adult with angina may not exhibit a typical pain profile because of the diminished pain transmission that can occur with aging. Often the presenting

symptom in older adults is dyspnea. Sometimes there are no symptoms ("silent" CAD), making recognition and diagnosis a clinical challenge. Older patients should be encouraged to recognize their chest pain–like symptom (e.g., weakness) as an indication that they should rest or take prescribed medications. Pharmacologic stress testing and cardiac catheterization may be used to diagnose CAD in older patients. Medications used to manage angina are given cautiously in older adults because they are associated with an increased risk of adverse reactions (Frandsen & Pennington, 2021). Invasive procedures (e.g., PCI) that were once considered too risky in older adults are now being performed successfully, and many older adults benefit from symptom relief and longer survival (Lattuca, Kerneis, & Zeitouni, 2019).

Assessment and Diagnostic Findings

The diagnosis of angina begins with the patient's history related to the clinical manifestations of ischemia. A 12-lead electrocardiogram (ECG) may show changes indicative of ischemia, such as T-wave inversion, ST-segment elevation, or the development of an abnormal Q wave (Norris, 2019). Laboratory studies are performed; these generally include cardiac biomarker testing to rule out ACS (see later discussion). The patient may undergo an exercise or pharmacologic stress test in which the heart is monitored continuously by an ECG, echocardiogram, or both. The patient may also be referred for a nuclear scan or invasive procedure (e.g., cardiac catheterization, coronary angiography).

Medical Management

The objectives of the medical management of angina are to decrease the oxygen demand of the myocardium and to increase the oxygen supply. Medically, these objectives are met through pharmacologic therapy and control of risk factors. Alternatively, reperfusion procedures may be used to restore the blood supply to the myocardium. These include PCI procedures (e.g., percutaneous transluminal coronary angioplasty [PTCA] and intracoronary stents) and CABG (see later discussion).

Pharmacologic Therapy

Table 23-2 summarizes drug therapy.

Nitroglycerin

Nitrates are a standard treatment for angina pectoris. Nitroglycerin is a potent vasodilator that improves blood flow to the heart muscle and relieves pain. Nitroglycerin dilates primarily the veins and, to a lesser extent, the arteries. Dilation of the veins causes venous pooling of blood throughout the body. As a result, less blood returns to the heart, and filling pressure (preload) is reduced. If the patient is hypovolemic (does not have adequate circulating blood volume), the decrease in filling pressure can cause a significant decrease in cardiac output and blood pressure (Frandsen & Pennington, 2021).

Nitrates also relax the systemic arteriolar bed, lowering blood pressure and decreasing afterload. These effects decrease myocardial oxygen requirements,

bringing about a more favorable balance between supply and demand.

Nitroglycerin may be given by several routes: sublingual tablet or spray, oral capsule, topical agent, and intravenous (IV) administration. Sublingual nitroglycerin is generally placed under the tongue or in the cheek (buccal pouch) and ideally alleviates the pain of ischemia within 3 minutes. Chart 23-3 provides more information on self-administration of sublingual nitroglycerin. Oral preparations and topical patches are used to provide sustained effects. A regimen in which the patches are applied in the morning and removed at bedtime allows for a nitrate-free period to prevent the development of tolerance.

TABLE 23-2 Select Medications Used to Treat Stable Angina

Medications	Major Indications
Nitrates	
Nitroglycerin	Short- and long-term reduction of myocardial oxygen consumption through selective vasodilation
Beta-Adrenergic Blocking Agents (Beta-Blockers)	
Metoprolol Atenolol	Reduction of myocardial oxygen consumption by blocking beta-adrenergic stimulation of the heart
Calcium Ion Antagonists (Calcium Channel Blockers)	
Amlodipine Diltiazem	Negative inotropic effects; indicated in patients not responsive to beta-blockers; used as primary treatment for vasospasm
Antiplatelet Medications	
Aspirin	Prevention of platelet aggregation
Clopidogrel Prasugrel Ticagrelor	
Anticoagulants	
Heparin (unfractionated) Low-molecular-weight heparins: Enoxaparin Dalteparin	Prevention of thrombus formation

Adapted from Rousan, T. A., Mathew, S. T., & Thadani, U. (2017). Drug therapy for stable angina pectoris. *Drugs*, *77*(3), 265–284.

A continuous or intermittent IV infusion of nitroglycerin may be given to the hospitalized patient with recurring signs and symptoms of ischemia or after a revascularization procedure. The rate of infusion is titrated to the patient's pain level and blood pressure. It usually is not given if the systolic blood pressure is less than 90 mm Hg. Generally, after the patient is symptom-free, the nitroglycerin may be switched to an oral or topical preparation within 24 hours. A common adverse effect of nitroglycerin is headache, which may limit the use of this drug in some patients.

Beta-Adrenergic Blocking Agents

Beta-blockers such as metoprolol reduce myocardial oxygen consumption by blocking beta-adrenergic sympathetic stimulation to the heart. The result is a reduction in heart rate, slowed conduction of impulses through the conduction system, decreased blood pressure, and reduced myocardial **contractility** (force of contraction). Because of these effects, beta-blockers balance the myocardial oxygen needs (demands) and the amount of oxygen available (supply). This helps control chest pain and delays the onset of ischemia during work or exercise. Beta-blockers reduce the incidence of recurrent angina, infarction, and cardiac mortality. The dose can be titrated to achieve a resting heart rate of 50 to 60 bpm (Frandsen & Pennington, 2021).

Cardiac side effects and possible contraindications include hypotension, bradycardia, advanced atrioventricular block, and acute heart failure. If a beta-blocker is given IV for an acute cardiac event, the ECG, blood pressure, and heart rate are monitored closely after the medication has been given. Side effects include depressed mood, fatigue, decreased libido, and dizziness. Patients taking beta-blockers are cautioned not to stop taking them abruptly, because angina may worsen, and MI may develop. Beta-blocker therapy should be decreased gradually over several days before being discontinued. Patients with diabetes who take beta-blockers are instructed to monitor their blood glucose levels as prescribed because beta-blockers can mask signs of hypoglycemia. Beta-blockers that are not cardioselective also affect the beta-adrenergic receptors in the bronchioles, causing bronchoconstriction, and therefore are contraindicated in patients with significant chronic pulmonary disorders, such as asthma.

Chart 23-3 **PHARMACOLOGY**

Self-Administration of Nitroglycerin

Most patients with angina pectoris self-administer nitroglycerin on an as-needed basis. A key nursing role in such cases is educating patients about the medication and how to take it. Sublingual nitroglycerin comes in tablet and spray forms.

- Instruct the patient to make sure that the mouth is moist, the tongue is still, and saliva is not swallowed until the nitroglycerin tablet dissolves. If the pain is severe, the patient can crush the tablet between the teeth to hasten sublingual absorption.
- Advise the patient to carry the medication at all times as a precaution. However, because nitroglycerin is very unstable, it should be carried securely in its original container (e.g., capped dark glass bottle); tablets should never be removed and stored in metal or plastic pillboxes.
- Explain that nitroglycerin is volatile and is inactivated by heat, moisture, air, light, and time. Instruct the patient to renew the nitroglycerin supply every 6 months.
- Inform the patient that the medication should be taken in anticipation of any activity that may produce pain. Because nitroglycerin increases tolerance for exercise and stress when taken prophylactically (i.e., before angina-producing activity, such as exercise, stair-climbing, or sexual intercourse), it is best taken before pain develops.
- Recommend that the patient note how long it takes for the nitroglycerin to relieve the discomfort. Advise the patient that if pain persists after taking three sublingual tablets at 5-minute intervals, emergency medical services should be called.
- Discuss possible side effects of nitroglycerin, including flushing, throbbing headache, hypotension, and tachycardia.
- Advise the patient to sit down for a few minutes when taking nitroglycerin to avoid hypotension and syncope.

Adapted from Comerford, K. C., & Durkin, M. T. (Eds.) (2020). *Nursing2020 Drug Handbook*. Philadelphia, PA: Wolters Kluwer.

Calcium Channel Blocking Agents

Calcium channel blockers have a variety of effects on the ischemic myocardium. These agents decrease sinoatrial node automaticity and atrioventricular node conduction, resulting in a slower heart rate and a decrease in the strength of myocardial contraction (negative inotropic effect). These effects decrease the workload of the heart. Calcium channel blockers also increase myocardial oxygen supply by dilating the smooth muscle wall of the coronary arterioles; they decrease myocardial oxygen demand by reducing systemic arterial pressure and the workload of the left ventricle (Frandsen & Pennington, 2021). The calcium channel blockers most commonly used are amlodipine and diltiazem. In addition to their use to treat angina, they are commonly prescribed for hypertension. Hypotension may occur after the administration of any of the calcium channel blockers, particularly when administered IV. Other side effects may include atrioventricular block, bradycardia, and constipation.

Antiplatelet and Anticoagulant Medications

Antiplatelet medications are given to prevent platelet aggregation and subsequent thrombosis, which impedes blood flow through the coronary arteries.

Aspirin

Aspirin prevents platelet aggregation and reduces the incidence of MI and death in patients with CAD (Frandsen & Pennington, 2021). A 162- to 325-mg dose of aspirin should be given to the patient with a new diagnosis of angina and then continued with 81 to 325 mg daily. Patients should be advised to continue aspirin even if they concurrently take other analgesics such as acetaminophen. Because aspirin may cause GI upset and bleeding, the use of histamine-2 (H_2) blockers (e.g., famotidine) or proton pump inhibitors (e.g., omeprazole) should be considered concomitant with continued aspirin therapy (Ibanez, James, Agewall, et al., 2018).

Adenosine Diphosphate Receptor Antagonists ($P2Y_{12}$)

These medications act on different pathways than aspirin to block platelet activation. However, unlike aspirin, these agents may take a few days to achieve antiplatelet effects. Clopidogrel is commonly prescribed in addition to aspirin in patients at high risk for MI. Newer oral agents such as prasugrel and ticagrelor may be used in place of clopidogrel during coronary events and interventions (Frandsen & Pennington, 2021). Both carry the risk of bleeding from the GI tract or other sites.

Heparin

Unfractionated IV heparin prevents the formation of new blood clots (i.e., it is an anticoagulant). Treating patients with unstable angina with heparin reduces the occurrence of MI. If the patient's signs and symptoms indicate a significant risk for a cardiac event, the patient is hospitalized and may be given an IV bolus of heparin and started on a continuous infusion. The dose of heparin given is based on the results of the activated partial thromboplastin time (aPTT). Heparin therapy is usually considered therapeutic when the aPTT is 2 to 2.5 times the normal aPTT value.

A subcutaneous injection of low-molecular-weight heparin (LMWH; enoxaparin or dalteparin) may be used instead of IV unfractionated heparin to treat patients with unstable angina or non–ST-segment elevation myocardial infarction (NSTEMI) (Frandsen & Pennington, 2021). LMWH provides effective and stable anticoagulation, potentially reducing the risk of rebound ischemic events, and eliminating the need to monitor aPTT results. LMWHs may be beneficial before and during PCIs as well as for ACS.

Because unfractionated heparin and LMWH increase the risk of bleeding, the patient is monitored for signs and symptoms of external and internal bleeding, such as low blood pressure, increased heart rate, and decreased serum hemoglobin and hematocrit. The patient receiving heparin is placed on bleeding precautions, which include:

- Applying pressure to the site of any needle puncture for a longer time than usual
- Avoiding intramuscular (IM) injections
- Avoiding tissue injury and bruising from trauma or use of constrictive devices (e.g., continuous use of an automatic blood pressure cuff)

A decrease in platelet count or evidence of thrombosis may indicate heparin-induced thrombocytopenia (HIT), an antibody-mediated reaction to heparin that may result in thrombosis. Patients who have received heparin within the past 3 months and those who have been receiving unfractionated heparin for 4 to 14 days are at high risk for HIT (Frandsen & Pennington, 2021). As an alternative to LMWH and unfractionated heparin, argatroban, a direct antithrombotic agent might be prescribed (Frandsen & Pennington, 2021; see Chapter 29 for further discussion of HIT).

Glycoprotein IIb/IIIa Agents

IV administration of glycoprotein (GP) IIb/IIIa agents, such as abciximab or eptifibatide, is indicated for hospitalized patients with unstable angina and as adjunct therapy for PCI. These agents prevent platelet aggregation by blocking the GP IIb/IIIa receptors on the platelets, preventing adhesion of fibrinogen and other factors that crosslink platelets to each other and thus form intracoronary clots (Urden, Stacy, & Lough, 2019). As with heparin, bleeding is the major side effect, and bleeding precautions should be initiated.

Oxygen Administration

Oxygen therapy is usually initiated at the onset of chest pain in an attempt to increase the amount of oxygen delivered to the myocardium and to decrease pain. The therapeutic effectiveness of oxygen is determined by observing the rate and rhythm of respirations and the color of skin and mucous membranes. Blood oxygen saturation is monitored by pulse oximetry; the normal oxygen saturation (SpO_2) level is >95% on room air (Urden et al., 2019).

NURSING PROCESS

The Patient with Angina Pectoris

Assessment

The nurse gathers information about the patient's symptoms and activities, especially those that precede and precipitate attacks of angina pectoris. Appropriate questions are listed in Chart 23-4. The answers to these questions form the basis for designing an effective program of treatment and prevention. In addition to assessing angina pectoris or its equivalent, the nurse also assesses the patient's risk factors for CAD, the patient's response to angina, the patient's and family's understanding of the diagnosis, and adherence to the current treatment plan.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include:

- Risk for impaired cardiac function
- Anxiety associated with cardiac symptoms and possible death
- Lack of knowledge about the underlying disease and methods for avoiding complications
- Able to perform self care

Chart 23-4 ASSESSMENT

Assessing Angina

Ask the following:

- "Where is the pain (or prodromal symptoms)? Can you point to it?"
- "Can you feel the pain anywhere else?"
- "How would you describe the pain?"
- "Is it like the pain you had before?"
- "Can you rate the pain on a 0–10 scale, with 10 being the most pain?"
- "When did the pain begin?"
- "How long does it last?"
- "What brings on the pain?"
- "What helps the pain go away?"
- "Do you have any other symptoms with the pain?"

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Potential complications may include the following:

- ACS and/or MI (described later in this chapter)
- Arrhythmias and cardiac arrest (see Chapters 22 and 25)
- Heart failure (see Chapter 25)

- Cardiogenic shock (see Chapter 11)

Planning and Goals

Major patient goals include immediate and appropriate treatment when angina occurs, prevention of angina, reduction of anxiety, awareness of the disease process and understanding of the prescribed care, adherence to the self-care program, and absence of complications.

Nursing Interventions

Treating Angina

If the patient reports pain (or cardiac ischemia is suggested by prodromal symptoms, which may include sensations of indigestion or nausea, choking, heaviness, weakness or numbness in the upper extremities, dyspnea, or dizziness), the nurse takes immediate action. The patient experiencing angina is directed to stop all activities and sit or rest in bed in a semi-Fowler position to reduce the oxygen requirements of the ischemic myocardium. The nurse assesses the patient's angina, asking questions to determine whether the angina is the same as the patient typically experiences. A change may indicate a worsening of the disease or a different cause. The nurse then continues to assess the patient, measuring vital signs and observing for signs of respiratory distress. If the patient is in the hospital, a 12-lead ECG is usually obtained and assessed for ST-segment and T-wave changes. If the patient has been placed on cardiac monitoring with continuous ST-segment monitoring, the ST segment is assessed for changes.

Nitroglycerin is given sublingually, and the patient's response is assessed (relief of chest pain and effect on blood pressure and heart rate). If the chest pain is unchanged or is lessened but still present, nitroglycerin administration is repeated up to three doses. Each time blood pressure, heart rate, and the ST segment (if the patient is on a monitor with ST-segment monitoring capability) are assessed. The nurse administers oxygen therapy if the patient's respiratory rate is increased or if the oxygen saturation level is decreased. Oxygen is usually given at 2 L/min by nasal cannula, even without evidence of desaturation, although there is no current evidence of a positive effect on patient outcome. If the pain is significant and continues after these interventions, the patient is further evaluated for acute MI and may be transferred to a higher-acuity nursing unit (Ibanez et al., 2018).

Reducing Anxiety

Patients with angina often fear loss of their roles within society and the family. They may also fear that the pain (or the prodromal symptoms) may lead to an MI or death. Exploring the implications that the diagnosis has for the patient and providing information about the illness, its treatment, and methods of preventing its progression are important nursing interventions. Various stress reduction methods, such as guided imagery or music therapy, should be explored with the patient (Meghani, 2017). Addressing the spiritual needs of the patient and family may also assist in allaying anxieties and fears.

Preventing Pain

The nurse reviews the assessment findings, identifies the level of activity that causes the patient's pain or prodromal symptoms, and plans the patient's activities

accordingly. If the patient has pain frequently or with minimal activity, the nurse alternates the patient's activities with rest periods. Balancing activity and rest is an important aspect of the educational plan for the patient and family.

PROMOTING HOME, COMMUNITY-BASED, AND TRANSITIONAL CARE

Educating Patients About Self-Care. The program for educating the patient with angina is designed so that the patient and family understand the illness, identify the symptoms of myocardial ischemia, state the actions to take when symptoms develop, and discuss methods to prevent chest pain and the advancement of CAD. The goals of education are to reduce the frequency and severity of anginal attacks, to delay the progress of the underlying disease if possible, and to prevent complications. The factors outlined in Chart 23-5 are important in educating the patient with angina pectoris.

The self-care program is prepared in collaboration with the patient and family or friends. Activities should be planned to minimize the occurrence of anginal episodes. The patient needs to understand that any pain unrelieved within 15 minutes by the usual methods, including nitroglycerin (see Chart 23-3), should be treated at the closest ED; the patient should call 911 for assistance.

Continuing and Transitional Care. For patient with disability or special needs, arrangements are made for transitional, home, or community care when appropriate. A home health or transitional care nurse can assist the patient with scheduling and keeping follow-up appointments. The patient may need reminders about follow-up monitoring, including periodic laboratory testing. In addition, the home health nurse may monitor the patient's adherence to dietary restrictions and to prescribed antianginal medications, including nitroglycerin. If the patient has severe anginal symptoms, the nurse may assess the home environment and recommend modifications that diminish the occurrence of anginal episodes. For instance, if a patient cannot climb stairs without experiencing ischemia, the home health nurse may help the patient plan daily activities that minimize stair-climbing.

Chart 23-5 **HOME CARE CHECKLIST**

Managing Angina Pectoris

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of angina pectoris on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in lifestyle (e.g., diet, activity) or home environment necessary to maintain health.
- Follow a diet low in saturated fat, high in fiber, and, if indicated, lower in calories.
- Reduce the probability of an episode of anginal pain by balancing rest with regular daily activities that do not produce chest discomfort, shortness of breath, or undue fatigue.
- Follow the prescribed exercise regimen.
  - Recognize that temperature extremes (particularly cold) may induce anginal pain; therefore, avoid exercise in temperature extremes.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Take medications, especially aspirin and beta-blockers, as prescribed.
- Carry nitroglycerin at all times; state when and how to use it; identify its side effects.
- Avoid using medications or any over-the-counter substances (e.g., diet pills, nasal decongestants) that can increase the heart rate and blood pressure without first discussing with the primary provider.
- Use appropriate resources for support during emotionally stressful times (e.g., counselor, nurse, clergy, primary provider).
- Stop smoking and the use of other forms of tobacco and avoid secondhand smoke (because smoking increases the heart rate, blood pressure, and blood carbon monoxide levels).
- Achieve and maintain normal blood pressure.
- Achieve and maintain normal blood glucose levels.
- State how to reach primary provider with questions or complications.
  - Report increase in symptoms to the primary provider.
  - State time and date of follow-up appointments and testing.
- Identify the need for health promotion (e.g., weight reduction, cessation of tobacco use, stress management), disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, independent activities of daily living.

Evaluation

Expected patient outcomes may include:

1. Reports that pain is relieved promptly
   a. Recognizes symptoms
   b. Takes immediate action
   c. Seeks medical assistance if pain persists or changes in quality

2. Reports decreased anxiety
    a. Expresses acceptance of diagnosis
    b. Expresses control over choices within medical regimen
    c. Does not exhibit signs and symptoms that indicate a high level of anxiety
3. Understands ways to avoid complications and is free of complications
    a. Describes the process of angina
    b. Explains reasons for measures to prevent complications
    c. Exhibits stable ECG
    d. Experiences no signs and symptoms of acute MI
4. Adheres to self-care program
    a. Takes medications as prescribed
    b. Keeps health care appointments
    c. Implements plan to reduce risk factors

Acute Coronary Syndrome and Myocardial Infarction

Acute coronary syndrome (ACS) is an emergent situation characterized by an acute onset of myocardial ischemia that results in myocardial death (i.e., MI) if definitive interventions do not occur promptly. (Although the terms *coronary occlusion, heart attack,* and *myocardial infarction* are used synonymously, the preferred term is *myocardial infarction.*) The spectrum of ACS includes unstable angina, NSTEMI, and ST-segment elevation myocardial infarction (STEMI).

Pathophysiology

In unstable angina, there is reduced blood flow in a coronary artery, often due to rupture of an atherosclerotic plaque. A clot begins to form on top of the coronary lesion, but the artery is not completely occluded. This is an acute situation that can result in chest pain and other symptoms that may be referred to as preinfarction angina because the patient will likely have an MI if prompt interventions do not occur.

In an MI, plaque rupture and subsequent thrombus formation result in complete occlusion of the artery, leading to ischemia and necrosis of the myocardium supplied by that artery. Vasospasm (sudden constriction or narrowing) of a coronary artery, decreased oxygen supply (e.g., from acute blood loss, anemia, or low blood pressure), and increased demand for oxygen (e.g., from a rapid heart rate, thyrotoxicosis, or ingestion of cocaine) are other causes of MI. In each case, a profound imbalance exists between myocardial oxygen supply and demand.

The area of infarction develops over minutes to hours. As the cells are deprived of oxygen, ischemia develops, cellular injury occurs, and the lack of oxygen results in infarction, or the death of cells. The expression “time is muscle” reflects the urgency of appropriate treatment to improve patient outcomes. Approximately every 40 seconds, an American will have an MI (Benjamin et al., 2019), and many of these

people will die as a result. Early recognition and treatment of patients presenting with an MI will improve their chances of survival.

Various descriptions are used to further identify an MI: the type (NSTEMI, STEMI), the location of the injury to the ventricular wall (anterior, inferior, posterior, or lateral wall), and the point in time within the process of infarction (acute, evolving, or old). The differentiation between NSTEMI and STEMI is determined by diagnostic tests and is explained later in this chapter.

The 12-lead ECG identifies the type and location of the MI, and other ECG indicators, such as a Q wave, and patient history, identify the timing. Regardless of the location, the goals of medical therapy are to relieve symptoms, prevent or minimize myocardial tissue death, and prevent complications. The pathophysiology of CAD and the risk factors involved were discussed earlier in this chapter.

Clinical Manifestations

Chest pain that occurs suddenly and continues despite rest and medication is the presenting symptom in most patients with ACS. Some of these patients have prodromal symptoms or a previous diagnosis of CAD, but others report no previous symptoms. Patients may present with a combination of symptoms, including chest pain, shortness of breath, indigestion, nausea, and anxiety. They may have cool, pale, and moist skin. Their heart rate and respiratory rate may be faster than normal. These signs and symptoms, which are caused by stimulation of the sympathetic nervous system, may be present for only a short time or may persist. In many cases, the signs and symptoms of MI cannot be distinguished from those of unstable angina; hence, the evolution of the term *acute coronary syndrome.*

Assessment and Diagnostic Findings

The diagnosis of ACS is generally based on the presenting symptoms (see Chart 23-6); the 12-lead ECG and laboratory tests (e.g., serial cardiac biomarkers) are performed to clarify whether the patient has unstable angina, NSTEMI, or STEMI (Ibanez et al., 2018). The prognosis depends on the severity of coronary artery obstruction and the presence and extent of myocardial damage. Physical examination is always conducted, but the examination alone does not confirm the diagnosis.

Patient History

The patient history includes the description of the presenting symptom (e.g., pain), the history of previous cardiac and other illnesses, and the family history of heart disease. The history should also include information about the patient's risk factors for heart disease.

Electrocardiogram

The 12-lead ECG provides information that assists in ruling out or diagnosing an acute MI. It should be obtained within 10 minutes from the time a patient reports pain or arrives in the ED. By monitoring serial ECG changes over time, the location, evolution, and resolution of an MI can be identified and monitored.

The ECG changes that occur with an MI are seen in the leads that view the involved surface of the heart. The expected ECG changes are T-wave inversion, ST-segment elevation, and development of an abnormal Q wave (see Fig. 23-5). Because infarction evolves over time, the ECG also changes over time. The first ECG signs of an acute MI are usually seen in the T wave and ST segment (Urden et al., 2019). As the area of injury becomes ischemic, myocardial repolarization is altered and delayed, causing the T wave to invert. Myocardial injury also causes ST-segment changes. The ST segment is normally flat on the ECG tracing. The injured myocardial cells depolarize normally but repolarize more rapidly than normal cells, causing the ST segment to rise at least 1 mm above the isoelectric line (the area between the T wave and the next P wave is used as the reference for the isoelectric line). This change is measured 0.06 to 0.08 seconds after the end of the QRS—a point called the *J point* (Urden et al., 2019) (see Fig. 23-6). An elevation in the ST segment in two contiguous leads is a key diagnostic indicator for MI (i.e., STEMI).

Chart 23-6 **ASSESSMENT**

Assessing for Acute Coronary Syndrome or Acute Myocardial Infarction

Be alert for the following signs and symptoms:

Cardiovascular

- Chest pain or discomfort not relieved by rest or nitroglycerin; palpitations. Heart sounds may include S_3, S_4, and new onset of a murmur.
- Increased jugular venous distention may be seen if the myocardial infarction (MI) has caused heart failure.
- Blood pressure may be elevated because of sympathetic stimulation or decreased because of decreased contractility, impending cardiogenic shock, or medications.
- Irregular pulse may indicate atrial fibrillation.
- In addition to ST-segment and T-wave changes, the electrocardiogram may show tachycardia, bradycardia, or other arrhythmias.

Respiratory

Shortness of breath, dyspnea, tachypnea, and crackles if MI has caused pulmonary congestion. Pulmonary edema may be present.

Gastrointestinal

Nausea, indigestion, and vomiting.

Genitourinary

Decreased urinary output may indicate cardiogenic shock.

Skin

Cool, clammy, diaphoretic, and pale appearance due to sympathetic stimulation may indicate cardiogenic shock.

Neurologic

Anxiety, restlessness, and lightheadedness may indicate increased sympathetic stimulation or a decrease in contractility and cerebral oxygenation. The same symptoms may also herald cardiogenic shock.

Psychological

Fear with feeling of impending doom, or denial that anything is wrong.

The appearance of abnormal Q waves is another indication of MI. Q waves develop within 1 to 3 days because there is no depolarization current conducted from necrotic tissue (Urden et al., 2019). A new and significant Q wave is 0.04 seconds or longer and 25% of the R wave depth. An acute MI may also cause a significant decrease in the height of the R wave. During an acute MI, injury and ischemic changes are usually present. An abnormal Q wave may be present without ST-segment and T-wave changes, which indicates an old, not acute, MI. For some patients, there is no persistent ST elevation or other ECG changes; therefore, an NSTEMI is diagnosed by blood levels of cardiac biomarkers.

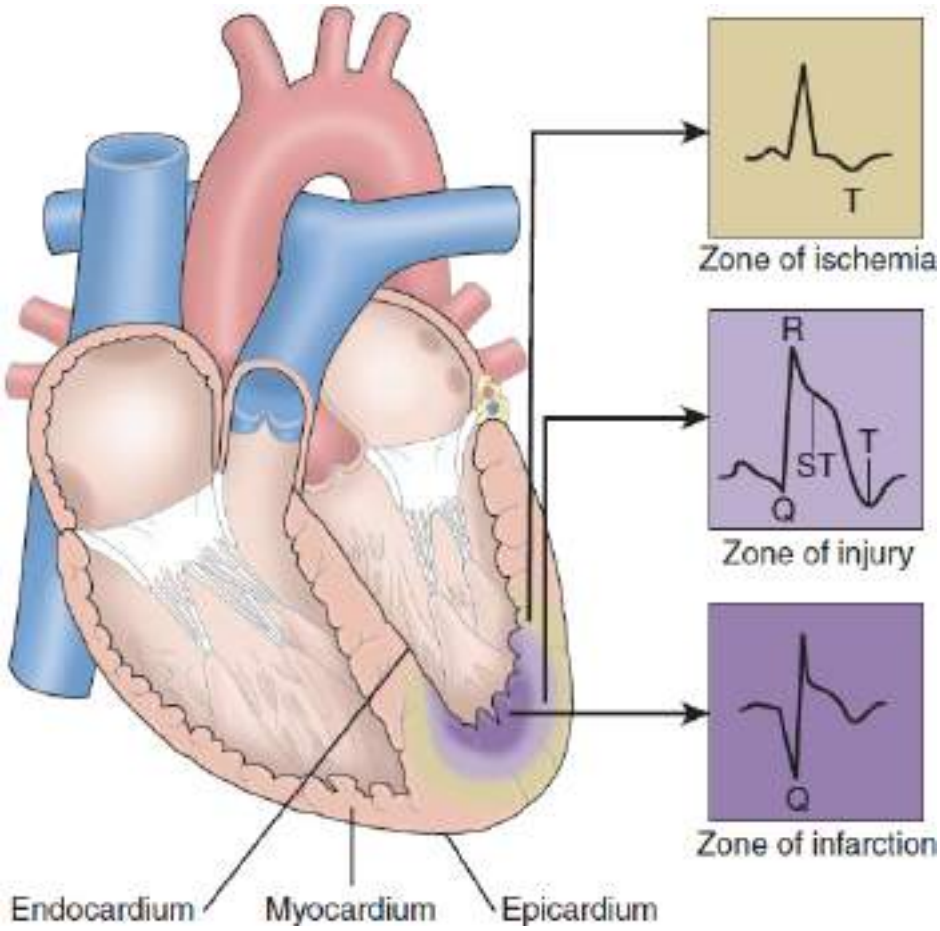

Figure 23-5 • Effects of ischemia, injury, and infarction on an electrocardiogram recording. Ischemia causes inversion of the T wave because of altered repolarization. Cardiac muscle injury causes elevation of the ST segment. Later, Q waves develop because of the absence of depolarization current from the necrotic tissue and opposing currents from other parts of the heart.

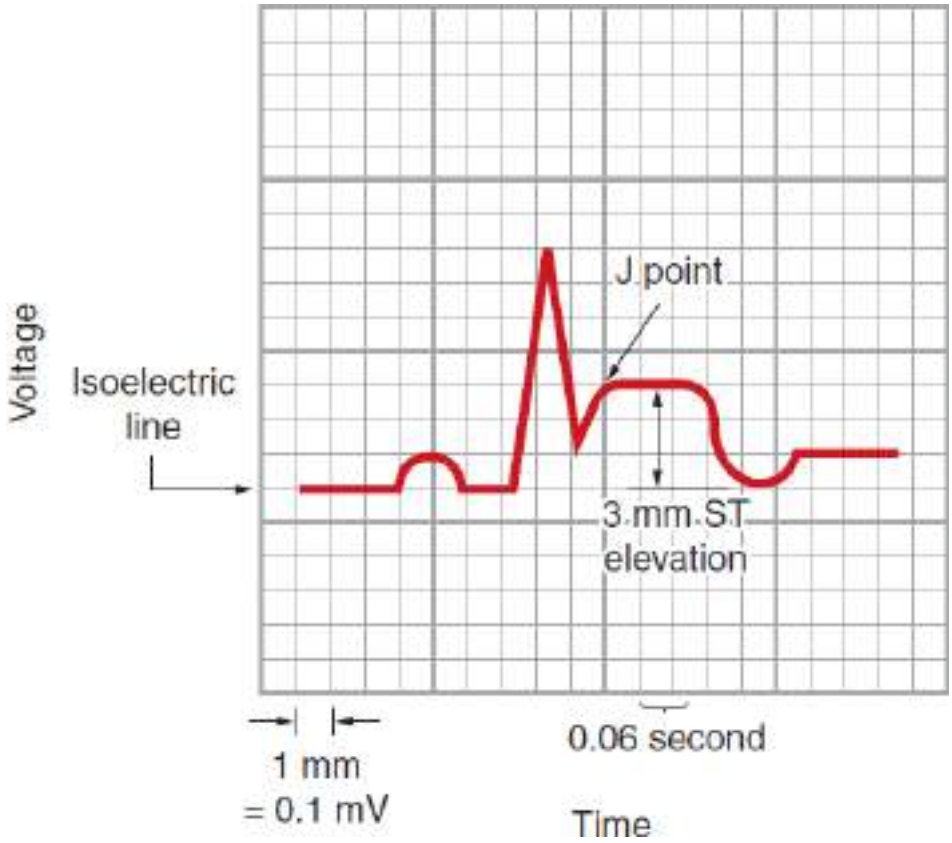

Figure 23-6 • Using the electrocardiogram to diagnose acute myocardial infarction (MI). (ST-segment elevation is measured 0.06 to 0.08 seconds after the J point. An elevation of more than 1 mm in contiguous leads is indicative of acute MI.)

Using the information presented, patients are diagnosed with one of the following forms of ACS:

- *Unstable angina:* The patient has clinical manifestations of coronary ischemia, but ECG and cardiac biomarkers show no evidence of acute MI.
- *STEMI:* The patient has ECG evidence of acute MI with characteristic changes in two contiguous leads on a 12-lead ECG. In this type of MI, there is a significant damage to the myocardium.
- *NSTEMI:* The patient has elevated cardiac biomarkers (e.g., troponin) but no definite ECG evidence of acute MI. In this type of MI, there may be less damage to the myocardium.

During recovery from an MI, the ST segment often is the first ECG indicator to return to normal. Q-wave alterations are usually permanent. An old STEMI is usually indicated by an abnormal Q wave or decreased height of the R wave without ST-segment and T-wave changes.

Echocardiogram

The echocardiogram is used to evaluate ventricular function. It may be used to assist in diagnosing an MI, especially when the ECG is nondiagnostic. The echocardiogram

can detect hypokinetic and akinetic wall motion and can determine the ejection fraction (see Chapter 21).

Laboratory Tests

Cardiac enzymes and biomarkers, which include troponin, creatine kinase (CK), and myoglobin, are used to diagnose an acute MI. Cardiac biomarkers can be analyzed rapidly, expediting an accurate diagnosis. These tests are based on the release of cellular contents into the circulation when myocardial cells die.

Troponin

Troponin, a protein found in myocardial cells, regulates the myocardial contractile process. There are three isomers of troponin: C, I, and T. Troponins I and T are specific for cardiac muscle, and these biomarkers are currently recognized as reliable and critical markers of myocardial injury (Norris, 2019). An increase in the level of troponin in the serum can be detected within a few hours during acute MI. It remains elevated for a long period, often as long as 2 weeks, and it therefore can be used to detect recent myocardial damage. It should be noted that cardiac troponin levels may rise during inflammation and other forms of mechanical stress on the myocardium. These include sepsis, heart failure, and respiratory failure (Felker & Fudim, 2018).

Creatine Kinase and Its Isoenzymes

There are three CK isoenzymes: CK-MM (skeletal muscle), CK-MB (heart muscle), and CK-BB (brain tissue). CK-MB is the cardiac-specific isoenzyme; it is found mainly in cardiac cells and therefore increases when there has been damage to these cells. Elevated CK-MB is an indicator of acute MI; the level begins to increase within a few hours and peaks within 24 hours of an infarct.

Myoglobin

Myoglobin is a heme protein that helps transport oxygen. Like the CK-MB enzyme, myoglobin is found in cardiac and skeletal muscle. The myoglobin level starts to increase within 1 to 3 hours and peaks within 12 hours after the onset of symptoms. An increase in myoglobin is not very specific in indicating an acute cardiac event; however, negative results can be used to rule out an acute MI.

Chart 23-7

Treatment Guidelines for Acute Myocardial Infarction

- Use rapid transit to the hospital.
- Obtain 12-lead electrocardiogram to be read within 10 minutes.
- Obtain laboratory blood specimens of cardiac biomarkers, including troponin.
- Obtain other diagnostics to clarify the diagnosis.
- Begin routine medical interventions:
  - Supplemental oxygen
  - Nitroglycerin
  - Morphine
  - Aspirin
  - Beta-blocker
  - Angiotensin-converting enzyme inhibitor within 24 hours
  - Anticoagulation with heparin and platelet inhibitors
  - Statin
- Evaluate for indications for reperfusion therapy:
  - Percutaneous coronary intervention
  - Thrombolytic therapy
- Continue therapy as indicated:
  - IV heparin, low-molecular-weight heparin, bivalirudin, or fondaparinux
  - Clopidogrel
  - Glycoprotein IIb/IIIa inhibitor
  - Bed rest for a minimum of 12–24 hours
  - Statin prescribed at discharge.

Adapted from Ibanez, B., James, S., Agewall, S., et al. (2018). 2017 ESC Guidelines for the management of acute myocardial infarction in patients presenting with ST-segment elevation. *European Heart Journal, 39*(2), 119–177.

Medical Management

The goals of medical management are to minimize myocardial damage, preserve myocardial function, and prevent complications. These goals are facilitated by the use of guidelines developed by the ACC and the AHA (see Chart 23-7).

The goal for treating patients with acute MI is to minimize myocardial damage by reducing myocardial oxygen demand and increasing oxygen supply with medications, oxygen administration, and bed rest. The resolution of pain and ECG changes indicate that demand and supply are in equilibrium; they may also indicate reperfusion. Visualization of blood flow through an open vessel in the catheterization laboratory is evidence of reperfusion.

Initial Management

The patient with suspected MI should immediately receive supplemental oxygen, aspirin, nitroglycerin, and morphine. Morphine is the drug of choice to reduce pain and anxiety. It also reduces preload and afterload, decreasing the work of the heart. The response to morphine is monitored carefully to assess for hypotension or decreased respiratory rate. Nurses should be aware that evolving research has

suggested an association between morphine and potential adverse outcomes, including larger infarct size, increased length of hospital stay, and mortality, and should stay abreast of changes to clinical guidelines impacting its use (McCarthy, Bhambhani, Pomerantsev, et al., 2018; Neto, 2018). A beta-blocker may also be used if arrhythmias occur. If a beta-blocker is not needed in the initial management period, it should be introduced within 24 hours of admission, once hemodynamics have stabilized and it is confirmed that the patient has no contraindications (Ibanez et al., 2018). Unfractionated heparin or LMWH may also be prescribed along with platelet-inhibiting agents to prevent further clot formation.

Emergent Percutaneous Coronary Intervention

The patient with STEMI is taken directly to the cardiac catheterization laboratory for an immediate PCI (if a cardiac catheterization laboratory is on site). The procedure is used to open the occluded coronary artery and promote reperfusion to the area that has been deprived of oxygen. Superior outcomes have been reported with the use of PCI when compared to thrombolytic agents (Urden et al., 2019) (also called *fibrinolytic* agents; see the Thrombolytics section). Thus, PCI is preferred as the initial treatment method for acute MI in all age groups (Urden et al., 2019). The procedure treats the underlying atherosclerotic lesion. Because the duration of oxygen deprivation determines the number of myocardial cells that die, the time from the patient's arrival in the ED to the time PCI is performed should be less than 60 minutes. This is frequently referred to as door-to-balloon time. A cardiac catheterization laboratory and staff must be available if an emergent PCI is to be performed within this short time. The nursing care related to PCI is presented later in this chapter.

Thrombolytics

Thrombolytic therapy is initiated when primary PCI is not available or the transport time to a PCI-capable hospital is too long. These agents are administered IV according to a specific protocol (see Chart 23-8). The thrombolytic agents used most often are alteplase, reteplase, and tenecteplase. The purpose of **thrombolytics** is to dissolve (i.e., lyse) the thrombus in a coronary artery (thrombolysis), allowing blood to flow through the coronary artery again (reperfusion), minimizing the size of the infarction and preserving ventricular function. However, although thrombolytics may dissolve the thrombus, they do not affect the underlying atherosclerotic lesion. The patient may be referred for a cardiac catheterization and other invasive procedures following the use of thrombolytic therapy. Thrombolytics should not be used if the patient is bleeding or has a bleeding disorder. They should be given within 30 minutes of symptom onset for best results (Norris, 2019). This is frequently referred to as door-to-needle time.

Inpatient Management

Following PCI or thrombolytic therapy, continuous cardiac monitoring is indicated, preferably in a cardiac intensive care unit (ICU). Continuing pharmacologic management includes aspirin, a beta-blocker, and an angiotensin-converting enzyme (ACE) inhibitor. ACE inhibitors prevent the conversion of angiotensin I to

angiotensin II. In the absence of angiotensin II, the blood pressure decreases and the kidneys excrete sodium and fluid (diuresis), decreasing the oxygen demand of the heart. The use of ACE inhibitors in patients after MI decreases mortality rates and prevents remodeling of myocardial cells that is associated with the onset of heart failure. Blood pressure, urine output, and serum sodium, potassium, and creatinine levels need to be monitored closely. If an ACE inhibitor is not suitable, an angiotensin receptor blocker (ARB) should be prescribed (Ibanez et al., 2018). Nicotine replacement therapy and tobacco cessation counseling should also be initiated for all tobacco users.

Chart 23-8 **PHARMACOLOGY**

Administration of Thrombolytic Therapy

Indications

- Chest pain lasting more than 20 minutes, unrelieved by nitroglycerin
- ST-segment elevation in at least two leads that face the same area of the heart
- Less than 12 hours from onset of pain

Absolute Contraindications

- Active bleeding
- Known bleeding disorder
- History of hemorrhagic stroke
- History of intracranial vessel malformation
- Recent major surgery or trauma
- Uncontrolled hypertension
- Pregnancy

Nursing Considerations

- Minimize the number of times the patient's skin is punctured.
- Avoid intramuscular injections.
- Draw blood for laboratory tests when starting the IV line.
- Start IV lines before thrombolytic therapy; designate one line to use for blood draws.
- Avoid continual use of noninvasive blood pressure cuff.
- Monitor for acute arrhythmias and hypotension.
- Monitor for reperfusion: resolution of angina or acute ST-segment changes.
- Check for signs and symptoms of bleeding: decrease in hematocrit and hemoglobin values, decrease in blood pressure, increase in heart rate, oozing or bulging at invasive procedure sites, back pain, muscle weakness, changes in level of consciousness, complaints of headache.
- Treat major bleeding by discontinuing thrombolytic therapy and any anticoagulants; apply direct pressure and notify the primary provider immediately.
- Treat minor bleeding by applying direct pressure if accessible and appropriate; continue to monitor.

Adapted from Urden, L. D., Stacy, K. M., & Lough, M. E. (2019). *Priorities in critical care nursing* (8th ed.). St. Louis, MO: Elsevier.

Cardiac Rehabilitation

After the patient with an MI is in a stable condition, an active rehabilitation program is initiated. Cardiac rehabilitation is an important continuing care program for patients with CAD that targets risk reduction by providing patient and family education, offering individual and group support, and encouraging physical activity and physical conditioning. The goals of rehabilitation for the patient who has had an MI are to extend life and improve the quality of life. The immediate objectives are to limit the

effects and progression of atherosclerosis, return the patient to work and a pre-illness lifestyle, enhance the patient's psychosocial and vocational status, and prevent another cardiac event. Cardiac rehabilitation programs increase survival, reduce recurrent events and the need for interventional procedures, and improve quality of life (Dickins & Braun, 2017).

Physical conditioning is achieved gradually over time. Many times, patients will "overdo it" in an attempt to achieve their goals too rapidly. Patients are observed for chest pain, dyspnea, weakness, fatigue, and palpitations and are instructed to stop exercise if any of these occur. Patients may also be monitored for an increase in heart rate above the target heart rate, an increase in systolic or diastolic blood pressure of more than 20 mm Hg, a decrease in systolic blood pressure, onset or worsening of arrhythmias, or ST-segment changes on the ECG.

Cardiac rehabilitation programs are categorized into three phases (Dickins & Braun, 2017). Phase I begins with the diagnosis of atherosclerosis, which may occur when the patient is admitted to the hospital for ACS. Because of brief hospital lengths of stay, mobilization occurs early and patient education focuses on the essentials of self-care rather than instituting behavioral changes for risk reduction. Priorities for in-hospital education include the signs and symptoms that indicate the need to call 911 (seek emergency assistance), the medication regimen, rest–activity balance, and follow-up appointments with the primary provider. The patient is reassured that although CAD is a lifelong disease and must be treated as such, they can likely resume a normal life after an MI. The amount and type of activity recommended at discharge depend on the patient's age, his or her condition before the cardiac event, the extent of the disease, the course of the hospital stay, and the development of any complications.

Phase II occurs after the patient has been discharged. The patient attends sessions three times a week for 4 to 6 weeks but may continue for as long as 6 months. The outpatient program consists of supervised, often ECG-monitored, exercise training that is individualized. At each session, the patient is assessed for the effectiveness of and adherence to the treatment. To prevent complications and another hospitalization, the cardiac rehabilitation staff alerts the referring primary provider to any problems. Phase II cardiac rehabilitation also includes educational sessions for patients and families that are given by cardiologists, exercise physiologists, dietitians, nurses, and other health care professionals. These sessions may take place outside a traditional classroom setting. For instance, a dietitian may take a group of patients to a grocery store to examine labels and meat selections or to a restaurant to discuss menu offerings for a heart-healthy diet.

Phase III is a long-term outpatient program that focuses on maintaining cardiovascular stability and long-term conditioning. The patient is usually self-directed during this phase and does not require a supervised program, although it may be offered. The goals of each phase build on the accomplishments of the previous phase.

NURSING PROCESS

The Patient with Acute Coronary Syndrome

Assessment

One of the most important aspects of care of the patient with ACS is the assessment. It establishes the patient's baseline, identifies the patient's needs, and helps determine the priority of those needs. Systematic assessment includes a careful history, particularly as it relates to symptoms: chest pain or discomfort, dyspnea (difficulty breathing), palpitations, unusual fatigue, syncope (faintness), or other possible indicators of myocardial ischemia. Each symptom must be evaluated with regard to time, duration, and the factors that precipitate the symptom and relieve it, and in comparison with previous symptoms. A focused physical assessment is critical to detect complications and any change in patient status. Chart 23-6 identifies important assessments and possible findings.

Two IV lines are typically placed for any patient with ACS to ensure that access is available for administering emergency medications. Medications are administered IV to achieve rapid onset and to allow for timely adjustment. After the patient's condition stabilizes, IV lines may be changed to a saline lock to maintain IV access.

Diagnosis

NURSING DIAGNOSES

Based on the clinical manifestations, history, and diagnostic assessment data, major nursing diagnoses may include:

- Acute pain associated with increased myocardial oxygen demand and decreased myocardial oxygen supply
- Risk for impaired cardiac function associated with reduced coronary blood flow
- Risk for hypovolaemia
- Impaired peripheral tissue perfusion associated with impaired cardiac output from left ventricular dysfunction
- Anxiety associated with cardiac event and possible death
- Lack of knowledge about post-ACS self-care

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Potential complications may include the following:

- Acute pulmonary edema (see Chapter 25)
- Heart failure (see Chapter 25)
- Cardiogenic shock (see Chapter 11)
- Arrhythmias and cardiac arrest (see Chapters 22 and 25)
- Pericardial effusion and cardiac tamponade (see Chapter 25)

Planning and Goals

The major goals for the patient include relief of pain or ischemic signs (e.g., ST-segment changes) and symptoms, prevention of myocardial damage, maintenance

of effective respiratory function, maintenance or attainment of adequate tissue perfusion, reduced anxiety, adherence to the self-care program, and early recognition of complications. Care of the patient with ACS who has an uncomplicated MI is summarized in the Plan of Nursing Care (see Chart 23-9).

Nursing Interventions

Relieving Pain and Other Signs and Symptoms of Ischemia

Balancing myocardial oxygen supply with demand (e.g., as evidenced by the relief of chest pain) is the top priority in the care of the patient with an ACS. Although administering medications as described previously is required to accomplish this goal, nursing interventions are also important. Collaboration among the patient, nurse, and primary provider is critical in evaluating the patient's response to therapy and in altering the interventions accordingly.

Oxygen should be given along with medication therapy to assist with relief of symptoms. Administration of oxygen raises the circulating level of oxygen to reduce pain associated with low levels of myocardial oxygen. The route of administration (usually by nasal cannula) and the oxygen flow rate are documented. A flow rate of 2 to 4 L/min is usually adequate to maintain oxygen saturation levels of at least 95% unless chronic pulmonary disease is present.

Vital signs are assessed frequently as long as the patient is experiencing pain and other signs or symptoms of acute ischemia. Physical rest in bed with the head of the bed elevated or in a supportive chair helps decrease chest discomfort and dyspnea. Elevation of the head and torso is beneficial for the following reasons:

- Tidal volume improves because of reduced pressure from abdominal contents on the diaphragm and better lung expansion.
- Drainage of the upper lung lobes improves.
- Venous return to the heart (preload) decreases, reducing the work of the heart.

The pain associated with an acute MI reflects an imbalance in myocardial oxygen supply and demand or ineffective myocardial tissue perfusion. The pain also results in increases in heart rate, respiratory rate, and blood pressure. Promptly relieving the pain helps to reestablish this balance, thus decreasing the workload of the heart and minimizing damage to the myocardium. Relief of pain also helps to reduce the patient's anxiety level, which in turn reduces the sympathetic stress response, leading to a decrease in workload of the already stressed heart.

Improving Respiratory Function

Regular and careful assessment of respiratory function detects early signs of pulmonary complications. The nurse monitors fluid volume status to prevent fluid overload and encourages the patient to breathe deeply and change position frequently to maintain effective ventilation throughout the lungs. Pulse oximetry guides the use of oxygen therapy.

Promoting Adequate Tissue Perfusion

Bed or chair rest during the initial phase of treatment helps reduce myocardial oxygen consumption. This limitation on mobility should remain until the patient is

pain free and hemodynamically stable. Skin temperature and peripheral pulses must be checked frequently to monitor tissue perfusion.

Reducing Anxiety

Alleviating anxiety and decreasing fear are important nursing functions that reduce the sympathetic stress response. Less sympathetic stimulation decreases the workload of the heart, which may relieve pain and other signs and symptoms of ischemia.

Chart 23-9 PLAN OF NURSING CARE

Care of the Patient with an Uncomplicated Myocardial Infarction

NURSING DIAGNOSIS: Risk for impaired cardiac function associated with reduced coronary blood flow
GOAL: Relief of chest pain/discomfort

Nursing Interventions	Rationale	Expected Outcomes

1. Initially assess, document, and report to the primary provider the following:
a. The patient's description of chest discomfort, including location, intensity, radiation, duration, and factors that affect it; other symptoms such as nausea, diaphoresis, or complaints of unusual fatigue
b. The effect of coronary ischemia on perfusion to the heart (e.g., change in blood pressure, heart rhythm), to the brain (e.g., changes in level of consciousness), to the kidneys (e.g., decrease in urine output), and to the skin (e.g., color, temperature)
2. Obtain a 12-lead ECG recording
	1. These data assist in determining the cause and effect of the chest discomfort and provide a baseline with which post-therapy symptoms can be compared.
	a. There are many conditions associated with chest discomfort. There are characteristic clinical findings of ischemic pain and symptoms.
	b. Myocardial infarction (MI) decreases myocardial contractility and ventricular compliance and may produce arrhythmias. Cardiac output is reduced, resulting in reduced blood pressure and decreased organ perfusion.
		• Reports beginning relief of chest discomfort and symptoms
		• Appears comfortable and is free of pain and other signs or symptoms
		• Respiratory rate, cardiac rate, and blood pressure return to prediscomfort level
		• Skin warm and dry
		• Adequate cardiac output as evidenced by:
		  • Stable/improving electrocardiogram (ECG)
		  • Heart rate and rhythm
		  • Blood pressure
		  • Mentation
		  • Urine output
		  • Serum blood urea nitrogen (BUN) and creatinine
		  • Skin color and temperature
		• No adverse effects from medications

during symptomatic events, as prescribed, to assess for ongoing ischemia.	2. An ECG during symptoms may be useful in the diagnosis of ongoing ischemia.	
3. Administer oxygen as prescribed.	3. Oxygen therapy increases the oxygen supply to the myocardium.	
4. Administer medication therapy as prescribed and evaluate the patient's response continuously.	4. Medication therapy (nitroglycerin, morphine, beta-blocker, aspirin) is the first line of defense in preserving myocardial tissue.	
5. Ensure physical rest: head of bed elevated to promote comfort; diet as tolerated; the use of bedside commode; the use of stool softener to prevent straining at stool. Provide a restful environment and allay fears and anxiety by being calm and supportive. Individualize visitation, based on patient response.	5. Physical rest reduces myocardial oxygen consumption. Fear and anxiety precipitate the stress response; this results in increased levels of endogenous catecholamines, which increase myocardial oxygen consumption.	

NURSING DIAGNOSIS: Risk for impaired cardiac function associated with left ventricular failure

GOAL: Absence of respiratory distress

Nursing Interventions	Rationale	Expected Outcomes
1. Initially, every 4 hours, and with chest discomfort or symptoms, assess, document, and report to the primary provider	1. These data are useful in diagnosing left ventricular failure. Diastolic filling sounds (S_3 and S_4) result from	• No shortness of breath, dyspnea on exertion, orthopnea, or paroxysmal nocturnal dyspnea • Respiratory rate <20 breaths/min with

abnormal heart sounds (S_3 and S_4 gallop or new murmur), abnormal breath sounds (particularly crackles), decreased oxygenation, and activity intolerance.	decreased left ventricular compliance associated with MI. Papillary muscle dysfunction (from infarction of the papillary muscle) can result in mitral regurgitation and a reduction in stroke volume. The presence of crackles (usually at the lung bases) may indicate pulmonary congestion from increased left heart pressures. The association of symptoms and activity can be used as a guide for activity prescription and a basis for patient education.	physical activity and 16 breaths/min with rest • Skin color and temperature normal • SpO_2, PaO_2, and $PaCO_2$ within normal limits • Heart rate <100 bpm and >60 bpm, with blood pressure within patient's normal limits • Chest x-ray unchanged • Appears comfortable and rested

NURSING DIAGNOSIS: Impaired peripheral tissue perfusion associated with impaired cardiac output
GOAL: Maintenance/attainment of adequate tissue perfusion

Nursing Interventions	Rationale	Expected Outcomes
1. Initially, every 4 hours, and with chest discomfort, assess, document, and report to the primary provider the following: a. Hypotension b. Tachycardia and other arrhythmia c. Activity intolerance d. Mentation changes (use	1. These data are useful in determining a low cardiac output state.	• Blood pressure within the patient's normal range • Ideally, normal sinus rhythm without arrhythmia is maintained, or patient's baseline rhythm is maintained between 60 and 100 bpm without further arrhythmia. • Prescribed activity is well tolerated.

family input) e. Reduced urine output (<0.5 mL/kg/h) f. Cool, moist, cyanotic extremities, decreased peripheral pulses, prolonged capillary refill		• Remains alert and oriented and without cognitive or behavioral change • Appears comfortable • Urine output >0.5 mL/kg/h • Extremities warm and dry with normal color
NURSING DIAGNOSIS: Anxiety associated with cardiac event **GOAL:** Reduction of anxiety		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Assess, document, and report to the primary provider the patient's and family's level of anxiety and coping mechanisms.	1. These data provide information about psychological well-being. Causes of anxiety are variable and individual, and may include acute illness, hospitalization, pain, disruption of activities of daily living at home and at work, changes in role and self-image due to illness, and financial concerns. Because anxious family members can transmit anxiety to the patient, the nurse must also identify strategies to reduce the family's fear and anxiety.	• Reports less anxiety • The patient and family discuss their anxieties and fears about illness and death. • The patient and family appear less anxious. • Appears restful, respiratory rate <16 breaths/min, heart rate <100 bpm without ectopic beats, blood pressure within patient's normal limits, skin warm and dry • Participates actively in a progressive rehabilitation program • Practices stress reduction techniques
2. Assess the need for spiritual counseling and refer as appropriate.	2. If a patient finds support in a religion, spiritual	
3. Assess the need for social service		

referral.	counseling may assist in reducing anxiety and fear. 3. Social services can assist with posthospital care and financial concerns.	

NURSING DIAGNOSIS: Lack of knowledge about post-MI self-care
GOAL: Adheres to the home health care program; chooses lifestyle consistent with heart-healthy recommendations (see Chart 23-10).

The development of a trusting and caring relationship with the patient is critical in reducing anxiety. Providing information to the patient and family in an honest and supportive manner encourages the patient to be a partner in care and greatly assists in developing a positive relationship. Other interventions that can be used to reduce anxiety include ensuring a quiet environment, preventing interruptions that disturb sleep, and providing spiritual support consistent with the patient's beliefs. The nurse provides frequent opportunities for the patient to privately share concerns and fears. An atmosphere of acceptance helps the patient know that these concerns and fears are both realistic and normal. Alternative therapies such as pet therapy can help certain patients relax and reduce anxiety (Waite, Hamilton, & O'Brien, 2018). Many hospitals have developed infection control and safety procedures pertaining to the animals, their handlers, and the patients eligible for pet therapy.

Monitoring and Managing Potential Complications

Complications that can occur after acute MI are caused by the damage that occurs to the myocardium and to the conduction system from reduced coronary blood flow. Because these complications can be life-threatening, close monitoring for and early identification of their signs and symptoms are critical (see Chart 23-9).

The nurse monitors the patient closely for changes in cardiac rate and rhythm, heart sounds, blood pressure, chest pain, respiratory status, urinary output, skin color and temperature, mental status, ECG changes, and laboratory values. Any changes in the patient's condition must be reported promptly to the primary provider and emergency measures instituted when necessary.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The most effective way to increase the probability that the patient will implement a self-care regimen after discharge is to identify the patient's priorities, provide adequate education about heart-healthy living, and facilitate the patient's involvement in a cardiac rehabilitation program (Ibanez et al., 2018). Patient participation in the development of an individualized program enhances the potential for an effective treatment plan (see Chart 23-10).

Continuing and Transitional Care. Depending on the patient's condition and the availability of family assistance, home, community-based, or transitional, care may be indicated. The nurse making a home visit can assist the patient with scheduling and keeping follow-up appointments and with adhering to the prescribed cardiac rehabilitation regimen. The patient may need reminders about follow-up monitoring, including periodic laboratory testing, as well as ongoing assessment of cardiac status. In addition, the home health nurse monitors the patient's adherence to dietary restrictions and to prescribed medications. If the patient is receiving home oxygen, the nurse ensures that the patient is using the oxygen as prescribed and that appropriate home safety measures are maintained. If the patient has evidence of heart failure secondary to an MI, appropriate home care guidelines for the patient with heart failure are followed (see Chapter 25).

Evaluation

Expected patient outcomes may include:

1. Experiences relief of angina
2. Has stable cardiac and respiratory status
3. Maintains adequate tissue perfusion
4. Exhibits decreased anxiety
5. Adheres to a self-care program
6. Has no complications

INVASIVE CORONARY ARTERY PROCEDURES

Methods to reperfuse ischemic myocardial tissue when patients are refractory to more conservative management methods include PCIs and CABG surgery, as noted previously. The following sections discuss specific indications for each of these and the nursing management of patients who are having either PCIs or CABGs.

Percutaneous Coronary Interventions

Invasive interventional procedures to treat CAD include PTCA and intracoronary stent implantation. These procedures are classified as **percutaneous coronary interventions (PCIs),** as they are performed through a skin puncture rather than a surgical incision.

Percutaneous Transluminal Coronary Angioplasty

In **percutaneous transluminal coronary angioplasty (PTCA)**, a balloon-tipped catheter is used to open blocked coronary vessels and resolve ischemia. It is used in patients with angina and as an intervention for ACS. Catheter-based interventions can also be used to open blocked CABGs (see later discussion). The purpose of PTCA is to improve blood flow within a coronary artery by compressing the atheroma. The

procedure is attempted when the interventional cardiologist determines that PTCA can improve blood flow to the myocardium.

Chart 23-10 **HEALTH PROMOTION**

Promoting Health After Myocardial Infarction and Other Acute Coronary Syndromes

To extend and improve the quality of life, a patient who has had a myocardial infarction (MI) must make lifestyle adjustments to promote heart-healthy living. With this in mind, the nurse and patient develop a program to help achieve desired outcomes.

Making Lifestyle Modifications during Convalescence and Healing

Adaptation to an MI is an ongoing process and usually requires some modification of lifestyle. Educate patients to make the following specific modifications:

- Avoid any activity that produces chest pain, extreme dyspnea, or undue fatigue.
- Avoid extremes of heat and cold and walking against the wind.
- Lose weight, if indicated.
- Stop smoking and the use of tobacco; avoid secondhand smoke.
- Develop heart-healthy eating patterns and avoid large meals and hurrying while eating.
- Modify meals to align with the AHA dietary recommendations, the Mediterranean diet, or other recommended diets.
- Adhere to medical regimen, especially in taking medications.
- Follow recommendations that ensure that blood pressure and blood glucose are in control.
- Pursue activities that relieve and reduce stress.

Adopting an Activity Program

In addition, the patient needs to undertake a structured program of activity and exercise for long-term rehabilitation. Advise patients to:

- Engage in a regimen of physical conditioning with a gradual increase in activity duration and then a gradual increase in activity intensity.
- Enroll in a cardiac rehabilitation program.
- Walk daily, increasing distance and time as prescribed.
- Monitor pulse rate during physical activity.
- Avoid physical exercise immediately after a meal.
- Alternate activity with rest periods (some fatigue is normal and expected during convalescence).
- Participate in a daily program of exercise that develops into a program of regular exercise for a lifetime.

Managing Symptoms

The patient must learn to recognize and take appropriate action for recurrent symptoms. Make sure that patients know to do the following:

- Call 911 if chest pressure or pain (or prodromal symptoms) is not relieved in 15 minutes by taking 3 nitroglycerin tablets at 5-minute intervals.
- Contact the primary provider if any of the following occur: shortness of breath, fainting, slow or rapid heartbeat, swelling of feet and ankles.

PTCA is carried out in the cardiac catheterization laboratory. Hollow catheters called *sheaths* are inserted, usually in the femoral artery (and sometimes the radial artery), providing a conduit for other catheters. Catheters are then threaded through the femoral or radial artery, up through the aorta, and into the coronary arteries. Angiography is performed using injected radiopaque contrast agents (commonly called *dye*) to identify the location and extent of the blockage. A balloon-tipped dilation catheter is passed through the sheath and positioned over the lesion. The physician determines the catheter position by examining markers on the balloon that can be seen with fluoroscopy. When the catheter is properly positioned, the balloon is inflated with high pressure for several seconds and then deflated. The pressure compresses and often "cracks" the atheroma (see Fig. 23-7). The media and adventitia of the coronary artery are also stretched.

Several inflations with different balloon sizes may be required to achieve the goal, usually defined as an improvement in blood flow and a residual stenosis of less than 10% (Urden et al., 2019). Other measures of the success of PTCA are an increase in the artery's lumen and no clinically obvious arterial trauma. Because the blood supply to the coronary artery decreases while the balloon is inflated, the patient may complain of chest pain and the ECG may display ST-segment changes. Intracoronary stents are usually positioned in the intima of the vessel to maintain patency of the artery after the balloon is withdrawn.

If thick, deep, or concentric calcification is present, the lesion may require the use of devices such as cutting, scoring, or high pressure balloons, rotational atherectomy, orbital atherectomy and excimer lasers to prepare the lesion for stenting (Shlofmitz, Shlofmitz, & Lee, 2019).

In addition to these approaches, intravascular lithotripsy (IVL) is currently being investigated to treat calcified artery blockages with sonic pressure waves in a similar way that is used to treat kidney stones. Pulsatile sonic pressure waves are used during balloon inflation to fracture both intimal and medial calcium in the artery wall but pass through the surrounding soft vascular tissue in a safe manner. This technology is approved for use in peripheral arteries at this time. Further studies are being done to assess their efficacy in coronary arteries (Riley, Corl, & Kereiakes, 2019).

Coronary Artery Stent

After PTCA, the area that has been treated may close off partially or completely—a process called *restenosis*. The intima of the coronary artery has been injured and responds by initiating an acute inflammatory process. This process may include release of mediators that leads to vasoconstriction, clotting, and scar tissue formation. A coronary artery stent may be placed to overcome these risks. A **stent** is a metal

mesh that provides structural support to a vessel at risk of acute closure. The stent is initially positioned over the angioplasty balloon. When the balloon is inflated, the mesh expands and presses against the vessel wall, holding the artery open. The balloon is withdrawn, but the stent is left permanently in place within the artery (see Fig. 23-7). Eventually, endothelium covers the stent and it is incorporated into the vessel wall. The original stents do not contain medications and are known as bare metal stents. Some stents are coated with medications, such as sirolimus or paclitaxel, which may minimize the formation of thrombi or scar tissue within the coronary artery lesion. These drug-eluting stents (DES) have increased the success of PCI (Mishra, Edla, Tripathi, et al., 2019). Because of the risk of thrombus formation within the stent, the patient receives antiplatelet medications, usually aspirin and clopidogrel. Aspirin should be continued indefinitely and clopidogrel is continued for 1 year following stent placement (Urden et al., 2019).

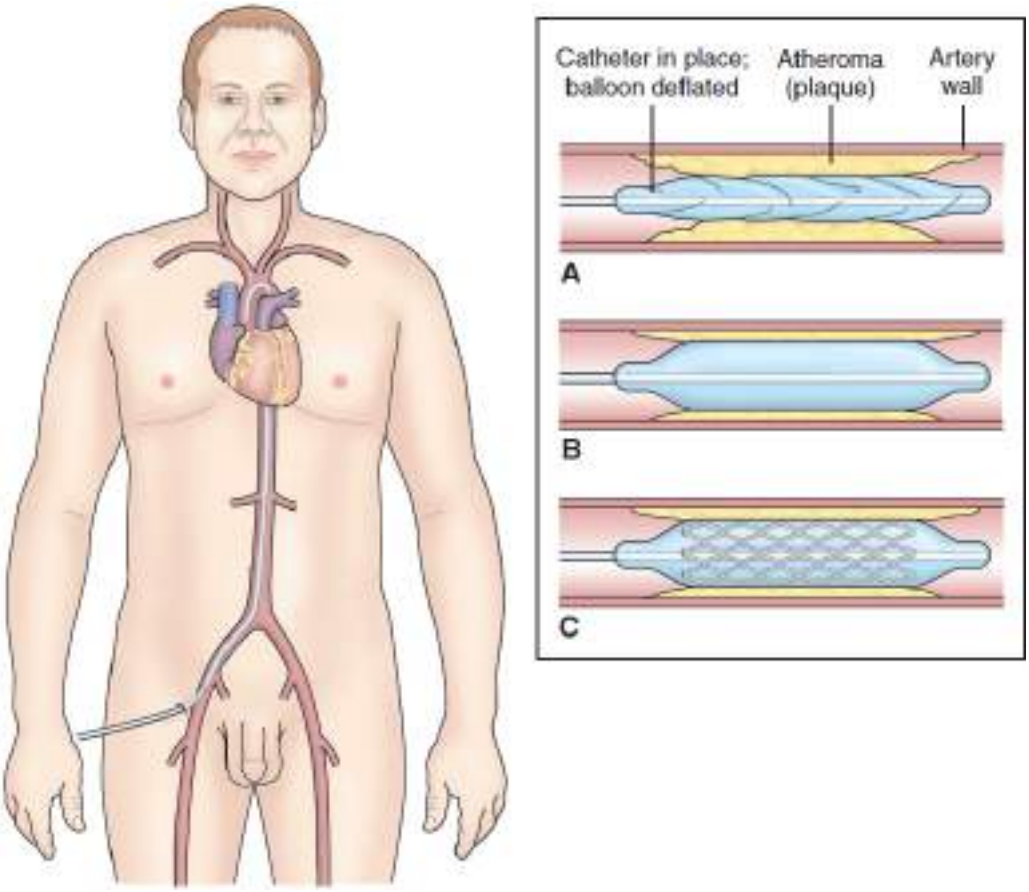

Figure 23-7 • Percutaneous transluminal coronary angioplasty. **A.** A balloon-tipped catheter is passed into the affected coronary artery and placed across the area of the atheroma (plaque). **B.** The balloon is then rapidly inflated and deflated with controlled pressure. **C.** A stent is placed to maintain patency of the artery, and the balloon is removed.

Complications

Complications that can occur during a PCI procedure include coronary artery dissection, perforation, abrupt closure, or vasospasm. Additional complications

include acute MI, serious arrhythmias (e.g., ventricular tachycardia), and cardiac arrest. Some of these complications may require emergency surgical treatment. Complications after the procedure may include abrupt closure of the coronary artery and a variety of vascular complications, such as bleeding at the insertion site, retroperitoneal bleeding, hematoma, and arterial occlusion (Urden et al., 2019). In addition, there is a risk of acute kidney injury from the contrast agent used during the procedure (see Table 23-3).

Postprocedure Care

Patient care is similar to that for a diagnostic cardiac catheterization (see Chapter 21). Patients who are not already hospitalized are admitted the day of the PCI. Those with no complications go home the same day. When the PCI is performed emergently to treat ACS, patients typically go to a critical care unit and stay in the hospital for a few days. During the PCI, patients receive IV heparin or a thrombin inhibitor (e.g., bivalirudin) and are monitored closely for signs of bleeding. Patients may also receive a GP IIb/IIIa agent (e.g., eptifibatide) for several hours following the PCI to prevent platelet aggregation and thrombus formation in the coronary artery (Urden et al., 2019). Hemostasis is achieved, and femoral sheaths may be removed at the end of the procedure by using a vascular closure device (e.g., Angio-Seal, VasoSeal) or a device that sutures the vessels. Hemostasis after sheath removal may also be achieved by direct manual pressure, a mechanical compression device (e.g., C-shaped clamp), or a pneumatic compression device (e.g., FemoStop).

Patients may return to the nursing unit with the large peripheral vascular access sheaths in place. The sheaths are then removed after blood studies (e.g., activated clotting time) indicate that the heparin is no longer active and the clotting time is within an acceptable range. This usually takes a few hours, depending on the amount of heparin given during the procedure. The patient must remain flat in bed and keep the affected leg straight until the sheaths are removed and then for a few hours afterward to maintain hemostasis. Because immobility and bed rest may cause discomfort, treatment may include analgesics and sedation. Nonpharmacologic interventions include repositioning and heat application for back pain. Sheath removal and the application of pressure on the vessel insertion site may cause the heart rate to slow and the blood pressure to decrease (vasovagal response). A dose of IV atropine is usually given to treat this response.

TABLE 23-3 Complications After Percutaneous Coronary Interventions

Complication	Clinical Manifestations	Possible Causes	Nursing Actions
Myocardial ischemia	Chest pain Ischemic changes on ECG Arrhythmias	Thrombosis Restenosis of coronary artery	Administer oxygen and nitroglycerin. Obtain 12-lead ECG. Notify cardiologist.
Bleeding and hematoma formation	Continuation of bleeding from vascular access site Swelling at site Formation of hard lump Pain with leg movement Possible hypotension and tachycardia	Anticoagulant therapy Vascular trauma Inadequate hemostasis Leg movement	Keep patient on bed rest. Apply manual pressure over sheath insertion site. Outline hematoma with marking pen. Notify primary provider if bleeding continues.
Retroperitoneal hematoma	Back, flank, or abdominal pain Hypotension Tachycardia Restlessness, agitation	Arterial leak of blood into the retroperitoneal space	Notify primary provider. Stop anticoagulants. Administer IV fluids. Anticipate diagnostic testing (e.g., computed tomography scan). Prepare patient for intervention.
Arterial occlusion	Lost/weakened pulse distal to sheath insertion site Extremity cool, cyanotic, painful	Arterial thrombus or embolus	Notify primary provider. Anticipate intervention.
Pseudoaneurysm formation	Swelling at vascular access site Pulsatile mass, bruit	Vessel trauma during the procedure	Notify primary provider. Anticipate intervention.
Arteriovenous fistula formation	Swelling at vascular access site Pulsatile mass, bruit	Vessel trauma during the procedure	Notify primary provider. Anticipate intervention.
Acute kidney injury	Decreased urine output Elevated BUN, serum creatinine	Nephrotoxic contrast agent	Monitor urine output, BUN, creatinine, electrolytes. Provide adequate hydration. Administer renal protective agents (acetylcysteine) before and after procedure as prescribed.

BUN, blood urea nitrogen; ECG, electrocardiogram; IV, intravenous.

Adapted from Urden, L. D., Stacy, K. M., & Lough, M. E. (2019). *Priorities in critical care nursing* (8th ed.). St. Louis, MO: Elsevier.

Some patients with unstable lesions and at high risk for abrupt vessel closure are restarted on heparin after sheath removal, or they receive an IV infusion of a GP IIb/IIIa inhibitor. These patients are monitored closely and may have a delayed recovery period.

After hemostasis is achieved, a pressure dressing is applied to the site. Patients resume self-care and ambulate unassisted within a few hours of the procedure. The duration of immobilization depends on the size of the sheath inserted, the type of anticoagulant given, the method of hemostasis, the patient's condition, and the physician's preference. On the day after the procedure, the site is inspected and the dressing removed. The patient is instructed to monitor the site for bleeding or development of a hard mass indicative of hematoma.

Surgical Procedures: Coronary Artery Revascularization

Advances in diagnostics, medical management, and surgical and anesthesia techniques, as well as the care provided in critical care and surgical units, home care, and rehabilitation programs, have continued to make surgery an effective treatment option for patients with CAD. CAD has been treated by myocardial revascularization since the 1960s, and the most common CABG techniques have been performed for more than 40 years. **Coronary artery bypass graft (CABG)** is a surgical procedure in which a blood vessel is grafted to an occluded coronary artery so that blood can flow beyond the occlusion; it is also called a *bypass graft.*

The major indications for CABG are:

- Alleviation of angina that cannot be controlled with medication or PCI
- Treatment for left main coronary artery stenosis or multivessel CAD
- Prevention of and treatment for MI, arrhythmias, or heart failure
- Treatment for complications from an unsuccessful PCI

The recommendation for CABG is determined by a number of factors, including the number of diseased coronary vessels, the degree of left ventricular dysfunction, the presence of other health problems, the patient's symptoms, and any previous treatment. CABG and PCI have shown similar results in outcomes, such as MI rate, mortality, and improvement of angina post-intervention. However, the requirement of a second reperfusion intervention has been shown to be lower with CABG compared to PCI therapy (Gaudino, Spadaccio, & Taggart, 2019).

CABG is performed less frequently in women (Angraal, Khera, Wang, et al., 2018). Compared with men, women referred for this surgery tend to be older and have more comorbidities such as diabetes. In addition, they have a higher risk of surgical complications and increased mortality (Angraal et al., 2018). Although some women have good outcomes following CABG, men generally have a better rate of graft patency and symptom relief.

For a patient to be considered for CABG, the coronary arteries to be bypassed must have at least a 70% occlusion, or at least a 50% occlusion in the left main coronary artery (Urden et al., 2019). If significant blockage is not present, flow

through the artery will compete with flow through the bypass, and circulation to the ischemic area of myocardium may not improve. The artery also must be patent beyond the area of blockage or the flow through the bypass will be impeded.

Current guidelines recommend use of the internal thoracic arteries (formerly called the internal mammary arteries) for CABG, because of their histologic characteristics and increased production of vasoactive molecules and anti-inflammatory cytokines which improve arterial patency. Recent studies demonstrate increased survival when using internal thoracic artery grafting. The left internal thoracic artery graft has been shown to have greater than 90% patency after 20 years and is the recommended conduit to use first (Gaudino et al., 2019). Arterial grafts are preferred to venous grafts because they do not develop atherosclerotic changes as quickly and remain patent longer. The surgeon leaves the proximal end of the thoracic artery intact and detaches the distal end of the artery from the chest wall. This end of the artery is then grafted to the coronary artery distal to the occlusion. The internal thoracic arteries may not be long enough to use for multiple bypasses. Because of this, many CABG procedures are performed with a combination of venous and arterial grafts.

A vein commonly used for CABG is the greater saphenous vein, followed by the lesser saphenous vein (see Fig. 23-8). The vein is removed from the leg and grafted to the ascending aorta and to the coronary artery distal to the lesion. Traditionally, a skin incision was made over the length of vein segment, but new techniques allow small leg incisions. Endovascular methods of vein harvesting have reduced complications such as infection and wound dehiscence, which are associated with longer leg incisions (Gaudino et al., 2019). Lower extremity edema continues to be a common adverse effect of vein removal. The degree of edema varies and usually diminishes over time. The patency of vein grafts can be limited. Within 5 to 10 years, atherosclerotic changes often develop in saphenous vein grafts.

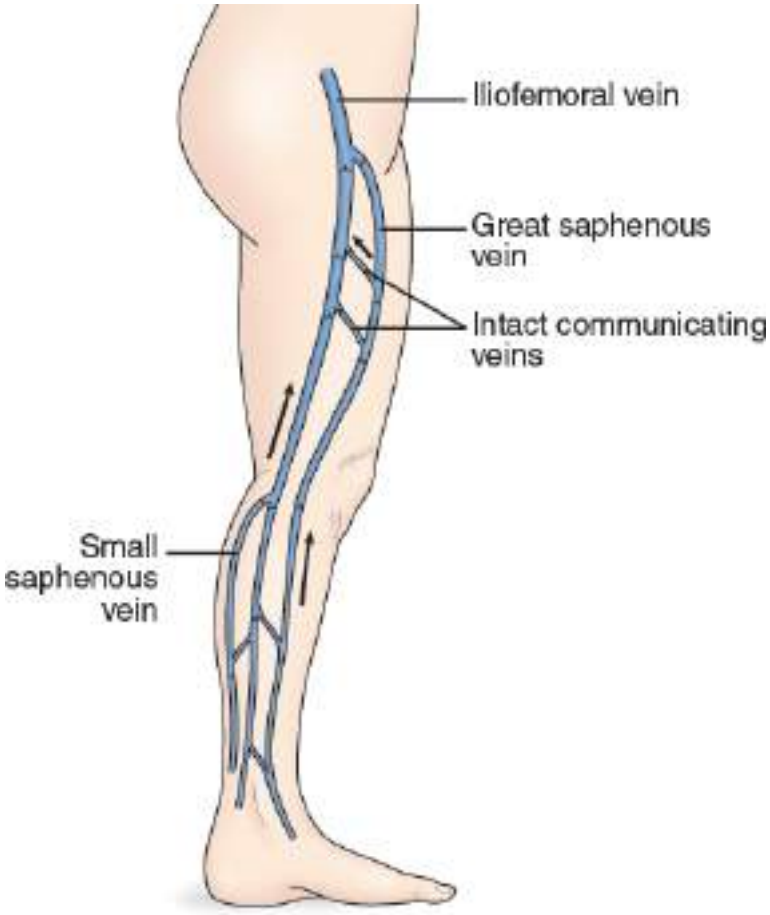

Figure 23-8 • The greater and lesser saphenous veins are commonly used in bypass graft procedures.

Traditional Coronary Artery Bypass Graft

CABG procedures are performed with the patient under general anesthesia. In the traditional CABG procedure, the surgeon performs a median sternotomy and connects the patient to the cardiopulmonary bypass (CPB) machine. Next, a blood vessel from another part of the patient's body (e.g., saphenous vein, left internal thoracic artery) is grafted distal to the coronary artery lesion, bypassing the obstruction (see Fig. 23-9). CPB is then discontinued, chest tubes and epicardial pacing wires are placed, and the incision is closed. The patient is then admitted to a critical care unit.

Cardiopulmonary Bypass

Many cardiac surgical procedures are possible because of CPB (i.e., extracorporeal circulation). The procedure mechanically circulates and oxygenates blood for the body while bypassing the heart and lungs. CPB maintains perfusion to body organs and tissues and allows the surgeon to complete the anastomoses in a motionless, bloodless surgical field.

CPB is accomplished by placing a cannula in the right atrium, vena cava, or femoral vein to withdraw blood from the body. The cannula is connected to tubing filled with an isotonic crystalloid solution. Venous blood removed from the body by the cannula is filtered, oxygenated, cooled or warmed by the machine, and then

returned to the body. The cannula used to return the oxygenated blood is usually inserted in the ascending aorta, or it may be inserted in the femoral artery (see Fig. 23-10). The heart is stopped by the injection of a potassium-rich cardioplegia solution into the coronary arteries. The patient receives heparin to prevent clotting and thrombus formation in the bypass circuit when blood comes in contact with the surfaces of the tubing. At the end of the procedure when the patient is disconnected from the bypass machine, protamine sulfate is given to reverse the effects of heparin.

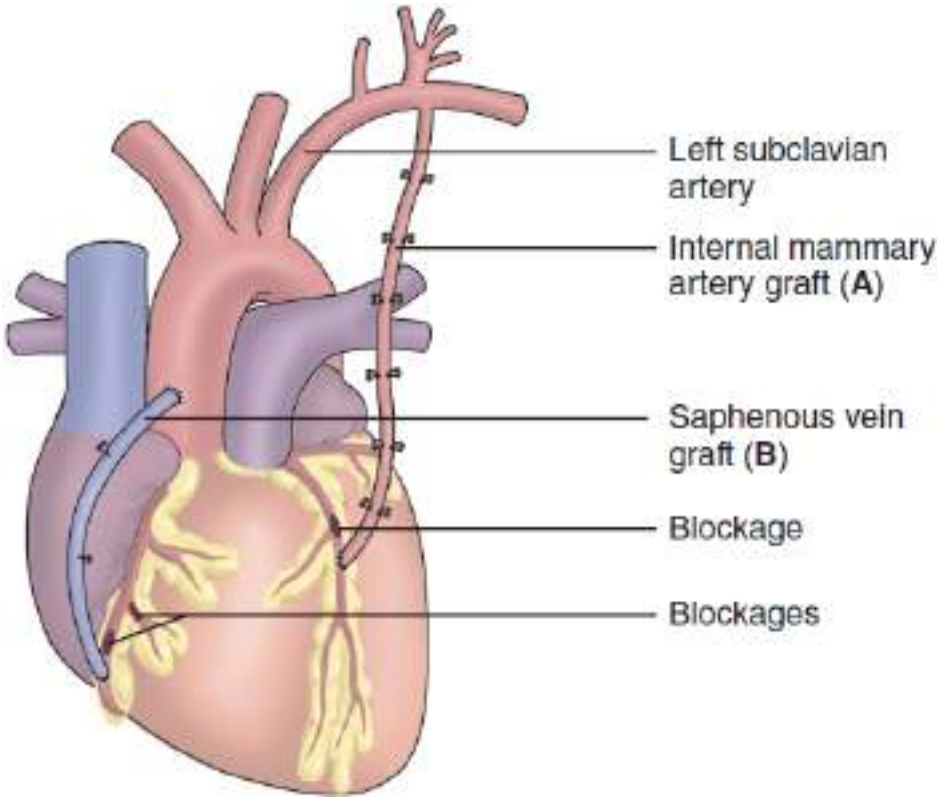

Figure 23-9 • Coronary artery bypass grafts. One or more procedures may be performed using various veins and arteries. **A.** Left internal thoracic artery (formerly called the left internal mammary artery), used frequently because of its functional longevity. **B.** Saphenous vein, also used as bypass graft.

During the procedure, hypothermia is maintained at a temperature of about 28°C (82.4°F) (Urden et al., 2019). The blood is cooled during CPB and returned to the body. The cooled blood slows the body's basal metabolic rate, thereby decreasing the demand for oxygen. Cooled blood usually has a higher viscosity, but the crystalloid solution used to prime the bypass tubing dilutes the blood. When the surgical procedure is completed, the blood is rewarmed as it passes through the CPB circuit. Urine output, arterial blood gases, electrolytes, and coagulation studies are monitored to assess the patient's status during CPB.

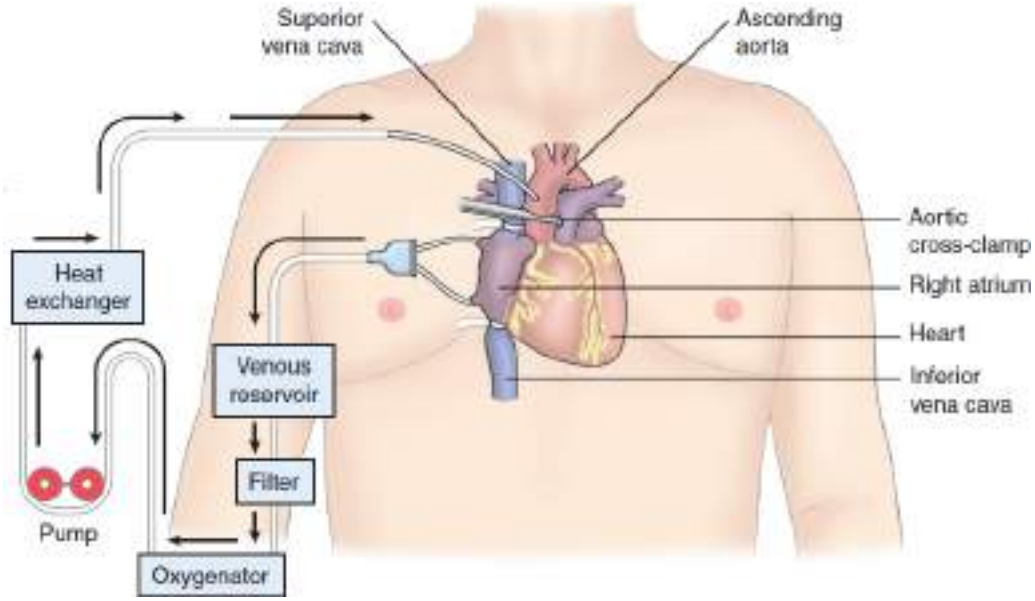

Figure 23-10 • The cardiopulmonary bypass system, in which cannulas are placed through the right atrium into the superior and inferior vena cavae to divert blood from the body and into the bypass system. The pump system creates a vacuum, pulling blood into the venous reservoir. The blood is cleared of air bubbles, clots, and particulates by the filter and then is passed through the oxygenator, releasing carbon dioxide and obtaining oxygen. Next, the blood is pulled to the pump and pushed out to the heat exchanger, where its temperature is regulated. The blood is then returned to the body via the ascending aorta.

Alternative Coronary Artery Bypass Graft Techniques

A number of alternative CABG techniques have been developed that may have fewer complications for some groups of patients. Off-pump coronary artery bypass (OPCAB) surgery has been used successfully in many patients. OPCAB involves a standard median sternotomy incision, but the surgery is performed without CPB. A beta-adrenergic blocker may be used to slow the heart rate. The surgeon also uses a myocardial stabilization device to hold the site still for the anastomosis of the bypass graft into the coronary artery while the heart continues to beat (see Fig. 23-11). Research suggests that OPCAB is associated with reduced short-term postoperative morbidity, including stroke and other complications. However, with on-pump CABG, graft patency rate is higher and long-term mortality may be lower (Gaudino et al., 2019).

Minimally invasive surgical techniques that eliminate median sternotomy have also been developed. These endoscopic techniques use smaller incisions via a right or left thoracotomy approach and a robotic system to place bypass grafts. The patient may or may not require CPB (Snyder, 2018). Minimally invasive heart surgery may be considered an acceptable alternative to conventional CABG for select patients, such as those who do not require bypass grafts to several vessels. It is most commonly used to bypass occlusions in the left anterior descending artery (Snyder, 2018). It has allowed patients to recover earlier, require fewer blood transfusions,

experience fewer respiratory complications, and be less likely to experience acute kidney injury (Urden et al., 2019).

The most important criterion when deciding whether a patient needs a CABG or a PCI is the predicted surgical mortality, which takes into consideration the patient's individual characteristics, the anatomic complexity of the coronary lesions, and the ability to achieve revascularization. The cardiac surgeon will assess the following factors to determine risk and the ability to revascularize: clinical history (age, sex, diabetes, hypertension, left ventricular function, arrhythmias), previous cardiovascular events (previous cardiovascular surgery, PCI, MI, or stroke), and disease complexity (number of diseased vessels, concomitant valve disease). In some cases, CABG may still be recommended over PCI for only one lesion to achieve better revascularization (Gaudino et al., 2019).

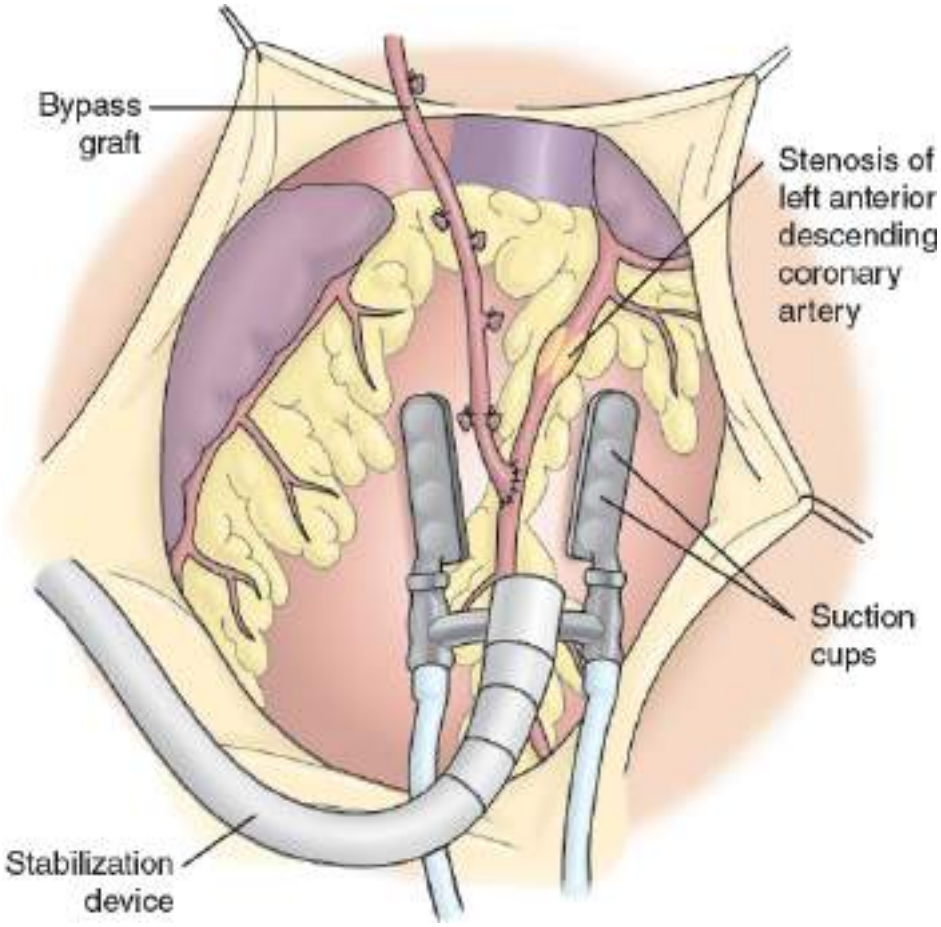

Figure 23-11 • Stabilizer device for off-pump coronary artery bypass surgery.

Complications of Coronary Artery Bypass Graft

CABG may result in complications such as hemorrhage, arrhythmias, and MI (see Table 23-4). The patient may require interventions for more than one complication at a time. Collaboration among nurses, physicians, pharmacists, respiratory therapists, and dietitians is necessary to achieve the desired patient outcomes. Although most patients improve symptomatically following surgery, CABG is not a cure for CAD,

and angina, exercise intolerance, or other symptoms experienced before CABG may recur. Medications required before surgery may need to be continued. Lifestyle modifications recommended before surgery remain important to treat the underlying CAD and for the continued viability of the newly implanted grafts.

Nursing Management

Cardiac surgery patients have many of the same needs and require the same perioperative care as other surgical patients (see Unit 3), as well as some special needs.

Preoperative Management

Comprehensive preoperative medical management prevents complications and improves outcomes. This is particularly important because patients undergoing CABG surgery tend to be older and often have multiple comorbidities. The use of aspirin, beta-blockers, and statins during the preoperative period is associated with better outcomes. Preoperative use of aspirin is associated with a reduction in perioperative morbidity and mortality (Aboul-Hassan, Stankowski, Marczak, et al., 2017). Beta-blockers, when given at least 24 hours before CABG, reduce the incidence of postoperative atrial fibrillation (Urden et al., 2019). Perioperative use of statins has been shown to reduce the rates of postoperative MI, atrial fibrillation, neurologic dysfunction, renal dysfunction, infection, and death (Katsiki, Triposkiadis, Giannoukas, et al., 2018).

Assessing the Patient

Patients are frequently admitted to the hospital the day of the procedure. Therefore, most of the preoperative evaluation is completed in the physician's office and during preadmission testing.

Nursing and medical personnel perform a history and physical examination. Preoperative testing consists of a chest x-ray; ECG; laboratory tests, including coagulation studies; and blood typing and cross-matching. The preoperative history and health assessment should be thorough and well documented because they provide a basis for postoperative comparison. The nurse assesses the patient for disorders that could complicate or affect the postoperative course, such as diabetes, hypertension, and lung disease.

TABLE 23-4 Potential Complications of Cardiac Surgery

Complication	Cause	Assessment and Management
Cardiac Complications		
Hypovolemia (most common cause of decreased cardiac output after cardiac surgery)	Net loss of blood and intravascular volume Vasodilation due to postoperative rewarming Intravascular fluid loss to the interstitial spaces because surgery and anesthesia increase capillary permeability	Arterial hypotension, tachycardia, low CVP, and low PAWP are often seen. Fluid replacement may be prescribed. Replacement fluids include colloid (albumin), packed red blood cells, or crystalloid solution (normal saline, lactated Ringer's solution).
Persistent bleeding	Cardiopulmonary bypass causes platelet dysfunction, and hypothermia alters clotting mechanisms. Surgical trauma causes tissues and blood vessels to ooze bloody drainage. Intraoperative anticoagulant (heparin) therapy. Postoperative coagulopathy may also result from liver dysfunction and depletion of clotting components.	Accurate measurement of wound bleeding and chest tube blood is essential. Drainage should not exceed 200 mL/h for the first 4–6 h. Drainage should decrease and stop within a few days, while progressing from serosanguinous to serous. Serial hemoglobin, hematocrit, and coagulation studies guide therapy. Administration of blood products: packed red blood cells, fresh frozen plasma, platelet concentrate, recombinant factor VII Protamine sulfate may be given to neutralize unfractionated heparin. Administration of desmopressin acetate (DDAVP) to enhance platelet function If bleeding persists, the patient may return to the operating room.
Cardiac tamponade	Fluid and clots accumulate in the pericardial sac, which compress the heart, preventing blood from filling the ventricles.	Signs and symptoms include arterial hypotension, tachycardia, decreased urine output, and ↑ CVP. Arterial pressure waveform may show pulsus paradoxus (decrease of >10 mm Hg systolic blood pressure during inspiration). The chest drainage system is checked to eliminate possible kinks or obstructions in the tubing. Chest x-ray may show a widening mediastinum. Bedside echocardiogram may be done to confirm tamponade. Emergency medical management is required; may include return to surgery.
Fluid overload	IV fluids and blood products increase circulating volume.	High CVP and pulmonary artery pressures, as well as crackles, indicate fluid overload. Diuretics are prescribed, and the rate of IV fluid administration is reduced.

		Alternative treatments include continuous renal replacement therapy and dialysis.
Hypothermia	Low body temperature leads to vasoconstriction, shivering, and arterial hypertension.	Patient is rewarmed gradually after surgery, decreasing vasoconstriction.
Hypertension	Results from postoperative vasoconstriction. It may stretch suture lines and cause postoperative bleeding. The condition is usually transient.	Vasodilators (nitroglycerin, nitroprusside) may be used to treat hypertension. Administer cautiously to avoid hypotension.
Tachyarrhythmias	Increased heart rate is common with perioperative volume changes. Rapid atrial fibrillation commonly occurs during the first few days postoperatively.	If a tachyarrhythmia is the primary problem, the heart rhythm is assessed and medications (e.g., amiodarone, diltiazem) may be prescribed. Antiarrhythmic agents (e.g., beta-blockers) are often given before coronary artery bypass graft to minimize the risk. Cardioversion and defibrillation are alternatives for symptomatic tachyarrhythmias.
Bradycardias	Decreased heart rate due to surgical trauma and edema affecting the cardiac conduction system	Many postoperative patients have temporary pacer wires that can be attached to an external pacemaker to stimulate the heart to beat faster. Less commonly, atropine or other medications may be used to increase heart rate.
Cardiac failure	Myocardial contractility may be decreased perioperatively.	The nurse observes for and reports signs of heart failure, including hypotension, ↑ CVP, ↑ PAWP, venous distention; labored respirations; and edema. Medical management includes diuretics and IV inotropic agents.
MI (may occur intraoperatively or postoperatively)	Portion of the cardiac muscle dies; therefore, contractility decreases. Impaired ventricular wall motion further decreases cardiac output. Symptoms may be masked by the postoperative surgical discomfort or the anesthesia–analgesia regimen.	Careful assessment to determine the type of pain the patient is experiencing; MI is suspected if the mean blood pressure is low with normal preload. Serial electrocardiograms and cardiac biomarkers assist in making the diagnosis (alterations may be due to the surgical intervention).
Pulmonary Complications		
Impaired gas exchange	During and after anesthesia, patients require mechanical assistance to breathe. Anesthetic agents stimulate production of mucus, and chest	Pulmonary complications are detected during assessment of breath sounds, oxygen saturation levels, arterial blood gases, and ventilator readings. Extended periods of mechanical ventilation may be required while

	incision pain may decrease the effectiveness of ventilation. Potential for postoperative atelectasis	complications are treated.
Neurologic Complications		
Neurologic changes; stroke	Thrombi and emboli may cause cerebral infarction, and neurologic signs may be evident when patients recover from anesthesia.	Inability to follow simple commands within 6 h of recovery from anesthetic; weakness on one side of body or other neurologic changes may indicate stroke. Patients who are older or who have renal or hepatic failure may take longer to recover from anesthesia.
Kidney Injury and Electrolyte Imbalance		
Acute kidney injury	May result from hypoperfusion of the kidneys or from injury to the renal tubules by nephrotoxic drugs	May respond to diuretics or may require continuous renal replacement therapy or dialysis. Fluids, electrolytes, and urine output are monitored frequently. May result in chronic kidney disease and require ongoing dialysis.
Electrolyte imbalance	Postoperative imbalances in potassium, magnesium, sodium, calcium, and blood glucose are related to surgical losses, metabolic changes, and the administration of medications and IV fluids.	Monitor electrolytes and basic metabolic studies frequently. Implement treatment to correct electrolyte imbalance promptly (see Chart 23-11).
Other Complications		
Hepatic failure	Surgery and anesthesia stress the liver. Most common in patients with cirrhosis, hepatitis, or prolonged right-sided heart failure.	The use of medications metabolized by the liver must be minimized. Bilirubin and albumin levels are monitored, and nutritional support is provided.
Infection	Surgery and anesthesia alter the patient's immune system. Multiple invasive devices used to monitor and support the patient's recovery may serve as a source of infection.	Monitor for signs of possible infection: body temperature, white blood cell and differential counts, incision and puncture sites, urine (clarity, color, and odor), bilateral breath sounds, sputum (color, odor, amount). Antibiotic therapy may be instituted or modified as necessary. Continuous insulin infusion to maintain blood glucose concentrations to ≤180 mg/dL while avoiding hypoglycemia may reduce the incidence of deep sternal wound infections. Invasive devices are discontinued as soon as they are no longer required. Institutional protocols for maintaining and replacing invasive lines and devices are followed to minimize the risk of infection.

↑, increased; CVP, central venous pressure; IV, intravenous; MI, myocardial infarction; PAWP, pulmonary artery wedge pressure.

Adapted from Urden, L. D., Stacy, K. M., & Lough, M. E. (2019). *Priorities in critical care nursing* (8th ed.). St. Louis, MO: Elsevier.

The health assessment focuses on obtaining baseline physiologic, psychological, and social information. Cognitive status is carefully assessed, as patients with impaired cognitive status will need more assistance after surgery and may require subacute care prior to returning home. Older adults are at a high risk for suffering adverse cognitive outcomes following cardiac surgery (Jones, Matalanis, Mårtensson, et al., 2019). The patient's and family's education needs are identified and addressed. Of particular importance are the patient's usual functional level, coping mechanisms, and available support systems. These factors affect the patient's postoperative course, discharge plans, and rehabilitation.

The status of the cardiovascular system is determined by reviewing the patient's symptoms, including past and present experiences with chest pain, palpitations, dyspnea, intermittent claudication (leg pain that occurs with walking), and peripheral edema. The patient's history of major illnesses; previous surgeries; medication; and the use of illicit and over-the-counter drugs, herbal supplements, alcohol, and tobacco is also obtained. Particular attention is paid to blood glucose control in patients with diabetes because there is a higher incidence of postoperative complications when glycemic control is poor (Gordon, Lauver, & Buck, 2018).

The psychosocial assessment and the assessment of the patient's and family's learning needs are also important. Anticipation of cardiac surgery is a source of great stress to the patient and family, and patients with high anxiety levels have poorer outcomes (Ramesh, Nayak, Pai, et al., 2017). However, some anxiety is expected, and the work of worrying can help patients identify priorities and find coping strategies that help them face the threat of surgery. Questions may be asked to obtain the following information:

- Knowledge and understanding of the surgical procedure, postoperative course, and recovery
- Fears and concerns regarding the surgery and future health status
- Coping mechanisms helpful to the patient
- Support systems available during and following hospitalization

Reducing Fear and Anxiety

The nurse gives the patient and family time and opportunity to express their fears. Topics of concern may be pain, changes in body image, fear of the unknown, and fear of disability or death. It may be helpful to describe the sensations that the patient can expect, including the preoperative sedation, surgical anesthesia, and postoperative pain management. The nurse reassures the patient that the fear of pain is normal, that some pain will be experienced, that medication to relieve pain will be provided, and that the patient will be closely monitored. In addition, the nurse instructs the patient to request analgesic medication before the pain becomes severe. If the patient has concerns about scarring from surgery, the nurse encourages them to discuss this issue and corrects any misconceptions. The patient and family may want to discuss their

fear of the patient dying. After the fear is expressed, the nurse can assure the patient and family that this fear is normal and further explore their feelings. For patients with extreme anxiety or fear and for whom emotional support and education are not successful, antianxiety medication such as lorazepam may be helpful.

Monitoring and Managing Potential Complications

Angina may occur because of increased stress and anxiety related to the forthcoming surgery. The patient who develops angina usually responds to typical therapy for angina, most commonly nitroglycerin. Some patients require oxygen and IV nitroglycerin infusions. Physiologically unstable patients may require preoperative management in a critical care unit.

Providing Patient Education

Prior to surgery, patients and their families are given specific instructions. This includes information on how the patient should take or stop specific medications, including anticoagulant agents, antihypertensive medications, and medications that control diabetes. The patient is instructed to shower with an antiseptic solution such as chlorhexidine gluconate and to apply mupirocin calcium 2% ointment to each nostril to help reduce the risk of surgical site infections (Reiser, Scherag, Forstner, et al., 2017). Cardiac surgical infections are often caused by *Staphylococcus aureus* which is found in the nasal passages. Studies have shown that decolonizing the nasal passage preoperatively is effective in reducing sternal wound infections associated with cardiac surgery (Lemaignen, Armand-Lefevre, Birgand, et al., 2018) (see Chapter 14 for further discussion of preoperative preparation).

Education also includes information about the hospitalization and surgery. The nurse informs the patient and family about the equipment, tubes, and lines that will be present after surgery and their purposes. They should expect monitors, several IV lines, chest tubes, and a urinary catheter. Explaining the purpose and the approximate time that these devices will be in place helps reassure the patient. Most patients remain intubated and on mechanical ventilation for several hours after surgery. It is important for patients to know that this will prevent them from talking, and the nurse should reassure them that the staff will be able to assist them with other means of communication.

The nurse takes care to answer the patient's questions about postoperative care and procedures. After the nurse explains deep breathing and coughing, the use of the incentive spirometer, and foot exercises, the nurse practices these procedures with the patient. The benefit of early and frequent ambulation is discussed. The family's questions at this time usually focus on the length of the surgery, who will discuss the results of the procedure with them after surgery, where to wait during the surgery, the visiting procedures for the critical care unit, and how they can support the patient before surgery and in the critical care unit.

Intraoperative Management

The perioperative nurse performs assessments and prepares the patient as described in Chapters 14 and 15. In addition to assisting with the surgical procedure, perioperative

nurses are responsible for the comfort and safety of the patient.

Possible intraoperative complications include low cardiac output, arrhythmias, hemorrhage, MI, organ failure from shock, and thromboembolic events including stroke (Urden et al., 2019). Astute intraoperative nursing assessment is critical to prevent, detect, and initiate prompt intervention for these complications. Before the chest incision is closed, chest tubes are inserted to evacuate air and drainage from the mediastinum and the thorax.

For the procedural guideline for setup and management of chest drainage systems, go to thepoint.lww.com/Brunner15e.

Temporary epicardial pacemaker electrodes may be implanted on the surface of the right atrium and the right ventricle. These epicardial electrodes can be connected to an external pacemaker if the patient has persistent bradycardia perioperatively (see Chapter 22 for a discussion of pacemakers).

Postoperative Nursing Management

Initial postoperative care focuses on achieving or maintaining hemodynamic stability and recovery from general anesthesia. Care may be provided in the postanesthesia care unit (PACU) or ICU. The immediate postoperative period for the patient who has undergone cardiac surgery presents many challenges to the health care team. All efforts are made to facilitate the transition from the operating room to the ICU or PACU with minimal risk. Specific information about the surgical procedure and important factors about postoperative management are communicated by the surgical team and anesthesia personnel to the critical care or PACU nurse, who then assumes responsibility for the patient's care. Figure 23-12 presents an overview of the many aspects of postoperative care of the cardiac surgical patient.

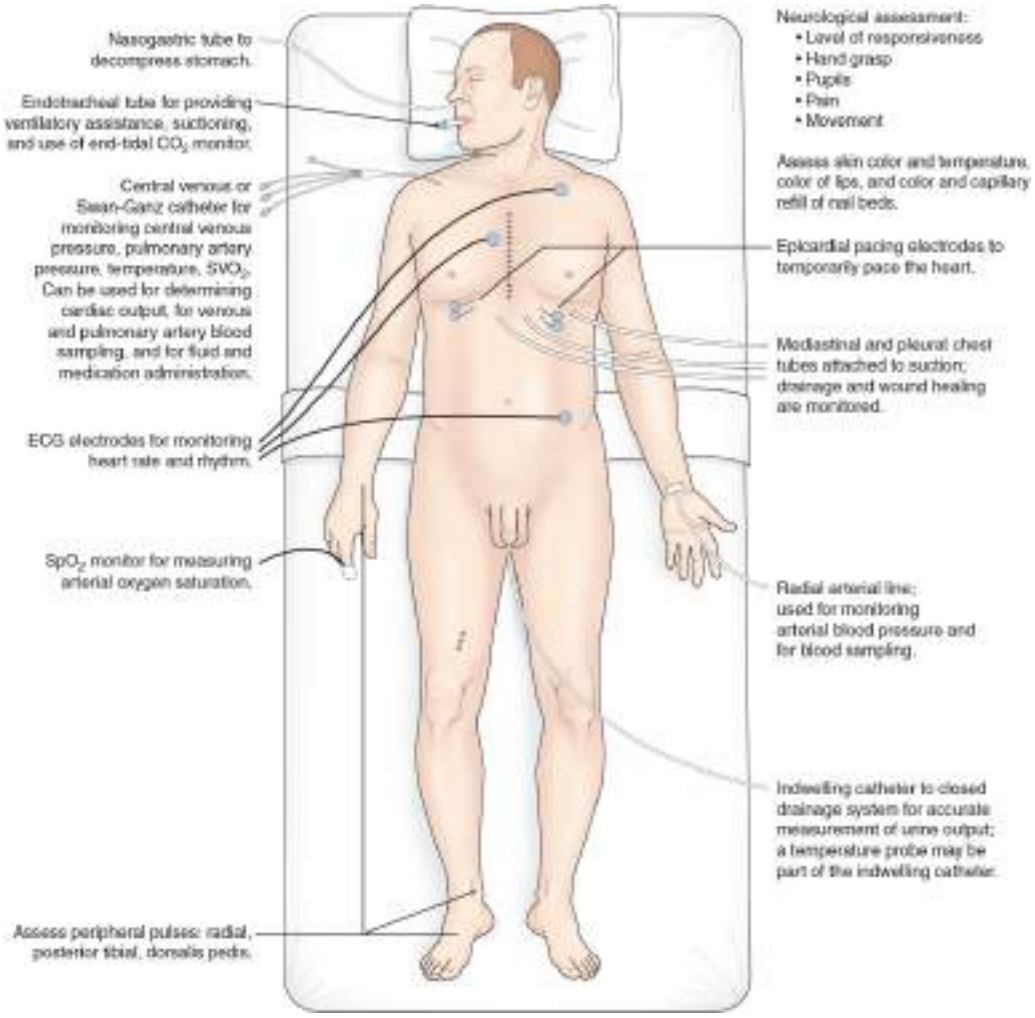

Figure 23-12 • Postoperative care of the patient who has undergone cardiac surgery requires the nurse to be proficient in interpreting hemodynamics, correlating physical assessment data with laboratory results, sequencing interventions, and evaluating progress toward desired outcomes.

After the patient's cardiac status and respiratory status are stable, the patient is transferred to a surgical progressive care unit with telemetry. Care in both the ICU and progressive care unit focuses on monitoring of cardiopulmonary status, pain management, wound care, progressive activity, and nutrition. Education about medications and risk factor modification is emphasized.

A typical plan of postoperative nursing care is presented in Chart 23-11.

Assessing the Patient

When the patient is admitted to the critical care unit or PACU, nursing and medical personnel perform a complete assessment of all systems at least every 4 hours. It is necessary to assess the following parameters:

Neurologic status: level of responsiveness, pupil size and reaction to light, facial symmetry, movement of the extremities, and hand grip strength

Cardiac status: heart rate and rhythm, heart sounds, pacemaker status, arterial blood pressure, central venous pressure (CVP); in select patients, hemodynamic

parameters: pulmonary artery pressure, pulmonary artery wedge pressure (PAWP), cardiac output and index, systemic and pulmonary vascular resistance, mixed venous oxygen saturation ($Sv–O_2$). A pulmonary artery catheter is often used to monitor these parameters. Alternatively, minimally invasive monitoring of stroke volume, systemic vascular resistance, and cardiac output are calculated through pressures obtained in the arterial line (e.g., Vigileo monitor with FloTrac sensor). (See Chapter 21 for a detailed description of hemodynamic monitoring.)

Chart 23-11 **PLAN OF NURSING CARE**

Care of the Patient After Cardiac Surgery

NURSING DIAGNOSIS: Impaired cardiac output associated with blood loss and compromised myocardial function

GOAL: Restoration of cardiac output to maintain organ and tissue perfusion

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor cardiovascular status. Serial readings of blood pressure, other hemodynamic parameters, and cardiac rhythm and rate are obtained, recorded, and correlated with the patient's overall condition.	1. Effectiveness of cardiac output is evaluated by continuous monitoring.	• The following parameters are within the patient's normal ranges: • Arterial pressure • Central venous pressure (CVP) • Pulmonary artery pressures • Pulmonary artery wedge pressure (PAWP) • Heart sounds • Pulmonary and systemic vascular resistance • Cardiac output and cardiac index • Peripheral pulses • Cardiac rate and rhythm • Cardiac biomarkers • Urine output • Skin and mucosal color • Skin temperature
a. Assess arterial blood pressure every 15 minutes until stable; then arterial or cuff blood pressure every 1–4 hours × 24 hours; then every 8–12 hours until hospital discharge.	a. Blood pressure is one of the most important physiologic parameters to monitor; vasoconstriction after cardiopulmonary bypass may require treatment with an IV vasodilator.	
b. Auscultate for heart sounds and rhythm.	b. Auscultation provides evidence of pericarditis (precordial rub), arrhythmias.	
c. Assess peripheral pulses (pedal, tibial, radial).	c. Presence or absence and quality of pulses provide data about cardiac output as well as obstructive lesions.	
d. Monitor hemodynamic parameters to assess cardiac output, volume status, and vascular tone.	d. Rising CVP and PAWP may indicate congestive heart failure or pulmonary edema. Low pressures may indicate need	• <200 mL/h of drainage through chest tubes during first 4–6 hours • Vital signs stable • CVP and other hemodynamic parameters within normal limits

e. Watch for trends in hemodynamics, and note that mechanical ventilation may alter hemodynamics. f. Monitor electrocardiogram (ECG) pattern for cardiac arrhythmias and ischemic changes. g. Assess cardiac biomarker results. h. Measure urine output every ½ to 1 hour at first, then with vital signs. i. Observe buccal mucosa, nail beds, lips, earlobes, and extremities. j. Assess skin; note temperature and color. 2. Observe for persistent bleeding: excessive chest tube drainage of blood; hypotension; low CVP; tachycardia. Prepare to	for volume replacement. e. Trends are more important than isolated readings. Mechanical ventilation increases intrathoracic pressure. f. Arrhythmias may occur with coronary ischemia, hypoxia, bleeding, and acid–base or electrolyte disturbances. ST-segment changes may indicate myocardial ischemia. Pacemaker capture and antiarrhythmic medications are used to maintain heart rate and rhythm and to support blood pressure. g. Elevations may indicate myocardial infarction. h. Urine output <0.5 mL/kg/h indicates decreased renal perfusion and may reflect decreased cardiac output. i. Duskiness and cyanosis may indicate decreased cardiac output. j. Cool moist skin indicates vasoconstriction and decreased cardiac output.	• Urinary output within normal limits • Skin color normal • Respirations unlabored, clear breath sounds • Pain limited to incision

administer blood products, IV fluids. 3. Observe for cardiac tamponade: hypotension; rising CVP and PAWP, pulsus paradoxus; jugular vein distention; decreasing urinary output. Check for diminished amount of blood in chest drainage collection system. Prepare for reoperation. 4. Observe for signs of cardiac failure. Prepare to administer diuretics, IV inotropic agents.	2. Bleeding can result from surgical trauma to tissues, anticoagulant medications, and clotting defects. 3. Cardiac tamponade results from bleeding into the pericardial sac or accumulation of fluid in the sac, which compresses the heart and prevents adequate filling of the ventricles. Decrease in chest drainage may indicate that fluid and clots are accumulating in the pericardial sac. 4. Cardiac failure results from decreased pumping action of the heart; can cause deficient perfusion to vital organs.	

NURSING DIAGNOSIS: Impaired gas exchange associated with chest surgery
GOAL: Adequate gas exchange

Nursing Interventions	Rationale	Expected Outcomes
1. Maintain mechanical ventilation until the patient is able to breathe independently. 2. Monitor ABGs, tidal volume, peak inspiratory pressure, and extubation parameters.	1. Ventilatory support is used to decrease work of the heart, to maintain effective ventilation, and to provide an airway in the event of complications. 2. ABGs and ventilator parameters indicate effectiveness of ventilator and changes that need to be made to improve gas exchange.	• Airway patent • Arterial blood gases (ABGs) within normal range • Endotracheal tube correctly placed, as evidenced by x-ray • Breath sounds clear bilaterally • Ventilator synchronous with respirations • Breath sounds clear after

3. Auscultate chest for breath sounds.	3. Crackles indicate pulmonary congestion; decreased or absent breath sounds may indicate pneumothorax, hemothorax, dislodgement of tube.	suctioning/coughing • Nail beds and mucous membranes pink • Mental acuity consistent with amount of sedatives and analgesics received • Oriented to person; able to respond "yes" and "no" appropriately • Able to be weaned successfully from ventilator
4. Sedate patient adequately, as prescribed, and monitor respiratory rate and depth.	4. Sedation helps the patient to tolerate the endotracheal tube and to cope with mechanical ventilation.	
5. Suction tracheobronchial secretions as needed, using strict aseptic technique.	5. Retention of secretions leads to hypoxia and possible infection.	
6. Assist in weaning and endotracheal tube removal.	6. Extubation decreases risk of pulmonary infections and enhances ability of patient to communicate.	
7. After extubation, promote deep breathing, coughing, and turning. Encourage the use of the incentive spirometer and compliance with breathing treatments. Instruct about incisional splinting with a "cough pillow" to decrease discomfort.	7. Aids in keeping airway patent, preventing atelectasis, and facilitating lung expansion	

NURSING DIAGNOSIS: Risk for hypovolaemia or hypervolaemia and electrolyte imbalance associated with alterations in blood volume
GOAL: Fluid and electrolyte balance

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor fluid and electrolyte balance. a. Accurately document intake	1. Adequate circulating blood volume is necessary for optimal cellular activity; fluid and electrolyte	• Fluid intake and output balanced • Hemodynamic assessment

and output; record urine volume every half hour to 4 hours while in critical care unit; then every 8–12 hours while hospitalized. b. Assess blood pressure, hemodynamic parameters, weight, electrolytes, hematocrit, jugular venous pressure, breath sounds, urinary output, and nasogastric tube drainage. c. Measure postoperative chest drainage; cessation of drainage may indicate kinked or blocked chest tube. Ensure patency and integrity of the drainage system. d. Weigh daily and correlate with intake and output.	imbalance can occur after surgery. a. Provides a method to determine positive or negative fluid balance and fluid requirements b. Provides information about state of hydration c. Excessive blood loss from chest cavity can cause hypovolemia. d. Indicator of fluid balance	parameters negative for fluid overload or hypovolemia • Normal blood pressure with position changes • Absence of arrhythmia • Stable weight • Arterial blood pH 7.35–7.45 • Serum potassium 3.5–5.0 mEq/L (3.5–5.0 mmol/L) • Serum magnesium 1.8–2.6 mg/dL (0.74–1.07 mmol/L) • Serum sodium 135–145 mEq/L (135–145 mmol/L) • Serum calcium 8.8–10.4 mg/dL (2.2–2.6 mmol/L) • Serum glucose ≤180 mg/dL
2. Be alert to changes in serum electrolyte levels. a. Hypokalemia (low potassium) *Effects:* Arrhythmias: premature ventricular contractions, ventricular tachycardia. Observe for	2. A specific concentration of electrolytes is necessary in both extracellular and intracellular body fluids to sustain life. a. *Causes:* Inadequate intake, diuretics, vomiting, excessive nasogastric drainage,	

	specific ECG changes. Administer IV potassium replacement as prescribed.	perioperative stress response
b.	Hyperkalemia (high potassium) *Effects:* ECG changes, tall peaked T waves, wide QRS, bradycardia. Be prepared to administer diuretic or an ion-exchange resin (sodium polystyrene sulfonate); or IV insulin and glucose.	b. *Causes:* Increased intake, hemolysis from cardiopulmonary bypass/mechanical assist devices, acidosis, renal insufficiency. The resin binds potassium and promotes intestinal excretion of it. Insulin assists the cells with glucose and potassium absorption.
c.	Monitor serum magnesium, sodium, and calcium.	c. Low levels of magnesium are associated with arrhythmias. Low levels of sodium are associated with weakness and neurologic symptoms. Low levels of calcium can lead to arrhythmias and muscle spasm.
d.	Hyperglycemia (high blood glucose) *Effects:* Increased urine output, thirst, impaired healing. Administer insulin as prescribed.	d. *Cause:* Stress response to surgery. Affects both patients with diabetes and those without diabetes.

NURSING DIAGNOSIS: Risk for acute confusion associated with alteration in sleep–wake cycle, impaired metabolic functioning, use of multiple medications
GOAL: Prevention of acute confusion/postcardiotomy delirium

Nursing Interventions	Rationale	Expected Outcomes
1. Use measures to prevent postcardiotomy delirium: a. Explain all procedures and the need for patient cooperation. b. Plan nursing care to provide for periods of uninterrupted sleep with patient's normal day–night pattern. c. Promote continuity of care. d. Orient to time and place frequently. Encourage family to visit. e. Assess for medications that may contribute to delirium. 2. Observe for perceptual distortions, hallucinations, disorientation, and paranoid delusions.	1. Postcardiotomy delirium may result from alterations in sleep–wake cycle, impaired metabolic functioning, and use of multiple medications. Normally, sleep cycles are at least 50 minutes long. The first cycle may be as long as 90–120 minutes and then shorten during successive cycles. Sleep deprivation results when the sleep cycles are interrupted or are inadequate in number. 2. Delirium can indicate a serious medical condition such as hypoxia, acid–base imbalance, metabolic abnormalities, and cerebral infarction.	• Cooperates with procedures • Sleeps for long, uninterrupted intervals • Oriented to person, place, time • Experiences no perceptual distortions, hallucinations, disorientation, delusions

NURSING DIAGNOSIS: Acute pain associated with surgical trauma and pleural irritation caused by chest tubes
GOAL: Relief of pain

Nursing Interventions	Rationale	Expected Outcomes

1. Record nature, type, location, intensity, and duration of pain. 2. Encourage routine pain medication dosing for the first 24–72 hours, and observe for side effects of lethargy, hypotension, tachycardia, respiratory depression.	1. Pain and anxiety increase pulse rate, oxygen consumption, and cardiac workload. 2. Analgesia promotes rest, decreases oxygen consumption caused by pain, and aids patient in performing deep-breathing and coughing exercises; pain medication is more effective when taken before pain is severe.	• States pain is decreasing in severity • Restlessness decreased • Vital signs stable • Participates in deep-breathing and coughing exercises • Verbalizes fewer complaints of pain each day • Positions self; participates in care activities • Gradually increases activity

NURSING DIAGNOSIS: Risk for impaired cardiac function associated with alterations in afterload that may compromise renal perfusion
GOAL: Maintenance of adequate cardiac output and renal perfusion

Nursing Interventions	Rationale	Expected Outcomes
1. Assess renal function: a. Measure urine output every half hour to 4 hours in critical care, then every 8–12 hours until hospital discharge. b. Monitor and report lab results: BUN, serum creatinine, serum electrolytes.	1. Renal injury can be caused by deficient perfusion, hemolysis, low cardiac output, and the use of vasopressor agents to increase blood pressure. a. <0.5 mL/kg/h indicates decreased renal function. b. These tests indicate the kidneys' ability to excrete waste products. 2. These agents promote renal function and increase cardiac output and renal blood flow. 3. Provides patient with the opportunity to ask questions and prepare for the procedure	• Urine output consistent with fluid intake; >0.5 mL/kg/h • Urine specific gravity 1.005–1.030 • Blood urea nitrogen (BUN), creatinine, electrolytes within normal limits

2. Prepare to administer rapid-acting diuretics or inotropic drugs (e.g., dobutamine). 3. Prepare patient for dialysis or continuous renal replacement therapy if indicated.		
NURSING DIAGNOSIS: Impaired thermoregulation associated with infection or postpericardiotomy syndrome **GOAL:** Maintenance of normal body temperature		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Assess temperature every hour. 2. Use aseptic technique when changing dressings, suctioning endotracheal tube; maintain closed systems for all IV and arterial lines and for indwelling urinary catheter. 3. Observe for symptoms of postpericardiotomy syndrome. 4. Obtain cultures and other lab work (CBC, ESR); administer antibiotic agents as prescribed. 5. Administer anti-inflammatory agents as directed.	1. Fever can indicate infectious or inflammatory process. 2. Decreases risk of infection 3. Occurs in 10% of patients after cardiac surgery. 4. Antibiotic agents treat documented infection. 5. Anti-inflammatory agents relieve symptoms of inflammation.	• Normal body temperature • Incisions are free of infection and are healing. • Absence of symptoms of postpericardiotomy syndrome: fever, malaise, pericardial effusion, pericardial friction rub, arthralgia
NURSING DIAGNOSIS: Lack of knowledge about self-care activities **GOAL:** Ability to perform self-care activities		

Nursing Interventions	Rationale	Expected Outcomes
1. Develop education plan for patient and family. Provide specific instructions for the following: • Diet and daily weights • Activity progression • Exercise • Deep breathing, coughing, lung expansion exercises • Temperature and pulse monitoring • Medication regimen • Incision care • Access to the emergency medical system	1. Each patient has unique learning needs.	• Patient and family members explain and comply with therapeutic regimen. • Patient and family members identify necessary lifestyle changes. • Has copy of discharge instructions (in the patient's primary language and at appropriate reading level; has an alternate format if indicated) • Keeps follow-up appointments
2. Provide verbal and written instructions; provide several education sessions for reinforcement and answering questions.	2. Repetition promotes learning by allowing for questions and clarification of misinformation.	
3. Involve family in education sessions.	3. Family members responsible for home care are usually anxious and require adequate time for learning. 4. Arrangements for contacts with health care personnel help to allay anxieties.	
4. Provide contact information for surgeon and	5. Learning, recovery, and lifestyle changes continue after discharge from the hospital.	

cardiologist and instructions about follow-up visit with surgeon.

5. Make appropriate referrals: home care agency, cardiac rehabilitation program, community support groups.

Respiratory status: chest movement, breath sounds, ventilator settings (e.g., rate, tidal volume, oxygen concentration, mode such as assist-control, positive end-expiratory pressure, pressure support), respiratory rate, peak inspiratory pressure, percutaneous oxygen saturation (SpO_2), end-tidal carbon dioxide (CO_2), pleural chest tube drainage, arterial blood gases. (See Chapters 17 and 19 for detailed descriptions of respiratory assessment and ventilatory management, respectively.)

Peripheral vascular status: peripheral pulses; color of skin, nail beds, mucosa, lips, and earlobes; skin temperature; edema; condition of dressings and invasive lines

Renal function: urinary output; serum creatinine and electrolytes

Fluid and electrolyte status: strict intake and output, including all IV fluids and blood products, output from all drainage tubes; clinical and laboratory indicators of imbalance

Pain: nature, type, location, and duration; apprehension; response to analgesics

Assessment also includes checking all equipment and tubes to ensure that they are functioning properly: endotracheal tube, ventilator, end-tidal CO_2 monitor, SpO_2 monitor, pulmonary artery catheter, $Sv–O_2$ monitor, arterial and IV lines, IV infusion devices and tubing, cardiac monitor, pacemaker, chest tubes, and urinary drainage system.

As the patient regains consciousness and progresses through the postoperative period, the nurse also assesses indicators of psychological and emotional status. The patient may exhibit behavior that reflects denial or depression or may experience postoperative delirium. Characteristic signs of delirium include transient perceptual illusions, visual and auditory hallucinations, disorientation, and paranoid delusions. Patients who have delirium after cardiac surgery have poorer outcomes than do similar patients without this complication (Jones et al., 2019).

The family's needs also must be assessed. The nurse ascertains how family members are coping with the situation; determines their psychological, emotional, and spiritual needs; and finds out whether they are receiving adequate information about the patient's condition.

Monitoring for Complications

The patient is continuously assessed for impending complications (see Table 23-4). The nurse and the surgical team function collaboratively to prevent complications, to

identify early signs and symptoms of complications, and to institute measures to reverse their progression.

Decreased Cardiac Output

A decrease in cardiac output is always a threat to the patient who has had cardiac surgery, and it can have a variety of causes. Preload alterations occur when too little blood volume returns to the heart as a result of persistent bleeding and hypovolemia. Excessive postoperative bleeding can lead to decreased intravascular volume, hypotension, and low cardiac output. Bleeding problems are common after cardiac surgery because of the effects of CPB, trauma from the surgery, and anticoagulation. Preload can also decrease if there is a collection of fluid and blood in the pericardium (cardiac tamponade), which impedes cardiac filling. Cardiac output is also altered if too much volume returns to the heart, causing fluid overload.

Afterload alterations occur when the arteries are constricted as a result of postoperative hypertension or hypothermia, increasing the workload of the heart. Heart rate alterations from bradycardia, tachycardia, and arrhythmias can lead to decreased cardiac output, and contractility can be altered in cardiac failure, MI, electrolyte imbalances, and hypoxia.

Fluid Volume and Electrolyte Imbalance

Fluid and electrolyte imbalance may occur after cardiac surgery. Nursing assessment for these complications includes monitoring of intake and output, weight, hemodynamic parameters, hematocrit levels, neck vein distention, edema, breath sounds (e.g., fine crackles, wheezing), and electrolyte levels. The nurse reports changes in serum electrolytes promptly so that treatment can be instituted. Especially important are dangerously high or dangerously low levels of potassium, magnesium, sodium, and calcium. Elevated blood glucose levels are common in the postoperative period. Administration of IV insulin is recommended in patients both with and without diabetes to achieve the glycemic control necessary to promote wound healing, decrease infection, and improve survival after surgery (Gordon et al., 2018). Implementing an insulin infusion protocol that targets moderate glycemic control has been demonstrated as effective in treating acute hyperglycemia following cardiac surgery while also decreasing the incidence of hypoglycemia (Gordon et al., 2018).

Impaired Gas Exchange

Impaired gas exchange is another possible complication after cardiac surgery. All body tissues require an adequate supply of oxygen for survival. To achieve this after surgery, an endotracheal tube with ventilator assistance may be used for hours to days. The assisted ventilation is continued until the patient's blood gas values are acceptable and the patient demonstrates the ability to breathe independently. Patients who are stable after surgery may be extubated as early as 2 to 4 hours after surgery, which reduces their discomfort and anxiety and facilitates patient–nurse communication.

While receiving mechanical ventilation, the patient is continuously assessed for signs of impaired gas exchange: restlessness, anxiety, cyanosis of mucous membranes and peripheral tissues, tachycardia, and fighting the ventilator. Breath sounds are assessed often to detect pulmonary congestion and monitor lung expansion. Arterial blood gases, SpO_2, and end-tidal CO_2 are assessed for decreased oxygen and

increased CO_2. Following extubation, aggressive pulmonary interventions such as turning, coughing, deep breathing, and early ambulation are necessary to prevent atelectasis and pneumonia.

Impaired Cerebral Circulation

Hypoperfusion or microemboli during or following cardiac surgery may produce injury to the brain. Brain function depends on a continuous supply of oxygenated blood. The brain does not have the capacity to store oxygen and must rely on adequate continuous perfusion by the heart. The nurse observes the patient for signs and symptoms of cerebral hypoxia: restlessness, confusion, dyspnea, hypotension, and cyanosis. An assessment of the patient's neurologic status includes the level of consciousness, response to verbal commands and painful stimuli, pupil size and reaction to light, facial symmetry, movement of the extremities, and hand grip strength. The nurse documents any indication of a change in status and reports abnormal findings to the surgeon because they may signal the onset of a complication such as a stroke.

Maintaining Cardiac Output

Ongoing evaluation of the patient's cardiac status continues as the nurse monitors the effectiveness of cardiac output through clinical observations and routine measurements: serial readings of blood pressure, heart rate, CVP, arterial pressure, and pulmonary artery pressures.

Renal function is related to cardiac function, as blood pressure and cardiac output drive glomerular filtration; therefore, urinary output is measured and recorded. Urine output less than 0.5 mL/kg/h may indicate a decrease in cardiac output or inadequate fluid volume.

Body tissues depend on adequate cardiac output to provide a continuous supply of oxygenated blood to meet the changing demands of the organs and body systems. Because the buccal mucosa, nail beds, lips, and earlobes are sites with rich capillary beds, they are observed for cyanosis or duskiness as possible signs of reduced cardiac output. Distention of the neck veins when the head of the bed is elevated to 30 degrees or more may signal right-sided heart failure.

Arrhythmias may develop due to decreased perfusion to or irritation of the myocardium from surgery. The most common arrhythmias encountered during the postoperative period are atrial fibrillation, bradycardias, tachycardias, and ectopic beats (Urden et al., 2019). Continuous observation of the cardiac monitor for arrhythmias is essential.

The nurse reports any indications of decreased cardiac output promptly. The assessment data are used to determine the cause of the problem. After a diagnosis has been made, the primary provider and the nurse work collaboratively to restore cardiac output and prevent further complications. When indicated, blood components; fluids; and antiarrhythmics, diuretics, vasodilators, or vasopressors are prescribed. If additional interventions are necessary, such as the placement of an intra-aortic balloon pump, the patient and family are prepared for the procedure.

Promoting Adequate Gas Exchange

To ensure adequate gas exchange, the patency of the endotracheal tube is assessed and maintained. The tube must be secured to prevent it from slipping out or down into the right mainstem bronchus. Suctioning is necessary when crackles or coughing is present.

For the procedural guideline for performing tracheal suction, go to thepoint.lww.com/Brunner15e.

Arterial blood gas determinations are compared with baseline data, and changes are reported to the primary provider promptly.

When the patient's hemodynamic parameters stabilize, body position is changed every 1 to 2 hours. Frequent changes of patient position provide for optimal pulmonary ventilation and perfusion, allowing the lungs to expand more fully.

Physical assessment and arterial blood gas results guide the process of weaning the patient from the ventilator. The nurse assists with the weaning process and eventually with the removal of the endotracheal tube. After extubation, the nurse encourages deep breathing and coughing at least every 1 to 2 hours to clear secretions, open the alveolar sacs, and promote effective ventilation. See Chapter 19 for discussion of weaning the patient from the ventilator.

Maintaining Fluid and Electrolyte Balance

To promote fluid and electrolyte balance, the nurse carefully assesses the intake and output to determine positive or negative fluid balance. It is necessary to record all fluid intake, including IV, nasogastric tube, and oral fluids, as well as all output, including urine, nasogastric drainage, and chest drainage.

Hemodynamic parameters (e.g., blood pressure, CVP, cardiac output) are correlated with intake, output, and weight to determine the adequacy of hydration and cardiac output. Serum electrolytes are monitored, and the patient is observed for signs of potassium, magnesium, sodium, or calcium imbalance (see Chapter 10).

Indications of dehydration, fluid overload, or electrolyte imbalance are reported promptly, and the primary provider and nurse work collaboratively to restore fluid and electrolyte balance and monitor the patient's response to therapies.

Minimizing Confusion

Some patients exhibit abnormal behaviors and acute confusion that occur with varying intensity and duration. The risk of delirium is high in patients who have undergone cardiac surgery and increases with patients' age (Jones et al., 2019; Smulter, Lingehall, Gustafson, et al., 2019; see the Nursing Research Profile in Chart 23-12). Clinical manifestations of postoperative delirium include restlessness, agitation, visual and auditory hallucinations, and paranoia. The delirium typically appears after a 2- to 5-day stay in an ICU. Patients are assessed for this problem with tools such as the Confusion Assessment Method for the ICU (CAM-ICU) (Price,

Garvan, Hizel, et al., 2017) (see Chapter 8, Chart 8-7, for discussion of CAM). The CAMU-ICU scale assesses for key indicators of delirium such as disorganized thinking and inattention. When this testing is positive, further assessment of the patient's physiologic and psychological status is required. Presumed causes of postoperative delirium include anxiety, sleep deprivation, increased sensory input, medications, and physiologic problems such as hypoxemia and metabolic imbalance (Blair, Mehmood, Rudnick, et al., 2019). Treatment includes correction of identified physiologic problems such as metabolic and electrolyte imbalances. In addition, behavioral interventions are used (e.g., frequent reorientation). Sedative medications such as haloperidol were once thought to reduce agitation and improve survival, but recent studies note that use of haloperidol causes oversedation and does not reliably treat or prevent delirium (Blair et al., 2019). The delirium often resolves after the patient is transferred from the unit, but nonetheless can be associated with negative outcomes including cognitive and functional decline, longer lengths of hospital stay, and higher mortality (Delaney, Hammond, & Litton, 2018).

Chart 23-12 **NURSING RESEARCH PROFILE**

Use of a Postoperative Delirium Screening Scale in Older Adults After Cardiac Surgery

Smulter, N., Lingehall, H. C., Gustafson, Y., et al. (2019). The use of a screening scale improves the recognition of delirium in older patients after cardiac surgery: A retrospective observational study. *Journal of Clinical Nursing, 28*(11-12), 2309–2318.

Purpose

Postoperative delirium (POD) is a frequent occurrence in older patients undergoing cardiac surgery. However, it is often not recognized by health care providers and therefore may go undiagnosed. The purpose of this study was to assess whether the use of a delirium screening tool by nurses postoperatively will improve the recognition and diagnosis of POD.

Design

This study was a retrospective observational analysis. Seventy eight patients aged 70 and older who had cardiac surgery were diagnosed with POD. Nurses used the Nursing Delirium Screening Scale (Nu-DESC) to screen for delirium symptoms. This scale uses five items to assess for delirium: disorientation, inappropriate behavior, inappropriate communication, illusions and hallucinations, and psychomotor retardation. Each item is graded from 0 to 2 with a maximum score of 10. A Nu-DESC score of 2 or greater is thought to indicate the presence of delirium. The screening was conducted three times daily, beginning post-op day 1 through discharge.

Data describing the incidence and nature of POD from the clinical database and discharge summaries were retrospectively collected. This information was compared to the results of symptom screening using the Nu-DESC.

Findings

POD was correctly identified in 41 of 78 (52.6%) patients. “Inappropriate behavior” was the most common descriptor used by nurses and physicians within discharge summaries. Terminology like “confused,” “aggressive/restless,” and “disoriented” were commonly used to describe delirium symptoms. The cause and specific treatment of delirium was not addressed within the discharge summaries

Screening using the Nu-DESC identified 56 of 78 (72%) patients with POD. Use of the Nu-DESC showed greater sensitivity in identifying symptoms of delirium than the information documented within the discharge summaries and database.

Nursing Implications

Delirium is a serious complication that is underdiagnosed in patients after cardiac surgery and, when present, not well documented. Use of a validated screening scale, such as the Nu-DESC, can improve the ability of nurses to recognize delirium in postoperative patients.

For all postoperative patients, basic comfort measures are used in conjunction with prescribed analgesics and sedatives to promote rest. Invasive lines and tubes are discontinued as soon as possible. Patient care is coordinated to provide undisturbed periods of rest. As the patient’s condition stabilizes and the patient is disturbed less frequently for monitoring and therapeutic procedures, rest periods can be extended.

Uninterrupted sleep is provided as much as possible, especially during the patient's normal hours of sleep.

Careful explanations of all procedures and of the patient's role in facilitating them help keep the patient positively involved throughout the postoperative course. Continuity of care is desirable; a familiar face and a nursing staff with a consistent approach help the patient feel safe. The patient's family should be welcomed at the bedside. A well-designed and individualized plan of nursing care can assist the nursing team in coordinating its efforts for the emotional well-being of the patient.

Relieving Pain

Patients who have had cardiac surgery may have pain in the peri-incisional area or throughout the chest, shoulders, and back. Pain results from trauma to the chest wall and irritation of the pleura by the chest tubes as well as incisional pain from peripheral vein or artery graft harvest sites.

The nurse assesses patients for verbal and nonverbal indicators of pain and records the nature, type, location, and duration of the pain. To reduce the amount of pain, the nurse encourages the patient to accept medication on a regular basis. The addition of adjunctive pain relievers (anti-inflammatory agents, muscle relaxants) to opioids decreases the amount of opioids required for pain relief and increases patient comfort. Patients report the most pain during coughing, turning, and moving. Physical support of the incision with a folded bath blanket or small pillow during deep breathing and coughing helps minimize pain. The patient should then be able to participate in respiratory exercises and to progressively increase self-care. Patient comfort improves after removal of the chest tubes.

Pain produces distress, which may stimulate the central nervous system to release catecholamines, resulting in constriction of the arterioles and increased heart rate. This can cause increased afterload and decreased cardiac output. Opioids alleviate pain and induce sleep and feelings of well-being, which reduce the metabolic rate and oxygen demands. After the administration of opioids, it is necessary to document observations indicating relief of apprehension and pain in the patient's record. The nurse observes the patient for any adverse effects of opioids, including respiratory depression, hypotension, constipation, ileus, or urinary retention. If respiratory depression occurs, an opioid antagonist (e.g., naloxone) may be required (see Chapter 9 for further discussion of nonpharmacologic pain interventions).

Maintaining Adequate Tissue Perfusion

The nurse routinely palpates peripheral pulses (e.g., pedal, tibial, femoral, radial, brachial) to assess for arterial obstruction. If a pulse is absent in any extremity, the cause may be prior catheterization of that extremity, chronic peripheral vascular disease, or a thromboembolic obstruction. The nurse immediately reports newly identified absence of any pulse.

Thromboembolic events can result from vascular injury, dislodgment of a clot from a damaged valve, loosening of mural thrombi, or coagulation problems. Air embolism can result from CPB or central venous cannulation. Symptoms of embolization vary according to site. The usual embolic sites are the lungs, coronary arteries, mesentery, spleen, extremities, kidneys, and brain. The patient is observed for the onset of the following:

- Acute onset of chest pain and respiratory distress, as occur in pulmonary embolus or MI
- Abdominal or back pain, as occur in mesenteric emboli
- Pain, cessation of pulses, blanching, numbness, or coldness in an extremity
- One-sided weakness and pupillary changes, as occur in stroke

The nurse promptly reports any of these symptoms.

Venous stasis, which can cause venous thromboembolism (e.g., deep vein thrombosis, pulmonary embolism), may occur after surgery. It can be prevented by using the following measures:

- Apply sequential pneumatic compression devices as prescribed.
- Discourage crossing of legs.
- Avoid elevating the knees on the bed.
- Omit pillows in the popliteal space.
- Begin passive exercises followed by active exercises to promote circulation and prevent venous stasis.

Inadequate renal perfusion can occur as a complication of cardiac surgery. One possible cause is low cardiac output. Trauma to blood cells during CPB can cause hemolysis of red blood cells, which then occlude the renal glomeruli. The use of vasopressor agents to increase blood pressure may constrict the renal arterioles and reduce blood flow to the kidneys.

Nursing management includes accurate measurement of urine output. An output less than 0.5 mL/kg/h may indicate hypovolemia or renal insufficiency. The primary provider may prescribe fluids to increase cardiac output and renal blood flow, or IV diuretics may be given to increase urine output. The nurse should be aware of the patient's blood urea nitrogen, serum creatinine, glomerular filtration rate, and serum electrolyte levels. The nurse should report abnormal levels promptly, because it may be necessary to adjust fluids and the dose or type of medication given. If efforts to maintain renal perfusion are ineffective, the patient may require continuous renal replacement therapy or dialysis (see Chapter 48).

Maintaining Normal Body Temperature

Patients are usually hypothermic when admitted to the critical care unit following the cardiac surgical procedure. Because induced hypothermia from CPB and anesthesia lower the patient's core temperature, the patient must be gradually warmed to a normal temperature. This is accomplished partially by the patient's own basal metabolic processes and often with the assistance of heated air blanket systems. While the patient is hypothermic, shivering and hypertension are common. Lowering the blood pressure with a vasodilator such as nitroprusside may be necessary. These problems typically resolve as warming occurs.

After cardiac surgery, the patient is at risk for developing elevated body temperature as a result of tissue inflammation or infection. The inflammatory/immune response to surgery includes the release of cytokines that cause fever (Norris, 2019). The resultant increase in metabolic rate increases tissue oxygen demands and increases cardiac workload. Antipyretics and other measures are used to lower body temperature.

Common sites of postoperative infection include the lungs, urinary tract, incisions, and intravascular catheters. Meticulous care is used to prevent contamination at the sites of catheter and tube insertions. Aseptic technique is used when changing dressings and when providing endotracheal tube and catheter care. Clearance of pulmonary secretions is accomplished by frequent repositioning of the patient, suctioning, and chest physical therapy, as well as educating and encouraging the patient to breathe deeply and cough. All invasive lines and tubes are discontinued as soon as possible after surgery to avoid infection.

Postpericardiotomy syndrome may occur in patients who undergo cardiac surgery. The syndrome is characterized by fever, pericardial pain, pleural pain, dyspnea, pericardial effusion, pericardial friction rub, and arthralgia. These signs and symptoms may occur days to weeks after surgery, often after the patient has been discharged from the hospital.

Postpericardiotomy syndrome must be differentiated from other postoperative complications (e.g., infection, incisional pain, MI, pulmonary embolus, bacterial endocarditis, pneumonia, atelectasis). Treatment depends on the severity of the signs and symptoms. Use of colchicine and anti-inflammatory agents may produce an improvement in symptoms (Lehto, Kiviniemi, Gunn, et al., 2018).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Depending on the type of surgery and postoperative progress, the patient may be discharged from the hospital 3 to 5 days after surgery. Following recovery from the surgery, patients can expect fewer symptoms from CAD and an improved quality of life. CABG has been shown to increase the lifespan of high-risk patients, including those with left main artery blockages and left ventricular dysfunction with multivessel blockages (Urden et al., 2019).

Although the patient may be eager to return home, the patient and family usually are apprehensive about this transition. Family members often express the fear that they are not capable of caring for the patient at home or that they are unprepared to handle complications that may occur.

The nurse helps the patient and family set realistic, achievable goals. An education plan that meets the patient's individual needs is developed with the patient and family. Specific instructions are provided about incision care; signs and symptoms of infection; diet; activity progression and exercise; deep breathing, incentive spirometry, and tobacco use cessation; weight and temperature monitoring; the medication regimen; and follow-up visits with home health nurses, the rehabilitation personnel, the surgeon, and the cardiologist or internist.

Some patients have difficulty learning and retaining information after cardiac surgery. The patient may experience recent memory loss, short attention span, difficulty with simple math, poor handwriting, and visual disturbances. Patients with these difficulties often become frustrated when they try to resume normal activities. The patient and family are reassured that the difficulty is almost always temporary and will subside, usually in 6 to 8 weeks. In the meantime, instructions are given to

the patient at a slower pace than normal, and a family member assumes responsibility for making sure that the prescribed regimen is followed.

Chart 23-13 **HOME CARE CHECKLIST**

Discharge After Cardiac Surgery

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify interventions and strategies (e.g., durable medical equipment, adaptive equipment) used in recovery period.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., walking and breathing exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
- State the name, dose, side effects, frequency, and schedule for all medications.
- State how to obtain medical supplies and carry out dressing changes, wound care, and other prescribed regimens.
- Identify durable medical equipment needs, proper usage, and maintenance necessary for safe utilization.
- Describe signs and symptoms of complications.
- State time and date of follow-up appointments.
- Relate how to reach the primary provider with questions or complications.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community)
  - Identify contact information of support groups for people and their caregivers/families
- Identify the need for health promotion (e.g., weight reduction, cessation of tobacco use, stress management), disease prevention, and screening activities

ADLs, activities of daily living; IADLs, independent activities of daily living.

Continuing and Transitional Care

Arrangements are made for home, community-based, or transitional care when appropriate. Because the hospital stay is relatively short, it is particularly important for the nurse to assess the patient's and family's ability to manage care in the home. The nurse making a home visit continues the education process (see Chart 23-13), monitors vital signs and incisions, assesses for signs and symptoms of complications, and provides support for the patient and family. Additional interventions may include dressing changes, diet counseling, and tobacco use cessation strategies. Patients and families need to know that cardiac surgery did not cure the patient's underlying heart disease process. Lifestyle changes for risk factor reduction are essential, and

medications taken before surgery to control problems such as blood pressure and hyperlipidemia will still be necessary.

The nurse encourages the patient to contact the surgeon, cardiologist, or office nurse with problems or questions. This provides the patient and family with reassurance that professional support is available. The patient is expected to have at least one follow-up visit with the surgeon.

Education does not end at the time of discharge from the hospital, transitional, or home health care. Many patients and families benefit from supportive programs, including cardiac rehabilitation. These programs provide monitored exercise; instructions about diet and stress reduction; information about resuming work, driving, and sex; assistance with tobacco use cessation; and support groups for patients and families. Hospital or community-based support groups provide information as well as an opportunity for families to share experiences.

CRITICAL THINKING EXERCISES

1 ipc You have been assigned to care for a 64-year-old woman who was admitted last night complaining of fatigue and mild shortness of breath. She tells you that she does not understand why the doctors are so concerned about her heart. She states, "there is nothing wrong with my heart. I am just tired. What's all the fuss about?" What education would you provide to the patient about women and heart disease? What clinical manifestations can indicate heart disease in women? What laboratory and diagnostic studies would you expect to be done for this patient? Which members of the interprofessional team would you want to involve in her care?

2 pq You are assigned to care for a 56-year-old man who is scheduled for a drug eluting stent today. You receive report from the cardiac catheter lab nurse that the patient tolerated the procedure well, is currently stable, and will be returning shortly to your unit. How will you prioritize care for this patient once he returns to his room? What assessments will you do first? What complications is he most at risk of developing and how will you know if they are occurring? What patient education should be initiated and when?

3 ebp You have been asked to provide an educational in-service to a group of nursing students on how to care for a patient presenting with a myocardial infarction (MI). One of the students asks you to explain how you determine if the patient is having an NSTEMI or a STEMI. How do you respond? According to evidence-based guidelines, what medications are used in the initial management of patients with an acute MI? According to these guidelines, under what conditions would a patient receive thrombolytic therapy rather than undergo a percutaneous coronary intervention?

24 Management of Patients with Structural, Infectious, and Inflammatory Cardiac Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Define valvular disorders of the heart and describe the pathophysiology, clinical manifestations, as well as the medical and nursing management of patients with mitral and aortic disorders.
2. Differentiate between the different types of cardiac valve repair and replacement procedures used to treat valvular problems and the care needed by patients who undergo these procedures.
3. Identify the pathophysiology, clinical manifestations, as well as the medical and nursing management of patients with cardiomyopathies.
4. Describe the pathophysiology, clinical manifestations, as well as the medical and nursing management of patients with infections of the heart.
5. Use the nursing process as a framework for care of the patient with a cardiomyopathy or the patient with pericarditis.

NURSING CONCEPTS

Infection
Inflammation
Perfusion

GLOSSARY

annuloplasty: repair of a cardiac valve's outer ring

aortic valve: semilunar valve located between the left ventricle and aorta

autograft: heart valve replacement made from the patient's own heart valve (e.g., pulmonic valve excised and used as an aortic valve)

bioprosthesis: heart valve replacement made of tissue from an animal heart valve (*synonym:* heterograft)

cardiomyopathy: disease of the heart muscle

chordae tendineae: nondistensible fibrous strands connecting papillary muscles to atrioventricular (mitral, tricuspid) valve leaflets

commissurotomy: splitting or separating fused cardiac valve leaflets

ejection fraction: percentage of the end-diastolic blood volume ejected from the ventricle with each heartbeat

homograft: heart valve replacement made from a human heart valve (*synonym:* allograft)

leaflet repair: repair of a cardiac valve's movable "flaps" (leaflets)

mitral valve: atrioventricular valve located between the left atrium and left ventricle

orthotopic transplantation: the recipient's heart is removed and a donor heart is grafted into the same site

prolapse: (of a valve): stretching of an atrioventricular heart valve leaflet into the atrium during systole

pulmonic valve: semilunar valve located between the right ventricle and pulmonary artery

regurgitation: backward flow of blood through a heart valve (*synonym:* insufficiency)

stenosis: narrowing or obstruction of a cardiac valve's orifice

total artificial heart: mechanical device used to aid a failing heart, replacing the right and left ventricles

tricuspid valve: atrioventricular valve located between the right atrium and right ventricle

valve replacement: insertion of either a mechanical prosthetic valve or a bioprosthetic, homograft, or autograft tissue valve at the site of a malfunctioning heart valve to restore normal blood flow through the heart

valvuloplasty: repair of a stenosed or regurgitant cardiac valve by commissurotomy, annuloplasty, or leaflet repair (or a combination of procedures)

ventricular assist device: mechanical device used to aid a failing right or left ventricle

Structural, infectious, and inflammatory disorders of the heart present many challenges for the patient, family, and health care team. Various mechanisms, heart valve disorders, cardiomyopathies, and infectious diseases of the heart alter cardiac output. Treatments for these disorders may be noninvasive or invasive. Noninvasive treatments often consist of medication therapy, diet changes, and activity modification. Invasive treatments include valve repair or replacement, ventricular assist devices (VADs), total artificial hearts (TAHs), cardiac transplantation, or other surgical procedures. Nurses have an integral role in the care of patients with structural, infectious, and inflammatory cardiac conditions.

VALVULAR DISORDERS

Valves of the heart control blood flow through the heart into the pulmonary artery and aorta by opening and closing in response to blood pressure changes during the cardiac cycle (systole, or heart contraction, and diastole, or relaxation of the heart).

Atrioventricular valves separate the atria from the ventricles and include the **tricuspid valve**, which separates the right atrium from the right ventricle, and the **mitral valve**, which separates the left atrium from the left ventricle. The tricuspid valve has three leaflets; the mitral valve has two. Both valves have **chordae tendineae**, which are nondistensible fibrous strands that anchor valve leaflets to papillary muscles of the ventricles.

Semilunar valves are located between the ventricles and their corresponding arteries. The **pulmonic valve** lies between the right ventricle and the pulmonary artery; the **aortic valve** lies between the left ventricle and the aorta. Figure 24-1 shows valves in the closed position (also refer to Chapter 21, Fig. 21-1 to review the structure of a normal heart).

When any heart valve does not close or open properly, blood flow is affected. When valves do not close completely, blood flows backward through the valve, a condition called **regurgitation** (also referred to as insufficiency). When valves do not open completely, a condition called **stenosis**, blood flow through the valve is reduced.

Regurgitation and stenosis may affect any heart valve. The mitral valve may also **prolapse** (i.e., stretching of the valve leaflet into the atrium during systole). For patients without symptoms, heart valve conditions may be monitored without treatment. If a patient has symptoms related to a valve disorder, treatment is based on the severity of symptoms, and patients may need to make lifestyle changes, take medications, or undergo repair or replacement of the valve. Disorders of the mitral and aortic valve typically cause more symptoms, require treatment, and cause more complications than

disorders of the tricuspid and pulmonic valves. Regurgitation and stenosis may occur at the same time in the same or different valves (Fig. 24-2).

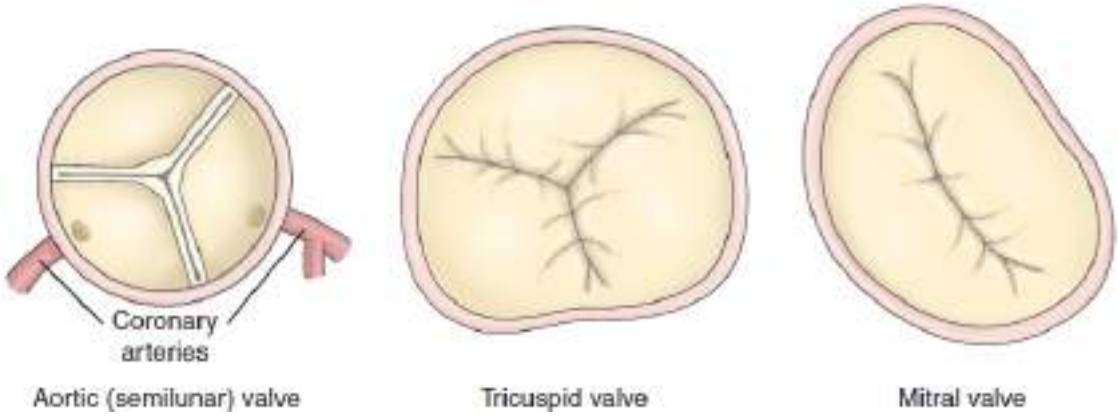

Figure 24-1 • Valves of the heart (aortic or semilunar, tricuspid, and mitral) in closed positions.

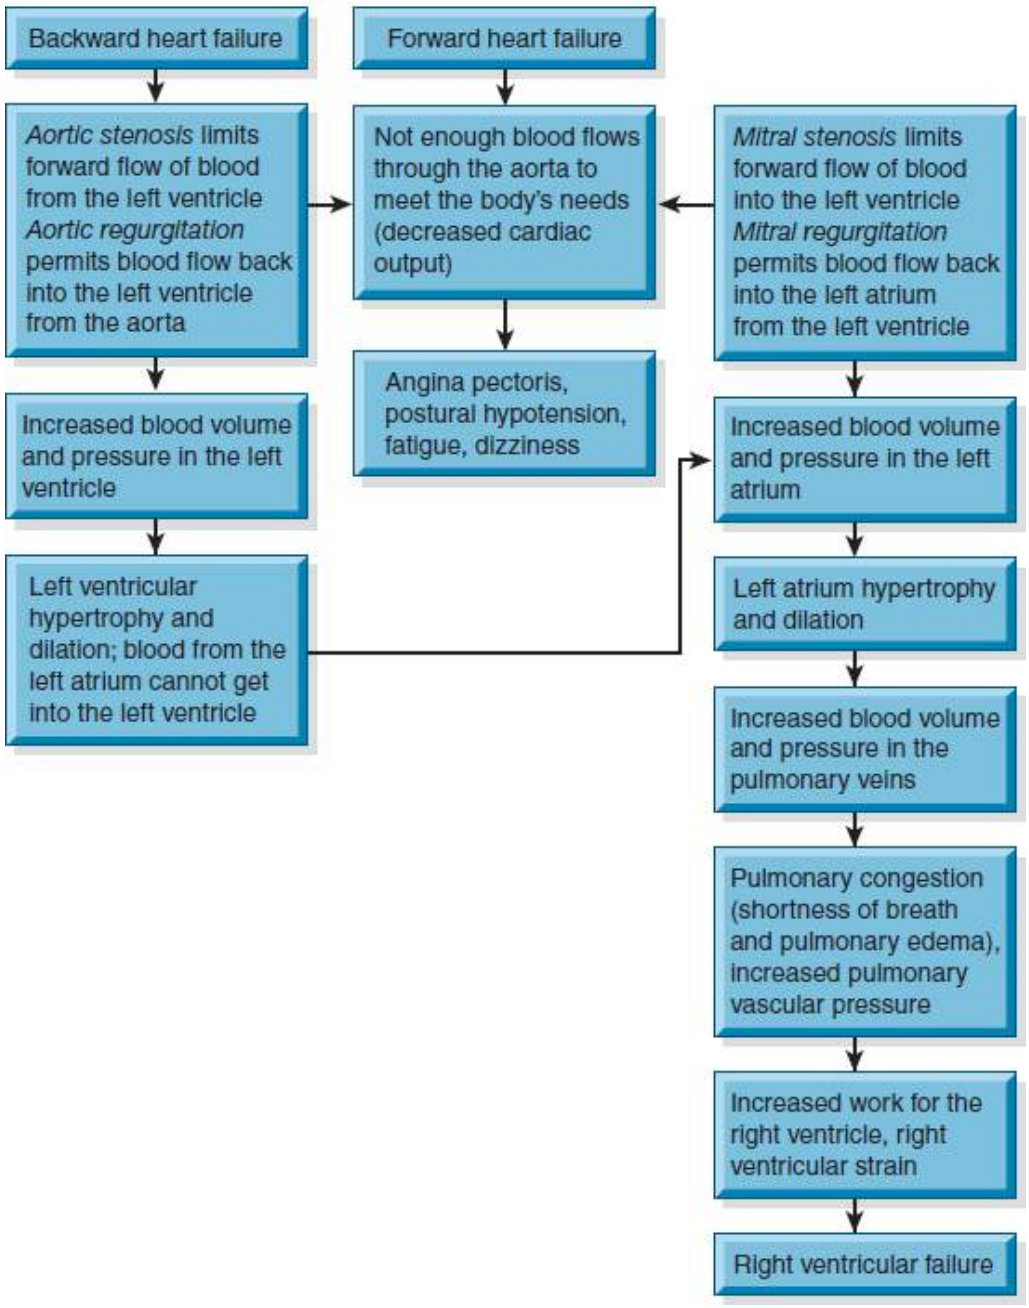

Figure 24-2 • Pathophysiology. Left-sided heart failure as a result of aortic and mitral valvular heart disease and development of right ventricular failure.

Mitral Valve Prolapse

Mitral valve prolapse is a deformity that usually produces no symptoms. Rarely, it progresses and can result in sudden death (Han, Ha, Teh, et al., 2018;

Nalliah, Mahajan, Elliott, et al., 2019). This condition occurs in up to 2.5% of the general population and twice as frequently in women as in men (Han et al., 2018). In most cases, there is no clear cause, but it has been associated with inherited connective tissue disorders, causing enlargement of one or both of the mitral valve leaflets (Asher, Chen, & Kallish, 2018; Wozniak-Mielczarek, Sabiniewicz, Drezek-Nojowicz, et al., 2019). The annulus often dilates; chordae tendineae and papillary muscles may elongate or rupture.

Pathophysiology

In mitral valve prolapse, a portion of one or both mitral valve leaflets balloons back into the atrium during systole. Rarely, ballooning stretches the leaflet to the point that the valve does not remain closed during systole. Blood then regurgitates from the left ventricle back into the left atrium. Although uncommon, mitral valve prolapse can result in mitral regurgitation, which can cause heart enlargement, atrial fibrillation, pulmonary hypertension, or heart failure (Ma, Igata, Strachan, et al., 2019).

Clinical Manifestations

Most people with mitral valve prolapse never have symptoms. A small number of patients will have fatigue, shortness of breath, lightheadedness, dizziness, syncope, palpitations, chest pain, or anxiety. To date, there has been no consensus about the cause of symptoms. Patients may report fatigue, regardless of activity level and amount of rest or sleep, as well as shortness of breath, palpitations, and chest pain (Althunayyan, Petersen, Lloyd, et al., 2019).

Assessment and Diagnostic Findings

Often, the first and only sign of mitral valve prolapse is an extra heart sound, referred to as a mitral click. A systolic click is an early sign that a valve leaflet is ballooning into the left atrium. In addition to the mitral click, a murmur of mitral regurgitation may be heard if the valve opens during systole and blood flows back into the left atrium. If mitral regurgitation exists, a patient may experience signs and symptoms of heart failure (see Chapter 25). Echocardiography is used to diagnose and monitor progression of mitral valve prolapse (Han et al., 2018).

Medical Management

Medical management is directed at controlling symptoms. If a patient who reports palpitations is found to have an arrhythmia, the patient may be advised

to eliminate caffeine and alcohol from the diet and to stop the use of tobacco products as well as electronic nicotine delivery systems (ENDS), including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars. Most patients do not require medication, but some are prescribed antiarrhythmic medications (see Chapter 22, Table 22-1). Prophylactic antibiotics are not recommended prior to dental or invasive procedures (Nishimura, Otto, Bonow, et al., 2017).

Patients who have chest pain related to mitral valve prolapse rarely require medical therapies, such as nitrates, calcium channel blockers, or beta-blockers. Heart failure, if present, is treated as it would be for any other case of heart failure (see Chapter 25). Patients with severe mitral regurgitation and symptomatic heart failure may require mitral valve repair or replacement (discussed later in this chapter).

Nursing Management

The nurse educates the patient about the diagnosis and the possibility that the condition is hereditary. First-degree relatives (e.g., parents, siblings) may be advised to have screening cardiac evaluations or echocardiograms. Because most patients with mitral valve prolapse are asymptomatic, the nurse explains the need to inform the patient's primary provider about any symptoms that may develop. The nurse encourages the patient to read product labels, particularly on over-the-counter products such as cough medicine, because these products may contain alcohol, caffeine, ephedrine, and epinephrine, which may produce arrhythmias and other symptoms. The nurse also explores diet, activity, sleep, and other lifestyle factors that may correlate with symptoms. (Treatment of arrhythmias, chest pain, heart failure, or other complications of mitral valve prolapse is described in Chapters 22 and 25.) Women diagnosed with mitral valve prolapse without mitral regurgitation or other complications may complete pregnancies without close cardiac monitoring and can safely proceed with vaginal deliveries (Yuan & Yan, 2016).

Mitral Regurgitation

Mitral regurgitation is a condition in which blood flows from the left ventricle back into the left atrium during systole. Often, the edges of mitral valve leaflets do not close completely during systole because leaflets and chordae tendineae have thickened and become fibrotic, resulting in abnormal contraction. Mitral regurgitation may be chronic or, less commonly, acute. The most common causes of mitral valve regurgitation in developed countries are degenerative changes of the mitral valve (including mitral valve prolapse) and ischemia of the left ventricle (Harb & Griffin, 2017). The most common cause

in developing countries is rheumatic heart disease and its sequelae (Negi, Mahajan, Rana, et al., 2018).

Other conditions that lead to chronic mitral regurgitation include pathologic myxomatous changes, which enlarge and stretch the left atrium and ventricle, causing leaflets and chordae tendineae to stretch or rupture (Harb & Griffin, 2017). Infective endocarditis may cause acute mitral regurgitation through leaflet perforation, or scarring following an infection that may cause retraction of leaflets or chordae tendineae (Watanabe, 2019). Collagen vascular diseases (e.g., systemic lupus erythematosus), cardiomyopathy, and ischemic heart disease may result in changes in the left ventricle, causing papillary muscles, chordae tendineae, or leaflets to stretch, shorten, or rupture. These conditions are often referred to as functional, or secondary, mitral regurgitation (Dziadzko, Dziadzko, Medina-Inojosa, et al., 2019).

Pathophysiology

Mitral regurgitation may result from problems with one or more leaflets, chordae tendineae, the annulus, or the papillary muscles. A mitral valve leaflet may shorten or tear, and chordae tendineae may elongate, shorten, or tear. The annulus may be stretched by heart enlargement, as in functional mitral regurgitation, or it may be deformed by calcification. A papillary muscle may rupture, stretch, or be pulled out of position by changes in the ventricular wall (e.g., scar from a myocardial infarction, ventricular dilation). Papillary muscles may be unable to contract because of ischemia, a condition referred to as ischemic mitral regurgitation. Regardless of the cause, the effect is backward blood flow into the atrium during systole.

In this disorder, each beat of the left ventricle pushes blood backward into the left atrium, adding to blood flowing in from the lungs. This excess blood causes the left atrium to stretch and eventually thicken, or hypertrophy, then dilate. Over time, blood coming in from the ventricle prevents blood flow from the lungs into the atrium. As a result, the lungs become congested, eventually adding extra strain to the right ventricle. During diastole, the increased blood volume from the atrium fills the ventricle. The volume overload causes ventricular hypertrophy. Eventually, the ventricle dilates, and systolic heart failure develops.

Clinical Manifestations

Chronic mitral regurgitation is often asymptomatic, but acute mitral regurgitation (e.g., resulting from a myocardial infarction) usually manifests as severe and sudden congestive heart failure (Harb & Griffin, 2017). Dyspnea, fatigue, and weakness are the most common symptoms. Palpitations, shortness of breath on exertion, and cough from pulmonary congestion also occur.

Assessment and Diagnostic Findings

The systolic murmur of mitral regurgitation is a blowing sound best heard at the apex. The murmur may radiate to the left axilla (Harb & Griffin, 2017). The pulse may be regular, or it may be irregular because of extrasystolic beats or atrial fibrillation. Echocardiography is used to diagnose and monitor progression of this disorder (Nishimura et al., 2017).

Medical Management

Patients with mitral regurgitation who develop pulmonary congestion are managed with medications used for heart failure. Patients with mitral regurgitation and heart failure benefit from afterload reduction (arterial dilation) by treatment with angiotensin-converting enzyme (ACE) inhibitors (e.g., captopril, lisinopril) or angiotensin receptor blockers (ARBs) (e.g., losartan, valsartan), direct arterial dilators (e.g., hydralazine), and beta-blockers (e.g., carvedilol, metoprolol) (see Chapter 25, Table 25-3). Symptoms of heart failure also are an indication to consider surgical intervention by mitral **valvuloplasty** (i.e., surgical repair of the valve) or **valve replacement** (replacement of the dysfunctional valve with either a mechanical valve or a type of tissue valve; discussed later in this chapter) (Nishimura et al., 2017).

Mitral Stenosis

Mitral stenosis results in reduced blood flow from the left atrium into the left ventricle. It is usually caused by rheumatic endocarditis, which progressively thickens mitral valve leaflets and chordae tendineae, causing the leaflets to fuse together (Negi et al., 2018). Eventually, the mitral valve orifice narrows and progressively obstructs blood flow into the ventricle.

Pathophysiology

Normally, the mitral valve orifice is as wide as the diameter of three fingers. In severe mitral stenosis, the orifice narrows to the width of a pencil. Because of increased resistance through the narrowed valve orifice, the left atrium is less able to push blood into the left ventricle. This results in increased residual blood volume in the left atrium, which over time causes left atrial hypertrophy and dilation. Decreased blood flow into the left ventricle leads to reduced ventricular filling and decreased cardiac output. A stenotic valve fails to protect pulmonary veins from backward flow of blood from the atrium, resulting in congestion of the pulmonary circulation. The right ventricle must then contract against abnormally high pulmonary arterial pressure and is subjected to excessive strain. Over time, the right ventricle hypertrophies,

enlarges, and eventually fails. If the heart rate increases, diastole is shortened; thus, the amount of time for forward flow of blood decreases, and more blood backs into the pulmonary veins. Therefore, as the heart rate increases, cardiac output further decreases, and pulmonary pressures increase.

Clinical Manifestations

Often, the first symptom of mitral stenosis is dyspnea on exertion (DOE) caused by pulmonary venous hypertension. Symptoms do not usually develop until after the valve opening is reduced by one third to one half its usual size (Harb & Griffin, 2017). Patients may experience progressive fatigue and decreased exercise tolerance because of low cardiac output. An enlarged left atrium may create pressure on the left bronchial tree, resulting in a dry cough or wheezing. In cases of severe mitral stenosis with significant pulmonary congestion, patients may expectorate blood (i.e., hemoptysis) or experience palpitations, orthopnea, paroxysmal nocturnal dyspnea (PND), or repeated respiratory infections. Increased blood volume and pressure cause the left atrium to dilate, hypertrophy, and become electrically unstable, which may result in patients developing atrial arrhythmias (Negi et al., 2018).

Assessment and Diagnostic Findings

Patients with mitral stenosis will have a low-pitched, rumbling diastolic murmur, best heard at the apex. Patients may have a weak and irregular pulse if they develop atrial fibrillation and may have signs or symptoms of heart failure (Nishimura et al., 2017). Echocardiography is used to diagnose and quantify the severity of mitral stenosis. Electrocardiography (ECG), exercise testing, and cardiac catheterization with angiography may be used to help determine the severity of mitral stenosis.

Prevention

Since rheumatic heart disease may result in mitral stenosis, prevention is aimed at decreasing the risk of contracting and providing early treatment for bacterial infections (see prevention of endocarditis later in this chapter). Prevention of acute rheumatic fever depends on effective antibiotic treatment of group A streptococcal infection (Nishimura et al., 2017). Antibiotic prophylaxis for recurrent rheumatic fever with rheumatic carditis may require 10 or more years of antibiotic coverage (e.g., penicillin G intramuscularly every 4 weeks, penicillin V orally twice daily, sulfadiazine orally daily, or erythromycin orally twice daily) (Szczygielska, Hernik, Kolodziejczyk, et al., 2018).

Medical Management

Congestive heart failure is treated as described in Chapter 25. Patients with severe left atrial dilation in mitral stenosis may benefit from anticoagulant medications to decrease the risk of developing atrial thrombi. If atrial fibrillation develops, cardioversion may be attempted to restore normal sinus rhythm. If unsuccessful, the ventricular rate is controlled with beta-blockers, digoxin, or calcium channel blockers; furthermore, patients will require anticoagulation for thromboembolism prevention (January, Wann, Calkins, et al., 2019). Patients with severe mitral stenosis are advised to avoid strenuous activities, competitive sports, and pregnancy, all of which increase heart rate (Nishimura et al., 2017). Surgical intervention consists of valvuloplasty, usually a **commissurotomy** (i.e., splitting or separating leaflets) to open the fused commissure of the valve. The *commissure* is the site where valve leaflets meet. Percutaneous transluminal valvuloplasty or valve replacement may be performed.

Aortic Regurgitation

Aortic regurgitation is backward flow of blood into the left ventricle from the aorta during diastole. It may be caused by a congenital valve abnormality (e.g., a bicuspid aortic valve), inflammatory lesions that deform aortic valve leaflets, or dilation of the aorta, preventing complete closure of the aortic valve. Chronic or acute aortic regurgitation may also be caused by infections such as rheumatic endocarditis or syphilis, or by a dissecting aortic aneurysm resulting in dilation or tearing of the ascending aorta, blunt chest trauma, or deterioration of a surgically replaced aortic valve (Akinseye, Pathak, & Ibebuogu, 2018; Nishimura et al., 2017).

Pathophysiology

During diastole, blood is normally delivered into the left atrium from the aorta. In aortic regurgitation, blood flows back into the left ventricle, which will dilate to accommodate increased blood volume. Over time, the left ventricle hypertrophies to expel more blood with above-normal force, thus increasing systolic blood pressure. Arteries attempt to compensate for higher pressures by reflex vasodilation; peripheral arterioles relax, reducing peripheral resistance and diastolic blood pressure.

Clinical Manifestations

Aortic regurgitation, also called aortic insufficiency, develops without symptoms in most patients. Some patients are aware of a pounding or forceful

heartbeat, especially in the head or neck. Patients who develop left ventricular hypertrophy may have visible or palpable arterial pulsations at the carotid or temporal arteries due to increased force and blood volume. As aortic regurgitation worsens, DOE and fatigue follow; there may eventually be signs and symptoms of progressive left ventricular failure including increased shortness of breath, orthopnea, or PND (Akinseye et al., 2018).

Assessment and Diagnostic Findings

A high-pitched, blowing diastolic murmur is heard at the third or fourth intercostal space at the left sternal border. The difference between systolic and diastolic pressures (i.e., the pulse pressure) may be widened in patients with aortic regurgitation. One characteristic sign is the water hammer (Corrigan's) pulse, in which the pulse strikes a palpating finger with a quick, sharp stroke and then collapses (Pabba & Boudi, 2019). The diagnosis may be confirmed by echocardiography (preferably transesophageal), cardiac magnetic resonance imaging (MRI), or cardiac catheterization. Patients with symptoms usually have echocardiograms every 6 months, and those without symptoms have echocardiograms every 2 to 5 years (Nishimura et al., 2017).

Prevention

Prevention of aortic regurgitation is primarily based on prevention of and treatment for bacterial infections (see prevention of endocarditis later in this chapter). The same strategies aimed at preventing acute and recurrent rheumatic fever previously described for the patient with mitral stenosis apply to patients with aortic regurgitation.

Medical Management

A patient who is symptomatic or has developed a significant decrease in left ventricular function is advised to avoid physical exertion, competitive sports, and isometric exercise until the valve has been replaced (Gati, Malhotra, & Sharma, 2019). If arrhythmias and heart failure occur, they are treated as described in Chapters 22 and 25. Controlling high blood pressure in patients with aortic regurgitation can improve forward blood flow through the heart. ACE inhibitors and dihydropyridine calcium channel blockers may be recommended for management of hypertension; these are effective at reducing afterload. Beta-blockers are less commonly used, due to concern that a lower heart rate may actually increase blood pressure through negative chronotropic effects (Akinseye et al., 2018). Patients who are symptomatic should be instructed to restrict sodium intake to prevent volume overload and will require valve replacement (Nishimura, Otto, Bonow, et al., 2014).

The treatment of choice is aortic valve replacement or valvuloplasty (described later), preferably performed before left ventricular failure occurs. Surgery is recommended for any patient with significant left ventricular dilation, regardless of the presence or absence of symptoms (Nishimura et al., 2014). Surgery is also recommended for any patient who is symptomatic (Flint, Wunderlich, Shmueli, et al., 2019).

Aortic Stenosis

Aortic valve stenosis is narrowing of the orifice between the left ventricle and aorta. In adults, stenosis is usually caused by degenerative calcification. Calcification may be caused by proliferative and inflammatory changes that occur in response to years of normal mechanical stress, similar to changes that occur in atherosclerotic cardiovascular disease (Joseph, Naqvi, Giri, et al., 2017). Congenital leaflet malformations or an abnormal number of leaflets (i.e., one or two rather than three) are less common causes. Rheumatic endocarditis may cause adhesions or fusion of the commissures and valve ring, stiffening of the cusps, and calcific nodules on the cusps.

Pathophysiology

Typically, aortic stenosis progresses gradually over several years to several decades. As the valve orifice narrows, the left ventricle overcomes obstruction by contracting more slowly and more forcibly. Obstruction to left ventricular outflow increases pressure on the left ventricle, so the ventricular wall hypertrophies. When these compensatory mechanisms are insufficient to allow for normal heart function, clinical signs and symptoms of heart failure will develop (Joseph et al., 2017).

Clinical Manifestations

Many patients with aortic stenosis are asymptomatic. Often, the first symptom to appear is DOE, caused by increased pulmonary venous pressure due to a dilating left ventricle. Over time, left ventricular failure may occur, causing orthopnea, PND, and pulmonary edema. Reduced blood flow to the brain may cause dizziness, and in more severe aortic stenosis, syncope. Patients may also report angina pectoris, which is caused by limited blood flow into the coronary arteries, decreased time in diastole to allow for myocardial perfusion, and simultaneously increased oxygen demand of the hypertrophied left ventricle. Blood pressure is usually normal but may be low. In the setting of decreased blood flow, there may be a low pulse pressure (30 mm Hg or less).

Assessment and Diagnostic Findings

On physical examination, a loud, harsh systolic murmur is heard over the aortic area (i.e., right second intercostal space) and may radiate to the carotid arteries and apex of the left ventricle. The murmur may be described as low pitched, crescendo–decrescendo, rough, rasping, and vibrating (Libby, Zipes, Bonow, et al., 2018). An S_4 sound may be heard (see Chapter 21 for discussion of heart sounds). By having the patient lean forward during auscultation and palpation, especially during exhalation, the murmur may be accentuated. There may also be a palpable vibration extending from the base of the heart (second intercostal space next to the sternum and above the suprasternal notch) and up along the carotid arteries. The vibration is caused by turbulent blood flow across the narrowed valve orifice.

Cardiac imaging is used to diagnose and monitor the progression of aortic stenosis. This may consist of echocardiography, cardiac MRI, or computed tomography (CT) scanning (Lindman, Dweck, Lancellotti, et al., 2019). Patients with symptoms usually have echocardiograms every 6 to 12 months, and those without symptoms have echocardiograms every 2 to 5 years, depending on how severely the orifice is narrowed (Lindman et al., 2019; Nishimura et al., 2014). Left ventricular hypertrophy may be seen on a 12-lead ECG or an echocardiogram. Once aortic stenosis has progressed sufficiently to consider surgical intervention, left-sided heart catheterization is needed to measure the severity of the valvular abnormality and to evaluate the coronary arteries. Pressure measurements are taken from the left ventricle and base of the aorta. The systolic pressure in the left ventricle is considerably higher than that in the aorta during systole. Graded exercise studies (stress tests) to assess exercise capacity are performed with caution for patients with severe aortic stenosis due to the high risk of inducing ventricular tachycardia or fibrillation, and should not be performed on symptomatic patients (Joseph et al., 2017).

Prevention

Prevention of aortic stenosis is primarily focused on controlling risk factors for proliferative and inflammatory responses—namely, through treating diabetes, hypertension, hypercholesterolemia, and elevated triglycerides, and avoiding tobacco products and ENDS (see prevention of endocarditis later in this chapter).

Medical Management

Medications are prescribed to treat arrhythmias or left ventricular failure (see Chapters 22 and 25). Definitive treatment for aortic stenosis is replacement of the aortic valve, which may be done surgically or nonsurgically. Nonsurgical

valve replacement, known as transcatheter aortic valve replacement (TAVR), is described in more detail later in this chapter. Patients who are symptomatic and are not candidates for valve replacement may benefit from one- or two-balloon percutaneous valvuloplasty procedures, which can provide symptom relief (Sandhu, Krishnamoorthy, Afif, et al., 2017).

Nursing Management: Valvular Heart Disorders

The nurse educates the patient with valvular heart disease about the diagnosis, progressive nature of the disease, and treatment plan. The patient is instructed to report new symptoms or changes in symptoms to the primary provider. The nurse also educates the patient that an infectious pathogen, usually a bacterium, can adhere to a diseased heart valve more readily than to a normal valve. Once attached to the valve, the infectious agent multiplies, resulting in endocarditis and further damage to the valve. In addition, the nurse educates the patient about how to minimize the risk of developing infective endocarditis (discussed later in this chapter).

The nurse measures the patient's heart rate, blood pressure, and respiratory rate, compares these results with previous data, and notes any changes. Heart and lung sounds are auscultated, and peripheral pulses palpated. The nurse assesses the patient with valvular heart disease for the following:

- Signs and symptoms of heart failure, such as fatigue, DOE, decreased activity tolerance, an increase in coughing, hemoptysis, multiple respiratory infections, orthopnea, and PND (see Chapter 25)
- Arrhythmias, by palpating the patient's pulse for strength and rhythm (i.e., regular or irregular) and asking whether the patient has experienced palpitations or felt forceful heartbeats (see Chapter 22)
- Symptoms such as dizziness, syncope, increased weakness, or angina pectoris (see Chapter 23)

The nurse collaborates with the patient to develop a medication schedule and provides education about the name, dosage, actions, adverse effects, and any drug–drug or drug–food interactions of prescribed medications for heart failure, arrhythmias, angina pectoris, or other symptoms. Specific precautions are emphasized, such as the risk to patients with aortic stenosis who experience angina pectoris and take nitroglycerin. The venous dilation that results from nitroglycerin use decreases blood return to the heart, thus decreasing cardiac output and increasing the risk of syncope and decreased coronary artery blood flow. The nurse educates the patient about the importance of attempting to relieve the symptoms of angina with rest and relaxation before taking nitroglycerin and to anticipate potential adverse effects.

For patients with heart failure, the nurse provides education on taking a daily weight and reporting sudden weight gain, as defined by the primary provider. The nurse may assist the patient with planning activity and rest periods to allow symptom relief while preventing deconditioning or loss of function. Care of patients treated with valvuloplasty or surgical valve replacement is described later in this chapter.

SURGICAL MANAGEMENT: VALVE REPAIR AND REPLACEMENT PROCEDURES

Valvuloplasty

Repair, rather than replacement, of a cardiac valve is referred to as valvuloplasty. The recommended procedure for valvuloplasty will depend on the cause and type of valve dysfunction. Repair may be made to commissures between the leaflets in a procedure known as commissurotomy, to the annulus of the valve by **annuloplasty** (i.e., specifically, repair of the cardiac valve's outer ring), or to leaflets. Transesophageal echocardiogram (TEE) is usually performed at the conclusion of a valvuloplasty to evaluate the effectiveness of the procedure.

Some valvuloplasty procedures are open-heart surgeries, which are performed under general anesthesia and usually use cardiopulmonary bypass. However, there are now several valvuloplasty procedures which utilize nonsurgical, or percutaneous, techniques; these do not require general anesthesia or cardiopulmonary bypass and can be performed in a cardiac catheterization laboratory or hybrid room. A hybrid room is an operating room with imaging capability (e.g., fluoroscopy, CT, MRI) and interventional devices for open, minimally invasive, image-guided and catheter-based procedures. Percutaneous partial cardiopulmonary bypass is used in some cardiac catheterization laboratories and hybrid rooms. (Cardiopulmonary bypass is described in Chapter 23.)

Commissurotomy

Valve leaflets may adhere to one another and close the commissure (i.e., stenosis). Less commonly, leaflets adhere to one another in a manner which creates stenosis as well as regurgitation, or backward blood flow. A commissurotomy is performed to separate the fused leaflets.

Closed Commissurotomy/Balloon Valvuloplasty

Commissurotomy is usually used for mitral valve stenosis. The preferred method is percutaneous transvenous mitral commissurotomy, which may be used for patients with congenital mitral stenosis, severe calcified mitral stenosis, left atrial thrombus, moderate to severe coexisting mitral regurgitation, or in patients with coexisting moderate to severe tricuspid regurgitation who would also benefit from tricuspid valve repair (Nishimura et al., 2014).

Most often used for mitral and aortic valve stenosis, balloon valvuloplasty is less commonly used to treat tricuspid and pulmonic valve stenosis. With more widely available percutaneous valve repair and replacement procedures, balloon valvuloplasty is becoming a less common procedure in the United States (Kumar, Paniagua, Hira, et al., 2016). Balloon valvuloplasty may still be used for mitral valve stenosis in younger patients, and for patients with complex medical conditions that place them at high risk for complications of more extensive surgical procedures. The procedure is contraindicated for patients with left atrial or ventricular thrombus, severe aortic root dilation, significant mitral valve regurgitation, and severe valvular calcification (Nishimura et al., 2014).

Balloon valvuloplasty (Fig. 24-3) is performed in a cardiac catheterization laboratory. The patient may receive light or moderate sedation and a local anesthetic. Mitral balloon valvuloplasty involves advancing one or two catheters into the right atrium, through the atrial septum into the left atrium, across the mitral valve, and into the left ventricle. A guidewire is placed through each catheter, and the original catheter is removed. Most often a specially designed balloon catheter is placed over the guidewire and positioned with the balloon across the mitral valve. The balloon has three sections with progressively greater resistance to inflation. The balloon first expands in the ventricle to help position the catheter at the valve. The second section of the balloon expands above the valve, holding the catheter across the valve. Finally, the middle section of the balloon expands in the valve orifice opening the commissures. Alternately, two balloons are used. Guidewires may be advanced into the aorta to stabilize the balloons' positions. These single-section balloons are inflated simultaneously and expand their entire length. The advantage of two balloons is that each is smaller than the one large balloon, making smaller atrial septal defects. As the two balloons are inflated, they usually do not completely occlude the valve, thereby permitting some forward flow of blood during the inflation period. Balloons are inflated with a dilute angiographic solution for 10 to 30 seconds. Multiple inflations usually are required to achieve the desired results (Hermann & Mack, 2019).

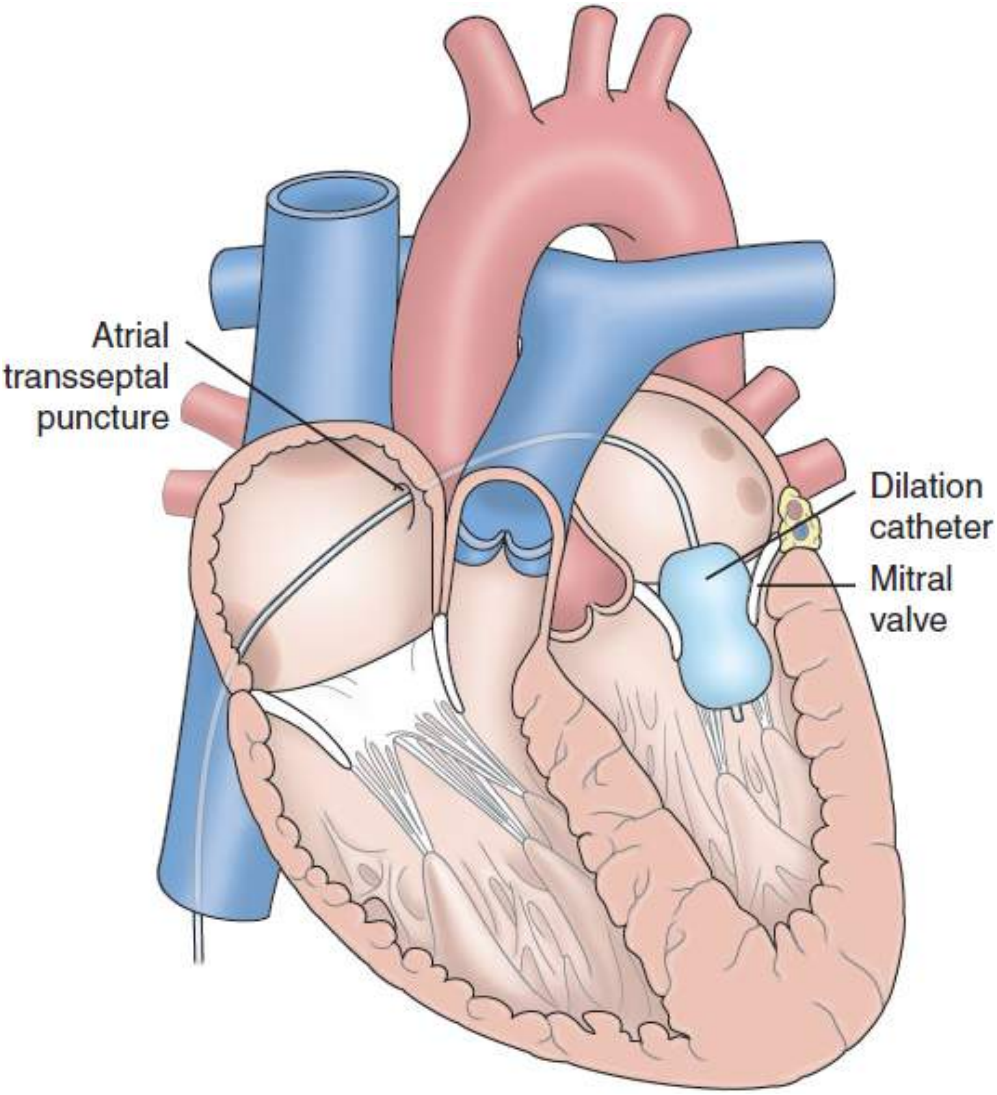

Figure 24-3 • Balloon valvuloplasty. Cross-section of heart illustrating the dilation catheter placed through an atrial transseptal puncture and across the mitral valve. The Inoue-Balloon inflates in three stages: first below the valve, then above, and finally in the valve orifice (this diagram shows the first two sections inflated).

All patients will have some degree of mitral regurgitation following mitral balloon valvuloplasty. Other possible complications include bleeding from the catheter insertion sites, emboli resulting in complications such as strokes, and, rarely, left-to-right atrial shunts through the atrial septal defect created during the procedure.

Aortic balloon valvuloplasty is usually performed by introducing a catheter through the aorta, across the aortic valve, and into the left ventricle; less commonly, it may be performed by passing the balloon or balloons through the atrial septum. The one- or two-balloon technique can be used for treating aortic stenosis. Balloons are inflated for 15 to 60 seconds, and inflation is usually repeated multiple times. Possible complications include aortic

regurgitation, emboli, ventricular perforation, rupture of the aortic valve annulus, ventricular arrhythmia, mitral valve damage, and bleeding from the catheter insertion sites. The aortic valve procedure is not as effective as the mitral valve procedure, and the rate of restenosis is approximately 50% in the first 6 months after the procedure. It is usually used for palliation of symptoms in patients who are not suitable candidates for TAVR, but may sometimes be used as a bridge to TAVR (Hermann & Mack, 2019; Kumar et al., 2016).

Open Commissurotomy

Since percutaneous commissurotomy has fewer risks with similar outcomes, open commissurotomy has become less commonly used in recent decades. The patient is under general anesthesia, and a midsternal or left thoracic incision is made. Cardiopulmonary bypass is initiated, and an incision is made into the heart. The valve is exposed, and a scalpel, finger, balloon, or dilator is used to open the commissures. One advantage of directly visualizing the valve and surrounding structures is that a thrombus or calcifications may be removed. Chordae or papillary muscles may also be inspected and surgically repaired as necessary.

Annuloplasty

The junction at which valve leaflets connect to the heart wall is an annulus. Annuloplasty refers to repair of the valve annulus, resulting in narrowing of the valve orifice. It is used for valvular regurgitation. For the mitral valve, there may be damage or rupture of the chordae tendineae resulting in severe mitral regurgitation, which is an indication for urgent valve repair by annuloplasty with resuspension of the chordae tendineae. General anesthesia and cardiopulmonary bypass are required for most annuloplasties.

There are two annuloplasty techniques. One technique uses an annuloplasty ring (Fig. 24-4), which may be rigid/semirigid or flexible. Leaflets of the valve are sutured to a ring, creating an annulus of the desired size. When the ring is in place, tension created by moving blood and the contracting heart is borne by the ring rather than by the valve or a suture line, thereby preventing progressive regurgitation.

A second technique to tighten the annulus involves folding elongated tissue over onto itself in leaflets or tacking leaflets to the atrium or each other with sutures. Because the valve's leaflets and suture lines are subjected to direct forces of the blood and heart muscle movement, the repair may degenerate more quickly than one using an annuloplasty ring (Maisano, Skantharaja, Denti, et al., 2019).

Leaflet Repair

Damage to cardiac valve leaflets may result from stretching, shortening, or tearing. **Leaflet repair** for elongated, ballooning, or other excess tissue leaflets is achieved by removing the extra tissue. Elongated tissue may be tucked and sutured, a technique called plication. A wedge of tissue may be cut from the middle of the leaflet and the gap sutured closed (i.e., leaflet resection) (Fig. 24-5). After short chordae are released, leaflets often unfurl and resume their normal function, allowing the valve to close during systole. A leaflet may be extended by suturing a piece of pericardium to it. A pericardial or synthetic patch may be used to repair holes in the leaflets.

Valve Replacement

Valve replacement is preferred for patients with valves with anatomy which decreases the chance of success with repair; this includes valves that have extensive calcification, or with severely fibrotic or fused leaflets, chordae tendineae, or papillary muscles. Ideally, a multidisciplinary team (e.g., cardiologists, cardiac thoracic surgeons, structural valve interventionalists, anesthesiologists, nurses) will work together with the patient to determine candidacy for surgical versus more minimally invasive replacement (Nishimura et al., 2014). General anesthesia and cardiopulmonary bypass are used for surgical valve replacements. The standard surgical procedure is performed through a median sternotomy (i.e., incision through the sternum), although the mitral valve may be approached through a right thoracotomy incision.

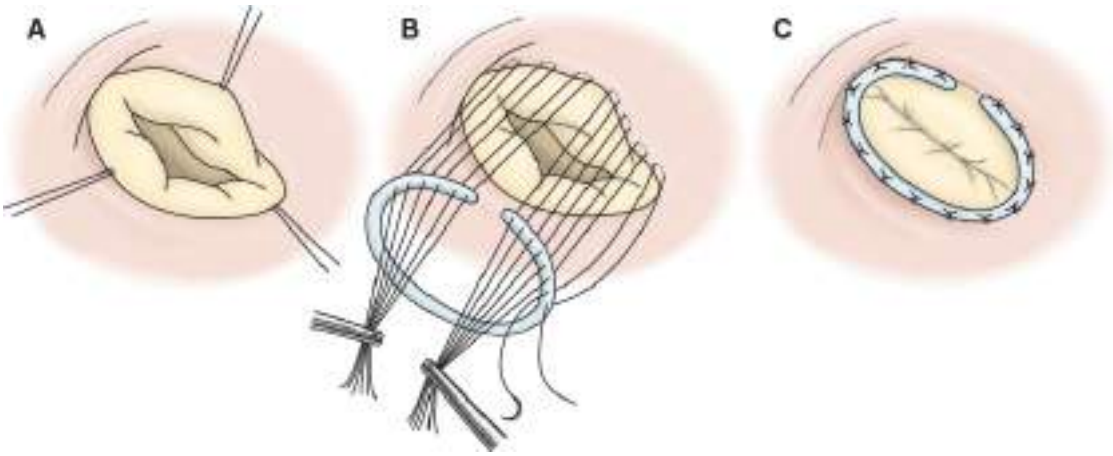

Figure 24-4 • Annuloplasty ring insertion. **A.** Mitral valve regurgitation; leaflets do not close. **B.** Insertion of an annuloplasty ring. **C.** Completed valvuloplasty; leaflets close.

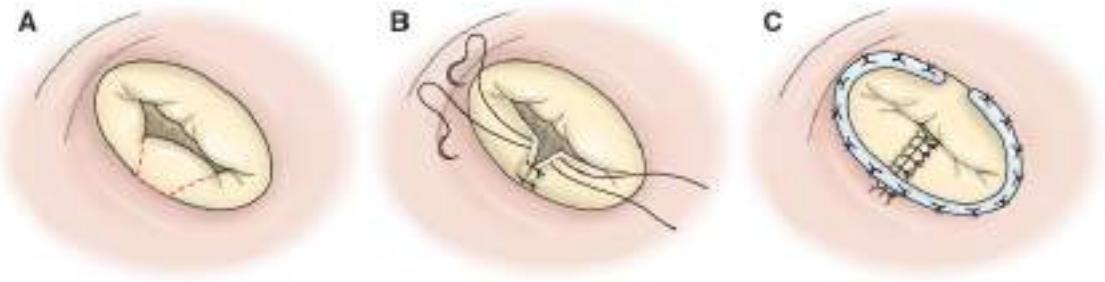

Figure 24-5 • Valve leaflet resection and repair with a ring annuloplasty. **A.** Mitral valve regurgitation; the section indicated by *dashed lines* is excised. **B.** Approximation of edges and suturing. **C.** Completed valvuloplasty, leaflet repair, and annuloplasty ring.

Mitral and aortic valve replacements may be performed with minimally invasive techniques that do not involve cutting through the length of the sternum. Instead, a 2- to 4-inch incision is made in only the upper or lower half of the sternum or between ribs, or performed percutaneously. Some minimally invasive procedures are robot assisted; surgical instruments are connected to a robot, and the surgeon, watching a video display, uses a joystick to control the robot and surgical instruments. With these procedures, patients have lower rates of bleeding, pain, infection, and scarring, and shorter length of stay in the hospital (Nishimura et al., 2014).

After the valve is visualized, leaflets of the aortic or pulmonic valve are removed, but some or all of the mitral valve structures (leaflets, chordae, and papillary muscles) are left in place to help maintain the shape and function of the left ventricle after mitral valve replacement. Sutures are placed around the annulus and then through the valve prosthesis. The replacement valve is slid down the suture into position and tied into place (Fig. 24-6). The patient is weaned from cardiopulmonary bypass, the quality of the surgical repair is often assessed with color flow Doppler TEE, and then surgery is completed.

TAVR, a minimally invasive aortic valve replacement procedure, may be performed in a catheterization laboratory or hybrid room. It does not involve cardiopulmonary bypass or sternotomy. TAVR was traditionally used only for patients who could not safely undergo surgical valve replacement, but more recently has been recommended for patients who have intermediate or even low risk (Nishimura et al., 2017). With the patient under general anesthesia, a balloon valvuloplasty is performed. Then, a bioprosthetic (tissue) replacement valve (Fig. 24-7A,B) attached to a catheter is inserted percutaneously, positioned at the aortic valve, and implanted. The MitraClip has been approved as a transcatheter procedure to treat degenerative forms of mitral regurgitation. This procedure is currently used primarily in patients with severe symptomatic mitral regurgitation and high surgical risk, but increasingly is considered even for lower-risk patients. The procedure creates a mechanical bridge between two leaflets and has demonstrated decreased regurgitant flow, resulting in

fewer symptoms, and decreased rates of hospitalization for heart failure (Dahl & Ailawadi, 2018).

In patients requiring valve replacement or repair, the heart had gradually adjusted to the pathology; surgery abruptly "corrects" the way blood flows through the heart and may result in complications related to the sudden changes in intracardiac pressures. All prosthetic valve replacements create a degree of stenosis when they are implanted in the heart. Usually, the stenosis is mild and does not affect heart function. If valve replacement was for a stenotic valve, blood flow through the heart is often improved, and signs and symptoms of heart failure resolve in a few hours or days. If valve replacement was for a regurgitant valve, it may take months for the chamber into which blood had been regurgitating to achieve its optimal postoperative function. Signs and symptoms of heart failure resolve gradually as heart function improves. Patients are at risk for many postoperative complications, such as bleeding, thromboembolism, infection, heart failure, hypertension, arrhythmias, hemolysis, and mechanical obstruction of the valve.

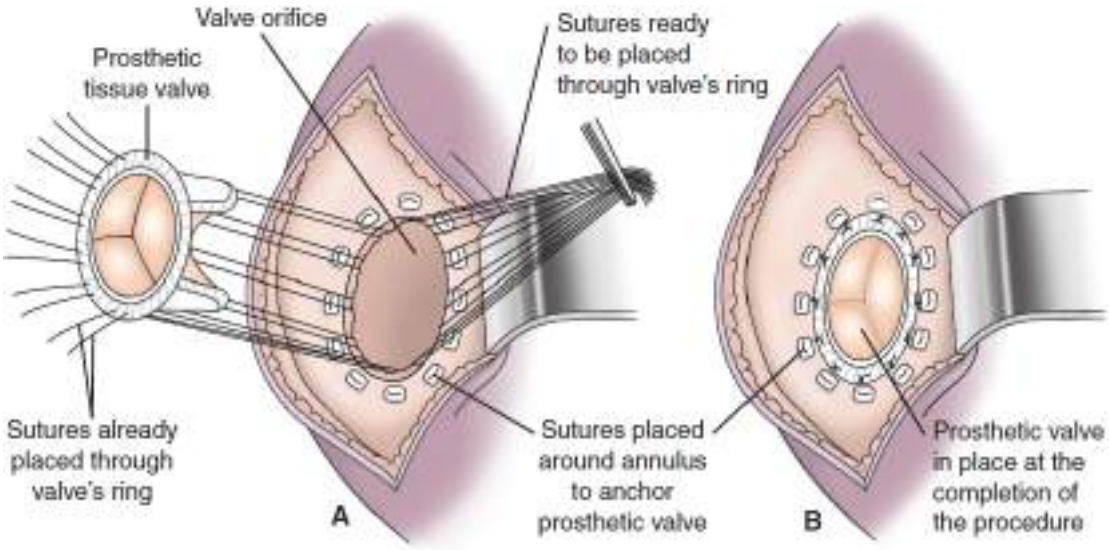

Figure 24-6 • Valve replacement. **A.** The native valve is trimmed, and the prosthetic valve is sutured in place. **B.** Once all sutures are placed through the ring, the surgeon slides the prosthetic valve down the sutures and into the natural orifice. Sutures are then tied off and trimmed.

mechanical). **E.** Caged ball valve (Starr-Edwards, mechanical). **F.** Porcine bioprosthesis valve (Carpenter-Edwards, tissue).

Several types of mechanical and tissue valve prostheses may be used (Chikwe & Castillo, 2017) (Fig. 24-7).

Mechanical Valves

Mechanical valves are of the bileaflet (Fig. 24-7C), tilting disc (Fig. 24-7D), or caged ball (Fig. 24-7E) design and are thought to be more durable than tissue prosthetic valves (Fig. 24-7F); therefore, they often are used for younger patients. These valves also are used for patients requiring valve replacement who also have kidney injury, hypercalcemia, endocarditis, or sepsis, since mechanical valves do not deteriorate or become infected as easily as tissue valves. Significant complications associated with mechanical valves are thromboemboli and complications that can be associated with long-term use of required anticoagulants (see Chapter 26 for further discussion).

Tissue Valves

There are three types of tissue valves: bioprostheses, homografts, and autografts. Tissue valves are less likely than mechanical valves to generate thromboemboli, and long-term anticoagulation is not required. Tissue valves are not as durable as mechanical valves and require replacement more rapidly (Chikwe & Castillo, 2017; Nishimura et al., 2014).

Bioprostheses

Bioprostheses are valves made from animal tissues (i.e., heterografts) used for aortic, mitral, and tricuspid valve replacement. They are not thrombogenic; therefore, patients do not need long-term anticoagulation therapy. They are used for women of childbearing age to avoid potential complications of long-term anticoagulation associated with menses, placental transfer to a fetus, and delivery of a child. They also are considered for patients older than 70 years and others who cannot tolerate long-term anticoagulation. Most bioprostheses are from pigs (porcine), but some are from cows (bovine) or horses (equine). They may be stented or nonstented. Viability is 7 to 15 years.

Homografts

Homografts, also called allografts (i.e., human valves), are obtained from cadaver tissue donations and are used for aortic and pulmonic valve replacement. The aortic valve and a portion of aorta or the pulmonic valve and a portion of pulmonary artery are harvested and stored cryogenically.

Homografts are not always available and are very expensive. They last for about 10 to 15 years and are typically used in younger patients who require replacement of the valve root (Tudorache, Horke, Cebotari, et al., 2016).

Autografts

Autografts (i.e., autologous valves) are obtained by excising the patient's own pulmonic valve and a portion of the pulmonary artery for use as the aortic valve. Anticoagulation is unnecessary because the valve is the patient's own tissue and is not thrombogenic. The autograft is an alternative for children (it may grow as the child grows), women of childbearing age, young adults, patients with a history of peptic ulcer disease, and people who cannot tolerate anticoagulation. Aortic valve autografts have remained viable for more than 20 years (Mazine, El-Hamamsy, Verma, et al., 2018). If pulmonary vascular pressures are normal, some surgeons elect not to then replace the pulmonic valve. Patients can recover without a valve between the right ventricle and pulmonary artery.

However, most aortic valve autograft procedures are double valve replacement procedures with a homograft pulmonic valve replacement also performed. If there is recurrent valve dysfunction after this procedure, patients may undergo further corrective surgery, often in the form of a reversal of the original homograft. In patients who are older and for whom this may no longer be an option, replacement with a prosthetic valve may be considered (Hussain, Majdalany, Dunn, et al., 2018).

Nursing Management: Valvuloplasty and Valve Replacement

The nurse assists the patient and family to prepare for the procedure, reinforces and supplements explanations provided by the primary provider, and provides psychosocial support. (See Chapters 14 through 16 for care of the surgical patient.)

Patients who have undergone percutaneous balloon valvuloplasty with or without percutaneous valve replacement may be admitted to a telemetry unit or intensive care unit (ICU). The nurse assesses for signs and symptoms of heart failure and emboli (see Chapter 25), auscultates the chest for changes in heart sounds at least every 4 hours, and provides the patient with the same care as for postprocedure cardiac catheterization or percutaneous transluminal coronary angioplasty (see Chapter 23). After undergoing percutaneous balloon valvuloplasty, the patient usually remains in the hospital for 24 to 48 hours.

Patients who have undergone surgical valvuloplasty or valve replacements are admitted to the ICU. Care focuses on recovery from anesthesia and

hemodynamic stability. Vital signs are assessed every 5 to 15 minutes and as needed until the patient recovers from anesthesia or sedation, and then are assessed according to unit protocol. Intravenous (IV) medications may be used to increase or decrease blood pressure, to treat arrhythmias, to increase or decrease heart rate; and, their effects are monitored. Medications are gradually decreased until they are no longer required, or the patient takes the needed medication by another route (e.g., oral, topical). Patient assessments are conducted every 1 to 4 hours and as needed, with attention to neurologic, respiratory, and cardiovascular systems (see Chapter 23, Chart 23-11).

After the patient has recovered from anesthesia and sedation, is hemodynamically stable without the use IV medications, and has stable physical assessment parameters, they are usually transferred to a telemetry unit, typically within 24 to 72 hours of surgery. Nursing care continues as for most postoperative patients, including wound care and patient education regarding diet, activity, medications, and self-care. The patient usually is discharged from the hospital in 3 to 7 days.

The nurse educates the patient about anticoagulant therapy, explaining the need for frequent follow-up appointments and blood laboratory studies. Patients who take warfarin have individualized target international normalized ratios, usually between 2 and 3.5 for mitral valve replacement and 1.8 and 2.2 for aortic valve replacement. Patients who have been treated with an annuloplasty ring or a tissue valve replacement usually require anticoagulation for only 3 months unless there are other risk factors such as atrial fibrillation or a history of thromboembolism. Aspirin is prescribed with warfarin for patients with bioprostheses or at high risk for embolic events (e.g., history of embolic event or having two or more preexisting conditions: diabetes, hypertension, coronary artery disease, congestive heart failure, older than 75 years) (Nishimura et al., 2014). The nurse provides education about all prescribed medications, including the name of medication, dosage, actions, prescribed schedule, potential adverse effects, and any drug–drug or drug–food interactions.

Patients with a mechanical valve prosthesis (including annuloplasty rings and other prosthetic materials used in valvuloplasty) require education to prevent infective endocarditis. Patients may be at risk for infective endocarditis, caused by bacteria entering the bloodstream and adhering to abnormal valve structures or prosthetic devices. The nurse educates the patient about how to minimize the risk of developing infective endocarditis (see prevention of endocarditis later in this chapter).

Transitional, home health, office, or clinic nurses help reinforce all new information and self-care instructions with patients and families for 4 to 8 weeks after the procedure (Chart 24-1). An echocardiogram may be performed 3 to 4 weeks after hospital discharge to further evaluate the effects and results of surgery. The echocardiogram also provides a baseline for future comparison

if cardiac symptoms or complications develop. Echocardiograms usually are repeated every 1 to 2 years.

Cardiomyopathy

Cardiomyopathy is disease of the heart muscle that is associated with cardiac dysfunction. It is classified according to the structural and functional abnormalities of the heart muscle: dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM), restrictive cardiomyopathy (RCM), arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D), and unclassified cardiomyopathy (Elliott, Andersson, Arbustini, et al., 2008). A patient may have pathology representing more than one of these classifications, such as a patient with HCM with restrictive physiology. *Ischemic cardiomyopathy* is a term frequently used to describe an enlarged heart caused by coronary artery disease, which is usually accompanied by heart failure (see Chapter 25). In 2006, the American Heart Association proposed a set of Contemporary Classifications for cardiomyopathies, which continues to be in widespread use. Under this classification system, cardiomyopathies are divided into two major groups based on predominant organ involvement. These include *primary cardiomyopathies* (genetic, nongenetic, and acquired), which are focused primarily on the heart muscle, and *secondary cardiomyopathies,* which show myocardial involvement secondary to the influence of a vast list of disease processes that include, but are not limited to, amyloidosis, Fabry disease, sarcoidosis, and scleroderma (Maron, Towbin, Thiene, et al., 2006). This chapter focuses on the primary cardiomyopathies.

Pathophysiology

The pathophysiology of all cardiomyopathies is a series of events that culminate in impaired cardiac output. Decreased stroke volume stimulates the sympathetic nervous system and the renin–angiotensin–aldosterone response, resulting in increased systemic vascular resistance and increased sodium and fluid retention, which place an increased workload on the heart. Often, the decrease in cardiac output can be seen on echocardiogram as a decrease in **ejection fraction**, expressed as a percentage of the end-diastolic blood volume ejected from the ventricle with each heartbeat. These alterations can lead to heart failure (see Chapter 25).

Chart 24-1 **HOME CARE CHECKLIST**

Discharge After Valve Replacement

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed, any complications that occurred, and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify interventions and strategies (e.g., durable medical equipment, adaptive equipment) used in recovery period.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., walking and breathing exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
- State the name, dose, side effects, frequency, and schedule for all medications, including anticoagulant.
  - Identify the need to take anticoagulant for prescribed length of time
  - Take anticoagulant at same time each day
  - Keep appointments for laboratory tests, if indicated
  - Avoid injury that can cause bleeding
  - Report signs that could suggest occult bleeding to primary provider (e.g., bleeding gums, petechiae formation, tarry stools)
- State how to obtain medical supplies and carry out dressing changes, wound care, and other prescribed regimens.
- Identify durable medical equipment needs, proper usage, and maintenance necessary for safe utilization.
- Describe signs and symptoms of complications, including infective endocarditis, if at risk.
  - Report fevers, chills, clusters of petechiae, malaise, and weight loss to primary provider
- Engage in activities aimed at preventing infective endocarditis, as indicated:
  - Notify all health care providers of surgery and possible need for antibiotic prophylaxis preprocedure, if endorsed by primary provider
  - Practice good oral hygiene, including brushing, flossing, and regular appointments with dental hygienist
- State time and date of follow-up appointments.
- Relate how to reach the primary provider with questions or complications.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community)
  - Identify the contact details for support services for patients and their caregivers/families

- Identify the need for health promotion (e.g., weight reduction, smoking cessation, stress management), disease prevention, and screening activities

ADL, activities of daily living; IADL, independent activities of daily living.

Concept Mastery Alert

Sodium is the major electrolyte involved with cardiomyopathy. Cardiomyopathy often leads to heart failure, which develops, in part, from fluid overload. Fluid overload is often associated with elevated sodium intake.

Dilated Cardiomyopathy

DCM is the most common form of cardiomyopathy, with a general prevalence of between 1 in 250 and 1 in 2500 (Merlo, Cannata, Gobbo, et al., 2018). DCM is distinguished by significant dilation of the ventricles without simultaneous hypertrophy and systolic dysfunction (Fig. 24-8). The ventricles have elevated systolic and diastolic volumes but a decreased ejection fraction.

Microscopic examination of the muscle tissue shows diminished contractile elements (actin and myosin filaments) of the muscle fibers and diffuse necrosis of myocardial cells. The result is poor systolic function. The structural changes decrease the amount of blood ejected from the ventricle with systole, increasing the amount of blood remaining in the ventricle after contraction. Less blood is then able to enter the ventricle during diastole, increasing end-diastolic pressure and eventually increasing pulmonary and systemic venous pressures. Altered valve function, usually regurgitation, can result from an enlarged stretched ventricle. Poor blood flow through the ventricle may also cause ventricular or atrial thrombi, which may embolize to other locations in the body.

More than 75 conditions and diseases may cause DCM, including pregnancy, hypertension, heavy alcohol intake, viral infection (e.g., influenza), chemotherapeutic medications (e.g., daunorubicin, doxorubicin), thyrotoxicosis, myxedema, persistent tachycardia, and Chagas disease. When the causative factor cannot be identified, the diagnosis is idiopathic DCM which accounts for 20% to 30% of nonischemic DCM cases (McNally & Mestroni, 2017; Merlo et al., 2018). Familial DCM accounts for approximately 30% to 50% of all DCM cases and approximately 40% of familial DCM cases have a definitive genetic etiology (McNally & Mestroni, 2017). An elucidation of family history by the nurse is therefore a very important component of the assessment process. Early diagnosis and treatment can prevent or delay significant symptoms and sudden death from DCM.

Hypertrophic Cardiomyopathy

The estimated prevalence of HCM is 0.16% to 0.29% of the adult population (Marian & Braunwald, 2017). HCM is an autosomal dominant genetic disorder that leads to increased heart muscle size and mass, especially along the septum (see Fig. 24-8) but can involve other areas of the heart. The phenotypic expression of the disease is age dependent. HCM is the leading cause of sudden death in adolescents and young adults, particularly in athletes (Marian & Braunwald, 2017). 12-lead ECGs, physical examinations, and echocardiograms are used to screen for the disease.

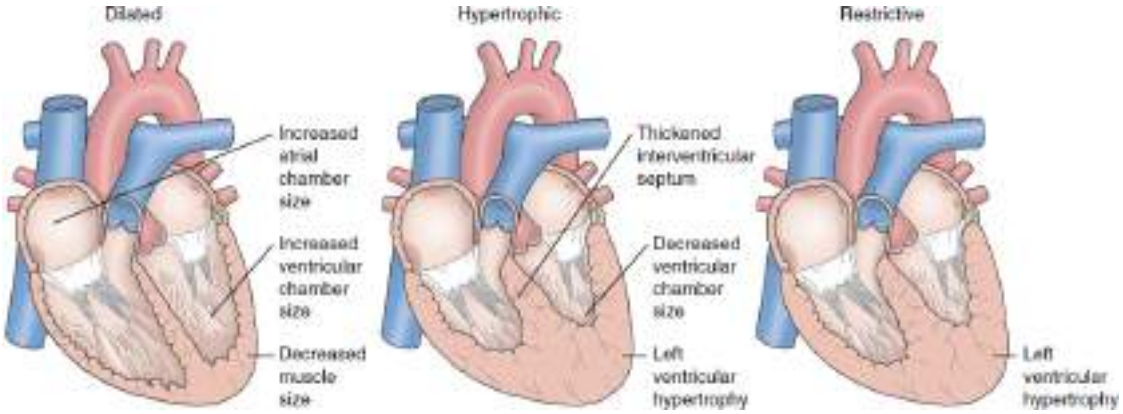

Figure 24-8 • Cardiomyopathies that lead to congestive heart failure. Adapted from Anatomical Chart Company. (2010). *Atlas of pathophysiology* (3rd ed.). Ambler, PA: Lippincott Williams & Wilkins.

Patients with a suspected diagnosis of HCM should undergo genetic testing; if negative, the diagnosis is not completely ruled out. If genetic testing is positive for known HCM genetic mutations, first-degree relatives should also be tested for the genetic mutation found in the patient. In patients that have positive genetic testing, but are asymptomatic for cardiomyopathy, annual screening with an ECG, physical examination and echocardiogram should be done, as the likelihood of clinical progression increases with increasing age. The phenotype typically manifests sometime between adolescence and the fifth decade of life (Marian & Braunwald, 2017).

Cardiac muscle cells normally lie parallel to and end to end with each other. The hypertrophied cardiac muscle cells are disorganized, oblique, and perpendicular to each other, decreasing the effectiveness of contractions. In HCM, the coronary arteriole walls are thickened, which decrease the internal diameter of the arterioles. The narrow arterioles restrict the blood supply to the myocardium, causing numerous small areas of ischemia and necrosis. The necrotic areas of the myocardium ultimately fibrose and scar, further impeding ventricular contraction and possibly increasing the risk of arrhythmias such as ventricular tachycardia and ventricular fibrillation (see Chapter 22).

Increased thickness of the heart muscle reduces the size of the ventricular cavities and causes the ventricles to take a longer time to relax after systole. During the first part of diastole, it is more difficult for the ventricles to fill with blood. The atrial contraction at the end of diastole becomes critical for ventricular filling and systolic contraction.

HCM can lead to obstruction of the left ventricular outflow tract (LVOT) if there is systolic anterior motion of the mitral valve that abuts the mitral valve against the hypertrophied septum during systole (Marian & Braunwald, 2017; Nishimura, Seggewiss, & Schaff, 2017). LVOT obstruction is a dynamic process that is dependent on both the volume of blood in the left ventricle as well as the ability of the myocytes to contract. Approximately one third of patients with HCM have LVOT obstruction at rest that worsens with provocation, another one third do not have obstruction at rest, but can get obstruction with provocation (e.g., exercise or the Valsalva maneuver), and roughly one third of patients have no LVOT obstruction even with provocation (Marian & Braunwald, 2017). Obstruction of the LVOT can lead to syncope, ventricular arrhythmias, dyspnea, and heart failure. The presence of a systolic ejection murmur can be indicative of LVOT, and echocardiography is then indicated to confirm its presence. Hydration, beta-blockers, calcium channel blockers, and lifestyle modification can be used to minimize LVOT obstruction. In particular, patients should avoid activities that can cause rapid alterations to preload (e.g., hot tubs, saunas, prolonged hot showers) (Nishimura et al., 2017). However, patients that do not respond to medical therapy should be considered for surgical myectomy or alcohol septal ablation to decrease the size of the hypertrophied septum and thereby eliminate LVOT obstruction.

Restrictive Cardiomyopathy

RCM is the least common type of cardiomyopathy (Muchtar, Blauwet, & Gertz, 2017; Pereira, Grogan, & Dec, 2018). RCM is characterized by diastolic dysfunction caused by rigid ventricular walls that impair diastolic filling and ventricular stretch (see Fig. 24-8). A rigid ventricle alters the curve in the Frank–Starling law (see Chapter 21) and leads to the rapid rise of filling pressures despite only small increases in blood volume. However, chamber size and systolic function are usually normal. Arrhythmias and conduction disturbances are common. Signs and symptoms are similar to constrictive pericarditis (see later discussion) and include dyspnea, nonproductive cough, and chest pain. Echocardiography may be useful in differentiating between these two conditions.

Generally, RCM is either due to an inherited or acquired disease that may be systemic. There are four general categories for the causes of RCM: infiltrative disease, storage disease, noninfiltrative, and endomyocardial.

An example of an infiltrative disease that may cause RCM is amyloidosis, in which amyloid, a misfolded protein, is deposited between cardiomyocytes. An inherited storage disease that can lead to RCM is hemochromatosis, in which iron deposits in the heart lead to cardiac stiffness. Scleroderma is a noninfiltrative connective tissue disorder that can cause RCM. Certain cancer treatments, such as radiation and use of various chemotherapeutic agents (e.g., anthracyclines) can cause endomyocardial damage that leads to RCM (Muchtar et al., 2017). Often, endomyocardial biopsy is needed to determine the etiology; treatment is then directed at the underlying cause.

Arrhythmogenic Right Ventricular Cardiomyopathy/Dysplasia

ARVC/D is an uncommon form of inherited heart muscle disease. The prevalence is estimated to be between 1 in 2000 and 1 in 5000 people in the general population (Bennett, Haqqani, Berruezo, et al., 2019). ARVC/D occurs when the myocardium is progressively infiltrated and replaced by fibrous scar and adipose tissue. Infiltration of fibrous and adipose tissue leads to ventricle dilatation, poor contractility, and arrhythmias.

Initially, only localized areas of the right ventricle are affected, but as the disease progresses, the entire heart is affected. Because of this typical pathologic progression, there is a move to change the name of this cardiomyopathy to a more general term of arrhythmogenic cardiomyopathy (ACM) to recognize the left ventricular involvement (Bennett et al., 2019).

In patients with ARVC/D, palpitations or syncope may develop between 15 and 40 years of age. Sudden cardiac death may also be the first presentation. Diagnosis is made based on the ECG, echocardiogram, cardiac MRI, and family history. Since this is a genetic disorder, patients that are diagnosed are referred to a genetic counselor for testing. However, genetic testing can be negative in up to 50% of patients (Bennett et al., 2019). If a genetic mutation is identified, first-degree relatives of the patient should undergo genetic testing. Patients affected by arrhythmias may benefit from having an implantable cardioverter defibrillator (ICD) placed (see Chapter 22).

Unclassified Cardiomyopathies

Unclassified cardiomyopathies are different from or have characteristics of more than one of the previously described types and are caused by fibroelastosis, noncompacted myocardium, systolic dysfunction with minimal dilation, and mitochondrial diseases. Examples of unclassified cardiomyopathies can include left ventricular noncompaction and stress-induced (Takotsubo) cardiomyopathy (Elliott et al., 2008).

Clinical Manifestations

Patients with cardiomyopathy may remain stable and without symptoms for many years. As the disease progresses, so do the symptoms. Frequently, dilated or restrictive cardiomyopathy is first diagnosed when the patient presents with signs and symptoms of heart failure (e.g., DOE, fatigue, PND, cough [especially with exertion or at night], orthopnea, peripheral edema, early satiety, nausea; see Chapter 25). The patient also may experience chest pain, palpitations, dizziness, nausea, and syncope with exertion.

Assessment and Diagnostic Findings

Physical examination at early stages may reveal tachycardia and extra heart sounds (e.g., S_3, S_4). Patients with DCM may have diastolic murmurs, and patients with DCM and HCM may have systolic murmurs. With disease progression, examination also reveals signs and symptoms of heart failure (e.g., crackles on pulmonary auscultation, jugular vein distention, pitting edema of dependent body parts, hepatomegaly [i.e., enlarged liver]).

Diagnosis is usually made from findings disclosed by the patient history and by ruling out other causes of heart failure such as myocardial infarction. The echocardiogram is one of the most helpful diagnostic tools because the structure and function of the ventricles can be observed easily. Cardiac MRI may also be used, particularly to assist with the diagnosis of HCM and ARCV/D. ECG may demonstrate arrhythmias (atrial fibrillation, ventricular arrhythmias) and changes consistent with left ventricular hypertrophy (left axis deviation, wide QRS, ST changes, inverted T waves). In ARVC/D, the ECG may show QRS widening, T-wave inversions in leads V_1–V_4, and ventricular ectopy. Additionally, there is often a small epsilon wave at the end of the QRS (Bennett et al., 2019). The chest x-ray reveals heart enlargement and possibly pulmonary congestion. Cardiac catheterization, coronary CT, or stress testing is often used to rule out coronary artery disease as a causative factor. Endomyocardial biopsy may be performed to analyze myocardial cells, particularly in RCM.

Medical Management

Medical management is directed toward identifying and managing possible underlying or precipitating causes; correcting the heart failure with medications, a low sodium diet, and an exercise/rest regimen (see Chapter 25); and controlling arrhythmias with antiarrhythmic medications and possibly with an implanted electronic device, such as an ICD (see Chapter 22). If the patient has signs and symptoms of congestion, fluid intake may be limited to 2 L each day. However, patients with HCM should avoid dehydration and may need beta-blockers to maintain cardiac output and minimize the risk of LVOT obstruction during systole. Anticoagulants are no longer routinely prescribed.

For some patients with DCM, biventricular pacing (also known as cardiac resynchronization therapy or CRT) increases the ejection fraction and reverses some of the structural changes in the myocardium (see Chapter 22).

As noted previously, some forms of cardiomyopathy are inherited/genetic. Any family history of cardiomyopathy should be noted when the nurse is taking a family health history. In appropriate cases, the patient should be referred to a genetic counselor for testing. If genetic mutations are found, it is recommended that first-degree relatives also be tested. Unfortunately, there are currently some problems with patients receiving insurance reimbursement for genetic testing in the United States.

Surgical Management

When heart failure progresses and medical treatment is no longer effective, surgical intervention, including heart transplantation, is considered. However, because of the limited number of organ donors, many patients die waiting for transplantation. In some cases, a VAD is implanted to support the failing heart until a suitable donor heart becomes available (see later discussion).

Left Ventricular Outflow Tract Surgery

When patients with HCM and LVOT obstruction become symptomatic despite optimal medical therapy or cannot tolerate medical therapy, surgery is considered. The most common procedure done is a myectomy (sometimes referred to as a myotomy–myectomy or the Morrow procedure), in which some of the heart tissue is excised. Septal tissue approximately 1 cm wide and deep is cut from the enlarged septum below the aortic valve. The length of septum removed typically extends to the papillary muscles. Possible complications include complete heart block and subsequent pacemaker dependence, ventricular septal defects, or failure to adequately alleviate the obstruction. Surgical mortality rates are reportedly between less than 1% and as high as 16% (Nishimura et al., 2017).

Heart Transplantation

Because of advances in surgical techniques and immunosuppressive therapies, heart transplantation is now a therapeutic option for patients with end-stage heart disease. Cyclosporine and tacrolimus are some of the more common immunosuppressants that decrease the body's rejection of foreign proteins, such as transplanted organs. Unfortunately, these drugs also decrease the body's ability to resist infections and increase the risk of various cancers, and a satisfactory balance must be achieved between suppressing rejection and avoiding infection. In 2017, there were 3273 heart transplants performed in the United States (Scientific Registry of Transplant Recipients, 2017).

Cardiomyopathy, ischemic heart disease, valvular disease, rejection of previously transplanted hearts, and congenital heart disease are the most common indications for transplantation. Typical candidates have severe symptoms uncontrolled by medical therapy, no other surgical options, and a prognosis of less than 1 to 2 years to live. A multidisciplinary team screens the candidate before recommending the transplantation procedure. The person's age, pulmonary status, other chronic health conditions, psychosocial status, family support, infections, history of other transplantations, adherence to therapeutic regimens, and current health status are considered. The United Network for Organ Sharing (UNOS), a national organization that is regulated by the U.S. government, is charged with maintaining organ transplant waiting lists and allocating donor organs. When a donor heart becomes available, UNOS generates a list of potential recipients on the basis of ABO blood group compatibility, the body sizes of the donor and the potential recipient, age, severity of illness, length of time on the waiting list, and the geographic locations of the donor and potential recipient (Organ Procurement and Transplant Network [OPTN], 2019). Some patients are candidates for more than one organ transplant (e.g., heart–lung, heart–kidney, heart–liver).

Orthotopic transplantation is the most common surgical procedure for cardiac transplantation. Some surgeons prefer to remove the recipient's heart but leave a portion of the recipient's atria (with the vena cava and pulmonary veins) in place, which is known as the biatrial technique. However, this technique has been modified to a more common approach called the *bicaval technique.* This technique includes removal of the recipient's heart, and the implantation of the donor heart with intact atria at the vena cava and pulmonary veins (Fig. 24-9) (Kittleson, Patel, & Kobashigawa, 2017). This newer approach is associated with decreased AV valve regurgitation, arrhythmias, and conduction abnormalities.

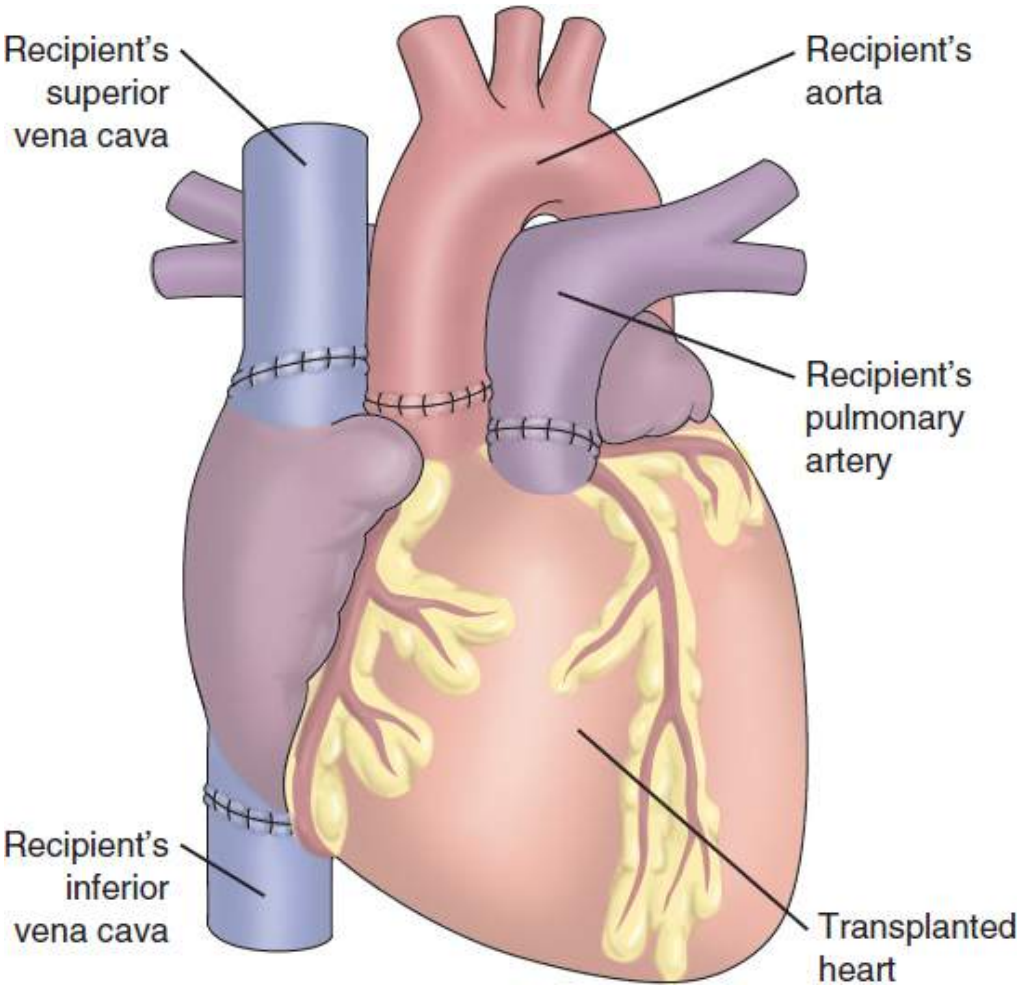

Figure 24-9 • Orthotopic method of heart transplantation.

Patients who have had heart transplantations are constantly balancing the risk of rejection with the risk of infection and diseases such as cancer. They must adhere to a complex regimen of diet, medications, activity, follow-up laboratory studies, biopsies of the transplanted heart (to diagnose rejection), and clinic visits. There are three classes of medications that are prescribed for a transplant patient to help minimize rejection: corticosteroids (e.g., prednisone), calcineurin inhibitors (tacrolimus, cyclosporine), and antiproliferative agents (mycophenolate mofetil, azathioprine, or sirolimus).

The transplanted heart has no nerve connections (i.e., denervated heart) to the recipient's body, so the sympathetic and vagus nerves do not affect the transplanted heart. The resting rate of the transplanted heart is approximately 90 to 110 bpm, but it increases gradually if catecholamines are in the circulation. Patients must gradually increase and decrease their exercise (i.e., extended warm-up and cool-down periods), because 20 to 30 minutes may be required to achieve the desired heart rate. Atropine does not increase the heart rate of transplanted hearts, and digoxin does not decrease the heart rate in atrial fibrillation. Additionally, many patients who have had heart transplantations do

not experience angina with ischemia and may present with congestive heart failure, silent myocardial infarction, or sudden death without a prior history of coronary artery disease (Kittleson et al., 2017).

In addition to rejection and infection, complications may include accelerated atherosclerosis of the coronary arteries (i.e., cardiac allograft vasculopathy, accelerated graft atherosclerosis, transplant coronary artery disease). Both immunologic and nonimmunologic factors cause arterial injury and inflammation of the coronary arteries. The arterial smooth muscle proliferates, and there is hyperplasia of the coronary artery intima, accelerating atherosclerosis along the entire length of the coronary arteries (Stehlik, Kobashigawa, Hunt, et al., 2018). Hypertension may occur in patients taking cyclosporine or tacrolimus due to the effect these medications have on the kidneys. Osteoporosis is a frequent side effect of the antirejection medications as well as pretransplantation dietary insufficiency and medications. Patients with a long-term sedentary lifestyle are at greater risk for osteoporosis. Posttransplantation lymphoproliferative disease and cancer of the skin and lips are the most common malignancies after transplantation, possibly caused by immunosuppression. Weight gain, obesity, diabetes, dyslipidemias (e.g., hypercholesterolemia), hypertension, and kidney failure, as well as central nervous system, respiratory, and gastrointestinal disturbances, may be adverse effects of corticosteroids or other immunosuppressants. Toxicity from immunosuppressant medications may occur as well. For patients receiving their transplanted hearts after the year 2000, the median survival is more than 12 years (Stehlik et al., 2018).

In the first year after transplantation, patients respond to the psychosocial stresses imposed by organ transplant in various ways. Most report a higher quality of life and can return to activities of daily living and to work with little to no functional limitations (Stehlik et al., 2018). Some have significant feelings of indebtedness to the donor, or experience guilt that someone had to die for them to be able to live, which can negatively affect their adherence to the medical regimen (Shemesh, Peles-Bortz, Peled, et al., 2017) (see Chart 24-2 Nursing Research Profile: Factors Affecting Nonadherence After Heart Transplant).

Mechanical Assist Devices and Total Artificial Hearts

The use of cardiopulmonary bypass in cardiovascular surgery and the possibility of performing heart transplantation in patients with end-stage cardiac disease, as well as the desire for a treatment option for patients who are not transplant candidates, have increased the need for mechanical assist devices. Patients who cannot be weaned from cardiopulmonary bypass and patients in cardiogenic shock may benefit from a period of mechanical heart assistance. The most commonly used device is the intra-aortic balloon pump

(see Chapter 11). This pump decreases the work of the heart during contraction but does not perform the actual work of the heart.

Ventricular Assist Devices

More complex devices that perform some or all of the pumping function for the heart are now being used. These more sophisticated **ventricular assist devices** can circulate as much blood per minute as the heart, if not more (Fig. 24-10). There are short- and long-term devices available, depending on the indication. Each VAD is used to support one ventricle, although in some instances, two VAD pumps may be used for biventricular support. Additionally, some VADs can be combined with an oxygenator; the combination is called *extracorporeal membrane oxygenation (ECMO)*. The oxygenator–VAD combination is used for the patient whose heart cannot pump adequate blood through the body or when the lungs fail to oxygenate the blood despite supplemental oxygen or ventilation.

VADs may be external, internal (i.e., implanted) with an external power source, or completely internal, and they may generate a pulsatile or continuous blood flow. There are four types of VADs: pneumatic, electric or electromagnetic, axial flow, and centrifugal. Pneumatic VADs are external or implanted pulsatile devices with a flexible reservoir housed in a rigid exterior. The reservoir usually fills with blood drained from the atrium or ventricle. The device then forces pressurized air into the rigid housing, compressing the reservoir and returning the blood to the circulation, usually into the aorta. Electric or electromagnetic VADs are similar to pneumatic VADs, but instead of using pressurized air to return the blood to the circulation, one or more flat metal plates are pushed against the reservoir. Generally, pulsatile VADs have been replaced by the newer generation of axial and centrifugal pumps. The axial and centrifugal pumps have lower rates of pump thrombus formation and are of smaller device sizes. Axial flow VADs use a rotary mechanism (an impeller) to create nonpulsatile blood flow. The impeller spins rapidly within the VAD, creating a vacuum that pulls blood into the VAD and then pushes the blood out into the systemic circulation—the process is similar to a fan spinning in a tunnel, pulling air in one end of the tunnel and pushing it out the other. Centrifugal VADs are nonpulsatile devices that consist of a single moving impeller that is suspended in the pump housing by a combination of magnetic and hydrodynamic forces. The impeller rotates and pulls blood into the pump housing and ejects the blood out to the systemic circulation (Kittleson et al., 2017).

Chart 24-2 **NURSING RESEARCH PROFILE**

Factors Affecting Nonadherence After Heart Transplant

Shemesh, Y., Peles-Bortz, A., Peled, Y., et al. (2017). Feelings of indebtedness and guilt toward donor and immunosuppressive medication adherence among heart transplant (HTx) patients, as assessed in a cross-sectional study with the Basel Assessment of Adherence to Immunosuppressive Medications Scale (BAASIS). *Clinical Transplantation, 31*(10). doi:10.1111/ctr.13053

Purpose

The purpose of this study was to assess immunosuppression medication adherence among patients who had heart transplants and to test if adherence was affected by feelings of indebtedness and guilt toward the donor.

Design

This was a descriptive correlational study with a cross-sectional design. It utilized a convenience sample consisting of 102 patients who had heart transplants and who engaged in outpatient follow up at the Sheba Medical Center in Israel. Participants were 76.5% male, 65.3% were born in Israel, and had a mean age of 56.66 y at the time of the study. The five-item BAASIS survey was used to assess adherence in the past 4 wks as it related to timing of medication intake, self-altering the prescribed dosage, and stopping or missing medication doses. Feelings of guilt and indebtedness were assessed with two survey questions via a Likert scale. Medical record review was also utilized. Data were evaluated using a variety of statistical analyses, which included *t*-tests, correlation analyses, and logistic regression analysis.

Findings

Sixty-four percent of participants reported nonadherence with immunosuppression within the previous 4 wks. Age, time since transplant, and feelings of guilt were statistically associated with variance in adherence. An increase in age was associated with an increase in adherence, whereas an increase in time since transplant and feelings of guilt were associated with an increase in nonadherence.

Nursing Implications

Nonadherence to immunosuppression is associated with an increase in morbidity and mortality among patients with heart transplants. Nurses should assess patients' adherence to immunosuppression and be aware of the various factors that may influence adherence. Understanding what can contribute to nonadherence, such as feelings of guilt, enables the nurse to attempt to alleviate those feelings and thereby improve patient adherence and transplant outcomes.

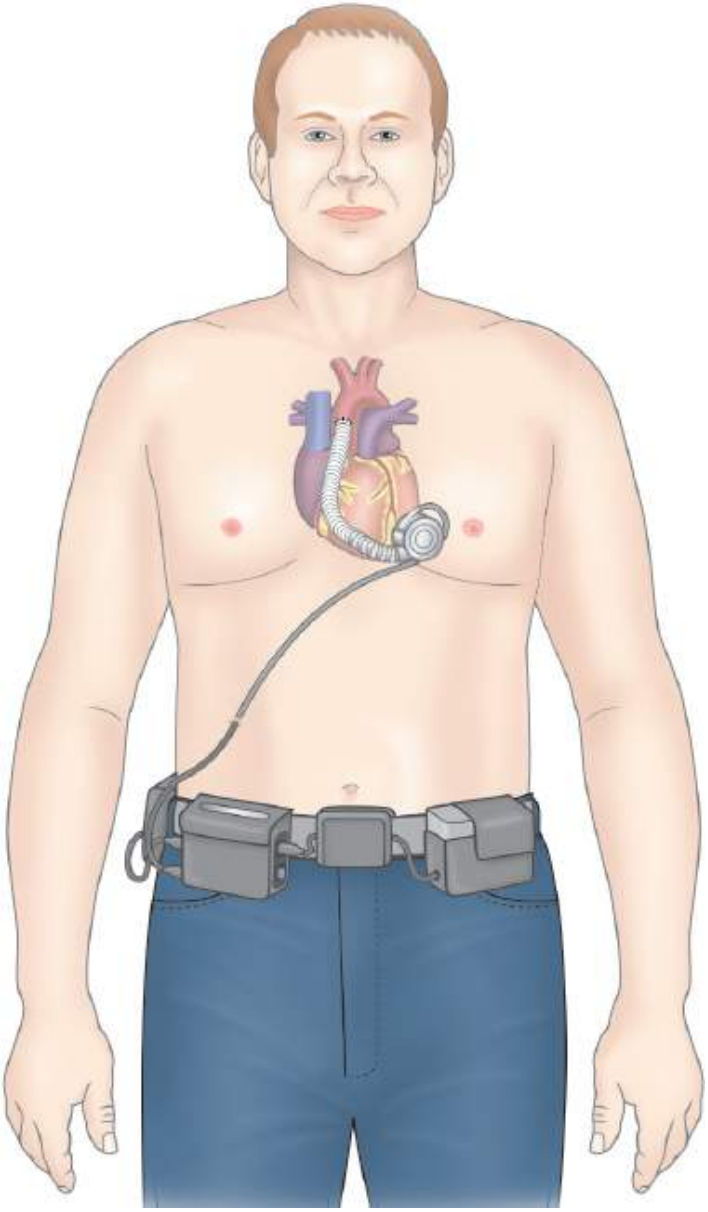

Figure 24-10 • Left ventricular assist device. Reproduced with permission of Medtronic.

VADs may be used as (1) a "bridge to recovery" for patients who require temporary assistance for reversible ventricular failure, (2) a "bridge to transplant" for patients with end-stage heart failure until a donor organ becomes available for transplant, and (3) "destination therapy" for patients with end-stage heart failure who are not candidates for or decline heart transplantation and have the VAD implanted for permanent use (Kittleson et al., 2017). As patients spend an increased length of time on the transplant list and more VADs are being implanted, destination therapy now accounts for 50% of patients on mechanical circulatory support (Han, Acker, & Atluri, 2018). Thus, the volume of patients with VADs in the community is rapidly expanding and it is important that first responders and other providers are

familiar with the basics of VAD management and equipment (Cook, Colvin, Francis, et al., 2017). In some instances, the patient may request deactivation of the VAD, which may cause ethical controversy (Chart 24-3).

Chart 24-3 **ETHICAL DILEMMA**

Can an Adult with a Left Ventricular Assist Device (LVAD) Have the LVAD Deactivated?

Case Scenario

You work on a cardiac intensive care unit (CICU) and are assigned to care for J.J., a 75-year-old man with an extensive cardiac history who received a left ventricular assist device (LVAD) 10 mo ago. When the device was implanted, J.J. knew the treatment was a destination therapy (i.e., a final treatment option) since he was not a candidate for a heart transplant. The goal was to improve his quality of life. However, this is now his 12th hospitalization since the LVAD was activated, and J.J. now questions the purported benefit of the LVAD. During morning rounds with the cardiologist, J.J. tells you, the cardiologist, his wife, and adult daughter that he feels that the quality of his life is poor and not going to improve. He pointedly asks the cardiologist to deactivate the device, saying that he realizes this will lead to his death. J.J. is mentally competent (i.e., possesses the mental capacity to understand the ramifications of his request). J.J.'s family, the cardiologist, and you are all stakeholders in this decision and each of you express reluctance at honoring his request.

Discussion

Many ethical dilemmas are inherent in this scenario. Although the LVAD is internally implanted, the control switch to deactivate the device is external. Some bioethicists argue that since the device has an external component, deactivating the device is similar to withdrawing treatment, which is ethical. Others argue that it becomes an integrated body part once it is implanted; therefore, to remove it is consistent with euthanasia. There is an obligation to respect J.J.'s autonomy and self-determination, especially since he has the capacity to make these decisions (i.e., he is mentally competent). Yet, there is a "slippery slope" at play here in terms of the principle of nonmaleficence.

Analysis

- Identify the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Which principle do you think should have preeminence as you work to resolve the conflicting emotions between J.J., his family, and the health care team?
- What arguments would you offer *in favor of* removal of the LVAD?
- What arguments would you offer *against* removal of the LVAD?
- Do you believe deactivation of an LVAD is the same as withdrawal of other life-sustaining treatments (e.g., extubation)? Do you believe deactivation of an LVAD constitutes euthanasia?
- Assume that J.J. is determined competent to make this decision and the deactivation is scheduled. Discuss the implications of this procedure on the stakeholders including you, the cardiologist, and the patient's wife and daughter. Do you have the right to refuse to

participate in the procedure? Identify what resources might be of help to you as you grapple with making the best decision for all stakeholders.

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

Total Artificial Hearts

Total artificial hearts are designed to replace both ventricles. Only one TAH has been approved by the U.S. Food and Drug Administration (FDA) as a bridge to transplant, the SynCardia TAH, and it requires the removal of the patient's heart for implant. Although there has been some short-term success, the long-term results have been disappointing. Researchers hope to develop a device that can be permanently implanted and will eliminate the need for donated human heart transplantation for end-stage cardiac disease. The CARMAT TAH is undergoing early clinical trials in Europe; it features biocompatible materials (Ewald, Milano, & Rogers, 2019).

Complications of VADs and TAHs include bleeding disorders, hemorrhage, thromboemboli, hemolysis, infection, kidney injury, right-sided heart failure, multisystem failure, and mechanical failure. Nursing care of patients with these mechanical assist devices focuses on assessment for and minimization of these complications as well as providing emotional support and education about the device and the underlying cardiac disease.

NURSING PROCESS

The Patient with Cardiomyopathy

Assessment

Nursing assessment for the patient with cardiomyopathy begins with a detailed history of the presenting signs and symptoms. The nurse identifies possible etiologic factors, such as heavy alcohol intake, recent illness or pregnancy, family history of sudden death or history of the disease in immediate family members. If the patient reports chest pain, a thorough review of the pain, including its precipitating factors, is warranted. The review of systems includes the presence of orthopnea, PND, and syncope or dyspnea with exertion. The number of pillows needed to sleep, usual weight, any weight change, and limitations on activities of daily living are assessed. The American College of Cardiology and American Heart Association Stages of Heart Failure classification is utilized to help identify disease progression, and the New York Heart Association Functional Classification for heart failure is determined based on the severity of the patient's symptoms (see Chapter 25, Tables 25-1 and 25-2). The patient's usual diet is evaluated to determine the need to reduce sodium intake, optimize nutrition, or supplement with vitamins.

Because of the chronicity of cardiomyopathy, the nurse conducts a careful psychosocial history, exploring the impact of the disease on the patient's role within the family and community. Identification of perceived stressors helps the patient and the health care team to implement activities that relieve anxiety associated with changes in health status. Very early on, the patient's support systems are identified, and members are encouraged to become involved in the patient's care and therapeutic regimen. The assessment addresses the effect the diagnosis has had on the patient and members of their support system and the patient's emotional status. Findings from a recent meta-analysis suggest that 19% of patients with heart failure meet criteria for depressive disorders and 21.5% have significant symptoms of depression (Celano, Villegas, Albanese, et al., 2018). Various screening tools are available to assess symptoms associated with heart failure, including depression, though no one screening tool has emerged as the generally accepted standard.

The physical assessment focuses on signs and symptoms of heart failure. The baseline assessment includes key components such as:

- Vital signs
- Calculation of pulse pressure and identification of pulsus paradoxus
- Current weight and any weight gain or loss
- Detection by palpation of the point of maximal impulse, often shifted to the left

- Cardiac auscultation for a systolic murmur and S_3 and S_4 heart sounds
- Pulmonary auscultation for crackles
- Measurement of jugular vein distention
- Assessment of edema and its severity

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired cardiac output associated with structural disorders caused by cardiomyopathy or to arrhythmia from the disease process and medical treatments
- Risk for impaired cardiac function, ineffective tissue perfusion, and impaired peripheral tissue perfusion associated with decreased peripheral blood flow (resulting from impaired cardiac output)
- Impaired gas exchange associated with pulmonary congestion caused by myocardial failure (resulting from impaired cardiac output)
- Activity intolerance associated with impaired cardiac output or excessive fluid volume, or both
- Anxiety associated with the change in health status and in role functioning
- Powerlessness associated with disease process
- Able to perform self care associated with medication and diet therapies

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Heart failure
- Ventricular arrhythmias
- Atrial arrhythmias
- Cardiac conduction defects
- Pulmonary or cerebral embolism
- Valvular dysfunction

These complications are discussed earlier in this chapter and in Chapters 22 and 25.

Planning and Goals

The major goals for patients include improvement or maintenance of cardiac output, increased activity tolerance, reduction of anxiety, effective management of the self-care program, increased sense of power with decision making, and absence of complications.

Nursing Interventions

Improving Cardiac Output and Peripheral Blood Flow

During a symptomatic episode, rest is indicated. Many patients with DCM find that sitting up with their legs down is more comfortable than lying down in a bed. This position is helpful in pooling venous blood in the periphery and reducing preload. Assessing the patient's oxygen saturation at rest and during activity may assist with determining a need for supplemental oxygen. Oxygen usually is given through a nasal cannula when indicated.

Ensuring that medications are taken as prescribed is important to preserving adequate cardiac output. The nurse may assist the patient with planning a schedule for taking medications and identifying methods to remember to follow it, such as associating the time to take a medication with an activity (e.g., eating a meal, brushing teeth) or obtaining a pillbox.

It is also important to ensure that the patient receives or chooses food selections that are appropriate for a low sodium diet. One way to monitor a patient's response to treatment is to determine the patient's weight every day and identify any significant change. Another indication of the effect of treatment involves assessment of shortness of breath after activity and comparison to before treatment, as well as a change in the number of pillows needed to comfortably sleep. Patients with low cardiac output may need assistance keeping warm and frequently changing position to stimulate circulation and reduce the possibility of skin breakdown.

Increasing Activity Tolerance and Improving Gas Exchange

The nurse plans the patient's activities so that they occur in cycles, alternating rest with activity periods. This benefits the patient's physiologic status, and it helps educate the patient about the need for planned cycles of rest and activity. For example, after taking a bath or shower, the patient should plan to sit and read a newspaper or engage in other relaxing activities. Suggesting that the patient sit while chopping vegetables, drying their hair, or shaving helps the patient learn to balance rest with activity. The nurse also makes sure that the patient recognizes the symptoms indicating the need for rest and actions to take when the symptoms occur. Patients with HCM, ARVC/D, or RCM must avoid strenuous activity, isometric exercises, and competitive sports.

Reducing Anxiety

Spiritual, psychological, and emotional support may be indicated for patients, families, and significant others. Interventions are directed toward eradicating or alleviating perceived stressors. Patients receive appropriate information about cardiomyopathy and self-management activities. It is important to provide an atmosphere in which patients feel free to verbalize concerns and receive assurance that their concerns are legitimate. If the

patient is awaiting transplantation or facing death, it is necessary to allow time to discuss these issues. Providing the patient with realistic hope helps reduce anxiety while they await a donor heart. The nurse helps the patient, family, and significant others with anticipatory grieving.

Decreasing the Sense of Powerlessness

Patients often go through a grieving process when cardiomyopathy is diagnosed. The patient is assisted in identifying the things in life that they have lost (e.g., foods that the patient enjoyed eating but are high in sodium, the ability to engage in an active lifestyle, the ability to play sports, the ability to lift grandchildren) and their emotional responses to the loss (e.g., anger, feelings of sadness). The nurse assists the patient in identifying the amount of control that they still have over life, such as making food choices, managing medications, and working with the patient's primary provider to achieve the best possible outcomes. A diary in which the patient records food selections and weight may help with understanding the relationship between sodium intake and weight gain and give patients a sense of control over their disease. Some patients can manage a self-titrating diuretic regimen in which they adjust the dose of diuretic to their symptoms.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. A key part of the plan of nursing care involves educating patients about the medication regimen, symptom monitoring, and symptom management (Chart 24-4). The nurse plays an integral role as the patient learns to balance lifestyle and work while accomplishing therapeutic activities. Helping patients cope with their disease status helps them adjust their lifestyles and implement a self-care program at home. Attainment of a goal, no matter how small, also promotes the patient's sense of well-being.

Continuing and Transitional Care. The nurse reinforces previous education and performs ongoing assessment of the patient's symptoms and progress. The nurse also assists the patient and family to adjust to lifestyle changes. Patients are taught to read nutrition labels, to maintain a record of daily weights and symptoms, and to organize daily activities to increase activity tolerance. In addition, the nurse assesses the patient's response to recommendations about diet and fluid intake and to the medication regimen and stresses the signs and symptoms that should be reported to the primary provider. Because of the risk of arrhythmia, it may be necessary to educate the patient's family about cardiopulmonary resuscitation and the use of an automated external defibrillator (see Chapter 25). Women are often advised to avoid pregnancy, but each case is assessed individually. The nurse assesses the psychosocial needs of the patient and family on an ongoing

basis. There may be concerns and fears about the prognosis, changes in lifestyle, effects of medications, and the possibility of others in the family having the same condition; these concerns often increase the patient's anxiety and interfere with effective coping strategies. Establishing trust is vital to the nurse's relationship with patients who are chronically ill and with these patients' families. This is particularly significant when the nurse is involved with a patient and family in discussions about end-of-life decisions. Patients who have significant symptoms of heart failure or other complications of cardiomyopathy may benefit from transitional or home care.

Evaluation

Expected patient outcomes may include:

1. Maintains or improves cardiac function
   a. Exhibits heart and respiratory rates within normal limits

Chart 24-4 **HOME CARE CHECKLIST**

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of cardiomyopathy on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Identify interventions and strategies (e.g., durable medical equipment, adaptive equipment) used in adapting to any permanent or temporary changes in structure or function.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Take or administer medications daily, exactly as prescribed.
- Monitor effects of medication such as changes in breathing and edema.
- Know signs and symptoms of arrhythmia formation (e.g., lightheadedness, dizziness, orthostatic hypotension, racing heartbeats, diaphoresis, confusion):
  - Identify how to initiate emergency response.
  - Demonstrate skill set in cardiopulmonary resuscitation.
  - Demonstrate use of an automated external defibrillator.
- Weigh self daily at the same time with same clothes.
- Restrict sodium intake to no more than 2 g/day:
  - Adapt diet by examining nutrition labels to check sodium content per serving.
  - Avoid canned or processed foods, eating fresh or frozen foods.
  - Consult the written diet plan and the list of permitted and restricted foods.
  - Avoid salt use.
  - Avoid excesses in eating and drinking.
- Participate in prescribed activity program:
  - Participate in a daily exercise program, with walking and other activities, provided they do not cause unusual fatigue or dyspnea.
  - Conserve energy by balancing activity with rest periods.
  - Avoid strenuous activity, isometric exercises, and competitive sports.
- Develop methods to manage and prevent stress:
  - Avoid tobacco.
  - Avoid alcohol.
  - Engage in social and diversional activities.
- Identify community resources for peer and caregiver/family support:

- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.
- State meeting locations and times.

- Report immediately to the primary provider or clinic any of the following:
  - Gain in weight of 2–3 lb (0.9–1.4 kg) in 1 d, or 5 lb (2.3 kg) in 1 wk
  - Unusual shortness of breath with activity or at rest
  - Increased swelling of ankles, feet, or abdomen
  - Persistent cough
  - Loss of appetite
  - Development of restless sleep; increase in number of pillows needed to sleep
  - Profound fatigue
- State how to reach primary provider with questions or complications.
- State time and date of follow-up appointments and diagnostic tests.
- Identify the need for health promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, independent activities of daily living.

   b. Reports decreased dyspnea and increased comfort; maintains or improves gas exchange
   c. Reports no weight gain; appropriate weight for height
   d. Maintains or improves peripheral blood flow
2. Maintains or increases activity tolerance
   a. Carries out activities of daily living (e.g., brushes teeth, feeds self)
   b. Reports increased tolerance to activity
3. Is less anxious
   a. Discusses prognosis freely
   b. Verbalizes fears and concerns
   c. Participates in support groups if appropriate
   d. Demonstrates appropriate coping mechanisms
4. Decreases sense of powerlessness
   a. Identifies emotional response to diagnosis
   b. Discusses control that they have
5. Effectively manages self-care program
   a. Takes medications according to prescribed schedule
   b. Modifies diet to accommodate sodium and fluid recommendations

c. Modifies lifestyle to accommodate activity and rest behavior recommendations
d. Identifies signs and symptoms to be reported to health care professionals

INFECTIOUS DISEASES OF THE HEART

Any of the heart's three layers may be affected by an infectious process. Infections are named for the layer of the heart most involved in the infectious process: infective endocarditis (endocardium), myocarditis (myocardium), and pericarditis (pericardium) (see Chapter 21, Fig. 21-1). Rheumatic endocarditis is a unique infective endocarditis syndrome. Diagnosis of infection is made primarily on the basis of the patient's symptoms and echocardiography. Ideal management for all infectious diseases is prevention. IV antibiotics usually are necessary once an infection has developed in the heart.

Rheumatic Endocarditis

Acute rheumatic fever, which occurs most often in school-age children, may develop after an episode of group A beta-hemolytic streptococcal pharyngitis (Chart 24-5). Patients with rheumatic fever may develop rheumatic heart disease as evidenced by a new heart murmur, cardiomegaly, pericarditis, and heart failure. Prompt and effective treatment of "strep" throat with antibiotics can prevent development of rheumatic fever. Streptococcus is spread by direct contact with oral or respiratory secretions. Although bacteria are the causative agents, malnutrition, overcrowding, poor hygiene, and lower socioeconomic status may predispose individuals to rheumatic fever. The incidence of rheumatic fever in developed countries has decreased and it is now primarily a disease of the developing world (Cannon, Roberts, Milne, et al., 2017). As noted earlier in the chapter, rheumatic heart disease may lead to mitral valve stenosis or regurgitation that remains an issue in adulthood. Further information about rheumatic fever and rheumatic endocarditis can be found in pediatric nursing books.

Chart 24-5

Rheumatic Fever

Rheumatic fever is a preventable disease. Diagnosing and effectively treating streptococcal pharyngitis can prevent rheumatic fever and, therefore, rheumatic heart disease. Signs and symptoms of streptococcal pharyngitis include:

- Sore throat that can start very quickly
- Pain when swallowing
- Fever
- Red and swollen tonsils, sometimes with white patches or streaks of pus
- Petechiae (tiny, red spots) on the roof of the mouth (the soft or hard palate)
- Swollen lymph nodes in the front of the neck

If signs and symptoms of streptococcal pharyngitis are present, a rapid strep test is necessary to make an accurate diagnosis. If the test is negative but strep throat is still suspected, then a throat culture can be done. For adults, it is usually not necessary to do a throat culture following a negative rapid strep test. Adults are generally not at risk for getting rheumatic fever following a strep throat infection. All patients with a positive rapid strep test or throat cultures positive for streptococcal pharyngitis must adhere to the prescribed antibiotic treatment. Penicillin or amoxicillin are typical first-line antibiotics used. Completing the course of prescribed antibiotics minimizes the risk of developing rheumatic fever (and subsequent rheumatic heart disease).

Adapted from Centers for Disease Control and Prevention (CDC). (2018). *Strep throat: All you need to know*. Retrieved on 12/3/2019 at: www.cdc.gov/groupastrep/diseases-public/strep-throat.html

Infective Endocarditis

Infective endocarditis is a microbial infection of the endothelial surface of the heart. The disease is rare, but it has a high mortality rate; approximately 14% to 22% of patients die during their hospital stay, and up to 40% of patients die within 1 year of diagnosis (Kaura, Byrne, Fife, et al., 2017). It usually develops in older adults, or in people with prosthetic heart valves or cardiac devices. Staphylococcal endocarditis infections of valves in the right side of the heart are common among adults who use illicit IV drugs (Baddour, Wilson, Bayer, et al., 2015). Hospital-acquired infective endocarditis occurs most often in patients with debilitating disease or indwelling catheters and in patients who are receiving hemodialysis or prolonged IV fluid or antibiotic therapy (Chart 24-6).

Pathophysiology

A deformity or injury of the endocardium leads to accumulation of fibrin and platelets (clot formation) on the endocardium. Infectious organisms, usually staphylococci or streptococci, invade the clot and endocardial lesion. Infection most frequently results in platelets, fibrin, blood cells, and microorganisms that cluster as vegetations on the endocardium. Vegetations may embolize to other vessels throughout the body. As the clot on the endocardium continues to expand, the infecting organism is covered by new clot and concealed from the body's normal defenses. Infection may erode through the endocardium into underlying structures (e.g., valve leaflets), causing tears or other deformities of valve leaflets, dehiscence of prosthetic valves, deformity of chordae tendineae, or mural abscesses.

Chart 24-6 RISK FACTORS

Infective Endocarditis

- Prosthetic cardiac valves or prosthetic material used for cardiac valve repair
- Implanted cardiac devices (e.g., pacemaker, implanted cardioverter defibrillator)
- History of bacterial endocarditis (even without heart disease)
- Congenital heart disease:
  - Unrepaired cyanotic disease, including patients with palliative shunts and conduits
  - Repaired with prosthetic material or device either by surgery or catheter intervention during the first 6 mo after the procedure
  - Repaired with residual defects at the site or adjacent to the site of a prosthetic patch or device
- Cardiac transplant recipients with valvulopathy
- IV drug abuse
- Body piercing (especially oral, nasal, and nipple), branding, and tattooing
- Hemodialysis

Adapted from Nishimura, R. A., Otto, C. M., Bonow, R. O., et al. (2014). 2014 AHA/ACC guidelines for the management of patients with valvular heart disease. *Journal of the American College of Cardiology, 63*(22), e57–e185.

Clinical Manifestations

Onset of infective endocarditis usually is insidious. Signs and symptoms develop from toxic effects of the infection, destruction of heart valves, and embolization of fragments of vegetative growths on the endocardium. Primary presenting symptoms of infective endocarditis are fever and a heart murmur. Fever may be intermittent or absent, especially in patients who are receiving antibiotics or corticosteroids, in older adults, and in those who have heart failure or kidney injury. A heart murmur may be absent initially but develops in 85% of patients (Karchmer, 2018). Murmurs that worsen over time may indicate progressive damage and extension of the infectious vegetation (Baddour et al., 2015).

In addition to fever and heart murmur, clusters of petechiae may be found on the body. Small, painful nodules (Osler nodes) may be present in pads of fingers or toes. Irregular, red or purple, painless flat macules (Janeway lesions) may be present on palms, fingers, hands, soles, and toes. Hemorrhages with pale centers (Roth spots) caused by emboli may be observed in fundi of the eyes. Splinter hemorrhages (i.e., reddish-brown lines and streaks) may be seen under the proximal half of fingernails and toenails. Petechiae may appear in conjunctiva and mucous membranes.

Systemic embolization occurs in 22% to 50% of patients. It can occur at any time and may even be a presenting symptom. Up to 65% of emboli target the central nervous system and the majority of those are to the middle cerebral artery, effectively causing an embolic stroke. Metastatic foci of infection can also occur from embolization; for example, patients may develop a splenic abscess that requires splenectomy (Baddour et al., 2015).

Heart failure is the most frequent complication of infective endocarditis and may result from perforation of a valve leaflet, rupture of chordae, blood flow obstruction due to vegetations, or intracardiac shunts from dehiscence of prosthetic valves. It indicates a poor prognosis with medical therapy alone and is an indication for surgery (Alpert & Klotz, 2017).

Assessment and Diagnostic Findings

Although characteristics described previously may indicate infective endocarditis, signs and symptoms may indicate other diseases as well. Vague complaints of malaise, anorexia, weight loss, cough, and back and joint pain may be mistaken for influenza. Virulence of the causative organism usually correlates with the speed and degree of symptom development. A definitive diagnosis is made when a microorganism is found in two separate blood cultures and there is evidence of vegetation on imaging of the heart (e.g., echocardiogram). At least two sets of blood cultures (with each set including one aerobic and one anaerobic culture) drawn from different venipuncture sites

over a 24-hour period (each set at least 2 hours apart), should be obtained before administration of any antibiotics (Karchmer, 2018). Negative blood cultures do not definitely rule out infective endocarditis. Patients may have elevated white blood cell (WBC) counts. In addition, patients may be anemic, have a positive rheumatoid factor, and an elevated erythrocyte sedimentation rate (ESR) or C-reactive protein.

Echocardiography may assist in diagnosis by demonstrating a mass on a valve, prosthetic valve, or supporting structures and by identifying vegetations, abscesses, new prosthetic valve dehiscence, or new regurgitation. An echocardiogram may reveal development of heart failure. TEE may provide additional data when transthoracic imaging is nondiagnostic; this method of echocardiography is superior in assessing vegetations and perivalvular complications (Karchmer, 2018).

Prevention

Antibiotic prophylaxis had been traditionally recommended in patients at high risk (e.g., those with previous infective endocarditis, prosthetic heart valves, patients with heart transplant and valve regurgitation, some patients with congenital heart disease) before and sometimes after dental procedures that involved manipulation of gingival tissue or periapical area of teeth or perforation of oral mucosa. Antibiotic prophylaxis was also indicated for patients at high risk having procedures which involved the airway, and procedures which involved manipulation of infected tissue (e.g., wound débridement). The latest U.S. guidelines assert that prophylaxis in patients at high risk is reasonable but admit that the data are mixed regarding whether prophylaxis really decreases rates of infective endocarditis (Nishimura et al., 2017).

Patients at high risk should practice good oral hygiene. Poor dental hygiene can lead to bacteremia, particularly in the setting of a dental procedure. Severity of oral inflammation and infection is a significant factor in the incidence and degree of bacteremia. Regular professional oral care combined with personal oral care may reduce the risk of bacteremia. Recommended ongoing personal oral care includes using a manual or electronic toothbrush, dental floss, and other plaque removing devices (Nishimura et al., 2017).

Any patient at risk with a fever of more than 7 days' duration should report that finding to a primary provider; patients should not self-medicate with antibiotics or stop taking them before the prescribed dosage has been completed (Nishimura et al., 2017).

Increased vigilance is also required in patients with IV catheters and during invasive procedures. To minimize the risk of infection, nurses must ensure meticulous hand hygiene, site preparation, and aseptic technique during insertion and maintenance procedures. All catheters, tubes, drains, and other

devices are removed as soon as they are no longer needed or no longer function.

Medical Management

The objective of treatment is to eradicate invading organisms through adequate doses of an appropriate antibiotic. Antibiotic therapy usually is given intravenously for 2 to 6 weeks. Parenteral therapy is given in doses that produce a high serum concentration for a significant period to ensure eradication of the dormant bacteria within dense vegetations. This therapy is often delivered in the patient's home and is monitored by a home health nurse. Serum levels of the antibiotic and blood cultures are monitored to gauge effectiveness of therapy. If there is insufficient bactericidal activity, increased dosages of the antibiotic are prescribed or a different antibiotic is used. After adequate antibiotic therapy is initiated, the infective organism is usually eliminated. The patient should begin to feel better, regain an appetite, and have less fatigue. During this time, patients require psychosocial support because although they feel well, they may find themselves confined to the hospital or home with restrictive IV therapy.

Surgical Management

Surgical intervention may be required if the patient develops heart failure or an intracardiac abscess, or the patient has recurrent systemic embolizations, or the infection does not respond to medications. Surgical interventions include valve repair and replacement, débridement of vegetations, débridement and closure of an abscess, and closure of a fistula. Surgical valve replacement greatly improves the prognosis for patients with severe symptoms from damaged heart valves. Most patients who have prosthetic valve endocarditis require repeat valve replacement (Alpert & Klotz, 2017).

Nursing Management

The nurse monitors the patient's temperature at regular intervals, because the course of fever is one indication of treatment effectiveness. However, febrile reactions also may occur as a result of medication. The nurse administers antibiotic, antifungal, or antiviral medication as prescribed and educates the patient to take them as prescribed. Timing of antimicrobial medication administration is critical to maintain therapeutic drug levels. Fever often increases fatigue; rest periods should be planned and activities spaced to provide rest between activities. Good infection control and prevention practices include appropriate hand hygiene by both patients and caregivers. Nonsteroidal anti-inflammatory drugs (NSAIDs) may be prescribed as

antipyretics or to decrease the discomfort of fever. Patients may be more comfortable with a light layer of linens and exposure of their skin to air. They may be cooled with a fan, tepid water baths, or cloth compresses; if shivering or piloerection occurs, these interventions should be discontinued due to increased oxygen consumption and potential to further increase of body temperature.

Heart sounds are assessed. A new or worsening murmur may indicate dehiscence of a prosthetic valve, rupture of an abscess, or injury to valve leaflets or chordae tendineae (Baddour et al., 2015). The nurse monitors for signs and symptoms of systemic embolization, or, for patients with right-sided heart endocarditis, for signs and symptoms of pulmonary infarction and infiltrates. In addition, the nurse assesses signs and symptoms of organ damage such as stroke, meningitis, heart failure, myocardial infarction, glomerulonephritis, and splenomegaly.

Patient care is directed toward management of infection. Long-term IV antimicrobial therapy often is necessary; therefore, many patients have peripherally inserted central catheters or other long-term IV access. All invasive lines and wounds must be assessed daily for redness, tenderness, warmth, swelling, drainage, or other signs of infection. The patient and family are educated about activity restrictions, medications, and signs and symptoms of infection. Patients with infective endocarditis are at high risk for another episode of infective endocarditis. If the patient has undergone surgical treatment, the nurse provides postoperative care and instructions (see Chapters 16 and 23).

As appropriate, the home health nurse supervises and monitors IV antibiotic therapy delivered in the home setting and educates the patient and family about prevention and health promotion. The nurse provides the patient and family with emotional support and facilitates coping strategies during the prolonged course of infection and antibiotic treatment.

Myocarditis

Myocarditis, an inflammatory process involving the myocardium, can cause heart dilation, thrombi on the heart wall (mural thrombi), infiltration of circulating blood cells around the coronary vessels and between the muscle fibers, and degeneration of the muscle fibers themselves. Mortality varies with the severity of symptoms. Most patients with mild symptoms recover completely; however, some patients develop cardiomyopathy and heart failure.

Pathophysiology

Myocarditis usually results from an infectious source, be it viral (e.g., coxsackieviruses A and B, human immune deficiency virus, influenza A), bacterial, rickettsial, fungal, parasitic, metazoal, protozoal (e.g., Chagas disease), or spirochetal. It also may be immune related, occurring after acute systemic infections such as rheumatic fever, or it may be related to an autoimmune disorder. It may also result from an inflammatory reaction to toxins such as pharmacologic agents used in the treatment of other diseases (Arbustini, Agozzino, Favalli, et al., 2017). It may begin in one small area of the myocardium and then spread throughout the myocardium. The degree of myocardial inflammation and necrosis determines the degree of interstitial collagen and elastin destruction. The greater the destruction, the greater is the hemodynamic effect and resulting signs and symptoms. It is thought that DCM and HCM are latent manifestations of myocarditis.

Clinical Manifestations

The symptoms of acute myocarditis depend on the type of infection, the degree of myocardial damage, and the capacity of the myocardium to recover. Patients may be asymptomatic, with an infection that resolves on its own. However, they may develop mild to moderate symptoms and seek medical attention, often reporting fatigue and dyspnea, syncope, palpitations, and occasional discomfort in the chest and upper abdomen. The most common symptoms are flulike. Patients may also sustain sudden cardiac death or quickly develop severe congestive heart failure in fulminant myocarditis.

Assessment and Diagnostic Findings

Assessment of the patient may reveal no detectable abnormalities; as a result, the illness can go undiagnosed. Patients may be tachycardic or may report chest pain. An endomyocardial biopsy can provide the definitive diagnosis (Arbustini et al., 2017), but cardiac MRI is being used more often as a diagnostic tool because of its noninvasive approach (Lakdawala, Stevenson, & Loscalzo, 2018). With contrast, cardiac MRI may be diagnostic and can guide clinicians to sites for endomyocardial biopsies, which may be also indicated to find an organism or its genome, an immune process, or a radiation reaction causing the myocarditis. Patients without any abnormal heart structure (at least initially) may suddenly develop arrhythmias or ST–T-wave changes. If the patient has structural heart abnormalities (e.g., systolic dysfunction), a clinical assessment may disclose cardiac enlargement, faint heart sounds (especially S_1), pericardial friction rub, a gallop rhythm, or a systolic murmur. The WBC count, C-reactive protein, leukocyte count, and ESR may be elevated.

Medical Management

Patients are given specific treatment for the underlying cause if it is known (e.g., penicillin for hemolytic streptococci) and are placed on bed rest to decrease cardiac workload. Bed rest also helps decrease myocardial damage and the complications of myocarditis. In young patients with myocarditis, activities, especially athletics, should be limited for a 6-month period or at least until heart size and function have returned to normal. Physical activity is increased slowly, and the patient is instructed to report any symptoms that occur with increasing activity, such as a rapidly beating heart. If heart failure or arrhythmia develops, management is essentially the same as for all causes of heart failure and arrhythmias (see Chapters 25 and 22, respectively). Although they are known for their anti-inflammatory effects, NSAIDs should not be used for pain control; they have been implicated in increased cardiac injury and viral replication in animal studies (Lakdawala et al., 2018).

Nursing Management

The nurse assesses for resolution of tachycardia, fever, and any other clinical manifestations. The cardiovascular assessment focuses on signs and symptoms of heart failure and arrhythmias. Patients with arrhythmias should have continuous cardiac monitoring with personnel and equipment readily available to treat life-threatening arrhythmias.

Quality and Safety Nursing Alert

Patients with myocarditis are sensitive to digitalis. Nurses must closely monitor these patients for digitalis toxicity, which is evidenced by a new onset of arrhythmia, anorexia, nausea, vomiting, headache, and malaise. The primary provider should be notified immediately if this is suspected.

Anti-embolism stockings and passive and active exercises should be used because embolization from venous thrombosis and mural thrombi can occur, especially in patients on bed rest. In some patients, pharmacologic prophylaxis may also be indicated (see Chapter 26).

Pericarditis

Pericarditis refers to an inflammation of the pericardium, which is the membranous sac enveloping the heart. It accounts for 5% of emergency room visits for chest pain (Adler, Charron, Imazio, et al., 2015; Imazio, Gaita, &

LeWinter, 2015). Classification of pericarditis may be acute, chronic, or recurrent. The etiology of pericarditis can be infectious or noninfectious (Imazio & Gaita, 2015). For example, pericarditis may occur after pericardiectomy (opening of the pericardium) following cardiac surgery. Pericarditis also may occur 10 days to 2 months after acute myocardial infarction (Dressler syndrome).

Pathophysiology

Causes underlying or associated with pericarditis are listed in Chart 24-7. The inflammatory process of pericarditis may lead to an accumulation of fluid in the pericardial sac (pericardial effusion) and increased pressure on the heart, leading to cardiac tamponade (see Chapter 25). Frequent or prolonged episodes of pericarditis also may lead to thickening and decreased elasticity of the pericardium, or scarring may fuse the visceral and parietal pericardium. These conditions restrict the heart's ability to fill with blood (constrictive pericarditis). The pericardium may become calcified, further restricting ventricular expansion during ventricular filling (diastole). With less filling, the ventricles pump less blood, leading to decreased cardiac output and signs and symptoms of heart failure. Restricted diastolic filling may result in increased systemic venous pressure, causing peripheral edema and hepatic failure.

Clinical Manifestations

Pericarditis may be asymptomatic. The most characteristic symptom of pericarditis is chest pain, although pain also may be located beneath the clavicle, in the neck, or in the left trapezius (scapula) region. Pain or discomfort usually remains fairly constant, but it may worsen with deep inspiration and when lying down or turning. The most characteristic clinical manifestation of pericarditis is a creaky or scratchy friction rub heard most clearly at the left lower sternal border. Other signs may include a mild fever, increased WBC count, anemia, and an elevated ESR or C-reactive protein level. Patients may have a nonproductive cough or hiccup. Dyspnea, as well as respiratory splinting because of pain upon inspiration, and other signs and symptoms of heart failure may occur as a result of pericardial compression due to constrictive pericarditis or cardiac tamponade. The heart rate may increase to maintain cardiac output.

Chart 24-7

Causes of Pericarditis

- Idiopathic or nonspecific causes
- Infection:
  - Viral: most commonly infectious cause (e.g., enteroviruses, herpes viruses, adenoviruses, parvoviruses)
  - Bacterial: rare (but if bacterial cause, most commonly *Mycobacterium tuberculosis* is implicated)
  - Fungal: rare (e.g., *Histoplasma, Aspergillus, Candida*)
  - Parasitic: rare (e.g., *Echinococcus, Toxoplasma*)
- Autoimmune disorders (e.g., systemic lupus erythematosus, rheumatic fever, rheumatoid arthritis, polyarteritis, sarcoidosis, scleroderma)
- Immune-mediated drug reactions:
  - Lupuslike reaction
  - Antineoplastic drugs
  - Hypersensitivity eosinophilia
- Disorders of adjacent structures (e.g., myocardial infarction, dissecting aneurysm, pneumonia)
- Neoplastic disease:
  - Metastasis from lung or breast cancer
  - Primary neoplasms (e.g., mesothelioma)
- Radiation therapy of chest and upper torso (peak occurrence 5–9 mo after treatment)
- Intentional or unintentional chest trauma (e.g., chest injury, cardiac surgery, cardiac catheterization, implantation of pacemaker, or implantation of a cardiac implantable electronic device)
- Metabolic:
  - Uremia
  - Anorexia
  - Myxedema

Adapted from Miranda, W. R., Imazio, M., Greason, K. L., et al. (2017). Pericardial diseases. In V. Fuster, R. A. Harrington, J. Narula, et al. (Eds.). *Hurst's the heart* (14th ed.). New York: McGraw-Hill.

Assessment and Diagnostic Findings

The diagnosis most often is made on the basis of history, signs, and symptoms. An echocardiogram may detect inflammation, pericardial effusion or tamponade, and heart failure. It may help confirm the diagnosis and may be used to guide pericardiocentesis (needle or catheter drainage of the pericardium). TEE may be useful in diagnosis but may underestimate the extent of pericardial effusions. CT imaging may be the best diagnostic tool for determining size, shape, and location of pericardial effusions and may be used

to guide pericardiocentesis. Cardiac MRI may assist with detection of inflammation and adhesions. Occasionally, a video-assisted pericardioscope-guided biopsy of the pericardium or epicardium is performed to obtain tissue samples for culture and microscopic examination. Because the pericardial sac surrounds the heart, a 12-lead ECG may show concave ST elevations in many, if not all, leads (with no reciprocal changes) and may show depressed PR segments or atrial arrhythmias (Imazio & Gaita, 2015).

Medical Management

Objectives of pericarditis management are to determine the cause, administer therapy for treatment and symptom relief, and detect signs and symptoms of cardiac tamponade. When cardiac output is impaired, the patient is placed on bed rest until fever, chest pain, and friction rub have subsided.

Analgesic medications and NSAIDs such as aspirin, indomethacin, or ibuprofen may be prescribed for pain relief during the acute phase. Corticosteroids (e.g., prednisone) can be used as an alternative when NSAIDs are contraindicated (e.g., kidney disease). Colchicine may be prescribed if the pericarditis is severe as an additive therapy to NSAIDs (Adler et al., 2015).

Pericardiocentesis, a procedure in which some pericardial fluid is removed, rarely is necessary. It may be performed to assist in identification of the cause or relieve symptoms, especially if there are signs and symptoms of heart failure or tamponade. Pericardial fluid is cultured if bacterial, tubercular, or fungal disease is suspected; a sample is sent for cytology if neoplastic disease is suspected. A pericardial window, a small opening made in the pericardium, may be performed to allow continuous drainage into the chest cavity. Surgical removal of tough encasing pericardium (pericardiectomy) may be necessary to release both ventricles from constrictive and restrictive inflammation and scarring.

Nursing Management

Patients with acute pericarditis require pain management with antispasmodic agents, assistance with positioning, and psychological support. Patients with chest pain often benefit from education and reassurance that the pain is not due to a heart attack. Pain may be relieved with a forward-leaning or sitting position. To minimize complications, the nurse helps the patient with activity restrictions until pain and fever subside. As the patient's condition improves, the nurse encourages gradual increases of activity. However, if pain, fever, or friction rub recurs, activity restrictions must be resumed. The nurse educates the patient and family about a healthy lifestyle to enhance the patient's immune system.

Nurses caring for patients with pericarditis must be alert to signs and symptoms of cardiac tamponade (see Chapter 25). The nurse monitors the patient for heart failure. Patients with hemodynamic instability or pulmonary congestion are treated as if they had heart failure (see Chapter 25).

NURSING PROCESS

The Patient with Pericarditis

Assessment

The primary symptom of pericarditis is pain, which is assessed by evaluating the patient in various positions. The nurse tries to identify whether pain is influenced by respiratory movements, while holding an inhaled breath or holding an exhaled breath; by flexion, extension, or rotation of the spine, including the neck; by movements of shoulders and arms; by coughing; or by swallowing. Recognizing events that precipitate or intensify pain may help establish a diagnosis and differentiate pain of pericarditis from pain of myocardial infarction.

When pericardial surfaces lose their lubricating fluid because of inflammation, a pericardial friction rub occurs. The rub is audible on auscultation and is synchronous with the heartbeat. However, it may be elusive and difficult to detect.

Quality and Safety Nursing Alert

A pericardial friction rub is diagnostic of pericarditis. It is a creaky or scratchy sound and is louder at the end of exhalation. Nurses should monitor for pericardial friction rub by placing the diaphragm of the stethoscope tightly against the patient's thorax and auscultating the left sternal edge in the fourth intercostal space, which is the site where the pericardium comes into closest contact with the left chest wall. The rub may be heard best when a patient is sitting and leaning forward.

If there is difficulty in distinguishing a pericardial friction rub from a pleural friction rub, the patient is asked to hold their breath; a pericardial friction rub will continue to be heard.

The patient's temperature is monitored frequently. Pericarditis may cause an abrupt onset of fever in a patient who has been afebrile.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, the major nursing diagnoses may be:

- Acute pain associated with inflammation of the pericardium
- Lack of knowledge of diagnosis and therapeutic self-care management

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Potential complications may include the following:

- Pericardial effusion
- Cardiac tamponade

Planning and Goals

The patient's major goals may include relief of pain and absence of complications.

Nursing Interventions

Relieving Pain

Relief of pain is achieved by rest. Because sitting upright and leaning forward is the posture that tends to relieve pain, chair rest may be more comfortable. The nurse instructs the patient to restrict activity until pain subsides. As chest pain and friction rub abate, activities of daily living may be resumed gradually. If the patient is taking antispasmodic agents, antibiotics, or corticosteroids for pericarditis, responses to these medications are monitored and recorded. Patients taking NSAIDs or colchicine are assessed for gastrointestinal adverse effects. If chest pain and friction rub recur, bed rest or chair rest is resumed.

Enhancing Knowledge About Pericarditis and Self-Care Management

There are a multitude of possible causes for pericarditis (see Chart 24-7). Some of these are life-threatening (e.g., metastatic cancers) while others are not; regardless, the patient is likely to be fearful and anxious because they are experiencing chest pain. Educating the patient about the cause of the pericarditis, and medications prescribed to treat it (e.g., NSAIDs), and methods to improve breathing patterns and alleviate pain (e.g., sitting up and leaning forward upon a pillow) can allay anxieties. The patient should verbalize when it is appropriate to follow up with the primary provider (i.e., for routine follow ups, with relapse of symptoms, with symptoms suggestive of cardiac tamponade, including lightheadedness, orthostasis and tachycardia [see following]).

Monitoring and Managing Potential Complications

Abnormal accumulation of fluid between the pericardial linings (i.e., in the pericardial sac) is called *pericardial effusion*. Most patients have no effects or symptoms. However, enough fluid can accumulate to constrict the myocardium, impairing ventricular filling and the myocardium's ability to pump, a condition known as *cardiac tamponade* (discussed below) (Imazio et al., 2015). Failure to identify and treat this problem can lead to death.

Signs and symptoms of cardiac tamponade may begin with the patient reporting shortness of breath, chest tightness, or dizziness. The nurse may observe that the patient is becoming progressively more restless. Assessment of blood pressure may reveal a decrease of 10 mm Hg or more

in systolic blood pressure during inspiration (pulsus paradoxus). Usually, the systolic pressure decreases and the diastolic pressure remains stable; hence, the pulse pressure narrows. The patient usually has tachycardia, and ECG voltage may be decreased or QRS complexes may alternate in height (electrical alternans). Heart sounds may progress from distant to imperceptible. Blood continues to return to the heart from the periphery but cannot flow into the heart to be pumped back into the circulation. The patient develops jugular vein distention and other signs of rising central venous pressure. The Beck triad (hypotension, muffled heart sounds, and an elevated jugular venous pressure) is a useful diagnostic parameter of severe tamponade.

In such situations, the nurse notifies the primary provider immediately and prepares to assist with diagnostic echocardiography and pericardiocentesis (see Chapter 25). The nurse stays with the patient and continues to assess and record signs and symptoms while intervening to decrease patient anxiety.

PROMOTING HOME, COMMUNITY-BASED, AND TRANSITIONAL CARE

Because patients, their family members, and health care providers tend to focus on the most obvious needs and issues related to pericarditis, the nurse reminds them about the importance of continuing health promotion and screening practices. The nurse educates patients who have not been involved in these practices in the past about their importance and refers them to appropriate health care providers.

Evaluation

Expected patient outcomes may include:

1. Freedom from pain
   a. Performs activities of daily living without pain, fatigue, or shortness of breath
   b. Temperature returns to normal range
   c. Exhibits no pericardial friction rub
2. Effectively manages self-care
   a. Identifies cause(s) of pericarditis and rationale for prescribed therapeutic regimen
   b. Follows-up with primary provider for ongoing appointments and as needed
3. Absence of complications
   a. Sustains blood pressure in normal range
   b. Heart sounds strong and can be auscultated
   c. Absence of jugular vein distention

CRITICAL THINKING EXERCISES

1 ebp A 67-year-old woman presents to the emergency department (ED) where you work as a staff nurse with reports of fevers, malaise, and painful nodules on the pads of her fingers. Upon review of her medical history, the patient reports an aortic valve replacement (prosthetic) as a child, but no other significant medical or surgical history. Based on the history and physical examination findings, the primary provider thinks that the patient may have infective endocarditis and prescribes antibiotics. What should you ensure happens before the antibiotics are given? What are the care priorities for this patient?

2 ipc A 57-year-old man presents to the cardiology clinic where you work with a complaint of ankle swelling and trouble breathing when he walks more than 20 feet. The cardiologist does an echocardiogram and diagnoses the patient with cardiomyopathy. The patient expresses anxiety about what this means. Based on what you know about cardiomyopathy, what would you focus on when educating this patient? What are the key roles of other members of the health care team in appropriately assisting the patient in managing a new diagnosis of cardiomyopathy?

3 pq A 47-year-old woman with HCM presents to the ED where you work after fainting. It is the middle of summer and the primary provider thinks the patient was dehydrated. Explain the pathophysiology of why dehydration in a patient with HCM might precipitate a syncopal episode. Describe your prioritized focused assessment of this patient in the ED.

25 Management of Patients with Complications from Heart Disease

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Recognize the etiology, pathophysiology, and clinical manifestations of the different classifications of heart failure.
2. Describe the medical management, including recommended pharmacologic treatments, for patients with heart failure.
3. Use the nursing process as a framework for care of the patient with heart failure.
4. Identify additional heart disease disorders and medical and nursing management of patients with complications from heart disease.

NURSING CONCEPT

Perfusion

GLOSSARY

anuria: urine output of less than 50 mL/24 h

ascites: an accumulation of serous fluid in the peritoneal cavity

cardiac resynchronization therapy (CRT): a treatment for heart failure in which a device paces both ventricles to synchronize contractions

congestive heart failure (CHF): a fluid overload condition (congestion) associated with heart failure

diastolic heart failure: the inability of the left ventricle of the heart to fill and pump sufficiently; term used to define a type of heart failure (*synonym:* Heart Failure with preserved Ejection Fraction [HFpEF])

ejection fraction (EF): percentage of blood volume in the ventricles at the end of diastole that is ejected during systole; a measurement of contractility

heart failure (HF): a clinical syndrome resulting from structural or functional cardiac disorders that impair the ability of a ventricle to fill or eject blood

Heart Failure with midrange Ejection Fraction (HFmrEF): clinical heart failure syndrome with left ventricular ejection fraction that is 40% to 49%

Heart Failure with preserved Ejection Fraction (HFpEF): clinical heart failure syndrome with left ventricular ejection fraction greater than or equal to 50% (*synonym:* diastolic heart failure)

Heart Failure with reduced Ejection Fraction (HFrEF): clinical heart failure syndrome with left ventricular ejection fraction less than or equal to 40% (*synonym:* systolic heart failure)

left-sided heart failure: inability of the left ventricle to fill or eject sufficient blood into the systemic circulation (*synonym:* left ventricular failure)

oliguria: diminished urine output; less than 0.5 mL/kg/h over at least 6 hours, or less than 400 mL in 24 hours

orthopnea: shortness of breath when lying flat

paroxysmal nocturnal dyspnea (PND): shortness of breath that occurs suddenly during sleep

pericardiocentesis: procedure that involves aspiration of fluid from the pericardial sac

pericardiotomy: surgically created opening of the pericardium

pulmonary edema: pathologic accumulation of fluid in the interstitial spaces and alveoli of the lungs causing severe respiratory distress

pulseless electrical activity (PEA): condition in which electrical activity is present on an electrocardiogram, but there is not a physiologically adequate pulse or blood pressure

pulsus paradoxus: systolic blood pressure that is more than 10 mm Hg lower during inhalation than during exhalation; difference is normally less than 10 mm Hg

right-sided heart failure: inability of the right ventricle to fill or eject sufficient blood into the pulmonary circulation (*synonym:* right ventricular failure)

systolic heart failure: inability of the heart to pump sufficiently because of an alteration in the ability of the heart to contract; term used to describe a type of heart failure (*synonym:* Heart Failure with reduced Ejection Fraction [HFrEF])

Cardiovascular disease is the leading cause of death in the United States (Centers for Disease Control and Prevention [CDC], 2017). Because of advancements in diagnostic and screening procedures, greater recognition of the importance of diligent self-care practices, and new discoveries in pharmacotherapies, it is now possible for a person diagnosed with heart disease to continue to live with a high quality of life years after being diagnosed. Despite this progress, heart disease remains a chronic and often progressive condition, associated with serious comorbidities, such as heart failure (Benjamin, Muntner, Alonso, et al., 2019). This chapter presents the complications most often associated with heart disease, including the medical management and nursing processes for managing patients with complications of cardiovascular disease.

HEART FAILURE

Heart failure (HF) is a clinical syndrome resulting from structural or functional cardiac disorders so that the heart is unable to pump enough blood to meet the body's metabolic demands or needs (American Heart Association [AHA], 2019a). The term *heart failure* indicates myocardial disease in which impaired contraction of the heart (systolic dysfunction) or filling of the heart (diastolic dysfunction) may cause pulmonary or systemic congestion. Some cases of HF are reversible, depending on the cause. Most often, HF is a chronic, progressive condition that is managed with lifestyle changes and medications to prevent episodes of acute decompensated heart failure. These episodes are characterized by increased symptoms of respiratory distress, decreased cardiac output (CO), and poor perfusion. These episodes are also associated with increased hospitalizations, increased health care costs, and decreased quality of life (Benjamin et al., 2019).

Approximately six million people in the United States have HF, and 870,000 new cases are diagnosed each year (AHA, 2019a). As more people

live longer with chronic heart diseases, HF has become an epidemic that challenges the country's health care resources. HF is the most common reason for hospitalization of people older than 65 years and is the second most common reason for visits to a provider's office. Emergency department (ED) visits and hospital readmissions for this disorder are very common, despite efforts to prevent rehospitalizations. Over 20% of patients discharged after treatment for HF are readmitted to the hospital within 30 days, and nearly 50% are readmitted to the hospital within 6 months (O'Connor, 2017). The estimated economic burden caused by HF in the United States is more than $30 billion annually in direct and indirect costs and is expected to continue to increase over time (CDC, 2017).

HF is more prevalent among African Americans and Hispanics than among Caucasians. The risk for having HF increases with advancing age. For adults over 60 years of age, HF is more prevalent among men than women (Benjamin et al., 2019). As typical for other major cardiovascular diseases and disorders, cigarette smoking, obesity, poorly managed diabetes, and metabolic syndrome are all risks for HF (Benjamin et al., 2019). The onset of HF is typically a morbid consequence of another disease or disorder, including coronary artery disease (CAD), hypertension, cardiomyopathy, valvular disorders, and renal dysfunction with volume overload (McCance, Huether, Brashers, et al., 2019).

Atherosclerosis of the coronary arteries is a primary cause of HF, and CAD is found in the majority of patients with HF. Ischemia causes myocardial dysfunction because it deprives heart cells of oxygen and causes cellular damage. Myocardial infarction (MI) causes focal heart muscle necrosis, the death of myocardial cells, and a loss of contractility; the extent of the infarction correlates with the severity of HF. Revascularization of the coronary artery by a percutaneous coronary intervention (PCI) or by coronary artery bypass surgery (coronary artery bypass graft [CABG]) may improve myocardial oxygenation and ventricular function and prevent more extensive myocardial necrosis that can lead to HF (see Chapter 23).

Systemic or pulmonary hypertension increases afterload (resistance to ejection), increasing the cardiac workload and leading to the hypertrophy of myocardial muscle fibers. This can be considered a compensatory mechanism because it initially increases contractility. However, sustained hypertension eventually leads to changes that impair the heart's ability to fill properly during diastole, and the hypertrophied ventricles may dilate and fail (Norris, 2019; Yancy, Jessup, Bozkurt, et al., 2017).

Cardiomyopathy is a disease of the myocardium. The various types of cardiomyopathy lead to HF and arrhythmias. Dilated cardiomyopathy (DCM), the most common type of cardiomyopathy, causes diffuse myocyte necrosis and fibrosis, and commonly leads to progressive HF (Norris, 2019). DCM can be idiopathic (unknown cause), or it can result from an inflammatory process, such as myocarditis, or from a cytotoxic agent, such as alcohol or certain

antineoplastic drugs. Usually, HF due to cardiomyopathy is chronic and progressive. However, cardiomyopathy and HF may resolve following removal of the causative agent. Genetic testing may be recommended for idiopathic cardiomyopathy (van der Meer, Gaggin, & Dec, 2019) (see Chapter 24).

Valvular heart disease is also a cause of HF. The valves ensure that blood flows in one direction. With valvular dysfunction, it becomes increasingly difficult for blood to move forward, increasing pressure within the heart and increasing cardiac workload, leading to HF (see Chapter 24).

Several systemic conditions, including progressive kidney failure, contribute to the development and severity of HF. Nearly 30% of patients with chronic HF also have chronic kidney disease (Benjamin et al., 2019). In addition, cardiac arrhythmias such as atrial fibrillation may either cause or result from HF; in both instances, the altered electrical stimulation impairs myocardial contraction and decreases the overall efficiency of myocardial function. Other factors, such as hypoxia, acidosis, and electrolyte abnormalities, can worsen myocardial function (Yancy et al., 2017).

Pathophysiology

Regardless of the etiology, the pathophysiology of HF results in similar changes and clinical manifestations. Significant myocardial dysfunction usually occurs before the patient experiences signs and symptoms of HF such as shortness of breath, edema, or fatigue.

As HF develops, the body activates neurohormonal compensatory mechanisms. These mechanisms represent the body's attempt to cope with the HF and are responsible for the signs and symptoms that develop (Norris, 2019). Understanding these mechanisms is important because the treatment for HF is aimed at correcting them and relieving symptoms.

The most common type of HF is systolic HF, also called Heart Failure with reduced Ejection Fraction (HFrEF; see later discussion in Assessment and Diagnostic Findings). **Systolic heart failure** results in decreased blood ejected from the ventricle. The decreased blood flow is sensed by baroreceptors in the aortic and carotid bodies, and the sympathetic nervous system is then stimulated to release epinephrine and norepinephrine (Fig. 25-1). The purpose of this initial response is to increase heart rate and contractility and support the failing myocardium, but the continued response has multiple negative effects. Sympathetic stimulation causes vasoconstriction in the skin, gastrointestinal tract, and kidneys. A decrease in renal perfusion due to low CO and vasoconstriction then causes the release of renin by the kidneys. Renin converts the plasma protein angiotensinogen to angiotensin I, which then circulates to the lungs. Angiotensin-converting enzyme (ACE) in the lumen of pulmonary blood vessels converts angiotensin I to angiotensin II, a potent vasoconstrictor, which then increases the blood pressure and afterload.

Angiotensin II also stimulates the release of aldosterone from the adrenal cortex, resulting in sodium and fluid retention by the renal tubules and an increase in blood volume. These mechanisms lead to the fluid volume overload commonly seen in HF. Angiotensin, aldosterone, and other neurohormones (e.g., endothelin) lead to an increase in preload and afterload, which increases stress on the ventricular wall, causing an increase in cardiac workload. A counterregulatory mechanism is attempted through the release of natriuretic peptides. Atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP; brain type) are released from the overdistended cardiac chambers. These substances promote vasodilation and diuresis. However, their effect is usually not strong enough to overcome the negative effects of the other mechanisms (Norris, 2019).

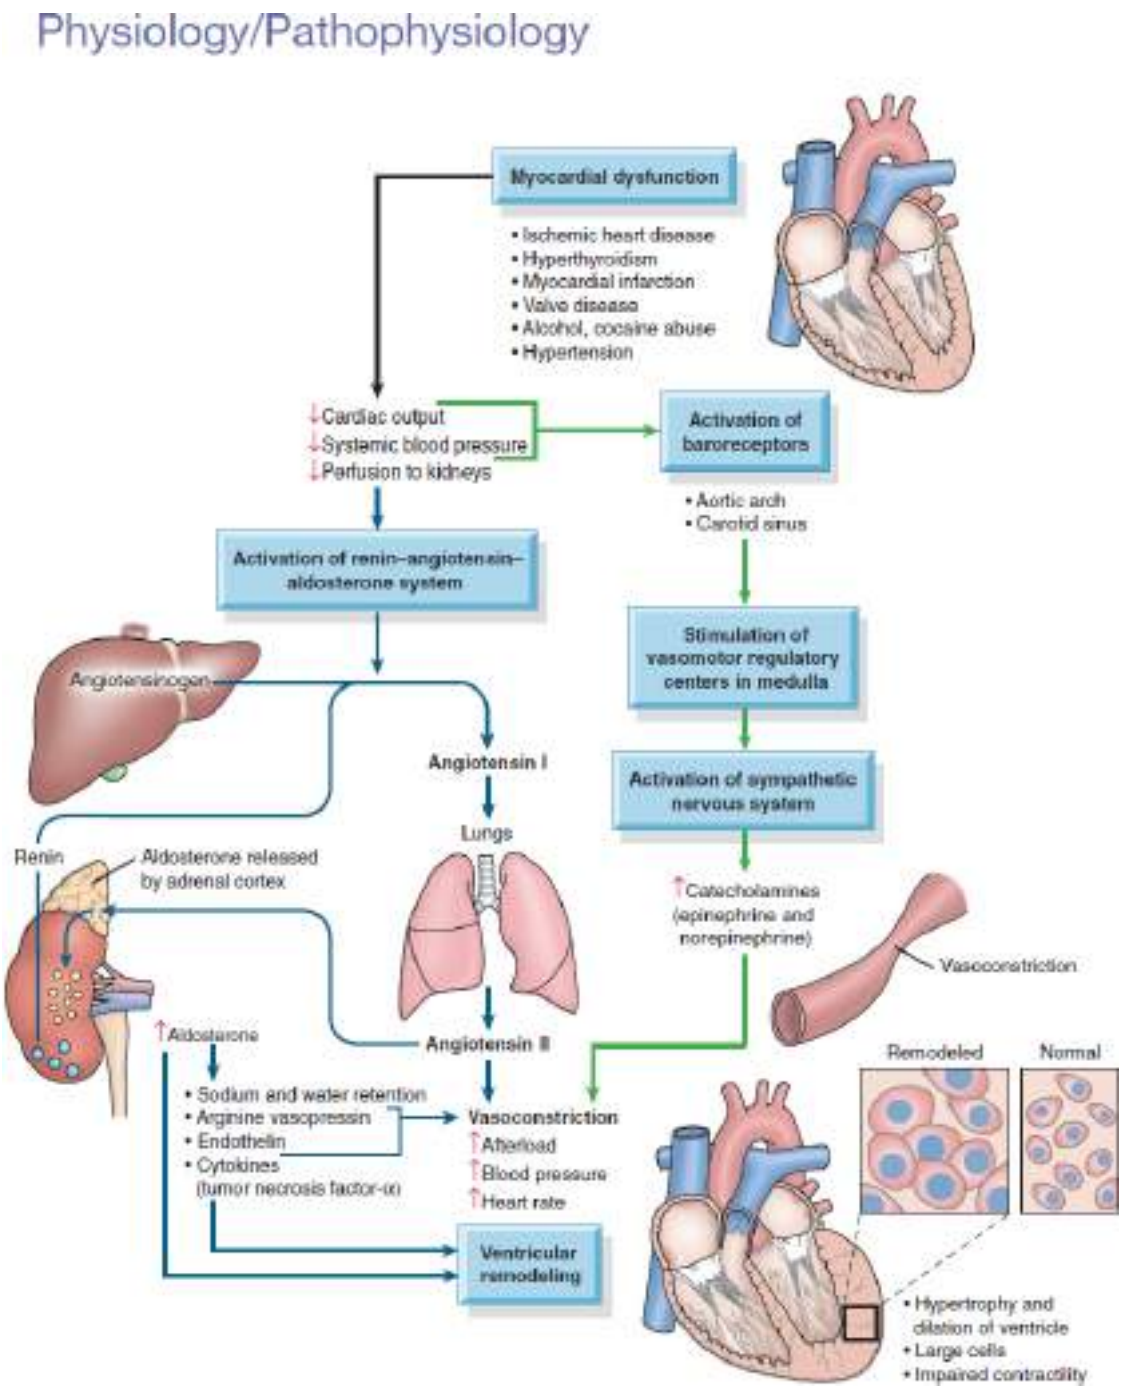

Figure 25-1 • The pathophysiology of heart failure. A decrease in cardiac output activates multiple neurohormonal mechanisms that ultimately result in the signs and symptoms of heart failure.

As the heart's workload increases, contractility of the myocardial muscle fibers decreases. Decreased contractility results in an increase in end-diastolic blood volume in the ventricle, stretching the myocardial muscle fibers and increasing the size of the ventricle (ventricular dilation). The heart compensates for the increased workload by increasing the thickness of the heart muscle (ventricular hypertrophy). Hypertrophy results in abnormal

changes in the structure and function of myocardial cells, a process known as ventricular remodeling. Under the influence of neurohormones (e.g., angiotensin II), enlarged myocardial cells become dysfunctional and die early (a process called *apoptosis*), leaving the other, functional myocardial cells struggling to maintain CO.

As cardiac cells die and the heart muscle becomes fibrotic, **diastolic heart failure**, also called Heart Failure with preserved Ejection Fraction (HFpEF) (see later discussion in Assessment and Diagnostic Findings), can develop, leading to further dysfunction. A stiff ventricle resists filling, and less blood in the ventricles causes a further decrease in CO. All of these compensatory mechanisms of HF have been referred to as the "vicious cycle of heart failure" because low CO leads to multiple mechanisms that make the heart work harder, worsening the HF.

Clinical Manifestations

Many clinical manifestations are associated with HF (Chart 25-1). However, the cardinal manifestations of HF are dyspnea; fatigue, which may limit exercise tolerance; and fluid retention, which may lead to congestion, evidenced by pulmonary and peripheral edema (Yancy, Jessup, Bozkurt, et al., 2013). The signs and symptoms of HF are related to the ventricle that is most affected. **Left-sided heart failure**, also referred to as left ventricular failure because of the inability of the left ventricle to fill or eject sufficient blood into the systemic circulation, causes different manifestations than **right-sided heart failure**, also referred to as right ventricular failure because of the inability of the right ventricle to fill or eject sufficient blood into the pulmonary circulation. In chronic HF, particularly congestive heart failure, patients may have signs and symptoms of both left- and right-sided heart failure. The patient with pulmonary edema manifests signs and symptoms of acute decompensation, warranting expeditious treatment.

Left-Sided Heart Failure

Pulmonary congestion occurs when the left ventricle cannot effectively pump blood out of the ventricle into the aorta and the systemic circulation. The increased left ventricular end-diastolic blood volume increases the left ventricular end-diastolic pressure, which decreases blood flow from the left atrium into the left ventricle during diastole. The blood volume and pressure build up in the left atrium, decreasing flow through the pulmonary veins into the left atrium. Pulmonary venous blood volume and pressure increase in the lungs, forcing fluid from the pulmonary capillaries into the pulmonary tissues and alveoli, causing pulmonary interstitial edema and impaired gas exchange.

The clinical manifestations of pulmonary congestion include dyspnea, cough, pulmonary crackles, and low oxygen saturation levels. An extra heart sound, the S_3, or "ventricular gallop," may be detected on auscultation. It is caused by abnormal ventricular filling (Colucci & Dunlay, 2017; Dumitru, 2018).

Chart 25-1 ASSESSMENT

Heart Failure

Be alert for the following signs and symptoms:

Congestion

- Dyspnea
- Orthopnea
- Paroxysmal nocturnal dyspnea
- Cough (recumbent or exertional)
- Pulmonary crackles that do not clear with cough
- Weight gain (rapid)
- Dependent edema
- Abdominal bloating or discomfort
- Ascites
- Jugular venous distention
- Sleep disturbance (anxiety or air hunger)
- Fatigue

Poor Perfusion/Low Cardiac Output

- Decreased exercise tolerance
- Muscle wasting or weakness
- Anorexia or nausea
- Unexplained weight loss
- Lightheadedness or dizziness
- Unexplained confusion or altered mental status
- Resting tachycardia
- Daytime oliguria with recumbent nocturia
- Cool or vasoconstricted extremities
- Pallor or cyanosis

Adapted from Colucci, W. S., & Dunlay, S. M. (2017). Clinical manifestations and diagnosis of advanced heart failure. *UpToDate*. Retrieved on 12/6/2019 at: www.uptodate.com/contents/clinical-manifestations-and-diagnosis-of-advanced-heart-failure; Dumitru, I. (2018). Heart failure. *Medscape.* Retrieved on 12/6/2019 at: www.emedicine.medscape.com/article/163062-overview

Dyspnea, or shortness of breath, may be precipitated by minimal to moderate activity (dyspnea on exertion [DOE]), yet dyspnea may also occur at rest. The patient may report **orthopnea**, difficulty breathing when lying flat. Patients with orthopnea may use multiple pillows to prop themselves up in bed, or they may sleep sitting up or in a high, reclined position. Some patients have sudden attacks of dyspnea at night, a condition known as **paroxysmal nocturnal dyspnea (PND)**. Fluid accumulating in the dependent extremities during the day may be reabsorbed into the circulating blood volume when the patient lies down. Because the impaired left ventricle cannot eject the increased circulating blood volume, the pressure in the pulmonary circulation increases, shifting fluid into the alveoli. The fluid-filled alveoli cannot exchange oxygen and carbon dioxide. Without sufficient oxygen, the patient experiences dyspnea and has difficulty sleeping (Colucci & Dunlay, 2017; Dumitru, 2018).

The cough associated with left ventricular failure is initially dry and nonproductive. Most often, patients complain of a dry hacking cough that may be mislabeled as asthma or chronic obstructive pulmonary disease (COPD). Over time, the cough may begin to accumulate secretions. Large quantities of frothy sputum, sometimes pink or tan, may be produced, indicating acute decompensated HF and pulmonary edema (Colucci & Dunlay, 2017; Dumitru, 2018).

Adventitious breath sounds may be heard in various areas of the lungs. Usually, bibasilar crackles that do not clear with coughing are detected in the early phase of left ventricular failure. As the failure worsens and pulmonary congestion increases, crackles may be auscultated throughout the lung fields. At this point, oxygen saturation may decrease.

In addition to pulmonary manifestations, the decreased amount of blood ejected from the left ventricle can lead to inadequate tissue perfusion. The diminished CO has widespread manifestations because not enough blood reaches all of the tissues and organs (low perfusion) to provide the necessary oxygen. The decrease in stroke volume (SV) can also stimulate the sympathetic nervous system to release catecholamines, which further impedes perfusion to many organs, including the kidneys.

As reduced CO and catecholamines decrease blood flow to the kidneys, urine output drops. Renal perfusion pressure falls, and the renin–angiotensin–aldosterone system is stimulated to increase blood pressure and intravascular volume. While the patient sleeps, the cardiac workload decreases, improving renal perfusion. This may cause **nocturia** (i.e., frequent urination at night) (Colucci & Dunlay, 2017; Dumitru, 2018).

As HF progresses, decreased output from the left ventricle may cause other symptoms. Decreased gastrointestinal perfusion causes altered digestion. Decreased brain perfusion causes dizziness, lightheadedness, confusion, restlessness, and anxiety due to decreased oxygenation and blood flow. As

anxiety increases, so does dyspnea, increasing anxiety and creating a vicious cycle. Stimulation of the sympathetic system also causes the peripheral blood vessels to constrict, so the skin appears pale or ashen and feels cool and clammy.

A decrease in SV causes the sympathetic nervous system to increase the heart rate (tachycardia), often causing the patient to complain of palpitations. The peripheral pulses become weak. Without adequate CO, the body cannot respond to increased energy demands, and the patient becomes easily fatigued and has decreased activity tolerance. Fatigue also results from the increased energy expended in breathing and the insomnia that results from respiratory distress, coughing, and nocturia (Colucci & Dunlay, 2017; Dumitru, 2018).

Right-Sided Heart Failure

When the right ventricle fails, congestion in the peripheral tissues and the viscera predominates. This occurs because the right side of the heart cannot eject blood effectively and cannot accommodate all of the blood that normally returns to it from the venous circulation. Increased venous pressure leads to jugular venous distention (JVD) and increased capillary hydrostatic pressure throughout the venous system. Systemic clinical manifestations include dependent edema (edema of the lower extremities), **hepatomegaly** (enlargement of the liver), **ascites** (accumulation of fluid in the peritoneal cavity), and weight gain due to retention of fluid. Edema usually affects the feet and ankles and worsens when the patient stands or sits for a long period. The edema may decrease when the patient elevates the legs. Edema can gradually progress up the legs and thighs and eventually into the external genitalia and lower trunk. Ascites is evidenced by increased abdominal girth and may accompany lower body edema or may be the only edema present. Sacral edema is common in patients who are on bed rest, because the sacral area is dependent. Pitting edema, in which indentations in the skin remain after even slight compression with the fingertips (Fig. 25-2), is generally obvious after retention of at least 4.5 kg (10 lb) of fluid (4.5 L).

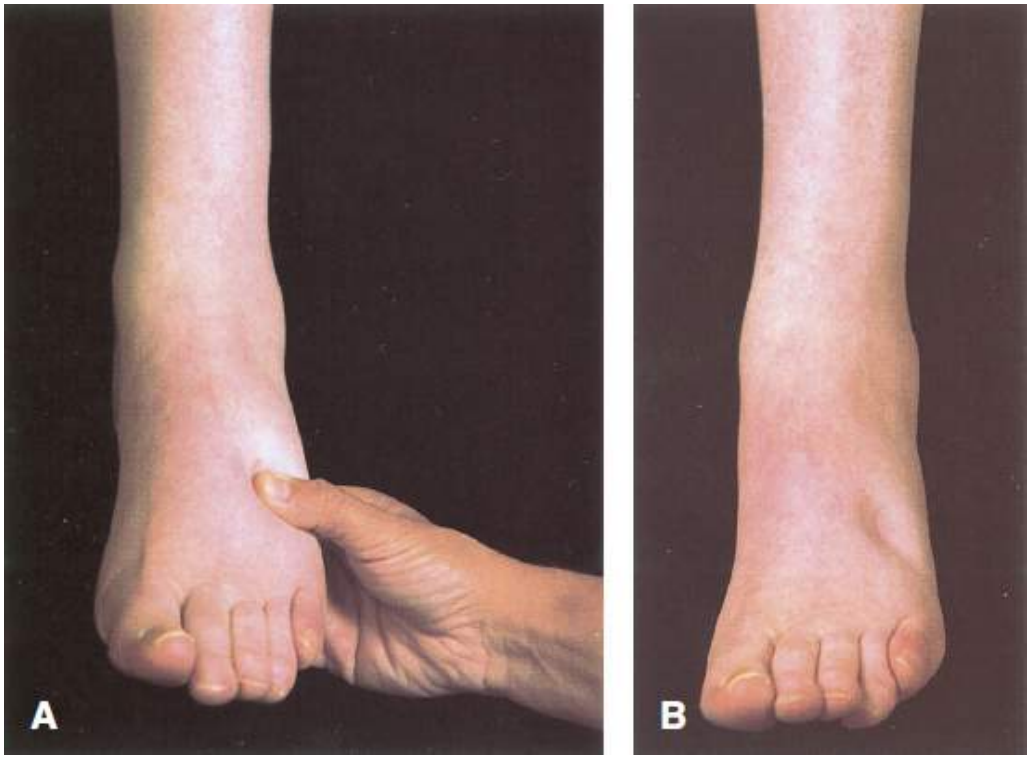

Figure 25-2 • Example of pitting edema. **A.** The nurse applies pressure to an area near the ankle. **B.** When the pressure is released, an indentation remains in the edematous tissue. Reprinted with permission from Bickley, L. S. (2017). *Bates' guide to physical examination and history taking* (12th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Hepatomegaly and tenderness in the right upper quadrant of the abdomen result from venous engorgement of the liver. The increased pressure may interfere with the liver's ability to function (secondary liver dysfunction). As hepatic dysfunction progresses, increased pressure within the portal vessels may force fluid into the abdominal cavity, causing ascites. Ascites may increase pressure on the stomach and intestines and cause gastrointestinal distress. Hepatomegaly may also increase pressure on the diaphragm, causing respiratory distress.

Anorexia (loss of appetite), nausea, or abdominal pain may result from the venous engorgement and venous stasis within the abdominal organs. The generalized weakness that accompanies right-sided HF results from reduced CO and impaired circulation (Colucci & Dunlay, 2017; Dumitru, 2018).

Congestive Heart Failure

Right-sided heart failure can sometimes occur as a result of left-sided failure. The failure of these dual mechanisms is sometimes referred to as **congestive heart failure**. When the left ventricle fails, increased fluid pressure is transferred back through the lungs, leading to damage of the right side of the

heart. When the right side loses pumping power, the blood backs up in the body's venous system. This may cause swelling or congestion in the legs, ankles, and swelling within the abdomen such as the GI tract and liver. Increased venous pressure may also lead to JVD and increased capillary hydrostatic pressure throughout the venous system. Edema may be present in the periphery as well as within the pulmonary vascular bed. Without appropriate treatment, this may progress to pulmonary edema.

Pulmonary Edema

Pulmonary edema is an acute event, reflecting a breakdown of physiologic compensatory mechanisms; hence, it is sometimes referred to as acute decompensated heart failure. It can occur following acute MI or as an exacerbation of chronic HF. When the left ventricle begins to fail, blood backs up into the pulmonary circulation, causing pulmonary interstitial edema. This may occur quickly in some patients, a condition sometimes called *flash pulmonary edema.* Pulmonary edema can also develop slowly, especially when it is caused by noncardiac disorders such as kidney injury and other conditions that cause fluid overload. The left ventricle cannot handle the volume overload, and blood volume and pressure build up in the left atrium. The rapid increase in atrial pressure results in an acute increase in pulmonary venous pressure, which produces an increase in hydrostatic pressure that forces fluid out of the pulmonary capillaries and into the interstitial spaces and alveoli (Norris, 2019).

As a result of decreased cerebral oxygenation, the patient may become increasingly restless and anxious. Along with a sudden onset of breathlessness and a sense of suffocation, the patient may be tachypneic with low oxygen saturation levels. The skin and mucous membranes may be pale to cyanotic, and the hands may be cool and clammy. Tachycardia and JVD may be present. Incessant coughing may occur, producing increasing quantities of foamy sputum. The patient may become progressively confused. The situation demands emergent action before oxygenation and perfusion levels become critical.

Assessment and Diagnostic Findings

For many years, the severity of HF was classified solely according to the patient's symptoms, using the New York Heart Association (NYHA) classification of HF. This classification system, which is still in widespread use, is described in Table 25-1. The American College of Cardiology and the American Heart Association (ACC/AHA) have developed another HF classification system (Yancy et al., 2013). This system, described in Table 25-2, takes into consideration the natural history and progressive nature of HF.

The ACC/AHA periodically issues evidence-based guidelines for patients with HF or at high-risk of having HF, using this classification system as a framework for treatment (Yancy et al., 2013; Yancy, Jessup, Bozkurt, et al., 2016; Yancy et al., 2017).

HF may go undetected until the patient presents with signs and symptoms of pulmonary and peripheral edema. Some of the physical signs that suggest HF may also occur with other diseases, such as kidney injury and COPD; therefore, diagnostic testing is essential to confirm a diagnosis of HF.

Assessment of ventricular function is an essential part of the initial diagnostic workup. An echocardiogram is performed to determine the ejection fraction (EF), identify anatomic features such as structural abnormalities and valve malfunction, and confirm the diagnosis of HF. The **ejection fraction** is a measure of ventricular contractility; it is the percentage of the end-diastolic blood volume that is ejected with each heartbeat. An expected EF is 55% to 65% of the ventricular volume; the ventricle does not completely empty between contractions (Wiegand, 2017).

TABLE 25-1 New York Heart Association (NYHA) Classification of Heart Failure

Classification	Signs and Symptoms
I	No limitation of physical activity Ordinary activity does not cause undue fatigue, palpitation, or dyspnea.
II	Slight limitation of physical activity Comfortable at rest, but ordinary physical activity causes fatigue, palpitation, or dyspnea.
III	Marked limitation of physical activity Comfortable at rest, but less than ordinary activity causes fatigue, palpitation, or dyspnea.
IV	Unable to carry out any physical activity without discomfort Symptoms of cardiac insufficiency at rest If any physical activity is undertaken, discomfort is increased.

Adapted from Yancy, C. W., Jessup, M., Bozkurt, B., et al. (2013). 2013 ACCF/AHA Guideline for the management of heart failure. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation*, *128*(16), e240–e327.

There are two recognized main types of left-sided HF, with a third, emerging category. In **heart failure with reduced ejection fraction (HFrEF)**, or systolic heart failure, the left ventricle loses the ability to contract effectively, manifesting as EFs of less than 40%, reflecting decreased CO and pump failure (Yancy et al., 2017).

Heart failure with preserved ejection fraction (HFpEF), or diastolic heart failure, is diagnosed when the left ventricular function measures greater

than or equal to 50%, yet the ventricle loses its ability to relax due to myocardial stiffness. Because of the noncompliance of the ventricular wall, the chamber is unable to fill at normal capacity during the relaxation phase of diastole (Yancy et al., 2017).

Heart failure with midrange ejection fraction (HFmrEF) is a third and emerging classification category, with EFs typically between 40% and 49% (van der Meer et al., 2019).

Diagnosing a patient with HFpEF is more challenging than diagnosing a patient with HFrEF, because the diagnosis of HFpEF is a *diagnosis of exclusion.* That is, it is made by excluding other potential noncardiac causes suggestive of HF. The incidence of HFpEF is increasing and is becoming more commonplace among older adult women with a history of hypertension; indeed, hypertension is the most common underlying cause of HFpEF. Comorbid conditions such as obesity, CAD, diabetes, atrial fibrillation, and hyperlipidemia are also common in patients with HFpEF (Yancy et al., 2013).

In addition to the echocardiogram, a chest x-ray and a 12-lead electrocardiogram (ECG) are obtained to assist in the diagnosis. Laboratory studies usually performed during the initial workup include serum electrolytes, blood urea nitrogen (BUN), creatinine, liver function tests, thyroid-stimulating hormone, complete blood count (CBC), BNP, and routine urinalysis. The results of these laboratory studies assist in determining the underlying cause and can also be used to establish a baseline to assess effects of treatment. The BNP level is a key diagnostic indicator of HF; high levels are a sign of high cardiac filling pressure and can aid in both the diagnosis and management of HF; in particular, rising levels may suggest an acute exacerbation of HF (Yancy et al., 2013). BNP levels are best used for diagnostic purposes when there is a baseline measurement and a measurement obtained at the time of treatment (e.g., hospital discharge) to help in determining a posttreatment prognosis (Yancy et al., 2017).

TABLE 25-2 American College of Cardiology and American Heart Association (ACC/AHA) Classification of Heart Failure

Classification	Criteria	Patient Characteristics	Treatment Recommendations for Appropriate Patients
Stage A	Patients at high risk for developing left ventricular dysfunction but without structural heart disease or symptoms of HF	Hypertension Atherosclerotic disease Diabetes Metabolic syndrome	Heart healthy lifestyle Risk factor control of hypertension, lipids, diabetes, obesity
Stage B	Patients with left ventricular dysfunction or structural heart disease who have not developed symptoms of HF	History of myocardial infarction Left ventricular hypertrophy Low ejection fraction	Implement stage A recommendations, plus: • ACE inhibitor, or ARB, or ARNI for low EF or history of MI • Beta-blocker • Statin
Stage C	Patients with left ventricular dysfunction or structural heart disease with current or prior symptoms of heart disease	Shortness of breath Fatigue Decreased exercise tolerance	Implement stage A and B recommendations, plus: • Diuretics • Aldosterone antagonist • Sodium restriction • Implantable defibrillator • Cardiac resynchronization therapy
Stage D	Patients with refractory end-stage HF requiring specialized interventions	Symptoms despite maximal medical therapy Recurrent hospitalizations	Implement stage A, B, and C recommendations, plus: • Fluid restriction • End-of-life care • Extraordinary measures: • Inotropes • Cardiac transplantation • Mechanical support

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ARNI, angiotensin receptor-neprilysin inhibitor, EF, ejection fraction; HF, heart failure; MI, myocardial infarction.

Medical Management

The prognosis for patients with HF has improved with the use of evidence-based protocols for patient management. Specific interventions are based on the stage of HF (Yancy et al., 2013; Yancy et al., 2016; Yancy et al., 2017). The management goals of HF include the following (Cyrille & Patel, 2017):

- Improvement of cardiac function with optimal pharmacologic management
- Reduction of symptoms and improvement of functional status
- Stabilization of patient condition and lowering of the risk of hospitalization
- Delay of the progression of HF and extension of life expectancy
- Promotion of a lifestyle conducive to cardiac health

Treatment options vary according to the severity of the patient's condition, comorbidities, and cause of the HF, and may include oral and intravenous (IV) medications, lifestyle modifications, supplemental oxygen, and surgical interventions, including implantation of cardiac devices, and cardiac transplantation (see Chapter 24).

Managing the patient with HF begins with providing comprehensive education and counseling to the patient and family. The patient and family must understand the nature of HF and the importance of their participation in the treatment regimen, including side and adverse effects of pharmacologic therapies. Lifestyle recommendations include restriction of dietary sodium; avoidance of smoking, including secondhand smoke; avoidance of excessive fluid and alcohol intake; weight reduction when indicated; and regular exercise. The patient must also know how to recognize signs and symptoms that need to be reported to the primary provider.

Pharmacologic Therapy

Several types of medications are routinely prescribed for patients with HF. The cornerstone of therapy for patients with HFrEF (systolic HF), which is the most common type of HF, includes a diuretic, an angiotensin system blocker,

and a beta-blocker (Table 25-3). Many of these medications, particularly angiotensin system blockers and beta-blockers, improve symptoms and extend survival. Others, such as diuretics, improve symptoms but may not affect survival (Meyer, 2019b). The patient with HFpEF (diastolic HF) may be prescribed a diuretic, most commonly an aldosterone antagonist (see Table 25-3), and may also be prescribed an angiotensin system blocker and/or a beta-blocker and find symptomatic relief; however, these drugs are not necessarily associated with improved survival in those patients (Borlaug & Colucci, 2019). Target doses for these medications and alternative medications for treating heart failure are identified in the ACC/AHA guidelines. Nurses, primary providers, and pharmacists work collaboratively toward achieving effective dosing of these medications (Yancy et al., 2013; Yancy et al., 2016; Yancy et al., 2017).

TABLE 25-3 Select Medications Used to Treat Heart Failure

Medication	Therapeutic Effects	Key Nursing Considerations
Diuretics		
Loop diuretics: furosemide *Thiazide diuretics:* metolazone hydrochlorothiazide	↓ Fluid volume overload ↓ Signs and symptoms of HF	Observe for electrolyte abnormalities, renal dysfunction, diuretic resistance, and ↓ BP. Carefully monitor I&O and daily weight (see Chart 25-2).
Aldosterone antagonists: spironolactone	Improves HF symptoms in advanced HF	Observe for ↑ serum K^+, ↓ serum Na^+.
Angiotensin System Blockers		
ACE Inhibitors: lisinopril enalapril	↓ BP and ↓ afterload Relieves signs and symptoms of HF Prevents progression of HF	Observe for symptomatic ↓ BP, ↑ serum K^+, cough, and worsening renal function.
ARBs: valsartan losartan	↓ BP and ↓ afterload Relieves signs and symptoms of HF Prevents progression of HF	Observe for symptomatic ↓ BP, ↑ serum K^+, and worsening renal function.
ARNI: sacubitril-valsartan	↓ BP and ↓ afterload ↓ Fluid volume overload ↓ Signs and symptoms of HF Prevents progression of HF	Observe for symptomatic ↓ BP, ↑ serum K^+, cough, dizziness, and renal failure.
Beta-Adrenergic–Blocking Agents (Beta-Blockers)		
carvedilol bisoprolol metoprolol	Dilates blood vessels and ↓ afterload ↓ Signs and symptoms of HF Improves exercise capacity	Observe for ↓ heart rate, symptomatic ↓ BP, dizziness, and fatigue.
Ivabradine	Decreases rate of conduction through the SA node	Observe for ↓ heart rate, symptomatic ↓ BP, dizziness, and fatigue.
Hydralazine-isosorbide dinitrate	Dilates blood vessels ↓ BP and ↓ afterload	Observe for symptomatic ↓ BP.
Digitalis		
digoxin	Improves cardiac contractility ↓ Signs and symptoms of HF	Observe for ↓ heart rate and digitalis toxicity.

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ARNI, angiotensin receptor-neprilysin inhibitor; BP, blood pressure; ↓, decreases; HF, heart failure; ↑, increases; I&O, input and output; K^+, potassium; Na^+, sodium; SA, sinoatrial.

Diuretics

Diuretics are prescribed to remove excess extracellular fluid by increasing diuresis in patients with signs and symptoms of fluid overload. ACC/AHA guidelines advocate using the smallest dose of diuretic necessary to control fluid volume (Yancy et al., 2013). The type and dose of diuretic prescribed depend on clinical signs and symptoms and renal function. Careful patient monitoring and dose adjustments are necessary to balance the effectiveness of these medications with the side effects (Chart 25-2). Loop, thiazide, and aldosterone-blocking diuretics may be prescribed; these medications differ in their site of action in the kidney and their effects on renal electrolyte excretion and reabsorption.

Loop diuretics, such as furosemide, inhibit sodium and chloride reabsorption mainly in the ascending loop of Henle. Patients with HF and with severe volume overload are generally treated with a loop diuretic first (Burchum & Rosenthal, 2019). *Thiazide diuretics,* such as metolazone, inhibit sodium and chloride reabsorption in the early distal tubules. Both of these classes of diuretics increase potassium excretion; therefore, patients treated with these medications must have their serum potassium levels closely monitored. Diuretics can also lead to orthostatic hypotension and kidney injury. Both a loop and a thiazide diuretic may be used in patients with severe HF who are unresponsive to a single diuretic. The need for diuretics can be decreased if the patient avoids excessive fluid intake (e.g., more than 2000 mL/day) and adheres to a low sodium diet (e.g., no more than 2 g/day).

Aldosterone antagonists, such as spironolactone, are potassium-sparing diuretics that block the effects of aldosterone in the distal tubule and collecting duct (Yancy et al., 2016). As noted previously, they are frequently prescribed for patients with HFpEF. Serum creatinine and potassium levels are monitored frequently (e.g., within the first week and then every 4 weeks) when spironolactone is first given. These drugs are not prescribed for patients with an elevated serum creatinine.

Chart 25-2 **PHARMACOLOGY**

Administering and Monitoring Diuretic Therapy

When nursing care involves diuretic therapy for conditions such as heart failure, the nurse needs to administer the medication and monitor the patient's response carefully, as follows:

- Prior to administration of the diuretic, check laboratory results for electrolyte depletion, especially potassium, sodium, and magnesium.
- Prior to administration of the diuretic, check for signs and symptoms of volume depletion, such as orthostatic hypotension, lightheadedness, and dizziness.
- Administer the diuretic at a time conducive to the patient's lifestyle—for example, early in the day to avoid nocturia.
- Monitor urine output during the hours after administration, and analyze intake, output, and daily weights to assess response.
- Monitor blood pressure for orthostatic changes.
- Continue to monitor serum electrolytes for depletion. Replace potassium with increased oral intake of food rich in potassium or potassium supplements. Replace magnesium as needed.
- Monitor for hyperkalemia in patients receiving potassium-sparing diuretics.
- Continue to assess for signs of volume depletion.
- Monitor creatinine for increased levels indicative of diuretic-induced renal dysfunction.
- Monitor for elevated uric acid level and signs and symptoms of gout.
- Assess lungs sounds and edema to evaluate response to therapy.
- Monitor for adverse reactions such as arrhythmias.
- Assist patients to manage urinary frequency and urgency associated with diuretic therapy.

Adapted from Burchum, J. R., & Rosenthal, L. D. (2019). *Lehne's pharmacology for nursing care* (10th ed.). St. Louis, MO: Elsevier.

Loop diuretics are administered IV for exacerbations of HF when rapid diuresis is necessary, as when pulmonary edema is present (see later discussion). Diuretics improve the patient's symptoms, provided that renal function is adequate. As HF progresses, cardiorenal syndrome may develop or worsen. Cardiorenal syndrome is a type of prerenal acute kidney injury characterized by a disruption in adequate blood flow to the kidneys. Patients

with this syndrome are resistant to diuretics and may require other interventions to deal with congestive signs and symptoms.

Angiotensin System Blockers

Angiotensin system blockers include classes of medications such as the ACE inhibitors, angiotensin receptor blockers (ARBs), and angiotensin receptor-neprilysin inhibitors (ARNIs).

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors, such as lisinopril, have been found to relieve clinical manifestations of HF and significantly decrease mortality and morbidity in patients with HFrEF. Specifically, they slow the progression of HF, improve exercise tolerance, and decrease the number of hospitalizations in patients with HFrEF (Yancy et al., 2013; Yancy et al., 2017). ACE inhibitors are also appropriate for hypertension management in patients with HFpEF (Yancy et al., 2017). Available as oral and IV medications, ACE inhibitors promote vasodilation and diuresis, ultimately decreasing both afterload and preload. Vasodilation reduces resistance to left ventricular ejection of blood, diminishing the heart's workload and improving ventricular emptying. ACE inhibitors decrease the secretion of aldosterone, a hormone that causes the kidneys to retain sodium and water. ACE inhibitors also promote renal excretion of sodium and fluid (while retaining potassium), thereby reducing left ventricular filling pressure and decreasing pulmonary congestion. These agents are also recommended for prevention of HF in patients at risk due to vascular disease and diabetes (Yancy et al., 2013; Yancy et al., 2017).

Patients receiving ACE inhibitors are monitored for hypotension, hyperkalemia (increased potassium in the blood), and alterations in renal function, especially if they are also receiving diuretics. Because ACE inhibitors cause the kidneys to retain potassium, the patient who is also receiving a loop diuretic or a thiazide diuretic may not need to take oral potassium supplements. However, the patient receiving a potassium-sparing diuretic, such as an aldosterone antagonist, which does not cause potassium loss with diuresis, must be carefully monitored for hyperkalemia. ACE inhibitors may be discontinued if the potassium level remains greater than 5.5 mEq/L or if the serum creatinine rises.

An adverse effect of ACE inhibitors includes a dry, persistent cough that may not respond to cough suppressants due to the inhibition of the enzyme kininase, which inactivates bradykinin. The nurse should carefully assess any cough in a patient taking an ACE inhibitor, as this symptom can also indicate a worsening of ventricular function and failure. In less than 1% of patients, ACE inhibitors may cause an allergic reaction accompanied by angioedema. This reaction tends to occur more frequently in African Americans and women (Yancy et al., 2016; Yancy et al., 2017). If angioedema affects the

oropharyngeal area and impairs breathing, the ACE inhibitor must be stopped immediately and appropriate emergency care must be provided.

If the patient cannot continue taking an ACE inhibitor because of development of cough, an elevated creatinine level, or hyperkalemia, an ARB, an ARNI, or a combination of hydralazine and isosorbide dinitrate is prescribed (see Table 25-3).

Angiotensin Receptor Blockers

Whereas ACE inhibitors block the conversion of angiotensin I to angiotensin II, ARBs, such as valsartan, block the vasoconstricting effects of angiotensin II at the angiotensin II receptors. ARBs are commonly prescribed as an alternative to ACE inhibitors, as they are associated with reduced morbidity and mortality in patients with HFrEF and can provide symptomatic relief in patients with HFpEF who are intolerant of ACE inhibitors (Yancy et al., 2013; Yancy et al., 2017). ARBs do not inhibit kininase; therefore, ARBs are not associated with the bothersome cough that occurs with some patients prescribed an ACE inhibitor.

Angiotensin Receptor-Neprilysin Inhibitors

An ARNI combines an ARB with a neprilysin inhibitor. Neprilysin is an enzyme that breaks down natriuretic peptides. Participants with HFrEF enrolled in clinical trials who were prescribed an ARNI demonstrated a significant reduction in cardiovascular death or hospitalization as compared with participants prescribed an ACE inhibitor (Meyer, 2019b). Based on these findings, updated ACC/AHA guidelines advocate prescribing an ARNI as first-line angiotensin system blocker therapy for most patients with symptomatic HFrEF. However, an ARNI is reportedly a costlier option than most ACE inhibitors and ARBs, which may preclude its practical use. For patients unable to take an ARNI, an ACE inhibitor or ARB is a good alternative. An ARNI should not be administered concurrently or within 36 hours of an ACE inhibitor as concomitant dosing with both agents is associated with angioedema (Yancy et al., 2016; Yancy et al., 2017). Adverse effects associated with use of an ARNI are similar to those associated with ACE inhibitor or ARB use; therefore, the nurse should assess for hypotension, renal insufficiency, and angioedema in patients taking an ARNI (Yancy et al., 2016; Yancy et al., 2017). The first U.S. Food and Drug Administration (FDA) approved ARNI for use in patients with HF is sacubitril-valsartan.

Beta-Blockers

Beta-blockers block the adverse effects of the sympathetic nervous system. They relax blood vessels, lower blood pressure, decrease afterload, and decrease cardiac workload. Beta-blockers, such as carvedilol, have been found to improve functional status and reduce mortality and morbidity in patients with HF (Burchum & Rosenthal, 2019). In addition, beta-blockers have been

recommended for patients with asymptomatic HFrEF to prevent progression and the onset of symptoms of HF, even if patients do not have a history of MI. The therapeutic effects of these drugs may not be seen for several weeks or even months (Yancy et al., 2013, Yancy et al., 2017).

Beta-blockers can produce a number of side effects, including dizziness, hypotension, bradycardia, fatigue, and depression. Side effects are most common in the initial few weeks of treatment. Because of the potential for side effects, beta-blockers are started at a low dose. The dose is titrated up slowly (every few weeks), with close monitoring after each dosage increase. Nurses educate patients about potential symptoms during the early phase of treatment and stress that adjustment to the drug may take several weeks. Nurses must also provide support to patients going through this symptom-provoking phase of treatment. Because beta-blockade can cause bronchiole constriction, these drugs are used with caution in patients with a history of bronchospastic diseases such as asthma.

Ivabradine

Ivabradine is a new agent that is a hyperpolarization-activated cyclic nucleotide channel blocker. It is a medication with unique electrophysiologic effects, characterized by its negative chronotropic effect on the sinoatrial node, thereby decreasing the heart rate without targeting the neurohormonal system. It is indicated as an adjunct agent to beta-blockers in patients with symptomatic HFrEF and with high resting heart rates of at least 70 bpm (Koruth, Lala, Pinney, et al., 2017). It may also be beneficial for patients with HFrEF who cannot tolerate beta-blockers (Yancy et al., 2017). Adverse effects of ivabradine include bradycardia resulting in dizziness and fatigue; it is also associated with an increased risk of atrial fibrillation (Koruth et al., 2017).

Hydralazine and Isosorbide Dinitrate

A combination of hydralazine and isosorbide dinitrate may be an alternative medication for patients who cannot take any of the three angiotensin system blockers (i.e., ACE inhibitor, ARB, and ARNI), so long as the patient's systolic BP is at least 90 mm Hg. Nitrates (e.g., isosorbide dinitrate) cause venous dilation, which reduces the amount of blood return to the heart and lowers preload. Hydralazine lowers systemic vascular resistance and left ventricular afterload. Hydralazine-isosorbide dinitrate is associated with decreased hospitalizations and improved survival in patients with HFrEF; however, these improvements are not as robust as those associated with angiotensin system blockers (Meyer, 2019b; Yancy et al., 2017). Adverse effects may include hypotension, and rarely, a lupus-type reaction (Meyer, 2019b).

Digitalis

For many years, digitalis (i.e., digoxin) was considered an essential agent for the treatment of HF. With the introduction of newer medications, it is not prescribed as often. Digoxin increases the force of myocardial contraction and slows conduction through the atrioventricular node. It improves contractility, increasing left ventricular output. Although the use of digoxin does not result in decreased mortality rates among patients with HFrEF, it can be effective in decreasing the symptoms of HF and may help prevent hospitalization (Yancy et al., 2013). Patients with renal dysfunction and older patients should receive smaller doses of digoxin, as it is excreted through the kidneys.

A key concern associated with digoxin therapy is digitalis toxicity. Clinical manifestations of toxicity include anorexia, nausea, visual disturbances, confusion, and bradycardia. The serum potassium level is monitored because the effect of digoxin is enhanced in the presence of hypokalemia and digoxin toxicity may occur. A serum digoxin level is obtained if the patient's renal function changes or there are symptoms of toxicity.

Intravenous Infusions

IV inotropes (e.g., dopamine, dobutamine, milrinone) increase the force of myocardial contraction; as such, they may be indicated for hospitalized patients with pulmonary edema (i.e., acute decompensated HF). These agents are used for patients who do not respond to routine pharmacologic therapy and are reserved for patients with severe ventricular dysfunction, low blood pressure, or impaired perfusion and evidence of significantly depressed CO, with or without congestion. They are used with caution, as some studies have associated their use with increased mortality (Malotte, Saguros, & Groninger, 2018; Yancy et al., 2013). Patients usually require admission to the intensive care unit (ICU) and may also have hemodynamic monitoring with a pulmonary artery catheter or alternative technology (see Chapter 21). Hemodynamic data are used to assess cardiac function and volume status and to guide therapy with inotropes, vasodilators, and diuretics (Urden, Stacy, & Lough, 2018). Patients with end-stage HF who cannot be weaned from IV inotropes may be candidates for continuous therapy at home (Malotte et al., 2018).

Dopamine

Dopamine is a vasopressor given to increase BP and myocardial contractility. Given at low doses, a dopamine infusion may be helpful as an adjunct therapy along with loop diuretics in improving diuresis, preserving renal function, and improving renal blood flow (Yancy et al., 2013).

Dobutamine

Dobutamine is given to patients with significant left ventricular dysfunction and hypoperfusion. A catecholamine, dobutamine stimulates the beta-1 adrenergic receptors. Its major action is to increase cardiac contractility and

renal perfusion to enhance urine output. However, it also increases the heart rate and can precipitate ectopic beats and tachyarrhythmias (Burchum & Rosenthal, 2019).

Milrinone

Milrinone is a phosphodiesterase inhibitor that leads to an increase in intracellular calcium within myocardial cells, increasing their contractility (Ayres & Maani, 2019). This agent also promotes vasodilation, resulting in decreased preload and afterload and reduced cardiac workload. Milrinone is administered IV to patients with severe HF, including patients who are waiting for heart transplantation (see Chapter 24). Because the drug causes vasodilation, the patient's blood pressure is monitored prior to administration; if the patient is hypovolemic, the blood pressure could drop quickly. The major side effects are hypotension and increased ventricular arrhythmias. Blood pressure and ECG are monitored closely during and following infusions of milrinone.

Vasodilators

Intravenous vasodilators such as IV nitroglycerin, nitroprusside, or nesiritide may enhance symptom relief for acutely decompensated HF (Yancy et al., 2013). Their use is contraindicated in patients who are hypotensive. Blood pressure is continually assessed in patients receiving IV vasodilator infusions.

Adjunct Medications for Heart Failure

The importance of ensuring that patients with hypertension take prescribed antihypertensive agents as prescribed is of paramount importance (see Chapter 27 for further discussion of antihypertensive medications). Target blood pressures should be less than 130/80 mm Hg. Maintaining BPs at these levels is associated with reduced likelihood of morbid progression to symptomatic HF in patients who are asymptomatic. It is also associated with improved morbidity in patients who are symptomatic with both HFrEF and HFpEF (Yancy et al., 2017).

Anemia is independently associated with HF disease severity, and iron deficiency appears to be uniquely associated with reduced exercise capacity. IV iron repletion in patients with HF may improve functional capacity and quality of life; however, there is mixed evidence to support the use of oral iron supplementation. Erythropoietin-stimulating agents, such as darbepoetin alfa, are not recommended in patients with both HF and anemia as a risk of thromboembolic events associated with their use has been observed during clinical trials (Yancy et al., 2017).

Anticoagulants may be prescribed, especially if the patient has a history of atrial fibrillation or a thromboembolic event. Antiarrhythmic drugs such as amiodarone may be prescribed for patients with arrhythmias, along with an evaluation for device therapy with an implantable cardioverter defibrillator

(ICD) (see Chapter 22). Medications to manage hyperlipidemia (e.g., statins) are also routinely prescribed, in tandem with guidance on nutritional therapy (see following section). It is recommended that patients with HF avoid nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen because the risk of decreased renal perfusion is higher, especially in older adults (Schwartz, Schmader, Hanlon, et al., 2018).

Adjunct Therapies for Heart Failure

Additional therapies that may be indicated in the treatment of patients with HF include nutritional therapy, supplemental oxygen, management of sleep disorders, and procedural or surgical interventions.

Nutritional Therapy

Following a low sodium (no more than 2 g/day) diet and avoiding excessive fluid intake are usually recommended, although studies differ regarding the effectiveness of sodium restriction (Yancy et al., 2013). Decreasing dietary sodium reduces fluid retention and the symptoms of peripheral and pulmonary congestion. The purpose of sodium restriction is to decrease the amount of circulating blood volume, which decreases myocardial work. A balance should be achieved between the patient's ability to adhere to the diet and the recommended guidelines.

Nutritional supplements, such as vitamins and antioxidants, are not recommended for patients with HF as no benefits are associated with their use. Omega-3 polyunsaturated fatty acid (PUFA) supplementation is associated with decreased fatal cardiovascular events and is recommended for patients with either HFrEF or HFpEF, unless contraindicated (Yancy et al., 2013).

Any change in eating patterns should consider good nutrition as well as the patient's likes, dislikes, and cultural food patterns. Patient adherence is important because dietary indiscretions may result in exacerbations of HF symptoms. However, behavioral changes in eating patterns are difficult for many patients to achieve.

Supplemental Oxygen

Oxygen therapy may become necessary as HF progresses based on the degree of pulmonary congestion and resulting hypoxia. Some patients require supplemental oxygen only during periods of activity (see Chapter 20 for further discussion of oxygen delivery systems).

Management of Sleep Disorders

Sleep disorders, including sleep apnea, are common in patients with HF. It is estimated that 61% of patients with HF have either central or obstructive sleep apnea (OSA). A formal sleep study should be performed. Continuous positive

airway pressure (CPAP) might be recommended if results from the sleep study suggest OSA (see Chapter 18). CPAP has been shown to improve sleep quality, reduce apneic episodes and excessive daytime sleepiness, and improve nocturnal oxygenation in patients with OSA and HF (Yancy et al., 2017).

Procedural and Surgical Interventions

A number of procedures and surgical approaches may benefit patients with HF. If the patient has underlying CAD, coronary artery revascularization with PCI or coronary artery bypass surgery (see Chapter 23) may be considered. Ventricular function may improve in some patients when coronary flow is increased.

Patients with HF are at high risk for arrhythmias, and sudden cardiac death is common among patients with advanced HF. In patients with severe left ventricular dysfunction and the possibility of life-threatening arrhythmias, placement of an ICD can prevent sudden cardiac death and extend survival (see Chapter 22). Candidates for an ICD include those with an EF less than 35%, including those with and without a history of ventricular arrhythmias (Yancy et al., 2013).

Patients with HF who do not improve with standard therapy may benefit from **cardiac resynchronization therapy (CRT)**. CRT involves the use of a biventricular pacemaker to treat electrical conduction defects and to synchronize ventricular contractions. A prolonged QRS duration on ECG indicates left bundle branch block, which is a type of delayed conduction that is frequently seen in patients with HF. This problem results in asynchronous conduction and contraction of the right and left ventricles, which can further decrease EF (Yancy et al., 2013). The use of a pacing device with leads placed in the right atrium, right ventricle, and left ventricular cardiac vein can synchronize the contractions of the right and left ventricles (Fig. 25-3). This intervention improves CO, optimizes myocardial energy consumption, reduces mitral regurgitation, and slows the ventricular remodeling process. For patients with a CRT, improvement of left ventricular EF is associated with reduced rates of ventricular arrhythmias. There are combination devices available for patients who require CRT and an ICD (Gulati & Udelson, 2018). See Chapter 22 for further discussion of care of patients with pacemakers, CRT, and ICDs.

Ultrafiltration is an alternative intervention for patients with severe fluid overload. It is reserved for patients with advanced HF who are resistant to diuretic therapy (Yancy et al., 2013). A dual-lumen central IV catheter is placed, and the patient's blood is circulated through a small bedside filtration machine. Liters of excess fluid and plasma are removed slowly from the patient's intravascular circulating volume over a number of hours. The patient's output of filtration fluid, blood pressure, and hemoglobin (analyzed for hemoconcentration) are monitored as indicators of volume status. Research

on ultrafiltration is ongoing, and targets comparisons of its efficacy to diuretics and the optimal fluid removal target (Costanzo, 2019).

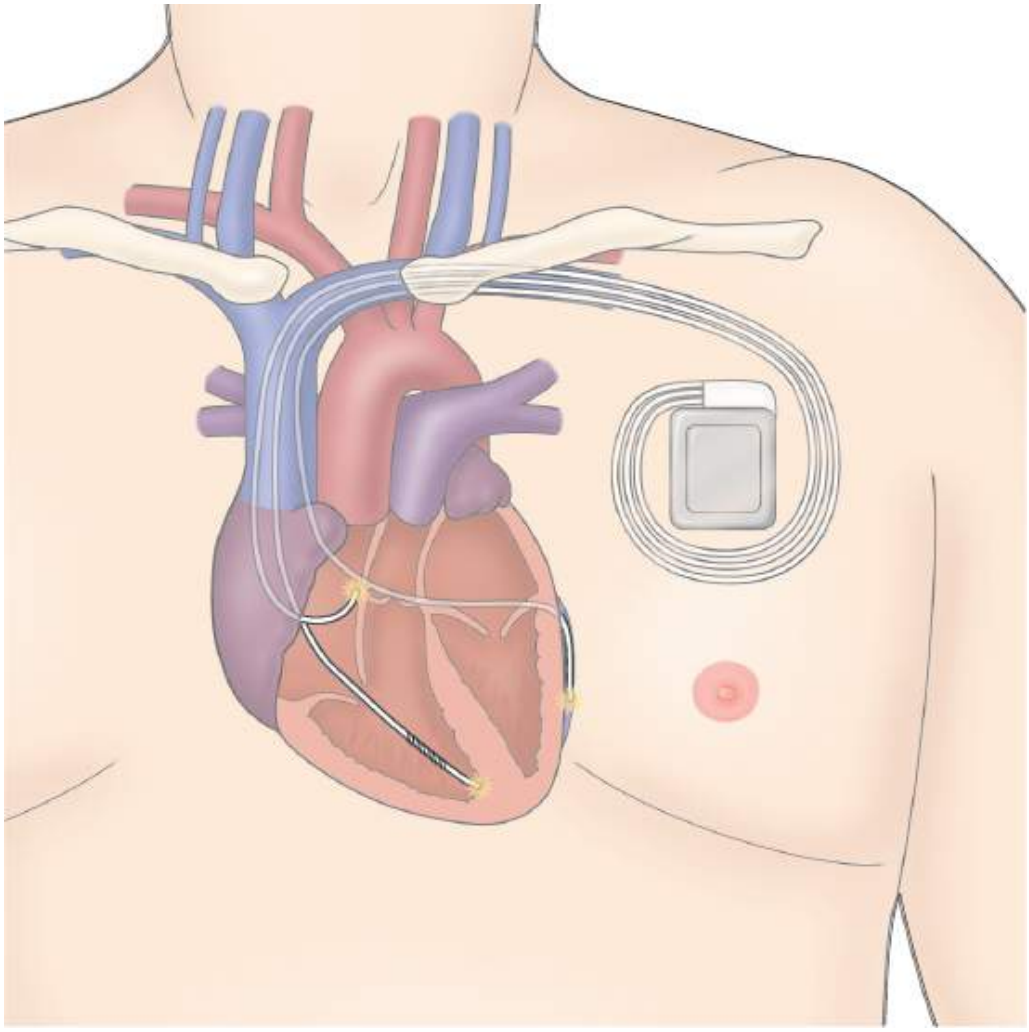

Figure 25-3 • Cardiac resynchronization therapy. To pace both ventricles, pacemaker leads are placed in the right atrium and right ventricle; a third lead is threaded through the coronary sinus into a lateral vein on the wall of the left ventricle.

For some patients with end-stage HF, cardiac transplantation is one of the few options for long-term survival. Patients with ACC/AHA stage D HF who may be eligible are referred for consideration of transplantation. Some of these patients require mechanical circulatory assistance with an implanted ventricular assist device as a bridge therapy to cardiac transplantation. A left ventricular assist device may also be implanted as *destination therapy* (permanent therapy) for select patients (Yancy et al., 2013).

Gerontologic Considerations

Several normal age-related changes increase the frequency of HF: increased systolic blood pressure, increased ventricular wall thickness, and increased myocardial fibrosis. There are a number of reasons that older adults may need to be hospitalized with HF (Albert, Barnason, Deswal, et al., 2015). Older adults may not always detect or accurately interpret common symptoms of HF such as shortness of breath, or they may have atypical symptoms such as weakness and somnolence. Decreased renal function can make the older patient resistant to diuretics and more sensitive to changes in volume. The administration of diuretics to older men requires nursing surveillance for bladder distention caused by urethral obstruction from an enlarged prostate gland. The bladder may be assessed with an ultrasound scanner or the suprapubic area palpated for an oval mass and percussed for dullness, indicative of bladder fullness. Urinary frequency and urgency may be particularly stressful to older patients, as many have arthritis and limited mobility.

NURSING PROCESS

The Patient with Heart Failure

Despite advances in treatment of HF, morbidity and mortality remain high. Nurses have a major impact on outcomes for patients with HF, especially in the areas of patient education and monitoring.

Assessment

Nursing assessment for the patient with HF focuses on observing for effectiveness of therapy and for the patient's ability to understand and implement self-care management strategies. Signs and symptoms of worsening HF are analyzed and reported to the patient's provider so that therapy can be adjusted. The nurse also explores the patient's emotional response to the diagnosis of HF, because it is a chronic and often progressive condition that is commonly associated with depression and other psychosocial issues (Jiang, Shorey, Seah, et al., 2018).

Health History

The health history focuses on the signs and symptoms of HF, such as dyspnea, fatigue, and edema. Sleep disturbances, particularly sleep suddenly interrupted by shortness of breath, may be reported. Patients are asked about the number of pillows needed for sleep, edema, abdominal symptoms, altered mental status, activities of daily living, and the activities that cause fatigue. Nurses need to be aware of the variety of clinical manifestations that may indicate worsening HF and assess the patient accordingly. While obtaining the patient's history, the nurse assesses the patient's understanding of HF, self-care management strategies, and the patient's ability and willingness to adhere to those strategies.

Physical Examination

The patient is observed for restlessness and anxiety that might suggest hypoxia from pulmonary congestion. The patient's level of consciousness is also evaluated for any changes, as low CO can decrease the flow of oxygen to the brain.

The rate and depth of respirations are assessed along with the effort required for breathing. The lungs are auscultated to detect crackles and wheezes (Meyer, 2019a). Crackles are produced by the sudden opening of edematous narrowed airways and alveoli. They may be heard at the end of inspiration and are not cleared with coughing. Wheezing may also be heard in some patients who have bronchospasm along with pulmonary congestion.

The blood pressure is carefully evaluated, because patients with HF may present with hypotension or hypertension. Patients may be assessed for

orthostatic hypotension, especially if they report lightheadedness, dizziness, or syncope. The heart is auscultated for an S_3 heart sound, which is an early sign that increased blood volume fills the ventricle with each beat. Heart rate and rhythm are also documented, and patients are often placed on continuous ECG monitoring in the hospital setting. When the heart rate is rapid or very slow, the CO decreases and potentially worsens the HF. JVD is assessed with the patient sitting at a 45-degree angle; distention greater than 4 cm above the sternal angle is considered abnormal and indicative of right ventricular failure (Bickley, 2017). This is an estimate, not a precise measurement, of high central venous pressure.

The nurse assesses peripheral pulses and rates their volume on a scale from 0 (not palpable) to 3+ (bounding). The skin is also assessed for color and temperature. With significant decreases in SV, there is a decrease in perfusion to the periphery, decreasing the volume of pulses and causing the skin to feel cool and appear pale or cyanotic. The feet and lower legs are examined for edema; if the patient is supine in bed, the sacrum and back are also assessed for edema. The upper extremities may also become edematous in some patients. Edema is typically rated on a scale from 0 (no edema) to 4+ (severe pitting edema).

The abdomen is examined for tenderness and hepatomegaly. The presence of firmness, distention, and possible ascites is noted. The liver may be assessed for hepatojugular reflux. The patient is asked to breathe normally while manual pressure is applied over the right upper quadrant of the abdomen for 30–60 s. If neck vein distention increases more than 1 cm, the finding is positive for increased venous pressure.

If the patient is hospitalized, the nurse measures urinary output and evaluates it in terms of diuretic use. Intake and output records are rigorously maintained and analyzed. It is important to track whether the patient has excreted excessive volume (i.e., negative fluid balance is generally the goal). The intake and output is then compared with changes in weight. Although diuresis is expected, the patient with HF must also be monitored for **oliguria** (diminished urine output, less than 0.5 mL/kg/h for at least 6 h or <400 mL/24 h) or **anuria** (urine output of less than 50 mL/24 h) because of the risk of renal dysfunction.

The patient is weighed daily in the hospital or at home, at the same time of day, with the same type of clothing, and on the same scale. If there is a significant change in weight (i.e., 2–3-lb increase in a day or 5-lb increase in a wk), the primary provider is notified and medications are adjusted (e.g., the diuretic dose is increased).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Activity intolerance associated with decreased CO
- Hypervolaemia associated with the HF syndrome
- Anxiety associated with clinical manifestations of HF
- Powerlessness associated with chronic illness and hospitalizations
- Impaired family ability to manage regime

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Pulmonary edema
- Hypotension, poor perfusion, and cardiogenic shock (see Chapter 11)
- Arrhythmias (see Chapter 22)
- Thromboembolism (see Chapter 26)
- Pericardial effusion (see later discussion in this chapter)

Planning and Goals

Major goals for the patient may include promoting activity and reducing fatigue, relieving fluid overload symptoms, decreasing anxiety or increasing the patient's ability to manage anxiety, encouraging the patient to verbalize their ability to make decisions and influence outcomes, and educating the patient and family about health management.

Nursing Interventions

Nursing interventions revolve around promoting the patient's activity tolerance, managing the patient's fluid volume status, assisting the patient so that anxiety is relieved, helping to minimize any feelings of powerlessness that the patient might experience, and assisting the patient and family members to effectively manage the patient's health. In addition, nursing interventions must be attuned to prevent and manage acute complications that can be experienced by patients with HF.

Promoting Activity Tolerance

Reduced physical activity caused by HF symptoms leads to physical deconditioning that worsens the patient's symptoms and exercise tolerance. Prolonged inactivity, which may be self-imposed, should be avoided because of its deconditioning effects and risks, such as pressure injuries (especially in edematous patients) and venous thromboembolism. An acute illness that exacerbates HF symptoms or requires hospitalization may be an indication for temporary bed rest. Otherwise, some type of physical activity every day should be encouraged. A typical program for a patient with HF might include a daily walking regimen, with the duration increased over a 6-wk period. The primary provider, nurse, and patient collaborate to

develop a schedule that promotes pacing and prioritization of activities. The schedule should alternate activities with periods of rest and avoid having two significant energy-consuming activities occur on the same day or in immediate succession. Before undertaking physical activity, the patient should be given guidelines similar to those noted in Chart 25-3. Because some patients may be severely debilitated, they may need to limit physical activities to only 3–5 min at a time, one to four times per day. The patient should increase the duration of the activity, then the frequency, before increasing the intensity of the activity (Piña, 2019).

Chart 25-3 HEALTH PROMOTION

An Exercise Program for Patients with Heart Failure

Before undertaking physical activity, the patient should be given the following guidelines:

- Talk with your primary provider for specific exercise program recommendations.
- Begin with low-impact activities such as walking.
- Start with warm-up activity followed by sessions that gradually build up to about 30 min.
- Follow your exercise period with cool-down activities.
- Avoid performing physical activities outside in extreme hot, cold, or humid weather.
- Wait 2 h after eating a meal before performing the physical activity.
- Ensure that you are able to talk during the physical activity; if you cannot do so, decrease the intensity of activity.
- Stop the activity if severe shortness of breath, pain, or dizziness develops.

Adapted from Piña, I. L. (2019). Cardiac rehabilitation in patients with heart failure. *UpToDate*. Retrieved on 9/11/2019 at: www.uptodate.com/contents/cardiac-rehabilitation-in-patients-with-heart-failure

Barriers to performing activities are identified, and methods of adjusting an activity are discussed. For example, vegetables can be chopped or peeled while sitting at the kitchen table rather than standing at the kitchen counter. Small, frequent meals decrease the amount of energy needed for digestion while providing adequate nutrition. The nurse helps the patient identify peak and low periods of energy, planning energy-consuming activities for peak periods. For example, the patient may prepare the meals for the entire day in the morning. Pacing and prioritizing activities help maintain the patient's energy to promote participation in regular physical activity.

The patient's response to activities needs to be monitored. If the patient is hospitalized, vital signs and oxygen saturation levels are monitored before, during, and immediately after an activity to identify whether they are within the desired range. Heart rate should return to baseline within 3 min following the activity. If the patient is at home, the degree of fatigue felt after the activity can be used to assess the response. If the patient tolerates the activity, short- and long-term goals can be developed to gradually increase the intensity, duration, and frequency of activity.

Adherence to exercise training is essential if the patient is to benefit from it, but it may be difficult for patients with other comorbid conditions (e.g., arthritis, anemia, cardiomyopathy, obesity, chronic kidney disease, chronic obstructive pulmonary disease) and those who have had HF for a longer time (Cattadori, Segurini, Picozzi, et al., 2018). Referral to a cardiac rehabilitation program may be indicated, especially for patients newly diagnosed with HF (Piña, 2019). A supervised program may also benefit those who need a structured environment, significant educational support, regular encouragement, and interpersonal contact.

Managing Fluid Volume

Patients with severe HF may receive IV diuretic therapy; however, patients with less severe symptoms are typically prescribed oral diuretics. Oral diuretics should be given early in the morning so that diuresis does not interfere with the patient's nighttime rest. Discussing the timing of medication administration is especially important for older patients who may have urinary urgency or incontinence. A single dose of a diuretic may cause the patient to excrete a large volume of fluid shortly after its administration.

The patient's fluid status is monitored closely by auscultating the lungs, monitoring daily body weight, and assisting the patient to adhere to a low sodium diet by reading food labels and avoiding high sodium foods such as canned, processed, and convenience foods (Chart 25-4). Weight gain in a patient with HF almost always reflects fluid retention. If the diet includes fluid restriction, the nurse can assist the patient to plan fluid intake throughout the day while respecting the patient's dietary preferences. If the patient is receiving IV fluids and medications, the amount of fluid needs to be monitored closely, and the primary provider or pharmacist can be consulted about the possibility of maximizing the amount of medication in the same volume of IV fluid (e.g., double concentrating to decrease the fluid volume given).

The patient is positioned or taught how to assume a position that facilitates breathing. The number of pillows may be increased, the head of the bed may be elevated, or the patient may sit in a recliner. In these positions, the venous return to the heart (preload) is reduced, pulmonary congestion is reduced, and pressure on the diaphragm is minimized. The

lower arms can be supported with pillows to eliminate the fatigue caused by the pull of the patient's weight on the shoulder muscles. If the patient is experiencing acute decompensation, positioning them upright, preferably with the legs dangling over the side of the bed, has the immediate effect of decreasing venous return, decreasing right ventricular stroke volume, and decreasing lung congestion.

Chart 25-4 HEALTH PROMOTION

Facts About Dietary Sodium

Although the major source of sodium in the average American diet is salt, many types of natural foods contain varying amounts of sodium. Even if no salt is added in cooking and if salty foods are avoided, the daily diet will still contain about 2000 mg of sodium. Fresh fruits and vegetables are low in sodium and should be encouraged.

Additives in Food

In general, food prepared at home is lower in sodium than restaurant or processed foods. Added food substances (additives), such as sodium alginate, which improves food texture, sodium benzoate, which acts as a preservative, and disodium phosphate, which improves cooking quality in certain foods, increase the sodium intake when included in the daily diet. Therefore, patients on low sodium diets should be advised to check labels carefully for words such as “salt” or “sodium,” especially on canned foods. For example, without looking at the sodium content per serving found on the nutrition labels, when given a choice between a serving of potato chips and a cup of canned cream of mushroom soup, most would think that soup is lower in sodium. However, when the labels are examined, the lower sodium choice is found to be the chips. Although potato chips are *not* recommended in a low sodium diet, this example illustrates that it is important to read food labels to determine both sodium content and serving size.

Nonfood Sodium Sources

Sodium is contained in municipal water. Water softeners also increase the sodium content of drinking water. Patients on sodium-restricted diets should be cautioned against using nonprescription medications such as antacids, cough syrups, and laxatives. Salt substitutes may be allowed, but it is recognized that they are high in potassium. Over-the-counter medications should not be used without first consulting the patient’s primary provider.

Promoting Dietary Adherence

If patients find food unpalatable because of the dietary sodium restrictions and/or the taste disturbances caused by the medications, they may refuse to eat or to follow the dietary regimen. For this reason, severe sodium restrictions should be avoided, and diuretic medication should be balanced with the patient’s ability to restrict dietary sodium. A variety of flavorings, such as lemon juice, vinegar, and herbs, may be used to improve the taste of the food and facilitate acceptance of the diet. It is important to consider the patient’s food preferences. Diet counseling and educational handouts can be geared toward a patient–family-centered approach and with cultural practices considered.

Adapted from American Heart Association (AHA). (2016). Shaking the salt habit. Retrieved on 10/24/2019 at: www.heart.org/HEARTORG/Conditions/HighBloodPressure/PreventionTreatmentofHighBloodPressure/Shaking-the-Salt-Habit_UCM_303241_Article.jsp#.Vzy9eNe3BK8

Because decreased circulation in edematous areas increases the risk of pressure injuries, the nurse assesses for skin breakdown and institutes preventive measures. Positioning to avoid pressure and frequent changes of position help prevent pressure injuries.

Controlling Anxiety

Patients with HF may exhibit signs and symptoms of anxiety. In addition to psychosocial sources of anxiety, the physiologic compensatory mechanisms include activation of neurohormones including catecholamines. Complex medical interventions, such as implantation of an ICD can provoke anxiety in patients and families. These sources of anxiety include living with the threat of shocks, role changes, and concerns about the patient's ability to carry out activities of daily living. The patient's anxiety may intensify at night and interfere with sleep. Emotional stress further stimulates the sympathetic nervous system, causing vasoconstriction, elevated arterial pressure, and increased heart rate. This sympathetic response increases cardiac workload.

When the patient exhibits anxiety, the nurse takes steps to promote physical comfort and provide psychological support. As mentioned previously, the patient may be more comfortable sitting in a recliner. Oxygen may be given during an acute event to diminish the work of breathing and increase the patient's comfort. In many cases, a family member's presence provides reassurance. Patients with HF rely on their families for many aspects of care; therefore, nurses should assess the needs of family caregivers and provide support to them (Hodson, Peacock, & Holtslander, 2019).

Along with reassurance, the nurse can begin educating the patient and family about techniques for controlling anxiety and avoiding anxiety-provoking situations. This includes how to identify factors that contribute to anxiety and how to use relaxation techniques to control anxious feelings. As the patient's anxiety decreases, cardiac function may improve and symptoms of HF may decrease.

Quality and Safety Nursing Alert

When patients with HF are delirious, confused, or anxious, restraints should be avoided. Restraints are likely to be resisted, and resistance inevitably increases the cardiac workload.

Minimizing Powerlessness

Patients with HF may feel overwhelmed with their diagnosis and treatment regimen, leading to feelings of powerlessness. Contributing factors may include lack of knowledge and lack of opportunity to make decisions, particularly if health care providers or family members do not encourage the patient to participate in the treatment decision-making process.

Nurses should help patients recognize their choices, and that they can positively influence the outcomes of their diagnosis and treatment. Taking time to listen actively to patients encourages them to express their concerns and ask questions. Other strategies include providing the patient with decision making opportunities, such as when activities are to occur, or encouraging food and fluid choices consistent with the dietary restrictions. Encouragement is provided, progress is identified, and the patient is assisted to differentiate between factors that can and cannot be controlled.

In addition to feelings of powerlessness, patients with HF have a high incidence of depressive symptoms, which are associated with increased morbidity and mortality (Jiang et al., 2018). Because depressive symptoms are known to increase as the disease worsens, patients with HF need to be screened for depression so that it can be treated, hopefully maintaining the patient's functional status and quality of life.

Assisting Patients and Families to Effectively Manage Health

Therapeutic regimens for HF are complex and require the patient and family to make significant lifestyle changes. An inability or unwillingness to adhere to dietary and pharmacologic recommendations can lead to episodes of acute decompensated HF and hospitalization. Nonadherence with prescribed diet and fluid restrictions and medications cause many hospital readmissions. Nursing research findings suggest that for some patients with HF who are taking more than one medication daily, the decision to not take HF medications as prescribed may actually reflect their efforts to best manage their personal health, and, therefore, may be a self-care strategy (see the Nursing Research Profile in Chart 25-5) (Meraz, 2020).

Nurses have a key role in managing episodes of acute decompensated HF and in developing a comprehensive education and discharge plan to prevent hospital readmissions and increase the patient's quality of life. Because of the high cost of hospitalization for HF, the Centers for Medicare & Medicaid Services (CMS) initiated a program that reduces reimbursement to hospitals with a high 30-d readmission rate (U.S. Department of Health and Human Services [HHS], 2019). Research continues to identify the most effective interventions that may decrease these rates. A number of evidence-based components are known to increase the effectiveness of a discharge plan for patients with HF, including providing them with comprehensive, patient-centered instructions,

scheduling follow-up visits with their primary providers within 7 d of discharge, and following up by telephone within 3 d of discharge (Yancy et al., 2013; Yancy et al., 2016; Yancy et al., 2017).

Monitoring and Managing Potential Complications

Because HF is a complex and progressive condition, patients are at risk for many complications, including acute decompensated HF and pulmonary edema; hypotension and cardiogenic shock (see Chapter 11); arrhythmias (see Chapter 22); thromboembolism formation (see Chapter 26); and pericardial effusion (see later discussion).

Pulmonary Edema. As described previously, pulmonary edema is associated with acute decompensated HF that can lead to acute respiratory failure and death. If it is recognized early, pulmonary edema may be alleviated by increasing dosages of diuretics and by implementing other interventions to decrease preload. For instance, placing the patient in an upright position with the feet and legs dependent reduces left ventricular workload. The treatment regimen and the patient's understanding of and adherence to it are assessed. The long-range approach for preventing pulmonary edema must be directed at identifying and managing its precipitating factors.

Chart 25-5 **NURSING RESEARCH PROFILE**

Medication Nonadherence or Self-Care?

Meraz, R. (2020). Medication nonadherence or self-care? Understanding the medication decision-making process and experiences of older adults with heart failure. *Journal of Cardiovascular Nursing, 35*(1), 26–34.

Purpose

It is estimated that over half of patients with heart failure do not take their medications as prescribed. The reasons why many patients with heart failure do not adhere to their prescribed medication regimen are elusive, particularly since nonadherence is associated with hospitalization and emergency department visits. Therefore, the purpose of this study was to discover why patients with heart failure might not take their heart failure medications as prescribed.

Design

This was a qualitative study that used narrative inquiry and storytelling to discover why community dwelling patients with heart failure might not adhere to their medication regimen. Eleven participants, all 65 y of age or older, volunteered to be interviewed. Each of these participants had to live independently in the community setting, had to take at least two medications daily to treat heart failure, and had to self-administer these medications in order to be eligible to participate in this study.

Findings

Results from participant interviews found that patients' nonadherence with the prescribed medication regimen was deliberate, and not because of forgetfulness. In all reported instances, it was not contingent upon financial constraints, either. Some participants stopped taking a medication while others adjusted the dosages. Participants' deliberate decisions to adjust their medication regimen tended to be made based on the belief that they knew their own bodies and needs best, and felt that they were best equipped to take care of their own needs. Others noted that at times it was too difficult to get in contact with their primary providers or nurses, and that their primary providers or nurses were too busy to discuss their medication regimen with them. Most noted that they researched online their medications' effects and felt competent to manage their medication dosage without necessarily consulting their providers. Paradoxically, participants did not view their decisions to self-adjust their prescribed medication regimens as consonant with nonadherence.

Nursing Implications

Patients with heart failure who are prescribed multiple medications to treat their heart failure may not view self-adjustment of their prescriptions as tantamount to nonadherence. It seems likely that these self-

care/nonadherent practices place these patients at risk for hospitalization and morbid complications. Participants in this study noted that one key reason that they self-adjusted their medications was because their primary providers and nurses were “too busy” to talk to them about their medications. Nurses are in an ideal position to talk to patients with heart failure about their prescriptions, discover their concerns about their medications, help them find ways to problem-solve and manage side effects, and help them proactively engage in self-care so that they avoid hospitalization.

Clinical management of a patient with acute pulmonary edema due to left ventricular failure is directed toward reducing volume overload, improving ventricular function, and increasing oxygenation. These goals are accomplished through a combination of oxygen and ventilatory support, IV medication, and nursing assessment and interventions.

The patient’s airway and breathing are assessed to determine the severity of respiratory distress, along with vital signs. The patient is placed on pulse oximetry, a cardiac monitor, and IV access is confirmed or established for administration of medications. Laboratory tests are obtained, including arterial blood gases, electrolytes, BUN, and creatinine; other laboratory tests that may be indicated include a complete blood cell count (CBC), BNP, or a serum troponin-I. A chest x-ray or an ultrasound of the lungs may be obtained to confirm the extent of pulmonary edema (Meyer, 2019a).

Oxygen is given in concentrations adequate to relieve hypoxemia and dyspnea; a non-rebreathing mask may be used initially. If respiratory failure is severe or persists, noninvasive positive-pressure ventilation is the preferred mode of assisted ventilation (Colucci, 2019). For some patients, endotracheal (ET) intubation and mechanical ventilation are required. The ventilator can provide positive end-expiratory pressure (PEEP), which is effective in reducing venous return, decreasing fluid movement from the pulmonary capillaries to the alveoli, and improving oxygenation (see Chapter 19). Oxygenation is monitored by pulse oximetry and by measurement of arterial blood gases.

The patient who is experiencing pulmonary edema is likely going to be highly anxious, as are the patient’s family members. As the ability to breathe decreases, the patient’s fear and anxiety rise proportionately, making the condition more severe. Reassuring the patient and family and providing skillful anticipatory nursing care are integral parts of the therapy. Because the patient is in an unstable condition, the nurse must remain with the patient. The nurse gives the patient simple, concise information in a reassuring voice about what is being done to treat the condition and the expected results.

Vasodilators such as IV nitroglycerin or nitroprusside may enhance symptom relief in pulmonary edema, as previously described (Meyer,

2019a). Blood pressure is continually assessed in patients receiving IV vasodilator infusions.

Furosemide or another loop diuretic is given by IV push or as a continuous infusion to produce a rapid diuretic effect. The blood pressure is closely monitored as the urine output increases, because it is possible for the patient to become hypotensive as intravascular volume decreases. The patient receiving diuretic therapy may excrete a large volume of urine within minutes after a potent diuretic is given. A bedside commode may be used to decrease the energy required by the patient and to reduce the resultant increase in cardiac workload induced by getting on and off a bedpan. If necessary, in order to carefully monitor urine output, an indwelling urinary catheter may be inserted.

Once the patient is stable, they may transition to oral diuretics; intake and output, daily weights, serum electrolytes, and creatinine are carefully monitored.

Many potential problems associated with HF therapy relate to the use of diuretics. These problems require ongoing nursing assessment and collaborative intervention:

Excessive and repeated diuresis can lead to hypokalemia (i.e., potassium depletion). Signs include ventricular arrhythmias, hypotension, muscle weakness, and generalized weakness. In patients receiving digoxin, hypokalemia can lead to digitalis toxicity, which increases the likelihood of dangerous arrhythmias. Patients with HF may also develop low levels of magnesium, which can add to the risk of arrhythmias. Hyperkalemia may occur, especially with the use of ACE inhibitors, ARBs, or spironolactone. Hyperkalemia can also lead to profound bradycardia and other arrhythmias. Prolonged diuretic therapy may produce hyponatremia (deficiency of sodium in the blood), which can result in disorientation, weakness, muscle cramps, and anorexia. Volume depletion from excessive fluid loss may lead to dehydration and hypotension. ACE inhibitors and beta-blockers may contribute to the hypotension. Other problems associated with diuretics include increased serum creatinine (indicative of renal dysfunction) and hyperuricemia (excessive uric acid in the blood), which leads to gout.

Promoting Home, Community-Based, and Transitional Care

Facilitating an easy and smooth transition back into the community is of paramount importance for the patient living with HF. Community-based nursing interventions for patients with HF can improve health outcomes and health care value as evidenced by reduced hospital readmissions for up to 6 mo. Important nursing interventions that keep the patient with HF out of the hospital incorporate a multidisciplinary care planning approach (Jones, Bowles, Richard, et al., 2017).

Educating Patients About Self-Care. The nurse provides patient education and involves the patient and family in the therapeutic regimen to promote understanding and adherence to the plan. When the patient recognizes that the diagnosis of HF can be successfully managed with lifestyle changes and medications, recurrences of acute HF lessen, unnecessary hospitalizations decrease, and life expectancy increases. Nurses play a key role in educating patients and their families about medication management, a low sodium diet, moderate alcohol consumption, activity and exercise recommendations, smoking cessation, how to recognize the signs and symptoms of worsening HF, and when to contact the primary provider (Jones et al., 2017). Use of the teach-back technique to assess the patient's comprehension of the instructions can increase education effectiveness and prevent rehospitalization (Esquivel, White, Carroll, et al., 2018) (see Chapter 3 for further discussion of teach-back methods). In order for teach-back to be effective, the nurse must ensure adequate time is dedicated to ensuring that patient learning occurs (Esquivel et al., 2018). A basic home education plan for the patient with HF is presented in Chart 25-6. The patient should receive a written copy of the instructions.

The patient's readiness to learn and potential barriers to learning are assessed. Patients with HF may have temporary or ongoing cognitive impairment due to their illness or other factors, increasing the need to rely on an identified caretaker (Hodson et al., 2019). An effective treatment plan incorporates both the patient's goals and those of the health care providers. The nurse must consider cultural factors and adapt the education plan accordingly. Patients and families need to understand that effective HF management is influenced by choices made about treatment options and their ability to follow the treatment plan. They also need to be informed that health care providers are available to assist them in reaching their health care goals.

Chart 25-6 **HOME CARE CHECKLIST**

The Patient with Heart Failure

At the completion of education, the patient and/or caregiver will be able to:

- Identify heart failure as a chronic disease that can be managed with medications and specific self-management behaviors.
- State the impact of heart failure on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Take or administer medications daily, exactly as prescribed.
- Monitor effects of medication such as changes in breathing and edema.
- Know signs and symptoms of orthostatic hypotension and how to prevent it.
- Weigh self daily at the same time, with same clothes.
- Restrict sodium intake to no more than 2 g/day:
  - Adapt diet by examining nutrition labels to check sodium content per serving.
  - Avoid canned or processed foods, eating fresh or frozen foods.
  - Consult the written diet plan and the list of permitted and restricted foods.
  - Avoid salt use.
  - Avoid excesses in eating and drinking.
- Participate in prescribed activity program:
  - Participate in a daily exercise program.
  - Increase walking and other activities gradually, provided they do not cause unusual fatigue or dyspnea.
  - Conserve energy by balancing activity with rest periods.
  - Avoid activity in extremes of heat and cold, which increase the work of the heart.
  - Recognize that air-conditioning may be essential in a hot, humid environment.
- Develop methods to manage and prevent stress:
  - Avoid tobacco.
  - Avoid alcohol.
  - Engage in social and diversional activities.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community).
  - Identify the contact details for support services for patients and their caregivers/families.

- Report immediately to the primary provider or clinic any of the following:
  - Gain in weight of 2–3 lb (0.9–1.4 kg) in 1 d, or 5 lb (2.3 kg) in 1 wk
  - Unusual shortness of breath with activity or at rest
  - Increased swelling of ankles, feet, or abdomen
  - Persistent cough
  - Loss of appetite
  - Development of restless sleep; increase in number of pillows needed to sleep
  - Profound fatigue
- State how to reach primary provider with questions or complications:
  - State time and date of follow-up appointments and diagnostic tests.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Continuing and Transitional Care. Successful management of HF requires adherence to a complex medical regimen that includes multiple lifestyle changes for most patients. Assistance may be provided through a number of options that optimize evidence-based recommendations for effective management of HF. Depending on the patient's physical status and the availability of family assistance, a home care referral or another type of disease management program may be indicated for a patient who has been hospitalized. Transitional care programs (hospital to home) that include telephone contact along with home visits have been shown to decrease rehospitalizations and increase patient quality of life (Cyrille & Patel, 2017; Jones et al., 2017). Home visits by nurses who are specially trained in managing patients with HF provide assessment and management tailored to specific individualized patient needs. Older patients and those who have long-standing heart disease with compromised physical stamina often require assistance with the transition to home after hospitalization for an acute episode of HF. The home health nurse assesses the physical environment of the home and makes suggestions for adapting the home environment to meet the patient's activity limitations. If stairs are a concern, the patient can plan the day's activities so that stair-climbing is minimized; for some patients, a temporary bedroom may be set up on the main level of the home. The home health nurse works with the patient and family to maximize the benefits of these changes.

The home health nurse also reinforces and clarifies information about dietary changes and fluid restrictions, the need to monitor symptoms and

daily body weight, and the importance of obtaining follow-up care with the primary provider's office or clinic. Assistance may be given in scheduling and keeping appointments as well. The patient is encouraged to gradually increase their self-care and responsibility for carrying out the therapeutic regimen.

Evidence-based HF guidelines also recommend patient referral to HF clinics, which provide intensive nursing management along with medical care in a collaborative model. Many of these clinics are managed by advanced practice nurses. Referral to an HF clinic gives the patient ready access to continuing education, professional nursing and medical staff, and timely adjustments to treatment regimens. HF clinics can also provide outpatient treatment (e.g., IV diuretics, laboratory monitoring) as an alternative to hospitalization. Because of the additional support and coordination of care, patients managed through HF clinics have fewer exacerbations of HF, fewer hospitalizations, decreased costs of medical care, and increased quality of life (Yancy, 2013).

Other disease management programs are carried out through telehealth, using telephones or computers to maintain contact with patients and to obtain patient data. This enables nurses and others to assess and manage patients on a frequent basis, without requiring patients to make frequent visits to health care providers. A variety of techniques ranging from simple telephone monitoring to sophisticated computer and video connections that monitor symptoms, daily weight, vital signs, heart sounds, and breath sounds may be used. Patient data may also include hemodynamics and other parameters transmitted from implantable devices. Studies have shown that telehealth management can decrease costs and hospitalizations for acute exacerbations of HF (Koehler, Koehler, Deckwart, et al., 2018).

End-of-Life Considerations. Because HF is a chronic and often progressive condition, patients and families need to consider issues related to the end-of-life and when palliative or hospice care should be considered (Cross, Kamal, Taylor, et al., 2019). Although the prognosis in patients with HF may be uncertain, issues often arise sooner or later related to the patient's thoughts and possible concerns about the use of complex treatment options (e.g., implantation of an ICD or a ventricular assist device [VAD]). VADs are an option for some patients with HF who have failed medical therapy and who are not candidates for cardiac transplantation. Discussions concerning the use of technology, preferences for end-of-life care, and advance directives should take place while the patient is able to participate and express preferences. For example, with the expanded use of ICDs in the HF population, patients with ICDs, their families, and their primary providers should receive instructions for ICD inactivation at the end-of-life to prevent inappropriate discharges. See Chapter 13 for further discussion of end-of-life care.

Evaluation

Expected patient outcomes may include:

1. Demonstrates tolerance for desired activity
   a. Describes adaptive methods for usual activities
   b. Schedules activities to conserve energy and reduce fatigue and dyspnea
   c. Maintains heart rate, blood pressure, respiratory rate, and pulse oximetry within the targeted range
2. Maintains fluid balance
   a. Exhibits decreased peripheral edema
   b. Verbalizes understanding of fluid intake and diuretic use
3. Decreased anxiety
   a. Avoids situations that produce stress
   b. Sleeps comfortably at night
   c. Reports decreased stress and anxiety
   d. Denies symptoms of depression
4. Makes sound decisions regarding care and treatment
   a. Demonstrates ability to influence outcomes
5. Patients and family members adhere to healthy regimen
   a. Performs and records daily weights
   b. Limits dietary sodium intake to no more than 2 g/day
   c. Takes medications as prescribed
   d. Reports symptoms of worsening HF
   e. Makes and keeps appointments for follow-up care
6. Exhibits no evidence of acute decompensation and pulmonary edema
7. Denies dyspnea
8. No apparent delirium or acute anxiety
9. Maintains fluid balance as noted previously
10. No evidence of electrolyte disturbances from diuretic therapy

COMPLICATIONS FROM HEART DISEASE

Cardiogenic Shock

Cardiogenic shock occurs when decreased CO leads to inadequate tissue perfusion and initiation of the shock syndrome. Cardiogenic shock most commonly occurs following acute MI when a large area of myocardium

becomes ischemic and hypokinetic. It also can occur as a result of end-stage HF, cardiac tamponade, pulmonary embolism (PE), cardiomyopathy, and arrhythmias. Cardiogenic shock is a life-threatening condition with a high mortality rate. (See Chapter 11 for detailed information about the pathophysiology and management of cardiogenic shock.)

Thromboembolism

Patients with cardiovascular disorders are at risk for the development of arterial thromboemboli and venous thromboemboli (VTE). Intracardiac thrombi can form in patients with atrial fibrillation because the atria do not contract forcefully, resulting in slow and turbulent flow, and increasing the likelihood of thrombus formation. Mural thrombi can also form on ventricular walls when contractility is poor. Intracardiac thrombi can break off and travel through the circulation to other structures, including the brain, where they cause a stroke. Clots within the cardiac chambers can be detected by an echocardiogram and treated with anticoagulant agents, such as heparin and warfarin (see Chapter 26 for further discussion of assessment and treatment of VTEs; Table 26-2 discusses specific anticoagulant medications).

Decreased mobility and other factors in patients with cardiac disease also can lead to clot formation in the deep veins of the legs. Although signs and symptoms of deep vein thrombosis (DVT) can vary, patients may report leg pain and swelling and the leg may appear erythematous and feel warm. These clots can break off and travel through the inferior vena cava and through the right side of the heart into the pulmonary artery, where they can cause a pulmonary embolus (PE) (see Chapter 26 for further discussion of assessment and treatment of PE).

Pericardial Effusion and Cardiac Tamponade

Pericardial effusion (accumulation of fluid in the pericardial sac) may accompany advanced HF, pericarditis, metastatic carcinoma, cardiac surgery, or trauma. Normally, the pericardial sac contains about 20 mL of fluid, which is needed to decrease friction for the beating heart. An increase in pericardial fluid raises the pressure within the pericardial sac and compresses the heart. This has the following effects:

- Elevated pressure in all cardiac chambers
- Decreased venous return due to atrial compression
- Inability of the ventricles to distend and fill adequately

Pericardial fluid may build up slowly without causing noticeable symptoms until a large amount (1 to 2 L) accumulates (Hoit, 2019). However, a rapidly

developing effusion (e.g., hemorrhage into the pericardial sac from chest trauma) can quickly stretch the pericardium to its maximum size and cause an acute problem. As pericardial fluid increases, pericardial pressure increases, reducing venous return to the heart and decreasing CO. This can result in cardiac tamponade, which causes low CO and obstructive shock.

Clinical Manifestations

The signs and symptoms of pericardial effusion can vary according to whether the problem develops quickly or slowly. In acute cardiac tamponade, the patient suddenly develops chest pain, tachypnea, and dyspnea. JVD results from poor right atrial filling and increased venous pressure. Hypotension occurs from low CO, and heart sounds are often muted. The subacute presentation of a pericardial effusion is less dramatic. The patient may report chest discomfort or a feeling of fullness. The feeling of pressure in the chest may result from stretching of the pericardial sac. These patients also develop dyspnea, JVD, and hypotension over time (Hoit, 2019). Patients with cardiac tamponade typically have tachycardia in response to low CO. In addition to hypotension, patients with cardiac tamponade may develop **pulsus paradoxus**, a systolic blood pressure that is markedly lower during inhalation. Also known as paradoxical pulse, this finding is characterized by an abnormal difference of at least 10 mm Hg in systolic pressure between the point that it is heard during exhalation and the point that it is heard during inhalation. This difference is caused by the variation in cardiac filling that occurs with changes in intrathoracic pressure during breathing. The cardinal signs of cardiac tamponade are illustrated in Figure 25-4.

Assessment and Diagnostic Findings

An echocardiogram is performed to confirm the diagnosis and quantify the amount of pericardial fluid. A chest x-ray may show an enlarged cardiac silhouette due to pericardial effusion. The ECG shows tachycardia and may also show low voltage (Hoit, 2019). See Chapter 22 for discussion of the significance of ECG abnormalities.

Medical Management

Acute management of cardiac tamponade may include a pericardiocentesis; whereas, recurrent effusions may be managed with a pericardiotomy.

Pericardiocentesis

If cardiac function becomes seriously impaired, **pericardiocentesis** (puncture of the pericardial sac to aspirate pericardial fluid) is performed. During this

procedure, the patient is monitored by continuous ECG and frequent vital signs. Catheter pericardiocentesis is performed using echocardiography to guide placement of the drainage catheter (Hoit, 2019).

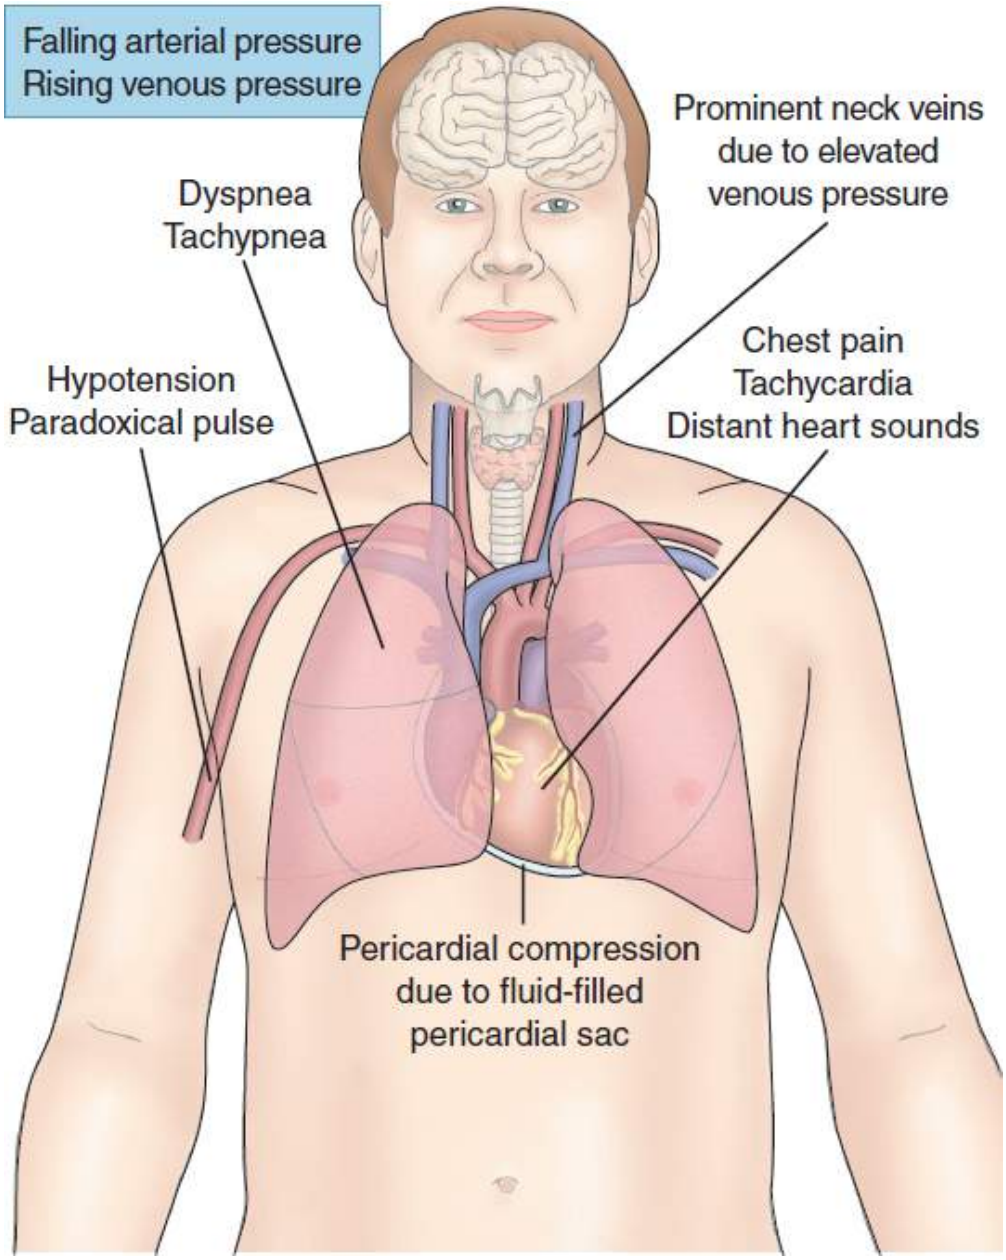

Figure 25-4 • Assessment findings in cardiac tamponade resulting from pericardial effusion include chest pain or fullness, dyspnea, tachypnea, jugular vein distention, hypotension, paradoxical pulse, tachycardia, and distant heart sounds.

A resulting decrease in central venous pressure and an associated increase in blood pressure after withdrawal of pericardial fluid indicate that the cardiac tamponade has been relieved. The patient almost always feels immediate relief. If there is a substantial amount of pericardial fluid aspirated, a small

catheter may be left in place to drain recurrent accumulation of blood or fluid. Pericardial fluid is sent to the laboratory for examination for tumor cells, bacterial culture, chemical and serologic analysis, and differential blood cell count.

Complications of pericardiocentesis include coronary artery puncture, myocardial trauma, arrhythmias, pleural laceration, and gastric puncture. After pericardiocentesis, the patient's heart rhythm, blood pressure, venous pressure, and heart sounds are monitored frequently to detect possible recurrence of cardiac tamponade. A follow-up echocardiogram is also performed. If the effusion recurs, repeat aspiration is necessary. Cardiac tamponade may require treatment by open surgical drainage (pericardiotomy) (Hoit, 2019).

Pericardiotomy

Recurrent pericardial effusions, usually associated with neoplastic disease, may be treated by a **pericardiotomy** (pericardial window). Under general anesthesia, a portion of the pericardium is excised to permit the exudative pericardial fluid to drain into the lymphatic system. The nursing care following the procedure includes routine postsurgical care (see Chapter 16) in addition to observation for recurrent tamponade.

Cardiac Arrest

In cardiac arrest, the heart is unable to pump and circulate blood to the body's organs and tissues. It is often caused by an arrhythmia such as ventricular fibrillation, progressive bradycardia, or asystole (i.e., absence of cardiac electrical activity and heart muscle contraction). Cardiac arrest can also occur when electrical activity is present on the ECG but cardiac contractions are ineffective, a condition called **pulseless electrical activity (PEA)**. PEA may be caused by a variety of problems such as profound hypovolemia (e.g., hemorrhage). Diagnoses that are commonly associated with cardiac arrest include MI, massive pulmonary emboli, hyperkalemia, hypothermia, severe hypoxia, and medication overdose. Rapid identification of these problems and prompt intervention can restore circulation in some patients.

Clinical Manifestations

In cardiac arrest, consciousness, pulse, and blood pressure are lost immediately. Breathing usually ceases, but ineffective respiratory gasping may occur. The pupils of the eyes begin dilating in less than a minute, and seizures may occur. Pallor and cyanosis are seen in the skin and mucous membranes. The risk of organ damage, including irreversible brain damage, and of death increases with every minute that passes. A patient's age and overall health

determine their vulnerability to irreversible damage. As soon as possible, the diagnosis of cardiac arrest must be made and action taken immediately to restore circulation.

Emergency Assessment and Management: Cardiopulmonary Resuscitation

Cardiopulmonary resuscitation (CPR) provides blood flow to vital organs until effective circulation can be reestablished. Following the recognition of unresponsiveness, a protocol for basic life support is initiated. The AHA Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care direct the current protocols for CPR, medical emergency teams, postcardiac arrest care, and acute respiratory compromise. The primary goal of resuscitation protocols is to save lives by preventing in-hospital cardiac arrest and optimizing outcomes (AHA, 2017).

The resuscitation process begins with the immediate assessment of the patient for breathing and consciousness, then a call for assistance, as CPR can be performed most effectively with the addition of more health care providers and equipment (e.g., defibrillator). The current resuscitation protocol recommends the following practices for CPR:

1. *Quick recognition of sudden cardiac arrest*. The patient is assessed for responsiveness and breathing.
2. *Activation of the Emergency Response System*. Within a medical facility, a call is made to alert the emergency response team. Outside of a medical facility, 911 is called to activate the Emergency Medical Service (EMS).
3. *Performance of high-quality CPR*. If there is no carotid pulse detected, chest compressions are initiated at a rate of 100 bpm.
4. *Rapid cardiac rhythm analysis and defibrillation* within 2 minutes for patients in ventricular fibrillation or pulseless ventricular tachycardia, followed by continuous chest compressions.

Rescue breathing is no longer recommended unless health care providers are present; if that is the case, it is then started after chest compressions. The airway is opened using a head-tilt/chin-lift maneuver, and any obvious material in the mouth or throat is removed. An oropharyngeal airway may be inserted if available to help maintain patency of the airway. Rescue ventilations are provided using a bag-valve mask or mouth-mask device. Oxygen is given at 100% during resuscitation to correct hypoxemia and improve tissue oxygenation.

Compressions are performed with the patient on a firm surface such as the floor or a cardiac board. The provider, facing the patient's side, places one hand in the center of the chest on the lower half of the sternum and positions the other hand on top of the first hand (Fig. 25-5). The chest is compressed 2

inches (approximately 5 cm) at a rate of 100 compressions/min. Complete recoil of the chest must be allowed between compressions to allow for cardiac filling. Interruptions in CPR to switch providers or check for a pulse are minimized (Panchal, Berg, Hirsch, et al., 2019). It is recommended providers switch every 2 minutes due to the exertion of delivering effective compressions.

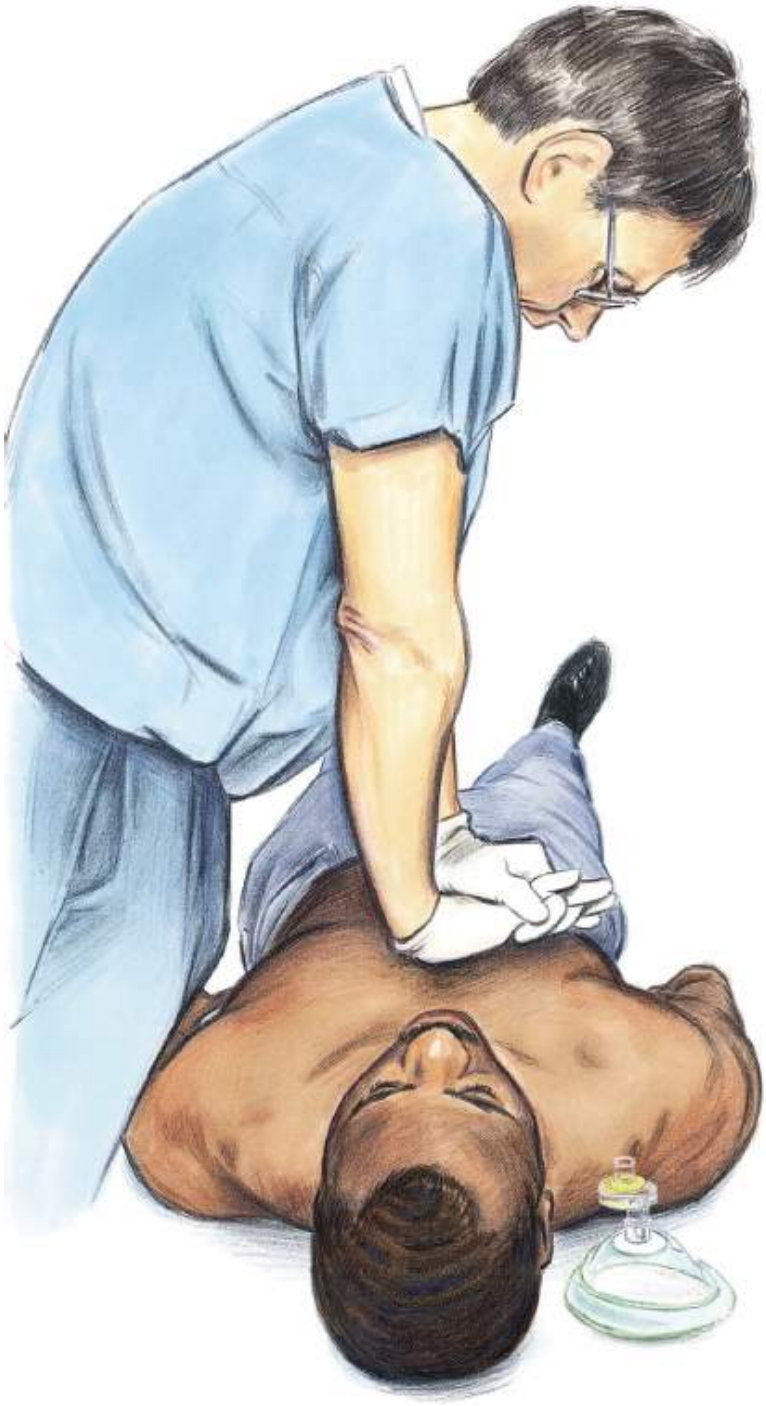

Figure 25-5 • Chest compressions in cardiopulmonary resuscitation are performed by placing the heel of one hand in the center of the chest over the sternum and the other hand on top of the first hand. Elbows are kept straight and body weight is used to apply forceful compressions to the lower sternum. The patient should be on a hard surface such as a cardiac board. Reprinted with permission from Field, J. M., Kudenchuk, P. J., O'Connor, R. E., et al. (2009). *The textbook of emergency cardiovascular care and CPR*. Philadelphia, PA: Lippincott Williams & Wilkins.

Defibrillation

As soon as a monitor/defibrillator is available, monitor electrodes are applied to the patient's chest and the heart rhythm is analyzed. When an automated external defibrillator (AED) is used, the device is turned on, the pads are applied to the patient's chest, and the rhythm is analyzed by the defibrillator to determine whether a shock is indicated. When the ECG shows ventricular fibrillation or pulseless ventricular tachycardia, immediate defibrillation is the treatment of choice.

The AHA (2017) recommends the first defibrillation to occur within 2 minutes of the first documented, pulseless rhythm. Survival time decreases for every minute that defibrillation is delayed. Following defibrillation, high-quality chest compressions are resumed immediately. Survival after cardiac arrest has been improved by extensive education of health care providers and by the use of AEDs.

Advanced Cardiovascular Life Support

During a resuscitation, an advanced airway (e.g., endotracheal tube, tracheal tube) may be placed by a primary provider, nurse anesthetist, or respiratory therapist to ensure a patent airway and adequate ventilation. Following confirmation of the placement of airway (auscultation of breath sounds, observation of equal chest expansion, or a carbon dioxide detector), positive-pressure ventilation should be delivered without pausing chest compressions at a rate of one breath every 6 seconds, or 10 breaths/min (Kleinman, Goldberger, Rea, et al., 2017; Panchal et al., 2019).

Specific subsequent advanced support interventions depend on the assessment of the patient's condition and response to therapy. For example, if asystole is detected on the monitor, CPR is continued while IV or intraosseous (IO) epinephrine is given. Additional medications (Table 25-4) may be indicated for the patient during and after resuscitation.

Each person on an effective Advanced Cardiac Life Support (ACLS) team, called a *CPR team* or sometimes a *code team,* has delineated roles. An efficient code team is characterized by individual members who are knowledgeable about their position and responsibilities. This ensures direct and clear lines of communication, effective team work, and a safe environment for the health care team and the patient (Panchal et al., 2019).

It is recommended practice to support family members of all patients who have had cardiac arrest and are undergoing resuscitation. In addition, there is clear support to have them present at the bedside if that is consonant with the patient's wishes. Written policies and procedures to support family presence during this time ought to be readily available for nurses and staff to easily access. Studies demonstrate family presence does not disrupt patient care, has no negative outcomes during the resuscitation event, and results in no adverse

psychological effects (American Association of Critical-Care Nurses [AACN], 2016).

CPR is stopped when vital signs are detected or the patient responds. If the patient does not respond to interventions, the resuscitation effort may be stopped by the code team leader or other provider in charge of the resuscitation after options have been exhausted. Many factors are considered in the decision, such as the initiating arrhythmia, potential etiology, length of time for initiation of life support, the patient's response to treatment, and the patient's overall clinical status.

TABLE 25-4 Medications Used in Cardiopulmonary Resuscitation

Agent and Action	Indications	Nursing Considerations
Epinephrine—vasopressor used to optimize BP and cardiac output; improves perfusion and myocardial contractility	Given to patients in cardiac arrest caused by asystole, pulseless electrical activity, pulseless VT or VF	Administer 1 mg every 3–5 min by IV push or IO push. Follow peripheral IV administration with 20-mL saline flush and elevate extremity for 10–20 s.
Norepinephrine—vasopressor given to increase BP	Given for hypotension and shock	Administer 0.1–0.5 mcg/kg/min as IV infusion, preferably through a central line.
Dopamine—vasopressor given to increase BP and contractility	Given for hypotension and shock	Administer 5–10 mcg/kg/min as IV infusion, preferably through a central line.
Atropine—blocks parasympathetic action; increases SA node automaticity and AV conduction	Given to patients with symptomatic bradycardia (i.e., hemodynamically unstable with hypotension)	Administer 0.5-mg IV push; may repeat to dose of 3 mg, follow with saline flush.
Amiodarone—acts on sodium–potassium and calcium channels to prolong action potential and refractory period	Used to treat pulseless VT and VF unresponsive to shock delivery	Administer 300 mg IV; may give second dose of 150 mg in 3–5 min.
Sodium bicarbonate ($NaHCO_3$)—corrects metabolic acidosis	Given to correct metabolic acidosis that is refractory to standard advanced cardiac life support interventions (cardiopulmonary resuscitation, intubation, and respiratory management)	Administer initial dose of 1 mEq/kg IV/IO; then administer dose based on base deficit. Recognize that to prevent development of rebound metabolic alkalosis, complete correction of acidosis is not indicated.
Magnesium sulfate—promotes adequate functioning of cellular sodium–potassium pump	Given to patients with torsade de pointes, a type of VT	May administer 1–2 g diluted in 10 mL D_5W over 5–20 min.

AV, atrioventricular; BP, blood pressure; D_5W, dextrose 5% in water; IO, intraosseous; IV, intravenous; SA, sinoatrial; VF, ventricular fibrillation; VT, ventricular tachycardia.

Follow-Up Monitoring and Care

The care provided to the patient following resuscitation is another determinant of survival (AHA, 2017). A 12-lead ECG is performed to detect any new ST segment elevation or myocardial ischemia (see Chapter 23). Continuous ECG monitoring and frequent blood pressure assessments are essential until hemodynamic stability is established and blood pressure is kept in a range to support adequate perfusion. Factors that precipitated the arrest such as arrhythmias or electrolyte or metabolic imbalances are identified and treated.

Following resuscitation and the return of spontaneous circulation, patients who are comatose may benefit from targeted temperature management (TTM). With TTM, core body temperature is decreased to 32° and 36°C (89.6° to 96.8°F) for at least 24 hours. This induced hypothermia decreases the cerebral metabolic rate and need for oxygen. Similarly, hyperthermic conditions, such as fever, are avoided to reduce oxygen demands (Callaway, Donnino, Fink, et al., 2015).

Advances in cardiac care, such as new techniques for effective resuscitation and postresuscitation hypothermia, have improved outcomes for patients. Research studies demonstrate better neurologic recovery and overall survival for patients when the correct algorithms and team dynamics are used after cardiac arrest; there is hope for even better outcomes in the future.

CRITICAL THINKING EXERCISES

1 ipc After recently being discharged from the hospital with an episode of acute decompensated HFrEF, a 62-year-old man presents to the cardiology clinic where you work. You note that this was the third hospitalization for this patient within the past 6 months. The patient is a widower, lives alone in a two-story home without a bathroom or bedroom on the first floor, and has been receiving disability benefits for several years. Identify how you intend to further assess the patient. What questions will you ask him? Which community-based resources and health care team members could be mobilized to facilitate his transition from the hospital-based setting to the community setting so that he avoids continued rehospitalization?

2 ebp You are a nurse educator working in a home health agency. You are tasked with presenting an educational session on HF self-care strategies. Using knowledge of evidence-based practice guidelines, list the most important topics to cover. Consider gender differences, medications, dietary recommendations, and suggestions for exercise.

3 pq A 75-year-old woman with an acute MI is admitted to the unit where you work as a staff nurse. You assess the patient and find that she is developing a cough, an increasing respiratory rate (32 breaths/min), and pink-tinged sputum. The patient seems agitated and becomes disoriented; she asks you why she is in the hospital. You call the rapid response team, and the following are prescribed: chest x-ray, arterial blood gases and basic metabolic panel, furosemide 40 mg IV, oxygen per nasal cannula to maintain a saturation greater than 94%. Place your planned interventions in priority order and explain your rationale.

26 Assessment and Management of Patients with Vascular Disorders and Problems of Peripheral Circulation

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Identify anatomic and physiologic factors that affect peripheral blood flow and tissue oxygenation.
2. Apply assessment parameters appropriate for determining the status of peripheral circulation.
3. Use the nursing process as a framework for care of the patient with arterial and venous disorders.
4. Compare the pathophysiology, clinical manifestations, management, and prevention of diseases of the arteries.
5. Describe the pathophysiology, clinical manifestations, management, and prevention of venous thromboembolism, venous insufficiency, leg ulcers, and varicose veins.
6. Describe the pathophysiology, clinical manifestations, and management of lymphatic disorders and cellulitis.

NURSING CONCEPTS

Assessment
Clotting
Functional Ability
Perfusion

GLOSSARY

anastomosis: junction of two vessels

aneurysm: a localized sac or dilation of an artery formed at a weak point in the vessel wall

angioplasty: an invasive procedure that uses a balloon-tipped catheter to dilate a stenotic area of a blood vessel

ankle-brachial index (ABI): ratio of the ankle systolic pressure to the brachial systolic pressure; an objective measurement of arterial disease that provides quantification of the degree of stenosis

arteriosclerosis: diffuse process whereby the muscle fibers and the endothelial lining of the walls of small arteries and arterioles thicken

atherectomy: an invasive procedure that uses a cutting device or laser to remove or reduce plaque in an artery

atherosclerosis: inflammatory process involving the accumulation of lipids, calcium, blood components, carbohydrates, and fibrous tissue on the intimal layer of a large- or medium-sized artery

bruit: sound produced by turbulent blood flow through an irregular, tortuous, stenotic, or dilated vessel

cyanosis: a bluish tint of the skin manifested when the amount of oxygenated hemoglobin contained in the blood is reduced

deep vein thrombosis (DVT): a blood clot or thrombus located within a deep vein that causes obstruction or occlusion

dissection: separation of the weakened elastic and fibromuscular elements in the medial layer of an artery

duplex ultrasonography: combines B-mode grayscale imaging of tissue, organs, and blood vessels with capabilities of estimating velocity changes by the use of a pulsed Doppler

embolus: a blood clot, fatty deposit, or air that travels through the blood, lodges in an artery or vein, and blocks flow

endovascular: a type of procedure that uses a puncture or small incision to place catheters inside a blood vessel to repair it or insert a device

intermittent claudication: a muscular, cramplike pain or fatigue in the extremities consistently reproduced with the same degree of exercise or activity and relieved by rest

ischemia: deficient blood supply

pulmonary embolism (PE): a blood clot or thrombus within a pulmonary artery that blocks or obstructs blood flow to the lungs

rest pain: persistent pain in the foot or digits when the patient is resting, indicating a severe degree of arterial insufficiency

rubor: reddish-blue discoloration of the extremities; indicative of severe peripheral arterial damage in vessels that remain dilated and unable to constrict

stenosis: narrowing or constriction of a blood vessel

thromboembolus: a blood clot that may become dislodged from the vessel where it originally formed

thrombus: a blood clot within an artery or a vein

venous thromboembolism (VTE): a blood clot that forms in the venous vasculature that may manifest as a DVT or a PE

Conditions of the vascular system include arterial disorders, venous disorders, lymphatic disorders, and cellulitis. These disorders may be seen in patients in both the inpatient and the outpatient setting. Nursing assessment and management depends on an understanding of the vascular system.

Anatomic and Physiologic Overview

Adequate perfusion ensures oxygenation and nourishment of body tissues, and it depends in part on a properly functioning cardiovascular system. Adequate blood flow depends on the efficiency of the heart as a pump, the patency and responsiveness of the blood vessels, and the adequacy of circulating blood volume. Nervous system activity, blood viscosity, and the metabolic needs of tissues influence the rate and adequacy of blood flow.

The vascular system consists of two interdependent systems. The right side of the heart pumps blood through the lungs to the pulmonary circulation, and the left side of the heart pumps blood to all other body tissues through the systemic circulation. The blood vessels in both systems channel the blood from the heart to the tissues and back to the heart (see Fig. 26-1). Contraction of the ventricles is the driving force that moves blood through the vascular system.

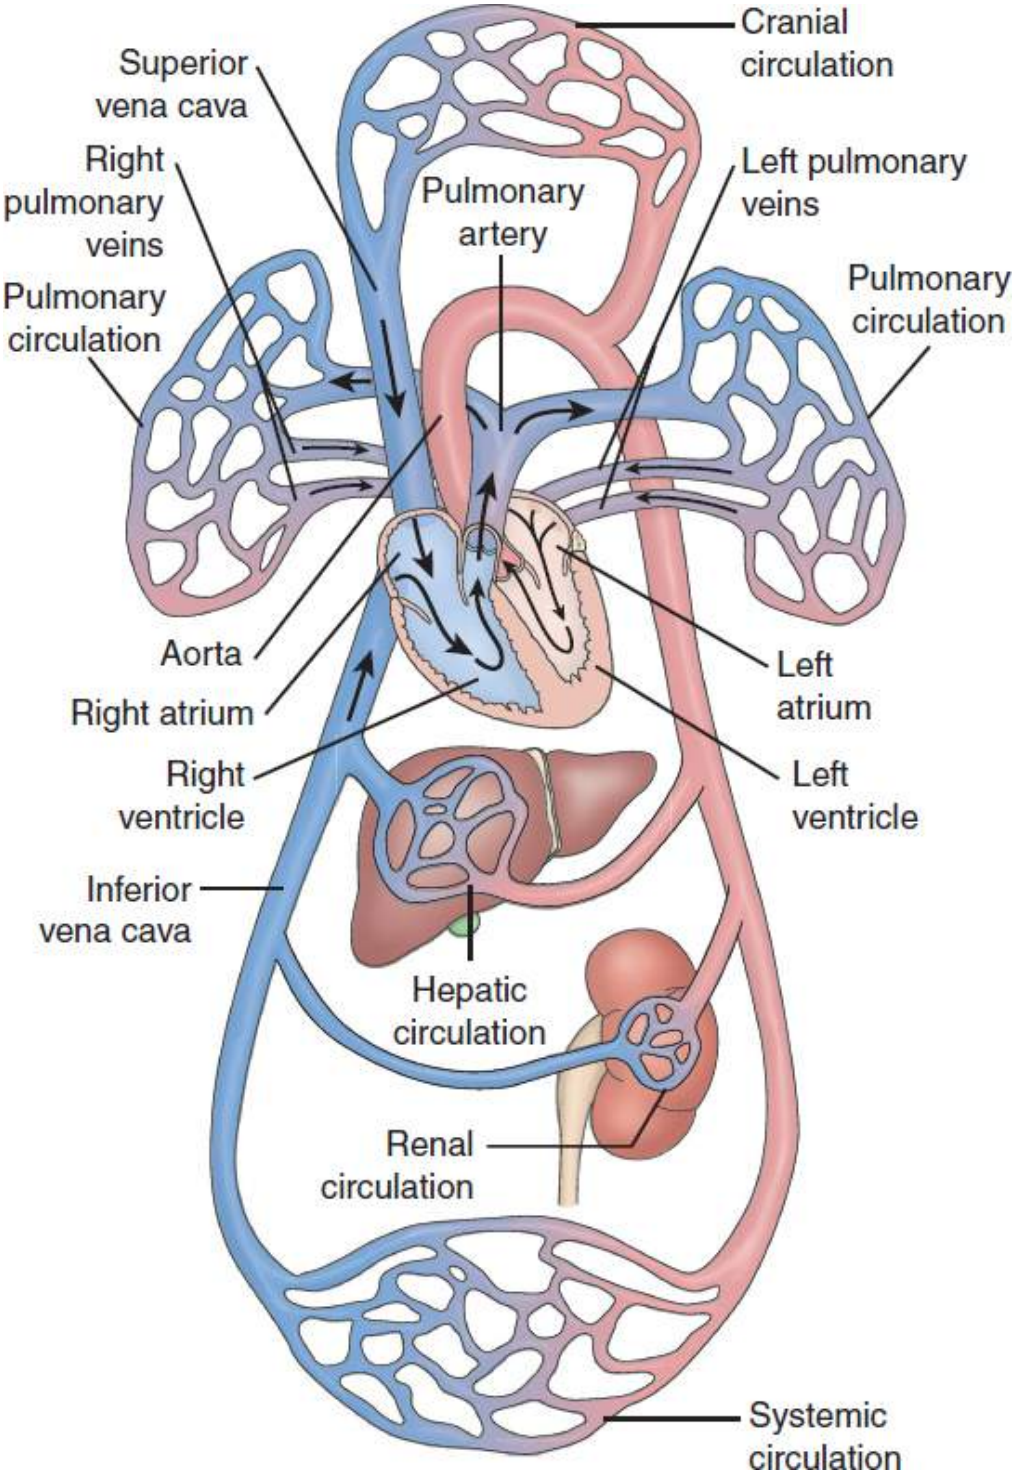

Figure 26-1 • Systemic and pulmonary circulation. Oxygen-rich blood from the pulmonary circulation is pumped from the left heart into the aorta and the systemic arteries to the capillaries, where the exchange of nutrients and waste products takes place. The deoxygenated blood returns to the right heart by way of the systemic veins and is pumped into the pulmonary circulation.

Arteries distribute oxygenated blood from the left side of the heart to the tissues, whereas the veins carry deoxygenated blood from the tissues to the right side of the heart. Capillary vessels located within the tissues connect the arterial and venous systems. These vessels permit the exchange of nutrients and metabolic wastes between the circulatory system and the tissues. Arterioles and venules immediately adjacent to the capillaries, together with the capillaries, make up the microcirculation.

The lymphatic system complements the function of the circulatory system. Lymphatic vessels transport lymph (a fluid similar to plasma) and tissue fluids (containing proteins, cells, and cellular debris) from the interstitial space to systemic veins. Lymphatic fluid empties into the subclavian and internal jugular veins.

Anatomy of the Vascular System

Arteries, arterioles, capillaries, veins, venules, and lymphatic vessels are the main structures that comprise the vascular system.

Arteries and Arterioles

Arteries are thick-walled structures that carry blood from the heart to the tissues. The aorta, which has a diameter of approximately 2.5 cm (1 inch) in the average-sized adult, gives rise to numerous branches, which continue to divide into progressively smaller arteries that are 4 mm (0.16 inches) in diameter. The vessels divide further, diminishing in size to approximately 30 mcm in diameter. These smallest arteries, called *arterioles,* are generally embedded within the tissues (Norris, 2019).

The walls of the arteries and arterioles are composed of three layers: the intima, an inner endothelial cell layer; the media, a middle layer of smooth muscle and elastic tissue; and the adventitia, an outer layer of connective tissue. The intima, a very thin layer, provides a smooth surface for contact with the flowing blood. The media makes up most of the vessel wall in the aorta and other large arteries of the body. This layer is composed chiefly of elastic and connective tissue fibers that give the vessels considerable strength and allow them to constrict and dilate to accommodate the blood ejected from the heart during each cardiac cycle (stroke volume) and maintain an even, steady flow of blood. The adventitia is a layer of connective tissue that anchors the vessel to its surroundings. There is much less elastic tissue in the smaller arteries and arterioles, and the media in these vessels is composed primarily of smooth muscle (Norris, 2019). Smooth muscle controls the diameter of the vessels by contracting and relaxing. Chemical, hormonal, and neuronal factors influence the activity of smooth muscle. Arterioles offer resistance to blood flow by altering their diameter and are often referred to as resistance vessels. Arterioles regulate the volume and pressure in the arterial system and the rate

of blood flow to the capillaries. There is a large amount of smooth muscle in the media, and the walls of the arteries are relatively thick, accounting for approximately 25% of the total diameter of the artery.

The intima and the inner third of the smooth muscle layer of the media are in such close contact with the blood that the blood vessels receive their nourishment by direct diffusion. The adventitia and the outer media layers require their own blood supply to meet metabolic needs. The vasa vasorum is a network of small blood vessels that supplies blood and nutrients to the larger arteries.

Capillaries

The walls of the capillaries, which lack smooth muscle and adventitia, are composed of a single layer of endothelial cells. This thin-walled structure permits rapid and efficient transport of nutrients to the cells and removal of metabolic wastes. The diameter of capillaries ranges from 5 to 10 mcm; this means that red blood cells must alter their shape to pass through these vessels. Changes in a capillary's diameter are passive and are influenced by contractile changes in the blood vessels that carry blood to and from a capillary. The capillary's diameter also changes in response to chemical stimuli. In some tissues, a cuff of smooth muscle, called the *precapillary sphincter,* is located at the arteriolar end of the capillary and is responsible, along with the arteriole, for controlling capillary blood flow (Norris, 2019).

Some capillary beds, such as those in the fingertips, contain arteriovenous anastomoses, through which blood passes directly from the arterial to the venous system. These vessels are believed to regulate heat exchange between the body and the external environment.

The distribution of capillaries varies with the type of tissue. For example, skeletal tissue, which has high metabolic requirements, has a denser capillary network than cartilage, which has low metabolic needs.

Veins and Venules

Capillaries join to form larger vessels called *venules,* which join to form veins. The venous system is therefore structurally analogous to the arterial system; venules correspond to arterioles, veins to arteries, and the vena cava to the aorta. Analogous types of vessels in the arterial and venous systems have approximately the same diameters (see Fig. 26-1).

The walls of the veins, in contrast to those of the arteries, are thinner and considerably less muscular. In most veins, the wall makes up only 10% of the diameter, in contrast to 25% in most arteries. In veins, the walls are composed of three layers, like those of arteries; however, in veins, these layers are not as well defined.

The thin, less muscular structure of the vein wall allows these vessels to distend more than arteries. Greater distensibility and compliance permit large volumes of blood to remain in the veins under low pressure. For this reason, veins are referred to as capacitance vessels. Approximately 75% of total blood volume is contained in the veins. The sympathetic nervous system, which innervates the vein musculature, can stimulate venoconstriction (constriction of the veins), thereby reducing venous volume and increasing the volume of blood in the general circulation. Contraction of skeletal muscles in the extremities creates the primary pumping action to facilitate venous blood flow back to the heart (Norris, 2019).

Some veins, unlike arteries, are equipped with valves. In general, veins that transport blood against the force of gravity, as in the lower extremities, have one-way bicuspid valves that prevent blood from retrograde flow as it is propelled toward the heart. Valves are composed of endothelial leaflets, the competency of which depends on the integrity of the vein wall.

Lymphatic Vessels

The lymphatic vessels are a complex network of thin-walled vessels similar to the capillaries. This network collects lymphatic fluid from tissues and organs, and transports the fluid to the venous circulation. The lymphatic vessels converge into two main structures: the thoracic duct and the right lymphatic duct. These ducts empty into the junction of the subclavian and internal jugular veins. The right lymphatic duct conveys lymph primarily from the right side of the head, neck, thorax, and upper arms. The thoracic duct conveys lymph from the remainder of the body. Peripheral lymphatic vessels join larger lymph vessels and pass through regional lymph nodes before entering the venous circulation. The lymph nodes play an important role in filtering foreign particles.

The lymphatic vessels are permeable to large molecules and provide the only means by which interstitial proteins can return to the venous system. With muscular contraction, lymph vessels become distorted to create spaces between the endothelial cells, allowing protein and particles to enter. Muscular contraction of the lymphatic walls and surrounding tissues aids in propelling the lymph toward the venous drainage points (Norris, 2019).

Function of the Vascular System

Important functions of the vascular system include supplying the circulatory needs of tissue, maintaining blood flow and blood pressure, and providing capillary filtration and reabsorption, hemodynamic resistance, and other peripheral vascular regulating mechanisms.

Circulatory Needs of Tissues

The amount of blood flow needed by the body's tissues constantly changes. The percentage of blood flow received by individual organs or tissues is determined by the rate of tissue metabolism, the availability of oxygen, and the function of the tissue. When metabolic requirements increase, blood vessels dilate to increase the flow of oxygen and nutrients to the tissues. When metabolic needs decrease, vessels constrict and blood flow to the tissues decreases. Metabolic demands of tissues increase with physical activity or exercise, local heat application, fever, and infection. Reduced metabolic requirements of tissues accompany rest or decreased physical activity, local cold application, and cooling of the body. If the blood vessels fail to dilate in response to the need for increased blood flow, tissue **ischemia** (deficient blood supply to a body part) results. The mechanism by which blood vessels dilate and constrict to adjust for metabolic changes ensures that normal arterial pressure is maintained (Norris, 2019).

As blood passes through tissue capillaries, oxygen is removed and carbon dioxide is added. The amount of oxygen extracted by each type of tissue differs. For example, the myocardium tends to extract about 50% of the oxygen from arterial blood in one pass through its capillary bed, whereas the kidneys extract only about 7% of the oxygen from the blood that passes through them. The average amount of oxygen removed collectively by all of the body tissues is about 25%. This means that the blood in the vena cava contains about 25% less oxygen than aortic blood. This is known as the systemic arteriovenous oxygen difference (Norris, 2019). This difference becomes greater when less oxygen is delivered to the tissues than they need.

Blood Flow

Blood flow through the cardiovascular system always proceeds in the same direction: left side of the heart to the aorta, arteries, arterioles, capillaries, venules, veins, vena cava, and right side of the heart. This unidirectional flow is caused by a pressure difference that exists between the arterial and venous systems. Because arterial pressure (approximately 100 mm Hg) is greater than venous pressure (approximately 40 mm Hg) and fluid flows from an area of higher pressure to an area of lower pressure, blood flows from the arterial system to the venous system.

The pressure difference (ΔP) between the two ends of the vessel propels the blood. Impediments to blood flow exert an opposing force, which is known as resistance (R). The rate of blood flow is determined by dividing the pressure difference by the resistance:

$$\text{Flow rate} = \Delta P/R$$

This equation shows that when resistance increases, a greater pressure is required to maintain the same degree of flow (Norris, 2019). In the body, an

increase in pressure is accomplished by an increase in the force of contraction of the heart. If arterial resistance is chronically elevated, the myocardium hypertrophies (enlarges) to sustain a greater contractile force.

In most long, smooth blood vessels, flow is laminar or streamlined, with blood in the center of the vessel moving slightly faster than the blood near the vessel walls. Laminar flow becomes turbulent when the blood flow rate increases, when blood viscosity increases, when the diameter of the vessel becomes greater than normal, or when segments of the vessel are narrowed or constricted (Norris, 2019). Turbulent blood flow creates an abnormal sound, called a **bruit,** which can be heard with a stethoscope.

Blood Pressure

Chapter 27 provides more information on the physiology and measurement of blood pressure.

Capillary Filtration and Reabsorption

Fluid exchange across the capillary wall is continuous. This fluid, which has the same composition as plasma without the proteins, forms the interstitial fluid. The equilibrium between hydrostatic and osmotic forces of the blood and interstitium, as well as capillary permeability, determines the amount and direction of fluid movement across the capillary. Hydrostatic force is a driving pressure that is generated by the blood pressure. Osmotic pressure is the pulling force created by plasma proteins. Normally, the hydrostatic pressure at the arterial end of the capillary is relatively high compared with that at the venous end. This high pressure at the arterial end of the capillaries tends to drive fluid out of the capillary and into the tissue space. Osmotic pressure tends to pull fluid back into the capillary from the tissue space, but this osmotic force cannot overcome the high hydrostatic pressure at the arterial end of the capillary. However, at the venous end of the capillary, the osmotic force predominates over the low hydrostatic pressure, and there is a net reabsorption of fluid from the tissue space back into the capillary (Norris, 2019).

Except for a very small amount, fluid that is filtered out at the arterial end of the capillary bed is reabsorbed at the venous end. The excess filtered fluid enters the lymphatic circulation. These processes of filtration, reabsorption, and lymph formation aid in maintaining tissue fluid volume and removing tissue waste and debris. Under normal conditions, capillary permeability remains constant.

Under certain abnormal conditions, the fluid filtered out of the capillaries may greatly exceed the amounts reabsorbed and carried away by the lymphatic vessels. This imbalance can result from damage to capillary walls and subsequent increased permeability, obstruction of lymphatic drainage, elevation of venous pressure, or a decrease in plasma protein osmotic force.

Accumulation of excess interstitial fluid that results from these processes is called *edema.*

Hemodynamic Resistance

The most important factor that determines resistance in the vascular system is the vessel radius. Small changes in vessel radius lead to large changes in resistance. The predominant sites of change in the caliber or width of blood vessels, and therefore in resistance, are the arterioles and the precapillary sphincter. Peripheral vascular resistance is the opposition to blood flow provided by the blood vessels. This resistance is proportional to the viscosity or thickness of the blood and the length of the vessel and is influenced by the diameter of the vessels. Under normal conditions, blood viscosity and vessel length do not change significantly, and these factors do not usually play an important role in blood flow. However, a large increase in hematocrit may increase blood viscosity and reduce capillary blood flow.

Peripheral Vascular Regulating Mechanisms

Even at rest, the metabolic needs of body tissues are continuously changing. Therefore, an integrated and coordinated regulatory system is necessary so that blood flow to individual tissues is maintained in proportion to the needs of those tissues. This regulatory mechanism is complex and consists of central nervous system influences, circulating hormones and chemicals, and independent activity of the arterial wall itself.

Sympathetic (adrenergic) nervous system activity, mediated by the hypothalamus, is the most important factor in regulating the caliber and therefore the blood flow of peripheral blood vessels. All vessels are innervated by the sympathetic nervous system except the capillary and precapillary sphincters. Stimulation of the sympathetic nervous system causes vasoconstriction. The neurotransmitter responsible for sympathetic vasoconstriction is norepinephrine (Norris, 2019). Sympathetic activation occurs in response to physiologic and psychological stressors. Diminution of sympathetic activity by medications or sympathectomy results in vasodilation.

Other hormones affect peripheral vascular resistance. Epinephrine, released from the adrenal medulla, acts like norepinephrine in constricting peripheral blood vessels in most tissue beds. However, in low concentrations, epinephrine causes vasodilation in skeletal muscles, the heart, and the brain. Angiotensin I, which is formed from the interaction of renin (synthesized by the kidney) and angiotensinogen, a circulating serum protein, is then converted to angiotensin II by an enzyme secreted by the pulmonary vasculature, called *angiotensin-converting enzyme* (ACE). Angiotensin II is a potent vasoconstrictor, particularly of the arterioles. Although the amount of angiotensin II concentrated in the blood is usually small, its profound vasoconstrictive effects

are important in certain abnormal states, such as heart failure and hypovolemia (Norris, 2019).

Alterations in local blood flow are influenced by various circulating substances that have vasoactive properties. Potent vasodilators include nitric oxide, prostacyclin, histamine, bradykinin, prostaglandin, and certain muscle metabolites. A reduction in available oxygen and nutrients and changes in local pH also affect local blood flow. Proinflammatory cytokines are substances liberated from platelets that aggregate at the site of damaged vessels, causing arteriolar vasoconstriction and continued platelet aggregation at the site of injury (Atherton, Sindone, De Pasquale, et al., 2018).

Pathophysiology of the Vascular System

Reduced blood flow through peripheral blood vessels characterizes all peripheral vascular diseases. The physiologic effects of altered blood flow depend on the extent to which tissue demands exceed the supply of oxygen and nutrients available. If tissue needs are high, even modestly reduced blood flow may be inadequate to maintain tissue integrity. Tissues become ischemic, malnourished, and ultimately die unless adequate blood flow is restored.

Pump Failure

Inadequate peripheral blood flow occurs when the heart's pumping action becomes inefficient. Heart failure with reduced left ventricular ejection fraction (HFrEF; also called systolic HF) causes an accumulation of blood in the lungs and a reduction in forward flow or cardiac output, which results in inadequate arterial blood flow to the tissues. Heart failure with preserved left ventricular ejection fraction (HFpEF; also called diastolic HF) causes systemic venous congestion and a reduction in forward flow (Atherton et al., 2018) (see Chapter 25).

Alterations in Blood and Lymphatic Vessels

Intact, patent, and responsive blood vessels are necessary to deliver adequate amounts of oxygen and nutrients to tissues and to remove metabolic wastes. Arteries can become damaged or obstructed as a result of atherosclerotic plaque, a **thromboembolus** (a blood clot that may become dislodged from the vessel from where it originally formed), chemical or mechanical trauma, infections or inflammatory processes, vasospastic disorders, and congenital malformations. A sudden arterial occlusion causes profound and often irreversible tissue ischemia and tissue death. When arterial occlusions develop gradually, there is less risk of sudden tissue death because collateral circulation may develop, giving that tissue the opportunity to adapt to gradually decreased blood flow.

Venous blood flow can be reduced by a thromboembolus obstructing the vein, by incompetent venous valves, or by a reduction in the effectiveness of the pumping action of surrounding muscles. Decreased venous blood flow results in increased venous pressure, a subsequent increase in capillary hydrostatic pressure, net filtration of fluid out of the capillaries into the interstitial space, and subsequent edema. Edematous tissues cannot receive adequate nutrition from the blood and consequently are more susceptible to breakdown, injury, and infection. Obstruction of lymphatic vessels also results in edema. Lymphatic vessels can become obstructed by a tumor or by damage from mechanical trauma or inflammatory processes.

Circulatory Insufficiency of the Extremities

Although many types of peripheral vascular diseases exist, most result in ischemia and produce some of the same symptoms: pain, skin changes, diminished pulses, and possible edema. The type and severity of symptoms depend in part on the type, stage, and extent of the disease process and on the speed with which the disorder develops. Table 26-1 highlights the distinguishing features of arterial and venous insufficiency. In this chapter, peripheral vascular disease is categorized as arterial, venous, or lymphatic.

Gerontologic Considerations

Aging produces changes in the walls of the blood vessels that affect the transport of oxygen and nutrients to the tissues. The intima thickens as a result of cellular proliferation and fibrosis. Elastin fibers of the media become calcified, thin, and fragmented, and collagen accumulates in the intima and the media. These changes cause the vessels to stiffen, which results in increased peripheral resistance, impaired blood flow, and increased left ventricular workload causing hypertrophy, ischemia and HFrEF, and thrombosis along with hemorrhage in the microvessels in the brain and kidney (Atherton et al., 2018).

TABLE 26-1 Characteristics of Arterial and Venous Insufficiency and Resulting Ulcers

Characteristic	Arterial	Venous
General Characteristics		
Pain	Intermittent claudication to sharp, unrelenting, constant	Aching, throbbing, cramping
Pulses	Diminished or absent	Present, but may be difficult to palpate through edema
Skin characteristics	Dependent rubor—with elevation pallor of foot; dry, shiny skin; cool-to-cold temperature; loss of hair over toes and dorsum of foot; nails thickened and ridged	Pigmentation in gaiter area (area of medial and lateral malleolus), skin thickened and tough, may be reddish blue, frequently with associated dermatitis
Ulcer Characteristics		
Location	Tip of toes, web spaces, heel or other pressure points if patient is immobile	Medial malleolus, lateral malleolus, or anterior tibial area
Pain	Very painful	Minimal pain to very painful
Depth of ulcer	Deep, often involving joint space	Superficial
Shape	Circular	Irregular border
Ulcer base	Pale to black and wet to dry gangrene	Granulation tissue—beefy red to yellow fibrinous in chronic long-term ulcer
Leg edema	Minimal unless extremity kept in dependent position constantly to relieve pain	Moderate to severe

Assessment of the Vascular System

The nurse should perform a focused health history and physical assessment to establish a patient's baseline and identify alterations in the vascular system.

Health History

The nurse obtains an in-depth description from the patient with peripheral vascular disorders of any pain and its precipitating factors. A muscular, cramp-type pain, discomfort, or fatigue in the extremities consistently reproduced with the same degree of activity or exercise and relieved by rest is experienced by patients with peripheral arterial insufficiency. Referred to as **intermittent**

claudication, this pain, discomfort, or fatigue is caused by the inability of the arterial system to provide adequate blood flow to the tissues in the face of increased demands for nutrients and oxygen during exercise. As the tissues are forced to complete the energy cycle without adequate nutrients and oxygen, muscle metabolites and lactic acid are produced. Pain is experienced as the metabolites aggravate the nerve endings of the surrounding tissue. Typically, about 50% of the arterial lumen or 75% of the cross-sectional area must be obstructed before intermittent claudication is experienced. When the patient rests and thereby decreases the metabolic needs of the muscles, the pain subsides. The progression of the arterial disease can be monitored by documenting the amount of exercise or the distance the patient can walk before the onset of pain. Distance is measured in blocks, feet, or meters. Persistent pain in the anterior portion of the foot (forefoot) when the patient is resting indicates a severe degree of arterial insufficiency and a critical state of ischemia. Known as **rest pain,** this discomfort is often worse at night and may interfere with sleep. This pain frequently requires that the extremity be lowered to a dependent position to improve perfusion to the distal tissues.

The site of arterial disease can be deduced from the location of claudication, because pain occurs in muscle groups distal to the diseased vessel. Calf pain may accompany reduced blood flow through the superficial femoral or popliteal artery, whereas pain in the hip or buttock may result from reduced blood flow in the abdominal aorta or the common iliac or hypogastric (also known as internal iliac) arteries.

Physical Assessment

A thorough assessment of the patient's skin color and temperature and the character or quality of the peripheral pulses is important in the diagnosis of arterial disorders.

Inspection of the Skin

Adequate blood flow warms the extremities and gives individuals with lighter skin tones a rosy coloring. Inadequate blood flow results in cool and pale extremities. In people with pigmented skin, the color changes are often more difficult to discriminate because of the darker skin tone. Further reduction of blood flow to these tissues, which occurs when the extremity is elevated, for example, results in pallor (a whiter or more blanched appearance). **Rubor,** a reddish-blue discoloration of the extremities, may be observed within 20 seconds to 2 minutes after the extremity is placed in the dependent position. Rubor suggests severe peripheral arterial damage in which vessels that cannot constrict remain dilated. Even with rubor, the extremity begins to turn pale with elevation. **Cyanosis,** a bluish tint of the skin, is manifested when the amount of oxygenated hemoglobin contained in the blood is reduced.

Additional changes resulting from a chronically reduced nutrient supply include loss of hair, brittle nails, dry or scaling skin, atrophy, and ulcerations. Edema may be apparent bilaterally or unilaterally and is related to the affected extremity's chronically dependent position because of rest pain. Gangrenous changes appear after prolonged, severe ischemia and represent tissue necrosis.

Palpation of Pulses

Determining the presence or absence, as well as the quality, of peripheral pulses is important in assessing the status of peripheral arterial circulation (see Fig. 26-2). Pulse assessment in an edematous extremity should be undertaken with caution. Palpation of pulses is subjective, and the nurse may mistake their own pulse for that of the patient. To prevent this, the nurse should use light touch and use more than just the index finger for palpation, because this finger has the strongest arterial pulsation of all the fingers. The thumb should not be used for the same reason. Absence of a pulse may indicate that the site of **stenosis** (narrowing or constriction) or occlusion is proximal to that level. Occlusive arterial disease impairs blood flow and can reduce or obliterate palpable pulsations in the extremities. Pulses should be palpated bilaterally and simultaneously, comparing both sides for symmetry in rate, rhythm, and quality.

Diagnostic Evaluation

The nurse should educate the patient on the purpose of the diagnostic studies, what to expect, and any possible side effects related to these examinations. Trends in results are noted because they provide information about disease progression as well as the patient's response to therapy. Various tests may be performed to identify and diagnose abnormalities that can affect the vascular structures (arteries, veins, and lymphatics).

Doppler Ultrasound Flow Studies

When pulses cannot be reliably palpated, a handheld continuous wave (CW) Doppler ultrasound device may be used to detect the blood flow. This handheld device emits a continuous signal through the patient's tissues. The signals are reflected by the moving blood cells and received by the device. The filtered-output Doppler signal is then transmitted to a loudspeaker or headphones, where it can be heard for interpretation as arterial or venous signals (Fischbach & Fischbach, 2018). The depth at which blood flow can be detected by Doppler is determined by the frequency (in megahertz [MHz]) it generates. The lower the frequency, the deeper the tissue penetration; a 5- to 10-MHz probe may be used to evaluate the peripheral arteries.

Figure 26-2 • Assessing peripheral pulses. **A.** Popliteal pulse. **B.** Dorsalis pedis pulse. **C.** Posterior tibial pulse. Reprinted with permission from Weber, J. R., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

To evaluate the lower extremities, the patient is placed in the supine position with the head of the bed elevated 20 to 30 degrees; the legs are externally rotated, if possible, to permit adequate access to the medial malleolus. Acoustic water soluble gel is applied to the patient's skin to permit uniform transmission of the ultrasound wave. The tip of the Doppler transducer is positioned at a 45- to 60-degree angle over the expected location of the artery and angled slowly to identify arterial blood flow. Excessive pressure is avoided because severely diseased arteries can collapse with even minimal pressure.

The transducer can detect blood flow in advanced arterial disease states, especially if collateral circulation has developed; thus, identifying a signal indicates only the presence of blood flow. The patient's provider must be notified of the absence of a signal if one had been detected previously.

CW Doppler is more useful as a clinical tool when combined with ankle blood pressures, which are used to determine the **ankle-brachial index (ABI)** (see Fig. 26-3). The ABI is the ratio of the systolic blood pressure in the ankle to the systolic blood pressure in the arm (Zierler & Dawson, 2016). It is an objective indicator of arterial disease that allows the examiner to quantify the degree of stenosis. With increasing degrees of arterial narrowing, there is a progressive decrease in systolic pressure distal to the involved sites.

Figure 26-3 • Continuous wave Doppler ultrasound detects blood flow in peripheral vessels. Combined with computation of ankle or arm pressures, this diagnostic technique helps health care providers characterize the nature of peripheral vascular disease. Photograph courtesy of Kim Cantwell-Gab, MN, ACNP, ANP.

The first step in determining the ABI is to have the patient rest in a supine position (not seated) for approximately 5 minutes. An appropriate-sized blood pressure cuff (typically, a 10-cm cuff for an average-sized adult) is applied to the patient's ankle above the malleolus. After identifying an arterial signal of the posterior tibial (see Fig. 26-4) and dorsalis pedis arteries, the systolic pressures, are obtained in both ankles, while listening to the Doppler signal of each artery. Diastolic pressures in the ankles cannot be measured with Doppler. If pressure in these arteries cannot be obtained, pressure can be measured in the peroneal artery, which can also be assessed at the ankle.

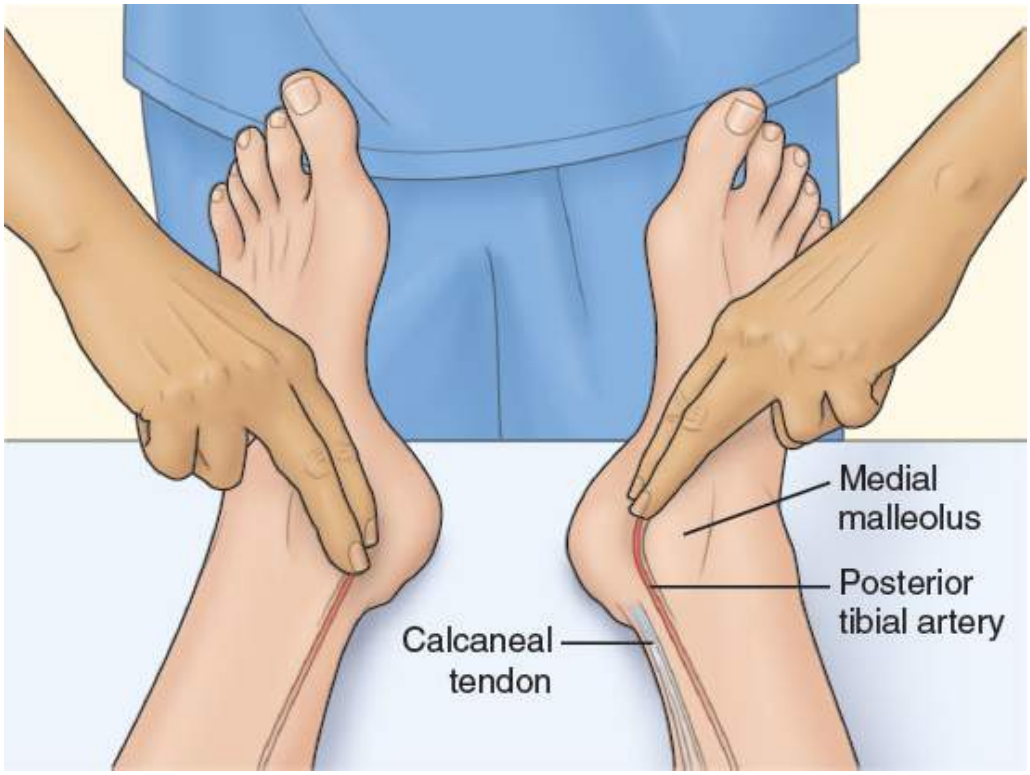

Figure 26-4 • Palpation of posterior tibial artery.

Doppler ultrasonography is used to measure brachial pressures in both arms. Both arms are evaluated because the patient may have an asymptomatic stenosis in the subclavian artery, causing brachial pressure on the affected side to be 15 to 20 mm Hg or more lower than systemic pressure. The abnormally low pressure should not be used for assessment.

To calculate the ABI, the highest systolic pressure for each ankle is divided by the higher of the two brachial systolic pressures (see Chart 26-1). The ABI can be computed for a patient with the following systolic pressures:

Right brachial: 160 mm Hg
Left brachial: 120 mm Hg
Right posterior tibial: 80 mm Hg
Right dorsalis pedis: 60 mm Hg
Left posterior tibial: 100 mm Hg
Left dorsalis pedis: 120 mm Hg

The highest systolic pressure for each ankle (80 mm Hg for the right, 120 mm Hg for the left) would be divided by the highest brachial pressure (160 mm Hg):

Right: 80/160 mm Hg = 0.50 ABI
Left: 120/160 mm Hg = 0.75 ABI

In general, systolic pressure in the ankle of a healthy person is the same or slightly higher than the brachial systolic pressure, resulting in an ABI of about 1.0 (no arterial insufficiency) (see Chart 26-2 for ABI pressure ranges).

Nursing Implications

Nurses should perform a baseline ABI on any patient with decreased pulses or any patient 65 years or older, especially patients with a history of diabetes or nicotine use (Gerhard-Herman, Gornik, Barrett, et al., 2016). Patients who undergo an arterial intervention or surgery should have ABIs performed per their institution's protocols. In addition, if there is a change in the clinical status of a patient, such as a sudden cold or painful limb, an ABI should be performed.

Prior to the procedure, nurses should educate patients about the indications for ABI and what to expect. Patients should be instructed to avoid use of nicotine products or drinking caffeinated beverages for at least 2 hours prior to testing (if it is done on a nonurgent basis). There may be some discomfort involved when the cuffs are inflated.

Chart 26-1

Avoiding Common Errors in Obtaining the Ankle-Brachial Index

Take the following precautions to ensure an accurate ankle-brachial index (ABI) calculation:

- *Use correctly sized blood pressure (BP) cuffs.* To obtain accurate BP measurements, use a cuff with a bladder width at least 40% and length at least 80% of the limb circumference.
- *On the nursing plan of care, document the cuff sizes used* (e.g., "12-cm adult cuff used for brachial pressures; 10-cm pediatric cuff used for ankle pressures"). This minimizes the risk of shift-to-shift discrepancies in ABIs.
- *Use sufficient cuff inflation.* To ensure complete closure of the artery and the most accurate measurements, inflate cuff 20 to 30 mm Hg beyond the point at which the last arterial signal is detected.
- *Do not deflate cuff too rapidly.* Try to maintain a deflation rate of 2 to 4 mm Hg/s for patients without arrhythmias and 2 mm Hg/s or slower for patients with arrhythmias. Deflating the cuff more rapidly may miss the patient's highest pressure and result in recording an erroneous (low) BP measurement.
- *Suspect medial calcific sclerosis any time an ABI is 1.20 or greater or ankle pressure is more than 250 mm Hg.* Medial calcific sclerosis is associated with diabetes, chronic kidney disease, and hyperparathyroidism. It produces falsely elevated ankle pressures by hardening the media of the arteries, making the vessels noncompressible.
- *Be suspicious of arterial pressures recorded at less than 40 mm Hg.* This may mean the venous signal has been mistaken for the arterial signal. If the arterial pressure, which is normally 120 mm Hg, is measured at less than 40 mm Hg, ask a colleague to double-check the readings before recording this as an arterial pressure.

Chart 26-2

Range of Ankle-Brachial Index (ABI) Pressure and Ischemic Manifestations

ABI >1.40 is abnormal; indicates noncompressible arteries; requires further testing with a toe-brachial index (TBI)
ABI of 1.00 to 1.40 is normal
ABI of 0.91 to 0.99 is borderline
ABI of ≤0.90 is abnormal
ABI of 0.50 to 0.90 (i.e., moderate to mild insufficiency) is usually found in patients with claudication
ABI of <0.50 is found in patients with ischemic rest pain
ABI of ≤0.40 is found in patients with severe ischemia or tissue loss

Exercise Testing

Exercise testing is used to determine how long a patient can walk and to measure the ankle systolic blood pressure in response to walking. The patient's brachial systolic blood pressure is obtained on each arm prior to treadmill walking. There are several exercise testing protocols; however, in most instances the patient walks on a treadmill at 1.5 mph with a 12% incline for a maximum of 5 minutes or walks with a gradual rise in speed and incline to the point of claudication. The exercise test can be modified to walking a set distance in a hallway. Most patients can complete the test unless they have significant arterial insufficiency, severe cardiac, pulmonary, or orthopedic problems, or a physical disability. A normal response is little or no drop in ankle systolic pressure after exercise. However, in a patient with true vascular claudication, the ankle pressure drops. Combining this hemodynamic information with the walking time helps to determine whether intervention is necessary. The nurse should reassure the patient that the treadmill test will not require running; rather, the test may require walking on a slight incline. In some instances cycling may be used to evaluate the patient's ability to walk.

Duplex Ultrasonography

Duplex ultrasonography involves B-mode grayscale imaging of the tissue, organs, and blood vessels (arterial and venous) and permits estimation of velocity changes by use of a pulsed Doppler (see Fig. 26-5). Color flow techniques, which can identify vessels, may be used to shorten the examination

time. Duplex ultrasound may be used to determine the level and extent of venous disease as well as chronicity of the disease. Using B mode and Doppler, it is possible to image and assess blood flow, evaluate flow of the distal vessels, locate the disease (stenosis versus occlusion), and determine anatomic morphology and the hemodynamic significance of plaque causing stenosis. Duplex ultrasound findings help in planning treatment and monitoring its outcomes. The test is noninvasive and usually requires no patient preparation. Patients who undergo abdominal vascular duplex ultrasound, however, should be advised to not eat or drink (i.e., NPO status) for at least 6 hours prior to the examination to decrease production of bowel gas that can interfere with the examination. The equipment is portable, making it useful anywhere for initial diagnosis, screening, or follow-up evaluations.

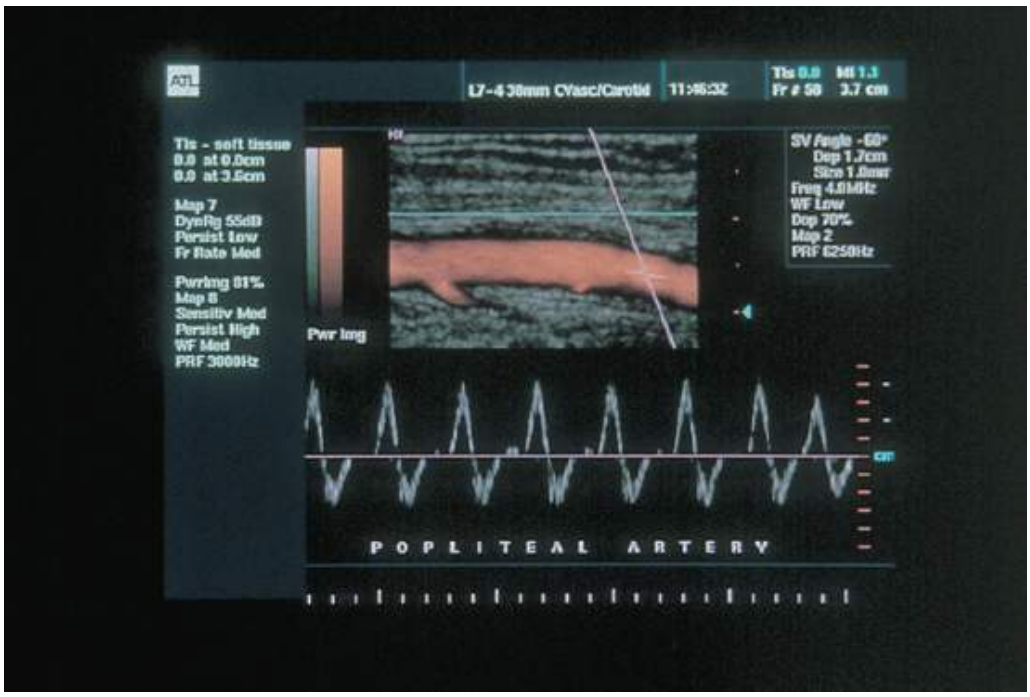

Figure 26-5 • Color flow duplex image of popliteal artery with normal triphasic Doppler flow.

Computed Tomography Scanning

Computed tomography (CT) scanning provides cross-sectional images of soft tissue and visualizes the area of volume changes to an extremity and the compartment where changes take place. CT scans of the abdomen are useful in assessing characteristics and monitoring changes within the aorta, such as an increasing aortic diameter indicating aneurysmal formation. CT of a lymphedematous arm or leg, for example, demonstrates a characteristic honeycomb pattern in the subcutaneous tissue. In multidetector-computed tomography (MDCT), a spiral CT scanner and rapid intravenous (IV) infusion

of contrast agent are used to image very thin sections of the target area, and the results are configured in three dimensions so that the image can be rotated and viewed from multiple angles. The scanner's head moves circumferentially around the patient as the patient passes through the scanner, creating a series of overlapping images that are connected to one another in a continuous spiral. Scan times are short. However, the patient is exposed to x-rays, and a contrast agent is injected to visualize the blood vessels. The high volume of contrast agent injected into a peripheral vein may contraindicate the use of MDCT in children and patients with significantly impaired renal function (Gerhard-Herman et al., 2016).

Nursing Implications

Patients with impaired renal function scheduled for MDCT may require preprocedural treatment to prevent contrast-induced nephropathy. This may include oral or IV hydration 6 to 12 hours preprocedure or administration of sodium bicarbonate, which alkalinizes urine and protects against free radical damage. Studies do not support the use of oral and IV *N*-acetylcysteine for protection against contrast-induced nephropathy (Fähling, Seeliger, Patzak, et al., 2017). The nurse should encourage fluids and monitor the patient's urinary output post procedure, which should be at least 0.5 mL/kg/h. Contrast-induced acute kidney injury may occur within 48 to 96 hours post procedure; therefore, the nurse should follow up with the patient's primary provider if this occurs (see Chapter 48 for discussion of acute kidney injury). Patients who have known iodine or shellfish allergies may need premedication with steroids and histamine blockers.

Angiography

An arteriogram produced by angiography may be used to confirm the diagnosis of occlusive arterial disease when surgery or other interventions are considered. It involves injecting a radiopaque contrast agent directly into the arterial system to visualize the vessels. The location of a vascular obstruction or an **aneurysm** (abnormal dilation of a blood vessel) and the collateral circulation can be demonstrated. Typically, the patient experiences a temporary sensation of warmth as the contrast agent is injected, and local irritation may occur at the injection site. Infrequently, a patient may have an immediate or delayed allergic reaction to the iodine contained in the contrast agent. Manifestations include dyspnea, nausea and vomiting, sweating, tachycardia, and numbness of the extremities. Any reaction must be reported to the interventionist at once; treatment may include the administration of epinephrine, antihistamines, or corticosteroids. Additional procedural risks include vessel injury, acute arterial occlusion, bleeding, or contrast nephropathy.

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) is performed with a standard magnetic resonance imaging (MRI) scanner and special software programmed to isolate the blood vessels. The resulting images can be rotated and viewed from multiple angles (Gerhard-Herman et al., 2016).

Nursing Implications

MRA is contraindicated in patients with metal implants. Prior to the MRA, the nurse should assess for the presence of any incompatible devices, such as aneurysm clips, old tattoos, which may contain trace elements (newer materials used in tattoos such as nitinol and titanium are MRI compatible), some medication patches, or a cardiac implantable electronic device. Patients with any type of cardiac implantable electronic device need to be screened to determine if they can safely undergo MRI (Indik, Gimbel, Abe, et al., 2017).

The nurse should educate the patient regarding what to expect during and after the procedure. The patient should be prepared to lie on a cold, hard table that slides into an enclosed small tube. The nurse should inform the patient that they will hear noises, including periodic banging and popping sounds. Patients with claustrophobia may be prescribed a sedative prior to the procedure. Patients should be instructed to close their eyes before entering the tube, and to keep them closed, as this may decrease claustrophobic symptoms. Patients should be reassured that they will be provided with a panic button to press if they feel a need to stop the procedure. MRA procedures require the use of IV contrast dye; therefore, nursing implications following MRA are the same as those for MDCT (discussed in CT section).

Contrast Phlebography (Venography)

Also known as venography, contrast phlebography involves injecting a radiopaque contrast agent into the venous system. If a **thrombus** (a blood clot within an artery or vein) exists, the x-ray image reveals an unfilled segment of vein in an otherwise completely filled vein. Injection of the contrast agent may cause brief but painful inflammation of the vein. This test is rarely performed, as duplex ultrasonography is considered the standard for diagnosing lower extremity venous thrombosis (Zierler & Dawson, 2016). The nurse should instruct the patient that they will receive contrast dye through a peripheral vein and will be monitored for 2 hours post venogram for access site oozing or hematoma. The guidelines for nursing care following venogram are the same as those for MDCT (see earlier discussion).

Lymphoscintigraphy

Lymphoscintigraphy involves injection of a radioactively labeled colloid subcutaneously in the second interdigital space. The extremity is then exercised to facilitate the uptake of the colloid by the lymphatic system, and serial images are obtained at preset intervals.

Nursing Implications

The nurse should educate the patient about what to expect. For instance, the blue dye typically used for this procedure may stain the injection site. If the patient has a lymphatic leak, as can occur with groin incisions, there may be blue drainage from the incision until the dye clears from the system, which may take several days.

ARTERIAL DISORDERS

Arterial disorders cause ischemia and tissue necrosis. These disorders may occur because of chronic progressive pathologic changes to the arterial vasculature (e.g., atherosclerotic changes) or an acute loss of blood flow to the tissues (e.g., aneurysm rupture).

Arteriosclerosis and Atherosclerosis

Arteriosclerosis (hardening of the arteries) is the most common disease of the arteries. It is a diffuse process whereby the muscle fibers and the endothelial lining of the walls of small arteries and arterioles become thickened. **Atherosclerosis** involves a different process, affecting the intima of large and medium-sized arteries. These changes consist of the accumulation of lipids, calcium, blood components, carbohydrates, and fibrous tissue on the intimal layer of the artery. These accumulations are referred to as atheromas or plaques.

Although the pathologic processes of arteriosclerosis and atherosclerosis differ, rarely does one occur without the other, and the terms are often used interchangeably. Atherosclerosis is a generalized disease of the arteries, and when it is present in the extremities, it is usually present elsewhere in the body.

Pathophysiology

The most common direct results of atherosclerosis in arteries include stenosis (narrowing) of the lumen, obstruction by thrombosis, aneurysm, ulceration, and rupture. Its indirect results are malnutrition and the subsequent fibrosis of the organs that the sclerotic arteries supply with blood. All actively functioning tissue cells require an abundant supply of nutrients and oxygen and are sensitive to any reduction in the supply of these nutrients. If such reductions are severe and permanent, the cells undergo ischemic necrosis (death of cells

due to deficient blood flow) and are replaced by fibrous tissues, which require much less blood flow.

Atherosclerosis can develop in any part of the vascular system, but certain sites are more vulnerable, such as regions where arteries bifurcate or branch into smaller vessels, with males having more below-the-knee pathology than females (Jelani, Petrov, Martinez, et al., 2018). In the proximal lower extremity, these include the distal abdominal aorta, the common iliac arteries, the orifice of the superficial femoral and profunda femoris arteries, and the superficial femoral artery in the adductor canal, which is particularly narrow. Distal to the knee, atherosclerosis can occur anywhere along the course of the artery.

Although many theories exist about the development of atherosclerosis, no single theory explains the pathogenesis completely; however, tenets of several theories are incorporated into the reaction-to-injury theory. According to this theory, vascular endothelial cell injury results from prolonged hemodynamic forces, such as shearing stresses and turbulent flow, irradiation, chemical exposure, or chronic hyperlipidemia. Injury to the endothelium increases the aggregation of platelets and monocytes at the site of the injury. Smooth muscle cells migrate and proliferate, allowing a matrix of collagen and elastic fibers to form (Norris, 2019).

Atherosclerotic lesions are of two types: fatty streaks and fibrous plaque.

- Fatty streaks are yellow and smooth, protrude slightly into the lumen of the artery, and are composed of lipids and elongated smooth muscle cells. These lesions have been found in the arteries of people of all ages, including infants. It is not clear whether fatty streaks predispose a person to the formation of fibrous plaques or whether they are reversible. They do not usually cause clinical symptoms.
- Fibrous plaques are composed of smooth muscle cells, collagen fibers, plasma components, and lipids. They are white to white-yellow and protrude to various degrees into the arterial lumen, sometimes completely obstructing it. These plaques are found predominantly in the abdominal aorta and the coronary, popliteal, and internal carotid arteries, and they are believed to be progressive lesions (see Fig. 26-6).

Gradual narrowing of the arterial lumen stimulates the development of collateral circulation (see Fig. 26-7). Collateral circulation arises from preexisting vessels that enlarge to reroute blood flow around a hemodynamically significant stenosis or occlusion. Collateral flow allows continued perfusion to the tissues, but it is often inadequate to meet increased metabolic demands, and ischemia results.

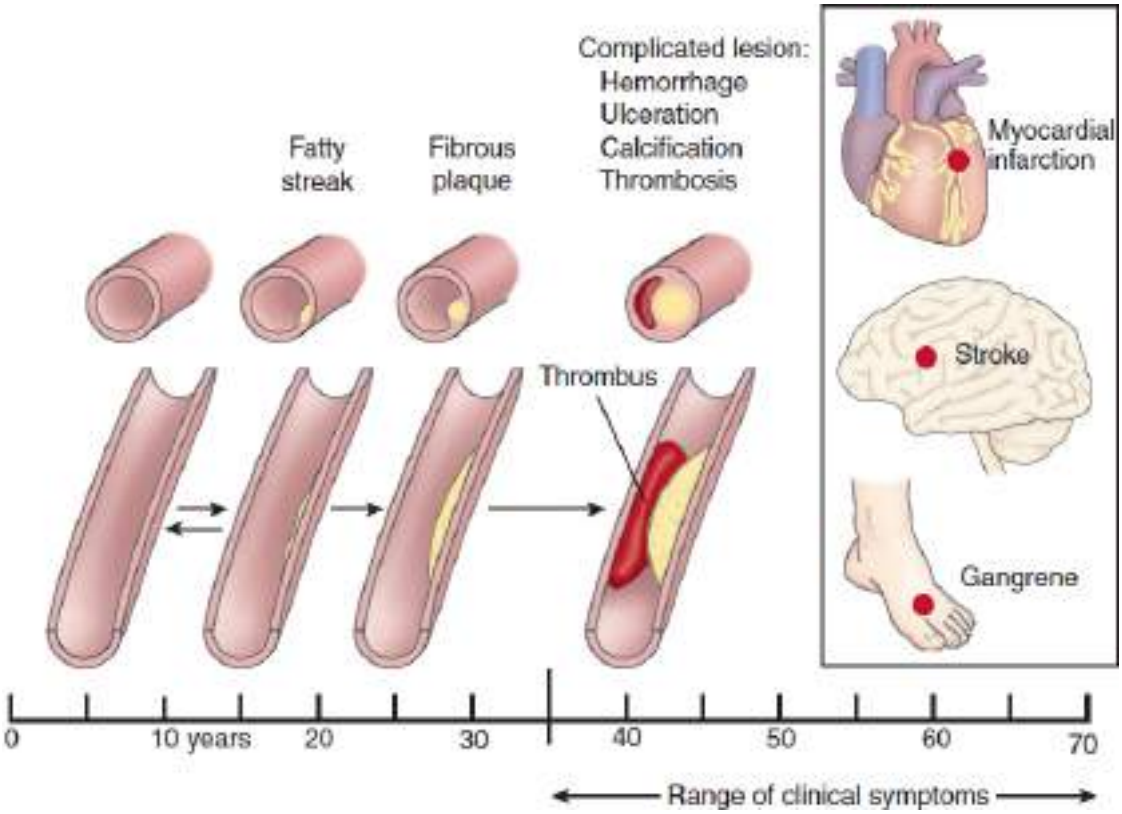

Figure 26-6 • Schematic concept of the progression of atherosclerosis. Fatty streaks are an early manifestation of atherosclerosis. Fatty streaks either regress or progress to fibrous plaques and eventually to atheroma. Atheromatous plaque may be complicated by hemorrhage, ulceration, calcification, or thrombosis leading to myocardial infarction, stroke, claudication, rest pain, or gangrene.

Risk Factors

Many risk factors are associated with atherosclerosis (see Chart 26-3). Although it is not entirely clear whether modification of these risk factors prevents the development of cardiovascular disease, evidence indicates that it may slow the process.

The use of nicotine products may be one of the most important risk factors in the development of atherosclerotic lesions. Nicotine in tobacco decreases blood flow to the extremities and increases heart rate and blood pressure by stimulating the sympathetic nervous system, causing vasoconstriction (Quintella Farah, Silva Rigoni, de Almeida Correia, et al., 2019). It also increases the risk of clot formation by increasing the aggregation of platelets. Carbon monoxide, a toxin produced by burning tobacco, combines more readily with hemoglobin than oxygen, depriving the tissues of oxygen. There is evidence that smoking decreases high-density lipoprotein (HDL; good cholesterol) levels and alters the ratios between HDL and low-density

lipoprotein (LDL; bad cholesterol), HDL and triglycerides, and HDL and total cholesterol levels (see Chapter 23 for discussion of HDL and LDL and their association with atherosclerosis). The amount of tobacco used—inhaled in traditional or e-cigarette form, or chewed—is directly related to the extent of the disease, and cessation of any type of nicotine product use reduces the risk (Jelani et al., 2018).

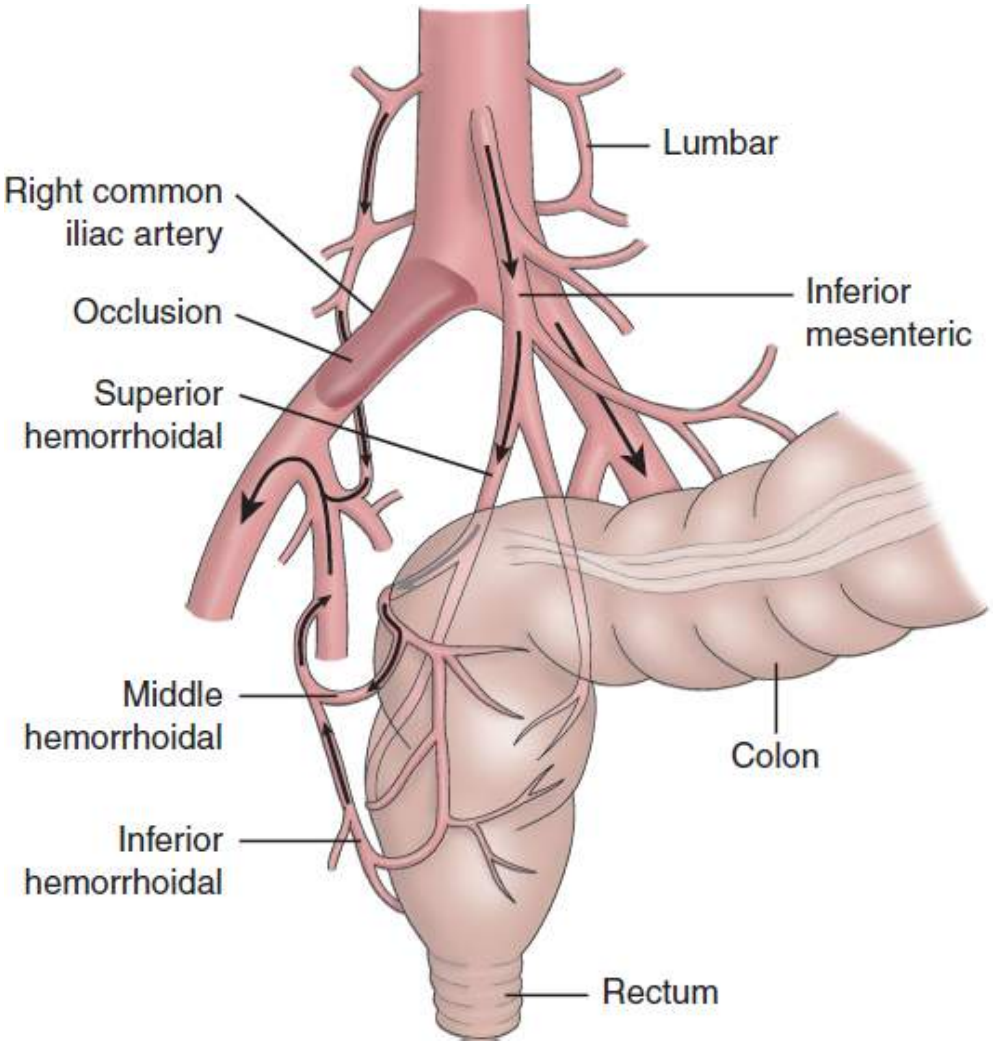

Figure 26-7 • Development of channels for collateral blood flow in response to occlusion of the right common iliac artery and the terminal aortic bifurcation.

Chart 26-3 RISK FACTORS

Atherosclerosis and Peripheral Artery Disease

Modifiable Risk Factors

- Nicotine use (i.e., tobacco product such as cigarettes, e-cigarettes, or chewing tobacco)
- Diabetes (speeds the atherosclerotic process by thickening the basement membranes of both large and small vessels)
- Hypertension
- Hyperlipidemia
- Diet (contributing to hyperlipidemia)
- Stress
- Sedentary lifestyle
- Elevated C-reactive protein
- Hyperhomocysteinemia

Nonmodifiable Risk Factors

- Increasing age
- Familial predisposition/genetics

Adapted from Sidawy, A. N., & Perler, B. A. (2019). *Rutherford's vascular surgery and endovascular therapy* (9th ed.). Philadelphia, PA: Elsevier.

Diabetes increases the overall risk of peripheral artery disease (PAD) two- to fourfold, with amputation rates 5 to 10 times higher than in patients without diabetes. Patients with diabetes show an earlier onset and more rapid progression of PAD than patients without diabetes; furthermore, they also exhibit a different anatomic distribution of pathology, with a greater severity of disease in the profunda femoris and in all segments below the knee (Gerhard-Herman et al., 2016). How diabetes affects the onset and progression of atherosclerosis is multifactorial and includes incitation of inflammatory processes, derangement of various cell types within vessel walls, promotion of coagulation, and inhibition of fibrinolysis (Hazarika & Annex, 2017). Many other factors, such as obesity, stress, and lack of exercise, have been identified as contributing to the disease process.

C-reactive protein (CRP) is a sensitive marker of cardiovascular inflammation, both systemically and locally. Slight increases in serum CRP levels are associated with an increased risk of damage in the vasculature, especially if these increases are accompanied by other risk factors, including increasing age, hypertension, hypercholesterolemia, obesity, elevated blood glucose levels, use of nicotine products, or a positive family history of cardiovascular disease (Hazarika & Annex, 2017).

In some studies, hyperhomocysteinemia has been positively correlated with the risk of peripheral, cerebrovascular, and coronary artery disease as well as

venous thromboembolism (VTE). Homocysteine is a protein that promotes coagulation by increasing factor V and factor XI activity while depressing protein C activation and increasing the binding of lipoprotein(a) in fibrin. These processes increase thrombin formation and the propensity for thrombosis. Folic acid and vitamin B_{12} have been reported to reduce serum homocysteine levels but there are no data demonstrating this therapy reduces adverse cardiovascular events. Thus, the use of B complex vitamins to reduce cardiovascular disease in patients with PAD is not recommended (Gerhard-Herman et al., 2016).

Prevention

Intermittent claudication is a symptom of generalized atherosclerosis and may be a marker of atherosclerosis in other arterial territories, such as the coronary and carotid arteries. The suspicion that a high-fat diet contributes to atherosclerosis means that it is reasonable to measure serum cholesterol and to begin disease prevention efforts that include diet modification. The American Heart Association recommends reducing the amount of fat ingested, substituting unsaturated fats for saturated fats, and decreasing cholesterol intake to reduce the risk of cardiovascular disease.

Certain medications that supplement dietary modification and exercise are used to reduce blood lipid levels. Current evidence-based guidelines established by the American College of Cardiology and the American Heart Association (ACC/AHA) recommend 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) as first-line therapy in patients with PAD for secondary prevention and cardiovascular risk reduction (Conte, Bradbury, Kolh, et al., 2019). These statins may include medications such as atorvastatin, lovastatin, pitavastatin, pravastatin, simvastatin, fluvastatin, and rosuvastatin. Several other classes of medications used to reduce lipid levels include bile acid sequestrants (cholestyramine, colesevelam, colestipol), nicotinic acid (niacin), fibric acid inhibitors (gemfibrozil, fenofibrate), and cholesterol absorption inhibitors (ezetimibe). Patients receiving long-term therapy with these medications require close monitoring.

Hypertension, which may accelerate the rate at which atherosclerotic lesions form in high-pressure vessels, can lead to a stroke, ischemic renal disease, severe PAD, or coronary artery disease. Hypertension is a major risk factor for the development of PAD and may be a more significant risk factor for women than men based on research findings from the classic Framingham Heart Study and a similar study performed in Europe (Jelani et al., 2018). The majority of patients with hypertension require more than two antihypertensive agents to reach target blood pressure, and at least one third require more than three antihypertensive agents to achieve effective blood pressure control

(Sidawy & Perler, 2019). See Chapter 27 for further discussion of hypertension.

Although no single risk factor has been identified as the primary contributor to the development of atherosclerotic cardiovascular disease, it is clear that the greater the number of risk factors, the greater the risk of atherosclerosis. Elimination of all controllable risk factors, particularly nicotine use, is strongly recommended.

Clinical Manifestations

The clinical signs and symptoms resulting from atherosclerosis depend on the organ or tissue affected. Coronary atherosclerosis (heart disease), angina, and acute myocardial infarction are discussed in Chapter 23. Cerebrovascular diseases, including transient ischemic attacks and stroke, are discussed in Chapter 62. Atherosclerosis of the aorta, including aneurysm, and atherosclerotic lesions of the extremities are discussed later in this chapter. Renovascular disease (renal artery stenosis and end-stage kidney disease) is discussed in Chapter 48.

Medical Management

The management of atherosclerosis involves modification of risk factors, a controlled exercise program to improve circulation and functional capacity, medication therapy, and interventional or surgical procedures.

Surgical Management

Vascular surgical procedures are divided into two groups: inflow procedures, which improve blood supply from the aorta into the femoral artery, and

outflow procedures, which provide blood supply to vessels below the femoral artery. Inflow surgical procedures are described with diseases of the aorta and outflow procedures with peripheral artery disease.

Endovascular Therapy

Endovascular therapies include various procedures that use a puncture or small incision to place catheters inside a blood vessel to repair it or insert a device and have replaced a large proportion of open surgical approaches to management. If an isolated lesion or lesions are identified on imaging, **angioplasty,** also called *percutaneous transluminal angioplasty* (PTA), or an atherectomy, may be performed. After the patient receives a local anesthetic agent, a balloon-tipped catheter is maneuvered across the area of stenosis. Although some clinicians theorize that PTA improves blood flow by overstretching (and thereby dilating) the elastic fibers of the nondiseased arterial segment, most believe that the procedure widens the arterial lumen by "cracking" and flattening the plaque against the vessel wall (see Chapter 23). An **atherectomy** reduces the plaque buildup within an artery using a cutting device or laser. Complications from PTA and atherectomy include hematoma formation, **embolus** (blood clot, fatty deposit, or air that travels through the blood, lodges in an artery or vein, and blocks flow), **dissection** (separation of the intima) of the vessel, acute arterial occlusion, and bleeding. To decrease the risk of restenosis, stents (small mesh tubes made of nitinol, titanium, or stainless steel) may be inserted to support the walls of the artery and prevent collapse immediately after balloon deflation (see Fig. 26-8). A variety of stents and stent grafts may be used for short-segment stenoses. Complications associated with stent or stent graft use include distal embolization, dissection, and dislodgment. The advantage of angioplasty, atherectomy, stents, and stent grafts is a decreased length of hospital stay; many of the procedures are performed on an outpatient basis.

Nursing Management

An overview of the care of a patient with peripheral artery problems is provided in Chart 26-4.

Improving Peripheral Arterial Circulation

Arterial blood supply to a body part can be enhanced by positioning the body part below the level of the heart. For the lower extremities, this is accomplished by elevating the head of the patient's bed or by having the patient use a reclining chair or sit with the feet resting on the floor.

Concept Mastery Alert

For patients with PAD, blood flow to the lower extremities needs to be enhanced; therefore, the nurse encourages keeping the lower extremities in a neutral or dependent position. In contrast, for patients with venous insufficiency, blood return to the heart needs to be enhanced, so the lower extremities are elevated. Exercise promotes the development of collateral circulation (arterial) and activates the musculovenous pump (venous).

The nurse can assist the patient with walking or other moderate or graded isometric exercises that promote blood flow and encourage the development of collateral circulation. The amount of exercise a patient can tolerate before the onset of pain is determined to provide a baseline for evaluation. The nurse instructs the patient to walk to the point of pain, rest until the pain subsides, and then resume walking so that endurance can be increased as collateral circulation develops. Pain can serve as a guide in determining the appropriate amount of exercise. The onset of pain indicates that the tissues are not receiving adequate oxygen, signaling the patient to rest. A supervised exercise therapy (SET) program should be prescribed for patients with claudication. SET can result in increased walking distance before the onset of claudication (Gerhard-Herman et al., 2016).

Before recommending any exercise program or SET, the patient's primary provider should be consulted. Conditions that worsen with exercise include leg ulcers, cellulitis, gangrene, or acute thrombotic occlusions.

Chart 26-4 **PLAN OF NURSING CARE**

Nursing Diagnosis: Impaired peripheral tissue perfusion associated with compromised circulation
Goal: Increased arterial blood supply to extremities

Nursing Interventions	Rationale	Expected Outcomes
1. Lower the extremities below the level of the heart (if condition is arterial). 2. Encourage moderate amount of walking or enrollment in supervised exercise therapy program if no contraindications exist.	1. Dependency of lower extremities enhances arterial blood supply. 2. Exercise promotes blood flow and the development of collateral circulation.	• Has extremities warm to touch • Has extremities with improved color • Experiences decreased muscle pain with exercise • Able to walk further distances

Goal: Decrease in venous congestion

Nursing Interventions	Rationale	Expected Outcomes
1. Elevate the extremities above the level of the heart (if condition is venous). 2. Discourage standing still or sitting for prolonged periods. 3. Encourage walking.	1. Elevation of extremities counteracts gravity, promotes venous return, and prevents venous stasis. 2. Prolonged standing still or sitting promotes venous stasis. 3. Walking promotes venous return by activating the "calf muscle pump."	• Elevates the extremities as prescribed • Has decreased edema of extremities • Avoids prolonged standing still or sitting • Gradually increases walking time daily

Goal: Promotion of vasodilation and prevention of vascular compression

Nursing Interventions	Rationale	Expected Outcomes
1. Maintain warm temperature and avoid chilling. 2. Discourage use of nicotine products. 3. Counsel to avoid emotional upsets;	1. Warmth promotes arterial flow by preventing vasoconstriction from chilling. 2. Nicotine in all tobacco products causes vasospasm, which	• Protects extremities from cold • Avoids all nicotine products • Uses stress management to

encourage stress management. 4. Encourage avoidance of constrictive clothing and accessories. 5. Encourage avoidance of crossing the legs. 6. Administer vasodilator medications and adrenergic-blocking agents as prescribed, with appropriate nursing considerations.	impedes peripheral circulation. 3. Emotional stress causes peripheral vasoconstriction by stimulating the sympathetic nervous system. 4. Constrictive clothing and accessories impede circulation and promote venous stasis. 5. Crossing the legs causes compression of vessels with subsequent impediment of circulation, resulting in venous stasis. 6. Vasodilators relax smooth muscle; adrenergic-blocking agents block the response to sympathetic nerve impulses or circulating catecholamines.	minimize emotional upset • Avoids constrictive clothing and accessories • Avoids crossing legs • Takes medication as prescribed

Nursing Diagnosis: Chronic pain associated with impaired ability of peripheral vessels to supply tissues with oxygen
Goal: Relief of pain

Nursing Interventions	Rationale	Expected Outcomes
1. Promote increased circulation through exercise (e.g., walking, upper extremity exercises, water aerobics, stationary cycling, supervised exercise therapy). 2. Administer analgesic agents as prescribed, with appropriate nursing considerations.	1. Enhancement of peripheral circulation increases the oxygen supplied to the muscle and decreases the accumulation of metabolites that cause muscle spasms. 2. Analgesic agents help reduce pain and allow the patient to participate in activities and exercises that promote circulation.	• Uses measures to increase arterial blood supply to extremities • Uses analgesic agents as prescribed

Nursing Diagnosis: Risk for impaired skin integrity associated with compromised circulation
Goal: Attainment/maintenance of tissue integrity

Nursing Interventions	Rationale	Expected Outcomes
1. Instruct in ways to avoid trauma to extremities. 2. Encourage wearing protective shoes and padding for pressure points; wear new shoes for short period of time and then inspect feet for signs of injury. 3. Encourage meticulous hygiene: bathing with neutral soaps, applying lotions (avoiding application between toes), and carefully trimming nails; see podiatrist for nail care. 4. Use caution to avoid scratching or vigorous rubbing. 5. Promote good nutrition; adequate intake of vitamins A and C, protein, and zinc; and weight reduction, if the patient is overweight or has obesity.	1. Poorly nourished tissues are susceptible to trauma and microbial invasion; wound healing is delayed or inhibited due to poor tissue perfusion. 2. Protective shoes and padding prevent foot injuries. 3. Neutral soaps and lotions prevent drying and cracking of skin; lotion application between toes increases moisture, which can lead to maceration of tissue. 4. Scratching and rubbing can cause skin abrasions and microbial invasion. 5. Good nutrition promotes healing and prevents tissue breakdown.	• Inspects skin daily for evidence of injury or ulceration • Avoids trauma and irritation to skin • Wears protective shoes • Adheres to meticulous hygiene regimen • Eats a healthy diet that contains adequate protein, zinc, and vitamins A and C

Nursing Diagnosis: Lack of knowledge regarding self-care activities
Goal: Adherence to the self-care program

Nursing Interventions	Rationale	Expected Outcomes
1. Include family/significant others in education. 2. Provide written instructions about foot and leg care and exercise therapy program. 3. Assist to obtain properly fitting clothing, shoes, and stockings. 4. Refer to self-help groups as indicated, such as smoking cessation clinics or stress management,	1. Adherence to the self-care program is enhanced when the patient receives support from family and from appropriate self-help groups and agencies. 2. Written instructions serve as a reminder and reinforcement of information. 3. Constrictive clothing and accessories impede circulation and promote venous stasis.	• Practices frequent position changes as prescribed • Practices postural exercises as prescribed • Takes medications as prescribed • Avoids vasoconstrictors

weight management, and supervised exercise therapy programs.	4. Reducing risk factors may reduce symptoms or slow disease progression.	• Uses measures to prevent trauma • Uses stress management • Accepts condition as chronic but amenable to therapies that will decrease symptoms

Promoting Vasodilation and Preventing Vascular Compression

Arterial dilation increases blood flow to the extremities and is therefore a goal for patients with PAD. However, if the arteries are severely sclerosed, inelastic, or damaged, dilation is not possible. For this reason, measures to promote vasodilation, such as medications, endovascular interventions or surgery, may be only minimally effective.

Nursing interventions may involve applications of warmth to promote arterial flow and instructions to the patient to avoid exposure to cold temperatures, which causes vasoconstriction. Adequate clothing and warm temperatures protect the patient from chilling.

Quality and Safety Nursing Alert

Patients are instructed to test the temperature of bath water and to avoid using hot-water bottles and heating pads on the extremities. It is safer to apply a hot-water bottle or a heating pad to the abdomen; this can cause reflex vasodilation in the extremities.

In patients with vasospastic disorders (e.g., Raynaud's disease), heat may be applied directly to ischemic extremities using a warmed or electric blanket; however, the temperature of the heat source must not exceed body temperature. Even at low temperatures, trauma to the tissues can occur in ischemic extremities.

Quality and Safety Nursing Alert

Excess heat may increase the metabolic rate of the extremities and the need for oxygen beyond that provided by the reduced arterial flow through the diseased artery. Heat must be used with great caution!

Nicotine from any tobacco product causes vasospasm and can thereby dramatically reduce circulation to the extremities. Tobacco smoke also impairs transport and cellular use of oxygen and increases blood viscosity. Patients with arterial insufficiency who smoke, chew tobacco, or use electronic nicotine delivery systems (ENDS), including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars, must be fully informed of the effects of nicotine on circulation and encouraged to stop.

Emotional stress can stimulate the sympathetic nervous system and cause peripheral vasoconstriction. Emotional stress can be minimized to some degree by avoiding stressful situations when possible or by consistently following a stress management program. Counseling services or use of alternative or complementary therapies (e.g., relaxation, yoga, aromatherapy, mindfulness) may be indicated for patients who cannot cope effectively with situational stressors.

Constrictive clothing and accessories such as tight socks or shoelaces may impede arterial circulation to the extremities and promote venous stasis and therefore should be avoided. Crossing the legs for more than 15 minutes at a time should be discouraged because it compresses vessels in the legs.

Relieving Pain

Frequently, the pain associated with peripheral arterial insufficiency is chronic, continuous, and disabling. It limits activities, affects work and life responsibilities, disturbs sleep, and alters the patient's sense of well-being. Patients may be depressed, irritable, and unable to exert the energy necessary to execute prescribed therapies, making pain relief even more difficult. Analgesic agents such as hydrocodone plus acetaminophen, oxycodone, oxycodone plus acetylsalicylic acid, or oxycodone plus acetaminophen may be helpful in reducing pain so that the patient can participate in therapies that can increase circulation and ultimately relieve pain more effectively. Particularly in older patients, these medications can be dangerous, contributing to delirium and falls. In all patients, issues of dependence need to be considered.

Maintaining Tissue Integrity

Poorly perfused tissues are susceptible to damage and infection. Patients with peripheral vascular disease and diabetes are at increased risk. When lesions develop, healing may be delayed or inhibited because of the poor blood supply to the area. Infected, nonhealing ulcerations of the extremities can be

debilitating and may require prolonged and often expensive treatments. Amputation of an ischemic toe, forefoot or limb may eventually be necessary. Measures to prevent these complications must be a high priority and vigorously implemented. Centers of excellence for the prevention of amputation which involve a multidisciplinary, specialty team approach to management have become increasingly important for early intervention and surveillance.

Trauma to the extremities must be avoided. Advising the patient to wear sturdy, well-fitting shoes or slippers to prevent injury to the skin may be helpful, and recommending neutral soaps and body lotions may prevent drying and cracking of skin. However, the nurse should instruct the patient not to apply lotion between the toes, because the increased moisture can lead to maceration of the interdigital skin. Scratching and vigorous rubbing can abrade skin and create sites for microbial invasion; therefore, feet should be patted dry. Stockings should be clean and dry. Fingernails and toenails should be carefully trimmed straight across and sharp corners filed to follow the contour of the nail. If the nails cannot be trimmed safely, it is necessary to consult a podiatrist, who can also remove corns and calluses. Special shoe inserts may be needed to prevent calluses from recurring. Blisters, ingrown toenails, infection, or other problems should be reported to health care professionals for treatment and follow-up. Patients with diminished vision and those with disability that limits mobility of the arms or legs may require assistance in periodically examining the lower extremities for trauma or evidence of inflammation or infection.

Good nutrition promotes healing and prevents tissue breakdown and is therefore included in the plan for patients with peripheral vascular disease. Eating a diet that contains adequate protein and vitamins is necessary for patients with arterial insufficiency. Key nutrients, such as vitamin C and zinc, play specific roles in wound healing. However, a meta-analysis of randomized controlled trials found no evidence to support that supplementation with vitamins and antioxidants prevents vascular diseases (Sultan, Murarka, Jahangir, et al., 2017). Obesity strains the heart, increases venous congestion, and reduces circulation; therefore, a weight reduction plan may be necessary for patients who are overweight or have obesity. A diet low in fats and lipids is indicated for patients with atherosclerosis.

Gerontologic Considerations

In older adults, the symptoms of PAD may be more pronounced than in younger people. In older patients who are inactive, limb ischemia or gangrene may be the first sign of disease (Schorr, Treat-Jacobson, Lindquist, et al., 2017). See the Nursing Research Profile in Chart 26-5. These patients may have adjusted their lifestyle to accommodate the limitations imposed by the

disease and may not walk far enough to develop symptoms of claudication due to other comorbid conditions such as chronic obstructive pulmonary disease (COPD) or heart failure. Circulation is decreased, although this is not apparent to the patient until trauma occurs. At this point, gangrene develops when minimal arterial flow is impaired further by edema formation resulting from the traumatic event.

Intermittent claudication may occur after walking only one half to one block or after walking up a slight incline. Any prolonged pressure on the foot can cause pressure injuries that may become ulcerated, infected, or gangrenous. The outcomes of arterial insufficiency can include reduced mobility and activity as well as a loss of independence. Older adults with reduced mobility are less likely to remain in the community setting, have higher rates of hospitalizations, and experience a poorer quality of life. Those with cognitive impairment may also be unable to verbalize symptoms such as pain.

Chart 26-5 **NURSING RESEARCH PROFILE**

Understanding the Relationship Between Peripheral Artery Disease (PAD) Symptoms and Ischemia

Schorr, E. N., Treat-Jacobson, D., Lindquist, R. (2017). The relationship between peripheral artery disease symptomatology and ischemia. *Nursing Research*, *66*(5), 378–387.

Purpose

Peripheral artery disease (PAD) impacts over eight million Americans and is associated with an increased risk for cardiovascular disease and mortality. It is typically identified when patients report claudication (i.e., aching, cramping pain, fatigue in calves with activity). However, less than 33% of individuals who have a diagnosis of PAD report classic claudication, potentially resulting in underdiagnosis of PAD. A better understanding of symptom presentation and changes in tissue oxygenation may enhance earlier detection and treatment of PAD. The aim of this study was to explore the range of symptoms (typical versus atypical, location, and description) that patients with PAD experience to better understand the relationship between symptom variation and calf muscle ischemia.

Design

This descriptive study explored symptoms during exercise testing and recovery in patients with a diagnosis of PAD. Individuals who were English speaking, 21 years of age or older, and met specific diagnostic criteria were recruited from a larger study. Participants with uncontrolled hypertension, angina or dyspnea on exercise testing, or vascular procedures performed within the last 3 months were excluded. Demographic and clinical data were collected. Ankle-brachial index (ABI) was used as a measure of disease severity. Participants exercised on a treadmill with a near-infrared spectroscopy device to measure calf muscle tissue saturation index (TSI). In addition, participants rated symptom intensity using a numerical rating scale (NRS) and provided self-report of symptom location and descriptors. Data were collected at three points (e.g., rest, exercise, recovery) during three successive treadmill tests. Descriptive statistics were generated and symptom variables and relevant demographic and clinical data (e.g., age, gender, race, ABI, diabetes, neuropathy) were examined with the TSI measurements during exercise and recovery using multilevel modeling procedures.

Findings

Three successive episodes of treadmill testing with 40 participants resulted in 120 exercise tests. The majority of participants were Caucasian males (80%) with an average age of 68 years (SD 0.92). More than half (69.2%) of tests were stopped due to discomfort in the calf, with only 55% of participants reporting typical descriptors of claudication. TSI declined rapidly between the start of exercise and symptom onset. The lowest TSI was often reached

before reported maximum discomfort. Changes in TSI were related to exercise time ($p < 0.001$), baseline TSI ($p < 0.001$), exercise rating ($p < 0.001$), and ABI ($p < 0.5$). In the recovery phase, TSI steadily increased as pain reduced; TSI was associated with recovery rating ($p < 0.001$) and ABI ($p < 0.03$).

Nursing Implications

Recognizing variations in symptom presentation (e.g., intensity, location, description) and associated ischemic changes in PAD is important in understanding individual patient experiences and tailoring education and treatment. Nurses should be aware that some patients with PAD may use terms such as *burn, pressure,* or *tight* to describe related discomfort and that patients may report discomfort in atypical locations, such as the foot. A better understanding of the full range of ischemic symptoms in PAD may prompt earlier diagnosis and facilitate risk factor modification and exercise therapy. Unlike other medical conditions, where the onset of pain indicates the potential of increasing tissue damage with ongoing activity, pain in PAD can be used as an indicator to adjust the exercise program to extend the person's walking distance. Exercise prescription can greatly reduce the progression of atherosclerosis, limiting not only distal disease but also coronary and cerebral disease. Although additional research is needed, nurses can consider these findings when planning care for patients with PAD to ensure they are providing appropriate education and encouraging safe exercise regimens.

Promoting Home, Community-Based, and Transitional Care

The self-care program is planned with the patient so that activities that promote arterial and venous circulation, relieve pain, and promote tissue integrity are acceptable. The patient and family are helped to understand the reasons for each aspect of the plan, the possible consequences of nonadherence, and the importance of keeping follow-up appointments. Long-term care of the feet and legs is of prime importance in the prevention of trauma, ulceration, and gangrene. Chart 26-6 provides detailed patient instructions for foot and leg care.

Peripheral Artery Disease

Arterial insufficiency of the extremities occurs most often in men and is a common cause of disability. The legs are most frequently affected; however, the upper extremities may be involved. The age of onset and the severity are influenced by the type and number of atherosclerotic risk factors (see Chart 26-3). In PAD, obstructive lesions are predominantly confined to segments of

the arterial system extending from the aorta below the renal arteries to the popliteal artery (see Fig. 26-9). Distal occlusive disease is frequently seen in patients with diabetes and in older patients (Gerhard-Herman et al., 2016).

Chart 26-6 **HOME CARE CHECKLIST**

Foot and Leg Care in Peripheral Vascular Disease

At the completion of education, the patient and/or caregiver will be able to:

- Describe the rationale for proper foot and leg care in managing peripheral vascular disease.
- Demonstrate daily foot hygiene: Wash between toes with mild soap and lukewarm water, then rinse thoroughly and pat rather than rub dry.
- Recognize the dangers of thermal injury.
  - Wear clean, loose, soft cotton socks (they are comfortable, allow air to circulate, and absorb moisture).
  - In cold weather, wear extra socks in extra-large shoes.
  - Avoid heating pads, whirlpools, and hot tubs.
  - Avoid sunburn.
- Identify safety concerns.
  - Inspect feet daily with a mirror for redness, dryness, cuts, blisters, and so forth.
  - Always wear soft shoes or slippers when out of bed.
  - Trim nails straight across after showering.
  - Consult podiatrist to trim nails if vision is decreased and for care of corns, blisters, and ingrown nails.
  - Clear pathways in house to prevent injury.
  - Avoid wearing thong sandals.
  - Use lamb's wool or foam between toes if they overlap or rub each other.
- Demonstrate the use of comfort measures.
  - Wear leather shoes with an extra-depth toe box. Synthetic shoes do not allow air to circulate.
  - If feet become dry and scaly, use cream or lotion with emollient. Never put cream or lotion between toes unless it has been prescribed.
  - Avoid scratching or vigorous rubbing, which could cause abrasions.
  - If feet perspire, especially between toes, use lamb's wool between toes to promote drying.
- Demonstrate strategies to decrease risk of constricting blood vessels.
  - Avoid circumferential compression around feet or legs—for example, by knee-high stockings or tight socks or constricting bandages.
  - Do not cross legs at knees.
  - Stop using all nicotine products (i.e., smoking or chewing) because nicotine causes vasoconstriction and vasospasm.

- Participate in regular walking or supervised exercise therapy to stimulate circulation.

- Recognize when to seek medical attention.
  - Contact health care provider at the onset of skin breakdown such as abrasions, blisters, fungal infection (athlete's foot), or pain.
  - Do not use any medication on feet or legs unless prescribed.
  - Avoid using iodine, alcohol, corn/wart-removing compound, or adhesive products before checking with primary provider.
- State understanding of community resources and referrals (if any).

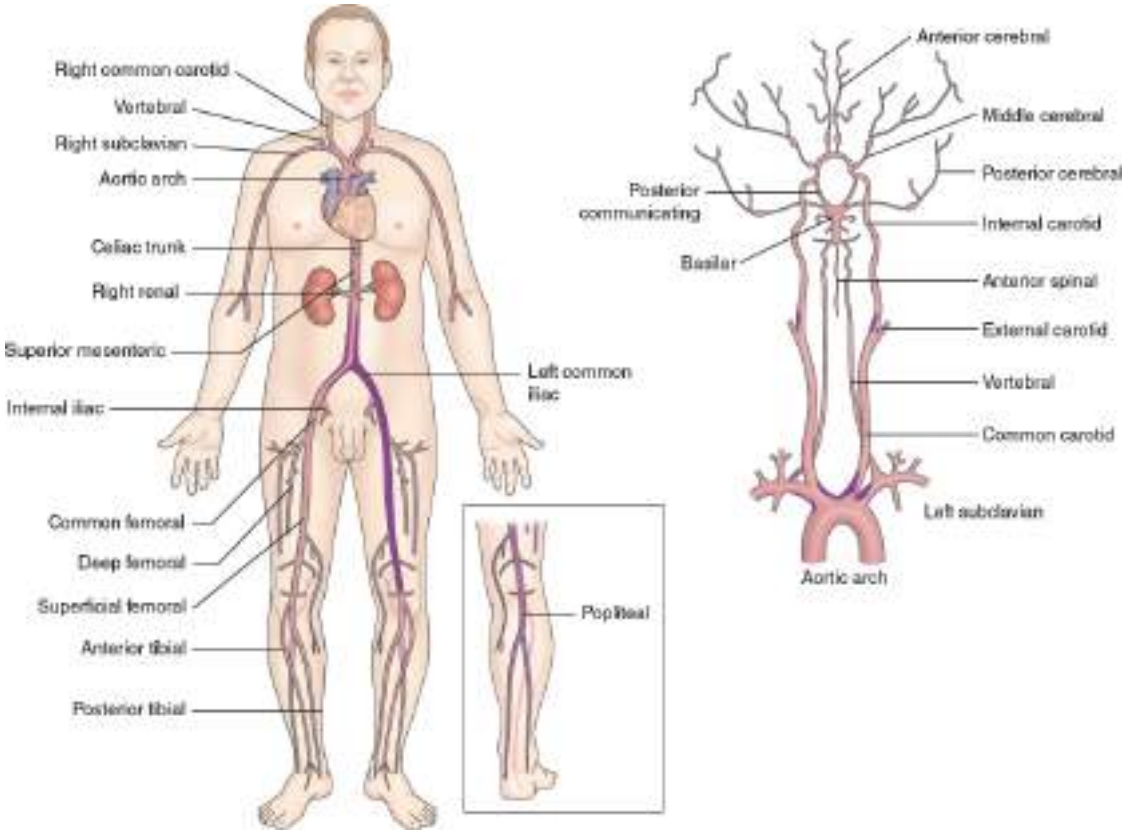

Figure 26-9 • Common sites of atherosclerotic obstruction in major arteries.

Clinical Manifestations

The hallmark symptom is intermittent claudication described as aching, cramping, or inducing fatigue or weakness that occurs with some degree of activity or exercise, which is relieved with rest. The pain commonly occurs in muscle groups distal to the area of stenosis or occlusion. As the disease progresses, the patient may have a decreased ability to walk the same distance as before or may notice increased pain with ambulation. When the arterial insufficiency becomes severe, the patient has rest pain. This pain is associated

with critical ischemia of the distal extremity and is described as persistent, aching, or boring; it may be so excruciating that it is unrelieved by opioids and can be disabling. Ischemic rest pain is usually worse at night and often wakes the patient. Elevating the extremity or placing it in a horizontal position increases the pain, whereas placing the extremity in a dependent position reduces the pain. In an attempt to prevent or relieve the pain, some patients sleep with the affected leg hanging over the side of the bed or sleep in a reclining chair.

Assessment and Diagnostic Findings

A sensation of coldness or numbness in the extremities may accompany intermittent claudication and is a result of reduced arterial flow. The extremity is cool and pale when elevated or ruddy and cyanotic when placed in a dependent position. Skin and nail changes, ulceration, gangrene, and muscle atrophy may be evident. Bruits may be auscultated with a stethoscope. Peripheral pulses may be diminished or absent.

Examination of the peripheral pulses is an important part of assessing PAD. Unequal pulses between extremities or the absence of a normally palpable pulse is a sign of PAD.

The presence, location, and extent of PAD are determined by a careful history of the symptoms and by physical examination. The color and temperature of the extremity are noted and the pulses palpated. The nails may be thickened and opaque, and the skin may be shiny, atrophic, and dry, with sparse or absent hair. The assessment includes comparison of the right and left extremities.

The diagnosis of PAD may be made using CW Doppler and ABIs, treadmill testing for claudication, duplex ultrasonography, or other imaging studies described earlier in this chapter.

Medical Management

Generally, patients feel better and have fewer symptoms of claudication after they participate in a SET program. SET programs are covered by insurance for a specific number of sessions. Reimbursement requires that SET is administered under direct provider supervision. A provider (e.g., physician, nurse practitioner, clinical nurse specialist, physician assistant) must be immediately and physically available, although not necessarily physically present, while SET is provided. The person providing the program supervision must be trained in the optimal delivery of SET and in both basic life support and advanced cardiac life support techniques. Unsupervised walking exercise programs are attractive for many patients with PAD with limited access to a SET program. Two recent trials in patients with PAD had similar findings

between the supervised and unsupervised groups, suggesting no greater therapeutic benefit for those who engage in supervised walking programs (McDermott, 2018). These findings suggest that home-based programs may be a viable and efficacious option for patients unable to participate in a structured, on-site, supervised exercise program. If a walking program is combined with weight reduction and cessation of nicotine use, patients often can further improve their activity tolerance. Patients should not be promised that their symptoms will be relieved if they stop nicotine use, however, because claudication may persist, and they may lose their motivation to stop using nicotine. In addition to these interventions, arm-ergometer exercise training effectively improves physical fitness, central cardiorespiratory function, and walking capacity in patients with claudication (Treat-Jacobson, McDermott, Beckman, et al., 2019).

Pharmacologic Therapy

Cilostazol is approved by the U.S. Food and Drug Administration (FDA) for the treatment of claudication. Cilostazol, a phosphodiesterase III inhibitor, is a direct vasodilator that inhibits platelet aggregation. Studies have shown it plays a role in decreasing intimal hyperplasia after angioplasty and stenting. Furthermore, patients prescribed cilostazol report improvement in maximal walking distance and pain-free walking distance within 4 to 6 weeks (Farkas, Járai, & Kolossváry, 2017). This agent is contraindicated in patients with a history of heart failure.

Antiplatelet agents, such as aspirin or clopidogrel, prevent the formation of thromboemboli which can lead to myocardial infarction and stroke and are recommended to treat patients with symptomatic PAD (Gerhard-Herman et al., 2016). Aspirin has been shown to reduce the risk of cardiovascular events (e.g., myocardial infarction, stroke, cardiovascular death) in patients with vascular disease; however, adverse events associated with aspirin use include gastrointestinal upset or bleeding (Gerhard-Herman et al., 2016).

Use of dual antiplatelet agents, such as aspirin and clopidogrel, in patients with symptomatic PAD has not been well established. However, dual antiplatelet agents may be effective and may be reasonable to reduce limb-threatening events after revascularization. Statins improve endothelial function in patients with PAD. Studies suggest that statins reduce severity of intermittent claudication and increase walking distance to the onset of claudication (Gerhard-Herman et al., 2016). These medications have beneficial effects on vascular inflammation, plaque stabilization, endothelial dysfunction, and thrombosis, and have been linked to decreased rates of repeat peripheral interventions, amputations, and major adverse cardiovascular events up to 3 years post procedure (Saxon, Safley, & Mena-Hurtado, 2020).

Endovascular Management

Endovascular interventions can include a balloon angioplasty, stent, stent graft, or an atherectomy. These revascularization procedures are less invasive than conventional surgery; their objective is to establish adequate inflow to the distal vessels. A meta-analysis reported that the efficacy and safety of all of these endovascular procedures are comparable to surgical interventions. Some stents that may be selected are drug eluting. Although costly, these are particularly efficacious in patients who have recurrent disease. By releasing antiproliferative drugs, drug-eluting balloons and stents have been shown to reduce the risk of restenosis. Eligible candidates for drug-eluting stents must be able to take antiplatelet medications for at least 6 months post procedure (Sidawy & Perler, 2019).

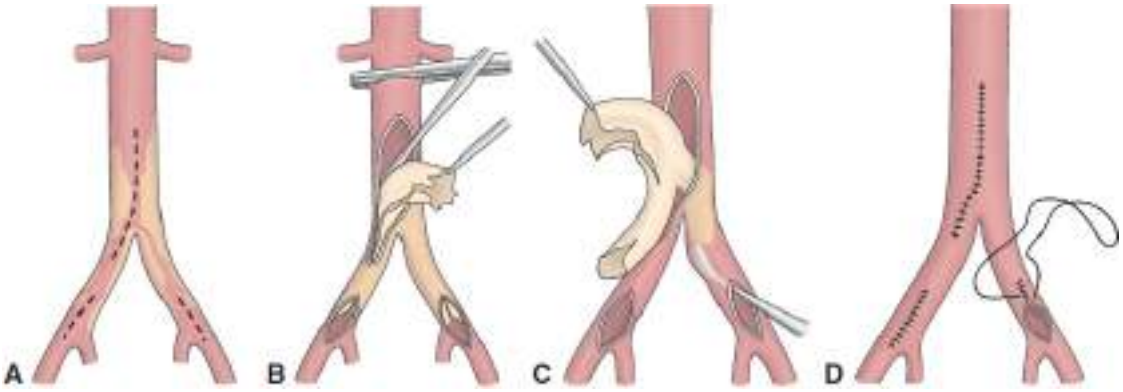

Figure 26-10 • In an aortoiliac endarterectomy, the vascular surgeon identifies the diseased area (**A**), clamps off the blood supply to the vessel (**B**), removes the plaque (**C**), and sutures the vessel shut (**D**), after which blood flow is restored. Adapted with permission from Sidawy, A. N., & Perler, B. A. (2019). *Rutherford's vascular surgery and endovascular therapy* (9th ed.). Philadelphia, PA: Elsevier.

Surgical Management

Surgery is reserved for the treatment of rest pain, severe and disabling claudication, or when the limb is at risk for amputation because of tissue necrosis. The choice of the surgical procedure depends on the degree, length, and location of the stenosis or occlusion and whether there are single or multiple lesions. Other important considerations are the overall health of the patient, the length of the procedure, and anesthesia required. If endarterectomy is performed, an incision is made into the artery and the atheromatous obstruction is removed (see Fig. 26-10).

Bypass grafts are performed to reroute the blood flow around the stenosis or occlusion. Before bypass grafting, the surgeon determines where the distal **anastomosis** (site where the vessels are surgically joined) will be placed. The distal outflow vessel must be at least 50% patent for the graft to remain open.

If the atherosclerotic occlusion is below the inguinal ligament in the superficial femoral artery, the surgical procedure of choice is the femoral-to-popliteal graft. This procedure is further classified as above- and below-knee grafts, referring to the location of the distal anastomosis. Bypass grafts may be synthetic materials or autologous vein. Several synthetic materials are available for use as a peripheral bypass graft: woven or knitted Dacron or expanded polytetrafluoroethylene (PTFE). Cryopreserved saphenous veins and umbilical veins are also available. When using an autologous conduit (i.e., the patient's own veins), the vein is either grafted to the artery in situ (the vein remains in place with the valves stripped and the vein is anastomosed to the proximal and distal target arteries), or the vein is harvested, reversed, and anastomosed to the proximal and distal target arteries.

Lower leg or ankle vessels with occlusions may also require grafts. Occasionally, the popliteal artery is completely occluded and only collateral vessels maintain perfusion. The distal anastomosis may be made onto any of the tibial arteries (posterior tibial, anterior tibial, or peroneal arteries) or the dorsalis pedis or plantar artery. The distal anastomosis site is determined by the ease of exposure of the vessel in surgery and by which vessel provides the best flow to the distal limb. These grafts require the use of an autologous vein to ensure patency. The greater or lesser saphenous vein or a combination of one of the saphenous veins and an upper extremity vein such as the cephalic vein is used to provide the required length.

How long the graft remains patent is determined by several factors, including the size of the graft, graft location, and development of intimal hyperplasia at anastomosis sites (Sidawy & Perler, 2019). Infection of synthetic grafts may result in sepsis and almost always requires removal.

If a vein graft is the surgical choice, care must be taken in the operating room not to damage the vein after harvesting (removing the vein from the patient's body). The vein is occluded at one end and inflated with a heparinized solution to check for leakage and competency. The graft is then placed in a heparinized solution to keep it from becoming dry and brittle until use during the operative procedure.

For patients who cannot tolerate an extensive vascular surgical procedure, a palliative approach involving primary amputation rather than an endarterectomy or bypass may be considered (Conte et al., 2019).

Nursing Management

Nursing care for patients with PAD is reviewed in Chart 26-4. Nursing care for the patient who has had endovascular revascularization procedures mostly mirrors the care of patients who have had endovascular repair to aortic aneurysms (see later section). The patient who has had an endovascular

procedure may be discharged home the day of the procedure, or by the following day.

Nursing Care of the Postoperative Patient

During the postoperative period, the nurse's care focuses on maintaining circulation, identifying and managing potential complications, and discharge planning.

Maintaining Circulation

The primary objective in the postoperative period is to maintain adequate circulation through the arterial repair. Pulses, Doppler assessment, color and temperature, capillary refill, and sensory and motor function of the affected extremity are checked and compared with those of the other extremity; these observations are recorded initially every 15 minutes and then at progressively longer intervals if the patient's status remains stable. Doppler evaluation of the vessels distal to the bypass graft should be performed, because it is more sensitive than palpation for pulses. The ABI is monitored at least once every 8 hours for the first 24 hours (not usually assessed with pedal artery bypasses due to the risk of compression of the anastomosis by the cuff) and then once each day until discharge; the typical hospital length of stay is 3 to 5 days. An adequate circulating blood volume should be established and maintained. Disappearance of a pulse that was present may indicate thrombotic occlusion of the graft; the surgeon is immediately notified.

Monitoring and Managing Potential Complications

Continuous monitoring of urine output, central venous pressure, mental status, and pulse rate and volume permits early recognition and treatment of fluid imbalances. Bleeding can result from the heparin given during surgery or from an anastomotic leak. A hematoma may form as well. The nurse should review the operative report to determine if the heparin was reversed (usually with protamine sulfate) in the operating room.

Leg crossing and prolonged extremity dependency are avoided to prevent thrombosis. Edema is a normal postoperative finding due to increased arterial flow; however, elevating the extremities and encouraging the patient to exercise the extremities while in bed reduces edema. Graduated compression or anti-embolism stockings may be prescribed for some patients, but care must be taken to avoid compressing distal vessel bypass grafts, inducing pressure injuries, and obscuring visualization of the extremity. Severe edema of the extremity, pain, and decreased sensation of toes or fingers can be an indication of compartment syndrome (see Chapter 37).

Promoting Home, Community-Based, and Transitional Care

Discharge planning includes assessing the patient's ability to manage activities of daily living (ADLs) independently. The nurse determines whether the patient has a network of family and friends to assist with ADLs. The patient is encouraged to make the lifestyle changes necessitated by the onset of disease, including pain management and modifications in diet, activity, and hygiene (skin care). The nurse ensures that the patient has the knowledge and ability to assess for any postoperative complications such as infection, occlusion of the artery or graft, and decreased blood flow. The nurse assists the patient in developing and implementing a plan to stop using tobacco products.

Upper Extremity Arterial Disease

Arterial stenosis and occlusions occur less frequently in the upper extremities (arms) than in the legs, and cause less severe symptoms because the collateral circulation is significantly better in the arms. The arms also have less muscle mass and are not subjected to the workload of the legs.

Clinical Manifestations

Stenosis and occlusions in the upper extremity result from atherosclerosis or trauma. The stenosis usually occurs at the origin of the vessel proximal to the vertebral artery, which results in the vertebral artery becoming the dominant vessel for blood flow. The patient typically complains of arm fatigue and pain with exercise (forearm claudication), inability to hold or grasp objects (e.g., combing hair, placing objects on shelves above the head), and occasionally difficulty driving.

The patient may develop a "subclavian steal" syndrome characterized by reverse flow in the vertebral and basilar arteries to provide blood flow to the arm. This syndrome may cause vertebrobasilar (cerebral) symptoms, including vertigo, ataxia, syncope, or bilateral visual changes.

Assessment and Diagnostic Findings

Findings on assessment include coolness and pallor of the affected extremity, decreased capillary refill, and a difference in arm blood pressures of more than 15 to 20 mm Hg (Zierler & Dawson, 2016). Noninvasive studies performed to evaluate upper extremity arterial occlusions include upper and forearm blood pressure determinations and duplex ultrasonography to identify the anatomic location of the lesion and to evaluate the hemodynamics of blood flow. Transcranial Doppler evaluation is performed to evaluate the intracranial circulation and to detect any siphoning of blood flow from the posterior

circulation to provide blood flow to the affected arm. If an endovascular or surgical procedure is planned, a diagnostic arteriogram may be necessary.

Medical Management

If a short focal lesion is identified in an upper extremity artery, a PTA with possible stent or stent graft placement may be performed. If the lesion involves the subclavian artery with documented siphoning of blood flow from the intracranial circulation and an endovascular procedure is not possible, a surgical bypass may be performed.

Nursing Management

Nursing assessment involves bilateral comparison of upper arm blood pressures (obtained by stethoscope and Doppler), radial, ulnar, and brachial pulses, motor and sensory function, temperature, color changes, and capillary refill every 2 hours. Disappearance of a pulse or Doppler flow that had been present may indicate an acute occlusion of the vessel, and the primary provider is notified immediately.

After surgery or an endovascular procedure, the arm is kept at heart level or elevated, with the fingers at the highest level. Pulses are monitored with Doppler assessment of the arterial flow every hour for 2 hours and then every shift. Blood pressure (obtained by stethoscope and Doppler) is also assessed every hour for 4 hours and then every shift. Motor and sensory function, warmth, color, and capillary refill are monitored with each arterial flow (pulse) assessment.

Quality and Safety Nursing Alert

Before surgery and for 24 hours after surgery, the patient's arm is kept at heart level and protected from cold, venous and arterial punctures, tape, pressure, and constrictive dressings.

Discharge planning is similar to that for the patient with PAD. Chart 26-4 describes nursing care for patients with peripheral vascular disease.

Aortoiliac Disease

If collateral circulation has developed, patients with a stenosis or occlusion of the aortoiliac segment may be asymptomatic, or they may complain of buttock or low back discomfort associated with walking. Men may have erectile

dysfunction or experience impotence. These patients may have decreased or absent femoral pulses.

Medical Management

The treatment of aortoiliac disease is essentially the same as that for atherosclerotic PAD. An endovascular procedure, such as bilateral common iliac stents, may be attempted if the aorta has a less than 50% diameter reduction (Gerhard-Herman et al., 2016). If there is significant aortic disease, the surgical procedure of choice is the aortoiliac graft. If possible, the distal graft is anastomosed to the iliac artery, and the entire surgical procedure is performed within the abdomen. If the iliac vessels are occluded, the distal anastomosis is made to the femoral arteries (aortobifemoral graft). A femoral–femoral crossover graft may also be needed to maintain circulation. Bifurcated woven or knitted Dacron grafts are preferred for this surgical procedure.

Nursing Management

Preprocedural or preoperative assessment, in addition to the standard parameters (see Chapter 14), includes evaluating the brachial, radial, ulnar, femoral, popliteal, posterior tibial, and dorsalis pedis pulses to establish a baseline for follow-up after arterial lines are placed and postoperatively. Patient education includes an overview of the procedure to be performed, the preparation for an endovascular procedure or surgery, and the anticipated postprocedural or postoperative plan of care. Sights, sounds, and sensations that the patient may experience are discussed.

Postprocedural endovascular care mirrors the care described for the patient who has had endovascular repair of an aortic aneurysm (see later discussion). Postoperative care includes monitoring for signs of thrombosis in arteries distal to the surgical site. The nurse assesses color and temperature of the extremity, capillary refill time, sensory and motor function, and pulses by palpation and Doppler initially every 15 minutes and then at progressively longer intervals if the patient's status remains stable. Any dusky or bluish discoloration, coldness, decrease in sensory or motor function, or decrease in pulse quality is reported immediately to the primary provider.

Postoperative care also includes monitoring urine output and ensuring that output is at least 0.5 mL/kg/h. Renal function may be impaired as a result of hypoperfusion from hypotension, ischemia to the renal arteries during the surgical procedure, hypovolemia, or embolization of the renal artery or renal parenchyma. Vital signs, pain, and intake and output are monitored with the pulse and extremity assessments. Results of laboratory tests are monitored and reported to the primary provider. Abdominal assessment for bowel sounds and paralytic ileus is performed at least every 8 hours. Bowel sounds may not

return before the third postoperative day. The absence of bowel sounds, absence of flatus, and abdominal distention are indications of paralytic ileus. Manual manipulation of the bowel during surgery may have caused bruising, resulting in decreased peristalsis. Nasogastric suction may be necessary to decompress the bowel until peristalsis returns. A liquid bowel movement before the third postoperative day may indicate bowel ischemia, which may occur when the mesenteric blood supply (celiac, superior mesenteric, or inferior mesenteric arteries) is occluded. Ischemic bowel usually causes increased pain and a markedly elevated white blood cell count (20,000 to 30,000 cells/mm^3).

Aneurysms

An aneurysm is a localized sac or dilation formed at a weak point in the wall of the artery (see Fig. 26-11). It may be classified by its shape or form. The most common forms of aneurysms are saccular and fusiform. A saccular aneurysm projects from only one side of the vessel. If an entire arterial segment becomes dilated, a fusiform aneurysm develops. Very small aneurysms due to localized infection are called *mycotic aneurysms.*

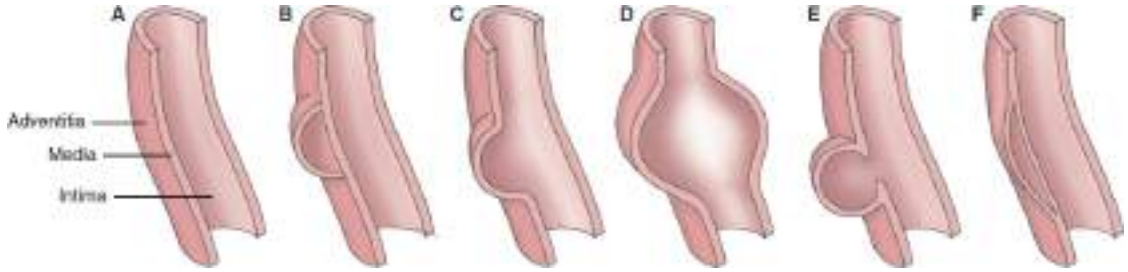

Figure 26-11 • Characteristics of arterial aneurysm. **A.** Normal artery. **B.** False aneurysm—actually a pulsating hematoma. The clot and connective tissue are outside the arterial wall. **C.** True aneurysm. One, two, or all three layers of the artery may be involved. **D.** Fusiform aneurysm—symmetric, spindle-shaped expansion of entire circumference of involved vessel. **E.** Saccular aneurysm—a bulbous protrusion of one side of the arterial wall. **F.** Dissecting aneurysm—this usually is a hematoma that splits the layers of the arterial wall. Adapted with permission from Sidawy, A. N., & Perler, B. A. (2019). *Rutherford's vascular surgery and endovascular therapy* (9th ed.). Philadelphia, PA: Elsevier.

Historically, the cause of abdominal aortic aneurysm, the most common type of degenerative aneurysm, has been attributed to atherosclerotic changes in the aorta. Other causes of aneurysm formation are listed in Chart 26-7.

Aneurysms are potentially serious; if they are located in large vessels that rupture, this can lead to hemorrhage and death.

Chart 26-7

Etiologic Classification of Arterial Aneurysms

Anastomotic (postarteriotomy) and graft aneurysms: Infection, arterial wall failure, suture failure, graft failure

Congenital: Primary connective tissue disorders (Marfan syndrome, Ehlers–Danlos syndrome) and other diseases (focal medial agenesis, tuberous sclerosis, Turner syndrome, Menkes syndrome)

Infectious (mycotic): Bacterial, fungal, spirochetal infections

Inflammatory (noninfectious): Associated with arteritis (Takayasu disease, giant cell arteritis, systemic lupus erythematosus, Behçet syndrome, Kawasaki disease) and periarterial inflammation (i.e., pancreatitis)

Mechanical (hemodynamic): Poststenotic and arteriovenous fistula and amputation related

Pregnancy-related degenerative: Nonspecific, inflammatory variant

Traumatic (pseudoaneurysms): Penetrating arterial injuries, blunt arterial injuries, pseudoaneurysms

Adapted from Sidawy, A. N., & Perler, B. A. (2019). *Rutherford's vascular surgery and endovascular therapy* (9th ed.). Philadelphia, PA: Elsevier.

Thoracic Aortic Aneurysm

Approximately 70% of all cases of thoracic aortic aneurysm are caused by atherosclerosis. They occur most frequently in men between the ages of 50 and 70 years, and are estimated to affect 10 of every 100,000 older adults. The thoracic area is the most common site for a dissecting aneurysm. Thoracic aortic emergencies are associated with high morbidity and mortality rates, but with the emergence of endovascular aortic repair there is an improvement in the mortality rate; in particular, the mortality rate for patients treated at high-volume aortic centers can be as low as 4.8% (Harris, Olson, Panthofer, et al., 2019).

Clinical Manifestations

Symptoms vary and depend on how rapidly the aneurysm dilates and how the pulsating mass affects surrounding intrathoracic structures. Some patients are asymptomatic. In most cases, pain is the most prominent symptom. The pain is usually constant and boring but may occur only when the person is supine. Other conspicuous symptoms are dyspnea, the result of pressure of the aneurysm sac against the trachea, a main bronchus, or the lung itself; cough,

frequently paroxysmal and with a brassy quality; hoarseness, stridor, or vocal weakness or aphonia (complete loss of the voice), resulting from pressure against the laryngeal nerve; and dysphagia (difficulty in swallowing) due to impingement on the esophagus by the aneurysm.

Assessment and Diagnostic Findings

When large veins in the chest are compressed by the aneurysm, the superficial veins of the chest, neck, or arms become dilated, and edematous areas on the chest wall and cyanosis are often evident. Pressure against the cervical sympathetic chain can result in unequal pupils. Diagnosis of a thoracic aortic aneurysm is principally made by chest x-ray, computed tomography angiography (CTA), MRA, or transesophageal echocardiography (TEE). CTAs are typically performed because they are widely available, can be completed rapidly, and can remove cardiac motion artifacts, enhancing their accuracy (Sidawy & Perler, 2019).

Medical Management

Treatment is based on whether the patient is symptomatic and whether the aneurysm is expanding in size, caused by an iatrogenic injury, contains a dissection, or involves branch vessels. General measures such as controlling blood pressure and correcting risk factors are helpful. For decades, beta-blockers (e.g., atenolol, metoprolol, carvedilol) have been the mainstay of medical treatment for aortic aneurysms; however, angiotensin receptor blockers (ARBs) (e.g., losartan, valsartan, irbesartan) may also retard aortic dilation (Rurali, Perrucci, Pilato, et al., 2018). It is also important to control blood pressure in patients with dissecting aneurysms. Preoperatively, the systolic pressure is maintained at approximately 90 to 120 mm Hg in order to maintain a mean arterial pressure at 65 to 75 mm Hg with a beta-blocker such as esmolol or metoprolol. Occasionally, antihypertensive agents such as hydralazine are used for this purpose. Sodium nitroprusside is the most established drug used for this purpose; it is given by continuous IV drip to emergently lower the blood pressure, as it has a rapid onset and short action of duration and is easily titrated (Sidawy & Perler, 2019). The goal of surgery is to repair the aneurysm and restore vascular continuity with a vascular graft. Intensive monitoring is required after this type of surgery, and the patient is cared for in the critical care unit.

Repair of thoracic aneurysms using endovascular grafts placed percutaneously in an interventional suite (e.g., interventional radiology, cardiac catheterization laboratory) or combined interventional suite and operating room (hybrid suite) may decrease postoperative recovery time and decrease complications compared with traditional surgical techniques. Thoracic

endografts are made of PTFE material reinforced with nitinol or titanium stents. These endovascular grafts are inserted into the thoracic aorta via various vascular access routes, usually the brachial or femoral artery. Because a large surgical incision is not necessary to gain vascular access, the overall patient recovery time tends to be shorter than with open surgical repair. Despite the absence of aortic cross-clamping, there is still a 2% to 15% chance of spinal cord ischemia as a potential complication (Miranda, Sousa, & Mansilha, 2018). To decrease the chances of spinal cord ischemia and paraplegia, lumbar spinal drains are usually placed in patients undergoing an endovascular repair of thoracic aortic aneurysms. Cerebrospinal fluid drainage is performed to decrease the arterial to cerebral spinal fluid gradient, thereby improving spinal perfusion. What appears to be most important in preventing neurologic deficit is to maintain the cerebrospinal fluid pressure less than or equal to 10 mm Hg (14 cm H_2O) and to keep the mean arterial pressure greater than 90 mm Hg for the first 36 to 48 hours postoperatively (Scali, Kim, Kubilis, et al., 2018).

Abdominal Aortic Aneurysm

The most common cause of abdominal aortic aneurysm is atherosclerosis. This condition affects men two to six times more often than women, is two to three times more common in White versus Black men, and is most prevalent in patients older than 65 years of age (Sidawy & Perler, 2019). Most of these aneurysms occur below the renal arteries (infrarenal aneurysms). Untreated, the eventual outcome may be rupture and death.

Pathophysiology

All aneurysms involve a damaged media layer of the vessel. This may be caused by congenital weakness, trauma, or disease. After an aneurysm develops, it tends to enlarge. Risk factors include genetic predisposition, nicotine use, and hypertension; more than half of patients with aneurysms have hypertension.

Clinical Manifestations

Only about 40% of patients with abdominal aortic aneurysms have symptoms. Some patients complain that they can feel their heart beating in their abdomen when lying down, or they may say that they feel an abdominal mass or abdominal throbbing. If the abdominal aortic aneurysm is associated with thrombus, a major vessel may be occluded or smaller distal occlusions may result from emboli. Small cholesterol, platelet, or fibrin emboli may lodge in

the interosseous or digital arteries, causing cyanosis and mottling of the toes (also referred to as trashing or trash toes).

Signs of impending rupture include severe back or abdominal pain, which may be persistent or intermittent. Abdominal pain is often localized in the middle or lower abdomen to the left of the midline. Low back pain may be present because of pressure of the aneurysm on the lumbar nerves. Indications that the abdominal aortic aneurysm may be leaking or rupturing include constant, intense back pain; falling blood pressure; and decreasing hematocrit. Rupture into the peritoneal cavity is rapidly fatal. A retroperitoneal rupture (contained rupture) of an aneurysm may result in hematomas in the scrotum, perineum, flank, or penis. Signs of heart failure or a loud bruit may suggest a rupture into the vena cava. If the aneurysm adheres to the adjacent vena cava, the vena cava may become damaged when rupture or leak of the aneurysm occurs. Rupture into the vena cava results in higher-pressure arterial blood entering the lower-pressure venous system and causing turbulence, which is heard as a bruit. The high blood pressure and increased blood volume returning to the right side of the heart from the vena cava may cause heart failure.

Assessment and Diagnostic Findings

The most important diagnostic indication of an abdominal aortic aneurysm is a pulsatile mass in the middle and upper abdomen. Most clinically significant aortic aneurysms are palpable during routine physical examination; however, the sensitivity depends on the size of the aneurysm, abdominal girth of the patient (i.e., more difficult to find in the patient with obesity), and the skill of the examiner (Sidawy & Perler, 2019). A systolic bruit may be heard over the mass. Duplex ultrasonography or CTA is used to determine the size, length, and location of the aneurysm. When the aneurysm is small, ultrasonography is conducted at 6-month intervals until the aneurysm reaches a size so that surgery to prevent rupture is of more benefit than the possible complications of a surgical procedure. Some aneurysms remain stable over many years of monitoring.

Gerontologic Considerations

Most abdominal aortic aneurysms occur in patients between 60 and 90 years of age. Rupture is likely with coexisting hypertension and with aneurysms more than 6 cm wide. In most cases at this point, the chances of rupture are greater than the chances of death during surgical repair. If the older patient is considered at risk for complications related to surgery or anesthesia, the aneurysm is not repaired until it is at least 5.5 cm (2 inches) wide (Chaikof, Dalman, Eskandari, et al., 2018).

Medical Management

Medical management consists of pharmacologic, endovascular, and surgical interventions.

Pharmacologic Therapy

If the aneurysm is stable in size based on serial duplex ultrasound scans, the blood pressure is closely monitored over time, because there is an association between increased blood pressure and aneurysm rupture (Sidawy & Perler, 2019). Antihypertensive agents, including diuretics, beta-blockers, ACE inhibitors, ARBs, and calcium channel blockers, are frequently prescribed to maintain the patient's blood pressure within acceptable limits (see Chapter 27).

Endovascular and Surgical Management

An expanding or enlarging abdominal aortic aneurysm is likely to rupture. When an abdominal aortic aneurysm measured at least 5.5 cm (2 inches) wide or was enlarging, the standard treatment had been open surgical repair of the aneurysm by resecting the vessel and sewing a bypass graft in place. However, endovascular aortic repair has become a mainstay of therapy for treating an infrarenal abdominal aortic aneurysm and involves the transluminal placement and attachment of a sutureless aortic graft across the aneurysm (see Fig. 26-12). This procedure can be performed under local or regional anesthesia. Endovascular grafting of abdominal aortic aneurysms may be performed if the patient's abdominal aorta and iliac arteries are not extremely tortuous, small, calcified, or filled with thrombi. Results from multiple, prospective studies suggest comparable mortality rates among patients with aneurysms treated by endovascular grafting and those treated with surgical repair, with similar 5-year survival rates (Chaikof et al., 2018). Potential complications include bleeding, hematoma, or wound infection at the arterial insertion site; distal ischemia or embolization; dissection or perforation of the aorta; graft thrombosis or infection; break of the attachment system; graft migration; proximal or distal graft leaks; delayed rupture; and bowel ischemia.

Nursing Management

Before endovascular repair or surgery, nursing assessment is guided by anticipating rupture and recognizing that the patient may have cardiovascular, cerebral, pulmonary, and renal impairment from atherosclerosis. The functional capacity of all organ systems should be assessed. Medical therapies designed to stabilize physiologic function should be promptly implemented. Hemorrhage that leads to shock is a serious adverse consequence that must be treated decisively (see Chapter 11).

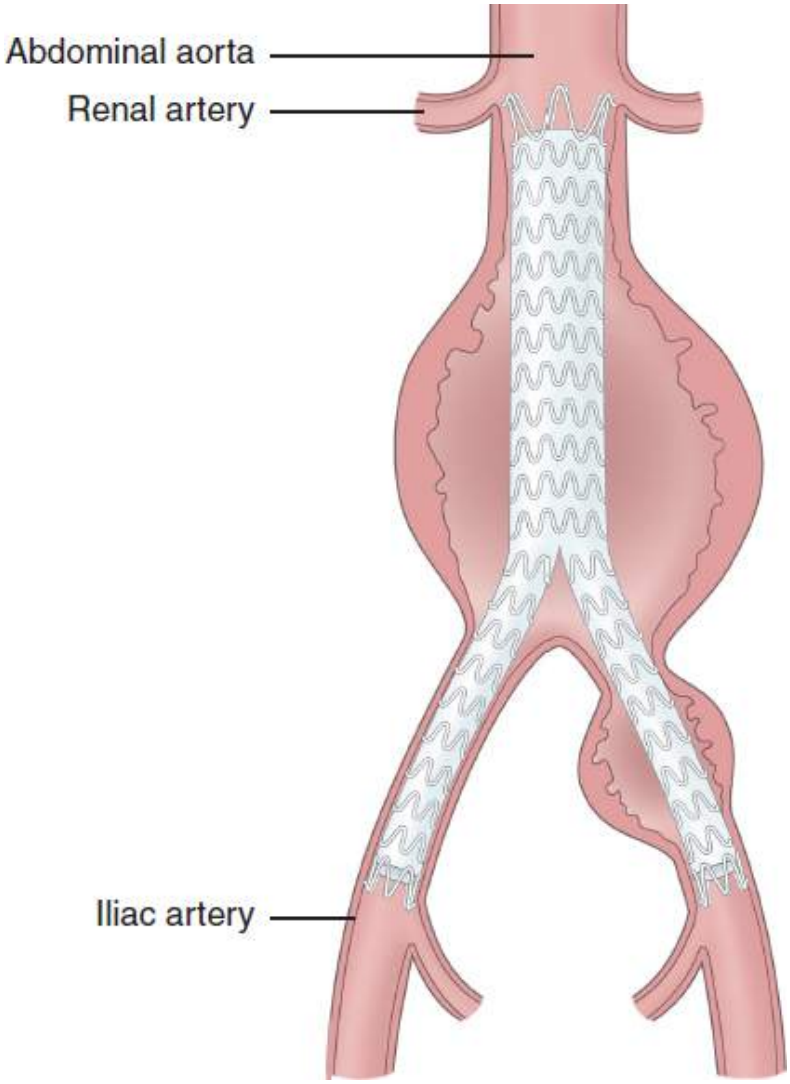

Figure 26-12 • Endograft repair of an abdominal aortic aneurysm.

The patient who has had an endovascular repair must lie supine for 6 hours; the head of the bed may be elevated up to 45 degrees after 2 hours. The patient needs to use a bedpan or urinal while on bed rest. Vital signs and Doppler assessment of peripheral pulses are performed initially every 15 minutes and then at progressively longer intervals if the patient's status remains stable. The access site (usually the femoral artery) is assessed when vital signs and pulses are monitored. The nurse assesses for bleeding and hematoma formation. Skin changes of the lower extremity, lumbar area, or buttocks that might indicate signs of embolization, such as extremely tender, irregularly shaped, cyanotic areas, as well as any changes in vital signs, pulse quality, bleeding, pulsation, swelling, pain, or hematoma, are immediately reported to the primary provider.

The patient's temperature should be monitored every 4 hours, and any signs of postimplantation syndrome should be reported. Postimplantation syndrome typically begins within 24 hours of stent graft placement and consists of a spontaneously occurring fever, leukocytosis, and occasionally, transient

thrombocytopenia. This condition has been attributed to complex immunologic changes that occur because of manipulations with sheaths and catheters with the aortic lumen, although the exact etiology is unknown. The symptoms are thought to be related to the activation of cytokines (Martinelli, Di Girolamo, Belli, et al., 2019). They can be managed with a mild analgesic (e.g., acetaminophen) or an anti-inflammatory agent (e.g., ibuprofen) and usually subside within a week.

Because of the increased risk of hemorrhage, the primary provider is also notified of persistent coughing, sneezing, vomiting, or systolic blood pressure greater than 180 mm Hg. Most patients can resume their preprocedure diet and are encouraged to drink fluids. An IV infusion may be continued until the patient can drink normally. Fluids are important to maintain blood flow through the arterial repair site and to assist the kidneys with excreting IV contrast agents and other medications used during the procedure. Six hours after the procedure, the patient may be able to roll from side to side and may be able to ambulate with assistance to the bathroom. Once the patient can take adequate fluids orally, the IV infusion may be discontinued.

Postoperative care requires frequent monitoring of pulmonary, cardiovascular, renal, and neurologic status. Possible complications of surgery include arterial occlusion, hemorrhage, infection, ischemic bowel, kidney injury, and erectile dysfunction.

Other Aneurysms

Aneurysms may also arise in the peripheral vessels, most often as a result of atherosclerosis. These may involve such vessels as the subclavian artery, renal artery, femoral artery, or (most frequently) popliteal artery. Between 50% and 60% of popliteal aneurysms are bilateral; the true incidence is unknown but has been reported to be between 0.1% and 3% of the adult population and is associated with abdominal aortic aneurysms (Sidawy & Perler, 2019).

The aneurysm produces a pulsating mass and disturbs peripheral circulation distal to it. Pain and swelling develop because of pressure on adjacent nerves and veins. Diagnosis is made by duplex ultrasonography or CTA to determine the size, length, and extent of the aneurysm. Arteriography may be performed to evaluate the level of proximal and distal involvement. The major complication associated with popliteal artery aneurysms is not rupture but distal embolization (Sidawy & Perler, 2019). Surgical repair is performed with replacement grafts. As an alternative, endovascular repair using a stent graft or wall graft, which is a Dacron or PTFE graft with external structures made from a variety of materials (e.g., nitinol, titanium, stainless steel) may be selected for additional support.

Aortic Dissection

Occasionally, in an aorta diseased by arteriosclerosis, a tear develops in the intima or the media degenerates, resulting in a dissection (see Fig. 26-11). Aortic dissections are three times more common in men than in women, occur most commonly in the 50- to 70-year age group and are associated with hypertension (Sidawy & Perler, 2019).

Pathophysiology

Aortic dissections (separations) are commonly associated with poorly controlled hypertension, blunt chest trauma, and cocaine use. The profound increase in sympathetic response caused by cocaine use creates an increase in the force of left ventricular contraction that causes heightened shear forces upon the aortic wall leading to disruption of the intima (Sidawy & Perler, 2019). Dissection is caused by rupture in the intimal layer. A rupture may occur through adventitia or into the lumen through the intima, allowing blood to reenter the main channel and resulting in chronic dissection (e.g., pseudoaneurysm) or occlusion of branches of the aorta.

As the separation progresses, the arteries branching from the involved area of the aorta shear and occlude. The tear occurs most commonly in the region of the aortic arch, with the highest mortality rate associated with ascending aortic dissection (Sidawy & Perler, 2019). The dissection of the aorta may progress backward in the direction of the heart, obstructing the openings to the coronary arteries or producing hemopericardium (effusion of blood into the pericardial sac) or aortic insufficiency, or it may extend in the opposite direction, causing occlusion of the arteries supplying the gastrointestinal tract, kidneys, spinal cord, and legs.

Clinical Manifestations

Onset of symptoms is usually sudden. Severe and persistent pain, described as tearing or ripping, may be reported. The pain is in the anterior chest or back and extends to the shoulders, epigastric area, or abdomen. Aortic dissection may be mistaken for an acute myocardial infarction, which confuses the clinical picture and initial treatment. Cardiovascular, neurologic, and gastrointestinal symptoms are responsible for other clinical manifestations, depending on the location and extent of the dissection. The patient may appear pale. Sweating and tachycardia may be detected. Blood pressure may be elevated or markedly different from one arm to the other if dissection involves the orifice of the subclavian artery on one side.

Assessment and Diagnostic Findings

Arteriography, multidetector-computed tomography angiography (MDCTA), TEE, duplex ultrasonography, and MRA, while limited in terms of expediency during an emergency situation, may aid in the diagnosis.

Medical Management

The medical or surgical treatment of an aortic dissection depends on the type of dissection present and follows the general principles outlined for the treatment of thoracic aortic aneurysms.

Nursing Management

A patient with an aortic dissection requires the same nursing care as a patient with an aortic aneurysm requiring intervention, as described earlier in this chapter. Nursing care as described in Chart 26-4 is also appropriate.

Arterial Embolism and Arterial Thrombosis

Acute vascular occlusion may be caused by an embolus or acute thrombosis. Acute arterial occlusions may result from iatrogenic injury, which can occur during insertion of invasive catheters such as those used for arteriography, PTA or stent placement, or an intra-aortic balloon pump, or it may occur as a result of illicit IV drug use. Other causes include trauma from a fracture or dislocation, crush injury, compartment syndrome, and penetrating wounds that disrupt the arterial intima. The accurate diagnosis of an arterial occlusion as embolic or thrombotic in origin is necessary to initiate appropriate treatment.

Pathophysiology

Arterial emboli arise most commonly from thrombi that develop in the chambers of the heart as a result of atrial fibrillation, myocardial infarction, infective endocarditis, or chronic heart failure. These thrombi become detached and are carried from the left side of the heart into the arterial system, where they lodge in and obstruct an artery that is smaller than the embolus. Emboli may also develop in advanced aortic atherosclerosis because the atheromatous plaques ulcerate or become rough. Acute thrombosis frequently occurs in patients with preexisting ischemic symptoms.

Clinical Manifestations

Symptoms of arterial emboli depend primarily on the size of the embolus, organ involvement, and the state of collateral vessels. The immediate effect is

cessation of distal blood flow. The blockage can progress distal and proximal to the site of the obstruction. Secondary vasospasm can contribute to the ischemia. The embolus can fragment or break apart, resulting in occlusion of distal vessels. Emboli tend to lodge at arterial bifurcations and areas narrowed by atherosclerosis. Cerebral, mesenteric, renal, and coronary arteries are often involved in addition to the large arteries of the extremities.

The symptoms of acute arterial embolism in extremities with poor collateral flow are acute, severe pain, and a gradual loss of sensory and motor function. The six Ps associated with acute arterial embolism are *p*ain, *p*allor, *p*ulselessness, *p*aresthesia, *p*oikilothermia (coldness), and *p*aralysis. Eventually, superficial veins may collapse because of decreased blood flow to the extremity. Because of ischemia, the part of the extremity distal to the occlusion is markedly colder and paler than the part proximal to the occlusion.

Arterial thrombosis can also acutely occlude an artery. A thrombosis is a slowly developing clot that usually occurs where the arterial wall has become damaged, generally as a result of atherosclerosis. Thrombi may also develop in an arterial aneurysm. The manifestations of an acute thrombotic arterial occlusion are similar to those described for an embolic occlusion. However, treatment is more difficult with a thrombus because the arterial occlusion has occurred in a degenerated vessel and requires more extensive reconstructive surgery to restore flow than is required with an embolic event (Sidawy & Perler, 2019).

Assessment and Diagnostic Findings

An arterial embolus is usually diagnosed on the basis of the sudden onset of symptoms and an apparent source for the embolus. Two-dimensional transthoracic echocardiography or transthoracic echocardiogram (TTE), chest x-ray, and electrocardiography (ECG) may reveal underlying cardiac disease. Noninvasive duplex and Doppler ultrasonography can determine the presence and extent of underlying atherosclerosis, and arteriography may be performed.

Medical Management

Management of arterial thrombosis depends on its cause. Management of acute embolic occlusion usually requires surgery because there is only a 4- to 6-hour window to restore blood flow before irreversible death of tissue. The event is acute with no collateral circulation developed, and the patient quickly moves through the list of six Ps to paralysis, the most advanced stage. Heparin therapy is initiated immediately to prevent further development of emboli and to prevent the extension of existing thrombi. Typically, an initial IV bolus of 60 to 80 U/kg body weight is given, followed by a continuous infusion of 12 to

18 U/kg/h until the patient undergoes an endovascular intervention or surgery (Comerford & Durkin, 2020; IBM Watson Health, 2020).

Endovascular Management

Emergency embolectomy is the procedure of choice if the involved extremity is viable (see Fig. 26-13). Arterial emboli are usually treated by insertion of an embolectomy catheter. The catheter is passed through an incision into the affected artery and extended through the embolus that is causing the arterial occlusion. The embolectomy catheter balloon is inflated with sterile saline solution, and the thrombus is extracted as the catheter is withdrawn. This procedure involves incising the vessel and removing the clot.

Percutaneous mechanical thrombectomy devices may also be used for the treatment of an acute thrombosis. All endovascular devices necessitate obtaining access to the patient's arterial system and inserting a catheter into the patient's artery to obtain access to the thrombus. The approach is similar to that used for angiograms, in that it is typically made through the groin to the femoral artery. In select cases, the radial or brachial artery can be accessed, allowing patients to be ambulatory post procedure. To qualify for this approach, the height of the patient is considered to ensure that the length of the catheter can reach the thrombus. Patients who are 5 feet 6 inches or shorter are potential candidates.

Some endovascular devices require that a small incision (cut-down) be made into the patient's artery. These devices may use a jet of fluid to disrupt the thrombus and then aspirate the particles; a rotating, sinusoidal-shaped wire that mixes a thrombolytic agent that simultaneously dissolves the clot; or high-frequency, low-energy ultrasound to dissolve an occlusive thrombus. Complications arising from the use of any endovascular device may include arterial dissection or distal artery embolization.

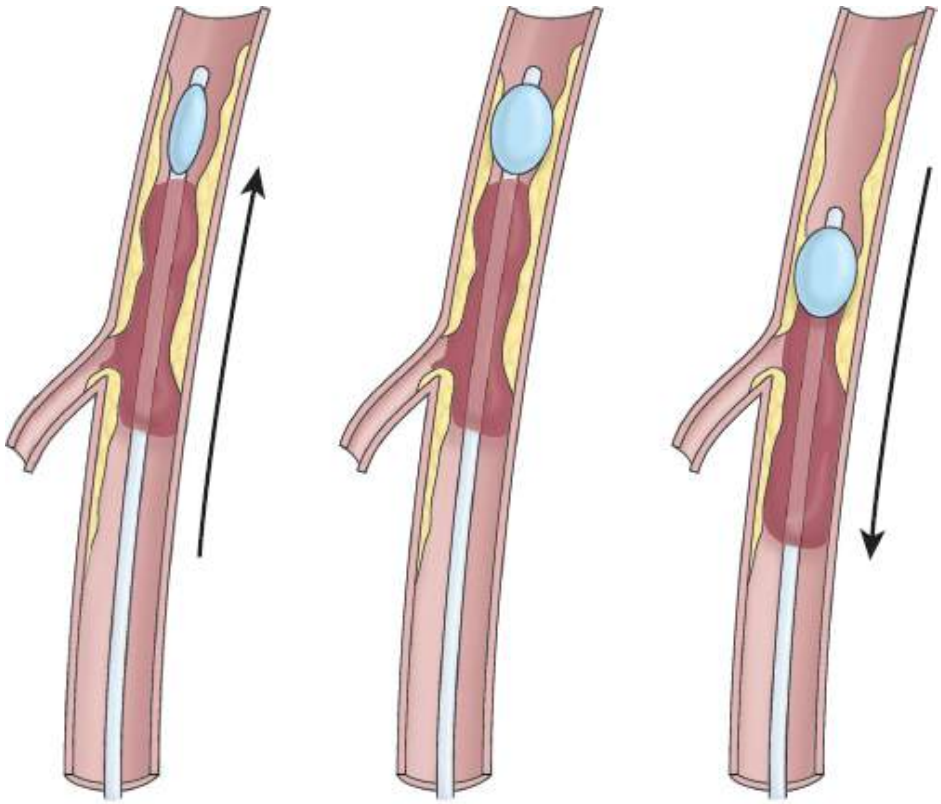

Figure 26-13 • Extraction of an embolus by a balloon-tipped embolectomy catheter. The deflated balloon-tipped catheter is advanced past the embolus, inflated, and then gently withdrawn, carrying the embolic material with it. Adapted with permission from Sidawy, A. N., & Perler, B. A. (2019). *Rutherford's vascular surgery and endovascular therapy* (9th ed.). Philadelphia, PA: Elsevier.

Pharmacologic Therapy

When the patient has adequate collateral circulation, treatment may include IV anticoagulation with heparin, which can prevent the thrombus from extending and reduce muscle necrosis. Intra-arterial thrombolytic medications are used to dissolve the embolus. Thrombolytic medications (e.g., tissue plasminogen activator [t-PA] and single-chain urokinase-type plasminogen activator) interact with plasminogen to generate plasmin which then breaks down fibrin clots. If t-PA is used for the treatment, heparin is usually given to prevent another thrombus from forming at the site of the lesion. The t-PA activates plasminogen on the thrombus, but it does not decrease the clotting factors as much as other thrombolytic therapies; therefore, patients receiving t-PA can make new thrombi more readily than if they receive other thrombolytics. Other thrombolytic medications are reteplase and tenecteplase (Millar & Laffan, 2017). Although these agents differ in their pharmacokinetics, they are given in a similar manner: A catheter is advanced under x-ray visualization to the clot, and the thrombolytic agent is infused.

Thrombolytic therapy should not be used when there are known contraindications to therapy or when the extremity cannot tolerate the several additional hours of ischemia that it takes for the agent to lyse (disintegrate) the clot. Contraindications to peripheral thrombolytic therapy include active internal bleeding, cerebrovascular hemorrhage, recent major surgery, uncontrolled hypertension, and pregnancy.

Nursing Management

Before an intervention or surgery, the patient remains on bed rest with the affected extremity level or slightly dependent (15 degrees). The affected extremity is kept at room temperature and protected from trauma. Heating and cooling pads are contraindicated because ischemic extremities are easily traumatized by alterations in temperature. If possible, tape and ECG electrodes should not be used on the extremity to protect from trauma. Pressure injury prevention through offloading the heel with a heel device and lifting the bedsheets using a bed cradle are important to protect the affected leg (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel, Pan Pacific Pressure Injury Alliance [EPUAP/NPIAP/PPPIA], 2019).

If the patient is treated with thrombolytic therapy, the dose is based on the patient's weight. The patient is admitted to a critical care unit for continuous monitoring. Vital signs are taken initially every 15 minutes and then at progressively longer intervals if the patient's status remains stable. The patient is closely monitored for bleeding. The nurse minimizes the number of punctures for inserting IV lines and obtaining blood samples, avoids intramuscular injections, prevents any possible tissue trauma, and applies pressure at least twice as long as usual after any puncture is performed.

During the recovery phase, the nurse collaborates with the primary provider about the patient's appropriate activity level based on the patient's condition. Generally, every effort is made to encourage the patient to move the extremity to stimulate circulation and prevent stasis. Anticoagulant therapy may be continued postendovascular intervention to prevent thrombosis of the affected artery and to diminish the development of subsequent thrombi at the initiating site. The nurse assesses for evidence of local and systemic hemorrhage, including mental status changes, which can occur when anticoagulants are given. Pulses, Doppler signals, ABI, and motor and sensory function are assessed every hour for the first 24 hours, because significant changes may indicate reocclusion. Metabolic abnormalities, acute kidney injury, and compartment syndrome may be complications after an acute arterial occlusion.

Raynaud's Phenomenon and Other Acrosyndromes

Raynaud's phenomenon is a form of intermittent arteriolar vasoconstriction that results in coldness, pain, and pallor of the fingertips or toes. There are two forms of this disorder. Primary or idiopathic Raynaud's (Raynaud's disease) occurs in the absence of an underlying disease. Secondary Raynaud (Raynaud syndrome) occurs in association with an underlying disease, usually a connective tissue disorder, such as systemic lupus erythematosus, rheumatoid arthritis, or scleroderma; trauma; or obstructive arterial lesions. Symptoms may result from a defect in basal heat production that eventually decreases the ability of cutaneous vessels to dilate. Episodes may be triggered by emotional factors, stress, or by unusual sensitivity to cold. Raynaud's phenomenon is five times more common in women with the typical onset before age 30 (Dean, 2018). Acrocyanosis has been thought to be a variant of Raynaud's phenomenon because both are aggravated by cold and emotional stress and both present with blue discoloration of the fingers and hyperhidrosis (excessive sweating).

The prognosis for patients with Raynaud's phenomenon varies; some slowly improve, some become progressively worse, and others show no change. Raynaud symptoms may be mild so that treatment is not required. However, secondary Raynaud is characterized by vasospasm and fixed blood vessel obstructions that may lead to ischemia, ulceration, and gangrene. Acrocyanosis is a poorly understood phenomenon that may be benign and require little or no treatment, or the patient may have chronic pain and ulcerations.

Clinical Manifestations

The classic clinical picture of Raynaud reveals pallor brought on by sudden vasoconstriction. The skin then becomes cyanotic because of pooling of deoxygenated blood during vasospasm. As a result of hyperemia (exaggerated reflow) due to vasodilation, rubor is produced when oxygenated blood returns to the digits after the vasospasm stops. The characteristic sequence of color change of Raynaud's phenomenon is described as white, blue, and red. Numbness, tingling, and burning pain occur as the color changes. The manifestations tend to be bilateral and symmetric and may involve toes and fingers.

Acrocyanosis is differentiated from Raynaud by a relative persistence of skin color changes, symmetry, and an absence of the paroxysmal pallor that is found with Raynaud. Almost all patients with acrocyanosis have marked clamminess and hyperhidrosis of their hands and feet, which tend to worsen in warmer temperatures while the color changes improve. Finger color normalizes when the hands are transferred from the dependent to horizontal position (Dean, 2018).

Medical Management

Avoiding the particular stimulus (e.g., cold, nicotine) that provokes vasoconstriction is a primary factor in controlling Raynaud's phenomenon. Decongestants and other over-the-counter preparations containing sympathomimetics should be avoided. Calcium channel blockers (nifedipine, amlodipine) may be effective in relieving symptoms. Sympathectomy (interrupting the sympathetic nerves by removing the sympathetic ganglia, or blocking or dividing their branches) may help some patients.

Avoidance of exposure to cold and trauma and implementing measures to improve local circulation are the primary focus of treatment for acrocyanosis. Calcium channel blockers have not been effective in treating acrocyanosis (Belch, Carlizza, Carpentier, et al., 2017).

Nursing Management

The nurse instructs the patient with Raynaud or acrocyanosis to avoid situations that may be stressful or unsafe. Stress management strategies may be helpful. Exposure to cold must be minimized, and in areas where the fall and winter months are cold, the patient should wear layers of clothing when outdoors. Hats and gloves or mittens should be worn at all times when outside. Fabrics specially designed for cold climates (e.g., Thinsulate™) are recommended. Patients should wear gloves when accessing freezers. Patients should warm up their vehicles before getting in so that they can avoid touching a cold steering wheel or door handle, which could elicit an attack. During summer, a sweater should be available when entering air-conditioned rooms.

Patients are often concerned about serious complications, such as gangrene and amputation; however, these complications are uncommon unless the patient has another underlying disease causing arterial occlusions. Patients should avoid all forms of nicotine, which may induce attacks; this includes nicotine gum or patches used to aid smoking cessation.

Patients should be cautioned to handle sharp objects carefully to avoid injuring their fingers. In addition, patients should be informed about the orthostatic hypotension that may result from medications, such as calcium channel blockers, used to treat Raynaud's phenomenon.

VENOUS DISORDERS

Venous disorders cause a reduction in venous blood flow, which results in stasis of blood. This may then cause a host of pathologic changes, including coagulation defects, edema, tissue breakdown, and an increased susceptibility to infections.

Venous Thromboembolism

Deep vein thrombosis (DVT) and pulmonary embolism (PE) collectively make up the condition called **venous thromboembolism (VTE).** The annual incidence of VTE is estimated at 1 to 2 per 1000 population (Peñaloza-Martínez, Demelo-Rodríguez, Proietti, et al., 2018; Serhal & Barnes, 2019). The incidence of VTE is 10% to 20% in general medical patients and up to 80% in critically ill patients. VTE is frequently not diagnosed because DVT and PE are often clinically silent or asymptomatic. It is estimated that as many as 30% of patients hospitalized with VTE develop long-term postthrombotic complications. In surgical patients, most symptomatic thromboembolic complications occur after hospital discharge due to shorter lengths of stay (Stubbs, Assareh, Curnow, et al., 2018).

COVID-19 Considerations

An underlying cause of death in patients with severe coronavirus disease 2019 (COVID-19) has been linked to VTE or primary pulmonary thrombi. The majority of patients who are severely ill with COVID-19 have a markedly elevated D-dimer assay (blood test for evidence of blood clots) and a presumed prothrombotic state. Because of this, routine thromboprophylaxis of all hospitalized patients with COVID-19 is recommended regardless of their risk score (see later discussion) (Obi, Barnes, Wakefield, et al., 2020). The systemic inflammatory changes in the vascular system in patients with COVID-19 likely contribute to thrombosis, hemodynamic instability, and autonomic dysregulation. Early reports suggest long-term cardiovascular effects of COVID-19 may include accelerated atherosclerosis, VTE, arterial thromboembolic disease, and aortic aneurysm formation (Becker, 2020).

Pathophysiology

Superficial veins, such as the greater saphenous, short saphenous (also known as lesser saphenous), cephalic, basilic, and external jugular veins, are thick-walled muscular structures that lie just under the skin. In contrast, deep veins are thin walled and have less muscle in the media. Deep veins run parallel to arteries and bear the same names as the arteries. Deep and superficial veins have valves that permit unidirectional flow back to the heart. The valves lie at the base of a segment of vein that is expanded into a sinus. This arrangement enables the valves to open without coming into contact with the wall of the vein, thus permitting rapid closure when the blood starts to flow backward. Other types of veins are known as perforating veins. These veins have valves that allow one-way blood flow from the superficial venous system to the deep venous system.

Although the exact cause of VTE remains unclear, three factors, known as Virchow triad, are believed to play a significant role in its development: endothelial damage, venous stasis, and altered coagulation (see Chart 26-8). Damage to the intimal lining of blood vessels creates a site for clot formation. Direct trauma to the veins may occur with fractures or dislocation, diseases of the veins, and chemical irritation of the vein from IV medications or solutions. Venous stasis occurs when blood flow is reduced, as in heart failure or shock; when veins are dilated, as an effect of some medication therapies; and when skeletal muscle contraction is reduced, as in immobility, paralysis of the extremities, or anesthesia. Altered coagulation occurs most commonly in patients for whom anticoagulant medications have been abruptly withdrawn. Oral contraceptive use, elevated CRP levels (Cauci, Francescato, Colannino, et al., 2020), and several blood dyscrasias (abnormalities) also can lead to hypercoagulability, with prevalence depending on the ethnicity of the patient. For example, factor V Leiden and prothrombin G20210A mutation is more prevalent in White persons, whereas antithrombin III deficiency, protein C deficiency, and protein S deficiency are found more commonly in patients of Southeast Asian descent (Sidawy & Perler, 2019). An increase in factor VIII concentrations is more common among African Americans (Folsom, Basu, Hong, et al., 2019). Pregnancy is also considered a hypercoagulable state, as it is accompanied by an increase in circulating clotting factors that may not return to baseline until longer than 6 weeks postpartum, increasing the risk of thrombosis. In addition, during pregnancy there is a 50% decrease in venous outflow due to hormonally decreased venous capacitance and reduced venous outflow due to compression from the uterus (Zheng, Chen, Fu, et al., 2019).

Chart 26-8 **RISK FACTORS**

Deep Vein Thrombosis and Pulmonary Embolism

Endothelial Damage

- Central venous catheters
- Dialysis access catheters
- Local vein damage
- Pacing wires
- Repetitive motion injury
- Surgery
- Trauma

Venous Stasis

- Age (>65 years)
- Bed rest or immobilization
- Heart failure
- History of varicosities
- Obesity
- Spinal cord injury

Altered Coagulation

- Antiphospholipid antibody syndrome
- Antithrombin III deficiency
- Cancer
- Elevated factors II, VIII, IX, XI
- Factor V Leiden defect
- Hyperhomocysteinemia
- Oral contraceptive use
- Polycythemia
- Pregnancy
- Protein C deficiency
- Protein S deficiency
- Prothrombin G20210A defect
- Septicemia

Deep Vein Thrombosis

Deep vein thrombosis (DVT) refers to thrombus formation in the deep veins, usually in the thigh or calf, but sometimes in the arm (e.g., patients with peripherally inserted central catheters).

Pathophysiology

Formation of a thrombus frequently accompanies phlebitis, which is an inflammation of the vein walls. When a thrombus develops initially in the veins as a result of stasis or hypercoagulability but without inflammation, the process is referred to as phlebothrombosis. Venous thrombosis can occur in any vein, but it occurs more often in the veins of the lower extremities. The superficial and deep veins of the extremities may be affected.

Upper extremity venous thrombosis accounts for 5% to 10% of all cases of DVT, but its incidence may be as high as 93% in the presence of central venous cannulation or upper extremity compression (Mintz & Levy, 2017). It typically involves more than one venous segment, with the subclavian vein the most frequently affected. In addition, upper extremity venous thrombosis is more common in patients with IV catheters or in patients with an underlying disease that causes hypercoagulability, such as cancer. Internal trauma to the vessels may result from pacemaker leads, chemotherapy ports, dialysis catheters, or parenteral nutrition lines. The lumen of the vein may be decreased as a result of the catheter or from external compression, such as by neoplasms or an extra cervical rib. Effort thrombosis, also known as Paget–Schroetter syndrome, of the upper extremity is caused by repetitive motion (e.g., as seen in competitive swimmers, tennis players, baseball players, weight lifters, or construction workers) that irritates the vessel wall, causing inflammation and subsequent thrombosis and is a manifestation of venous thoracic outlet syndrome where the veins becomes distorted and narrowed (Sidawy & Perler, 2019).

Venous thrombi are aggregates of platelets attached to the vein wall that have a tail-like appendage containing fibrin, white blood cells, and many red blood cells. The “tail” can grow or can propagate in the direction of blood flow as successive layers of the thrombus form. A propagating venous thrombosis is dangerous because parts of the thrombus can break off and occlude the pulmonary blood vessels. Fragmentation of the thrombus can occur spontaneously as it dissolves naturally, or it can occur with an elevated venous pressure, as may occur after standing suddenly or engaging in muscular activity after prolonged inactivity. After an episode of acute DVT, reestablishment of the lumen of the vessel, or recanalization, typically occurs. Lack of recanalization within the first 6 months after DVT appears to be an important predictor of postthrombotic syndrome, which is one complication of venous thrombosis (Sidawy & Perler, 2019) (see later discussion). Other complications of venous thrombosis are listed in Chart 26-9.

Clinical Manifestations

A major challenge in recognizing DVT is that the signs and symptoms are nonspecific. The exception is phlegmasia cerulea dolens (massive iliofemoral venous thrombosis), in which the entire extremity becomes massively swollen, tense, painful, and cool to the touch. The large DVT creates severe and sudden venous hypertension that leads to tissue ischemia with resultant translocation of fluid into the interstitial space. Venous gangrene occurs in 20% to 50% of cases and is associated with poor survival (Sidawy & Perler, 2019).

Chart 26-9

Complications of Venous Thrombosis

Chronic venous occlusion
Pulmonary emboli from dislodged thrombi
Valvular destruction:

- Chronic venous insufficiency
- Increased venous pressure
- Varicosities
- Venous ulcers

Venous obstruction:

- Edema
- Fluid stasis
- Increased distal pressure
- Venous gangrene

Adapted from Kahn, S. R., Galanaud, J. P., Vedantham, S., et al. (2016). Guidance for the prevention and treatment of the post-thrombotic syndrome. *Journal of Thrombosis and Thrombolysis*, *41*(1), 144–153.

Deep Veins

Clinical manifestations of obstruction of the deep veins include edema and swelling of the extremity because the outflow of venous blood is inhibited. The affected extremity may feel warmer than the unaffected extremity, and the superficial veins may appear more prominent. Tenderness, which usually occurs later, is produced by inflammation of the vein wall and can be detected by gently palpating the affected extremity. In some cases, signs and symptoms of a PE are the first indication of DVT.

Superficial Veins

Thrombosis of superficial veins, or superficial thrombophlebitis, produces pain or tenderness, redness, and warmth in the involved area. The risk of the superficial venous thrombi becoming dislodged or fragmenting into emboli is

very low because most of them dissolve spontaneously. This condition can be treated at home with bed rest, elevation of the leg, analgesic agents, and possibly, anti-inflammatory medication.

Assessment and Diagnostic Findings

Careful assessment is invaluable in detecting early signs of venous disorders of the lower extremities (see Chart 26-8). Diagnostic tests for VTE include laboratory and venous duplex studies. Laboratory tests are conducted to determine baseline levels and include complete blood count (CBC) and coagulation studies that include prothrombin time (PT), activated partial thromboplastin time (aPTT), and international normalized ratio (INR). If an underlying hypercoagulable state is suspected, additional laboratory testing may include CRP, factor V Leiden, prothrombin G20210A mutation, antithrombin III, protein C, and protein S (Fischbach & Fischbach, 2018). Duplex ultrasound findings may show veins that appear larger than normal with thrombus formation or veins that are incompressible and dilated. The thrombus may appear to be adherent to the vein wall or mobile with a thrombus tail.

Prevention

Patients with a prior history of VTE are at increased risk of a new episode; the rate of recurrence can be as high as 13.7% in men and 14.1% in women (Serhal & Barnes, 2019). VTE can be prevented, especially if patients who are considered at high risk are identified and preventive measures are instituted without delay. Preventive measures include encouragement of early ambulation and leg exercises, the application of graduated compression stockings, and the use of intermittent pneumatic compression devices (see later discussion). An additional method to prevent venous thrombosis in surgical patients is administration of subcutaneous unfractionated heparin or low-molecular-weight heparin (LMWH). Patients should be advised to make lifestyle changes as appropriate, which may include weight loss, smoking cessation, and regular exercise.

Medical Management

The objectives of treatment for DVT are to prevent the thrombus from extending and fragmenting (thus risking PE), recurrent thromboemboli, and postthrombotic syndrome (discussed later in the chapter) (Peñaloza-Martínez et al., 2018). Anticoagulant therapy involves the administration of a medication to delay the clotting time of blood, prevent the formation

of a thrombus in postoperative patients, and forestall the extension of a thrombus after it has formed; it can be used to meet the treatment goals for DVT (Witt, Nieuwlaat, Clark, et al., 2018). However, anticoagulant agents cannot dissolve a thrombus that has already formed. Combining anticoagulation with mechanical thrombectomy and ultrasound-guided thrombolytic therapy may eliminate venous obstruction, maintain venous patency, and prevent postthrombotic syndrome by early removal of the thrombus (Kruger, Eikelboom, Douketis, et al., 2019).

Pharmacologic Therapy

Medications for preventing or reducing blood clotting within the vascular system are indicated in patients diagnosed with DVT. These medications are also indicated for patients with thrombophlebitis, recurrent embolus formation, persistent leg edema from heart failure, and in select patients who must be immobilized for a protracted time (e.g., older adults with hip fractures). The primary pharmacologic treatment for the prevention and management of DVT is anticoagulant therapy which consists of vitamin K antagonists (e.g., warfarin), indirect and direct thrombin inhibitors, and factor Xa inhibitors (see Table 26-2).

Endovascular Management

Endovascular management is necessary for DVT when anticoagulant or thrombolytic therapy is contraindicated, the danger of PE is extreme, or venous drainage is so severely compromised that permanent damage to the extremity is likely. A thrombectomy may be necessary. This mechanical method of clot removal may involve using intraluminal catheters with a balloon or other devices. Some of these spin to break the clot, and others use oscillation to break up the clot to facilitate removal. Ultrasound-assisted thrombolysis may be another option. This intervention uses bursts or continuous high-frequency ultrasound waves emanating from the catheters to cause cavitation of the thrombus, making it more permeable to the thrombolytic agent (Kruger et al., 2019). A vena cava filter may be placed at the time of the thrombectomy or thrombolysis; this filter traps large emboli and prevents PE (see later discussion). Retrievable caval filters can be left in place and retrieved up to 6 months after placement. In patients with chronic iliac vein compression (e.g., as is seen in May–Thurner syndrome), balloon angioplasty with stent placement may successfully treat the patient's chronic leg symptoms (Ignatyev, Pokrovsky, & Gradusov, 2019).

Nursing Management

When performing the nursing assessment, key concerns include limb pain, a feeling of heaviness, functional impairment, ankle engorgement, and edema; increase in the surface temperature of the leg, particularly the calf or ankle; and areas of tenderness or superficial thrombosis (i.e., cordlike venous segment). The amount of swelling in the extremity can be determined by measuring the circumference of the affected extremity at various levels (i.e., thigh to ankle) with a tape measure and comparing one extremity with the other at the same level to determine size differences. If both extremities are swollen, a size difference may be difficult to detect. Homan sign (pain in the calf after the foot is sharply dorsiflexed) is *not* a reliable sign of DVT because it can be elicited in any painful condition of the calf and has no clinical value in assessment for DVT.

Assessing and Monitoring Anticoagulant Therapy

If the patient is receiving anticoagulant therapy, the nurse monitors laboratory values as indicated. The aPTT, PT, INR, ACT, hemoglobin and hematocrit values, platelet count, and fibrinogen levels can be affected, depending on the anticoagulant prescribed; baseline assessments before the initiation of therapy should be performed. Close observation is required to detect bleeding; if bleeding occurs, it must be reported immediately and anticoagulant therapy reversed or discontinued if appropriate (see Table 26-2).

Monitoring and Managing Potential Complications

Potential complications of anticoagulant therapy consist of bleeding, thrombocytopenia, and drug–drug interactions. The nurse should monitor for these potential complications, be familiar with medications approved to reverse effects of various anticoagulants, and educate patients and caregivers on ways to reduce these potential risks (see Table 26-2 and Chart 26-10).

Reducing Discomfort

Elevation of the affected extremity, graduated compression stockings (see later discussion), and analgesic agents for pain relief are adjuncts to therapy. They help improve circulation and increase comfort. Warm

packs applied to the affected extremity reduce the discomfort associated with DVT.

Positioning the Body and Encouraging Exercise

When the patient is on bed rest, the feet and lower legs should be elevated periodically above the level of the heart. This position allows the superficial and tibial veins to empty rapidly and to remain collapsed. Active and passive leg exercises, particularly those involving calf muscles, should be performed to increase venous flow. Early ambulation is most effective in preventing venous stasis. The patient is encouraged to walk once anticoagulation therapy has been initiated and is advised that walking is better than standing or sitting for long periods. Once ambulatory, the patient is instructed to avoid sitting for more than an hour at a time. The goal is to walk at least 10 minutes every 1 to 2 hours. The patient is also instructed to perform active and passive leg exercises as frequently as necessary when they cannot ambulate, such as during long car, bus, train, and plane trips. In addition, deep breathing exercises are beneficial because they produce increased negative pressure in the thorax, which assists in emptying the large veins.

TABLE 26-2 Select Anticoagulant and Thrombolytic Agents Prescribed to Treat Venous Thromboemboli (VTE)

Medication	Mechanism of Action	Actions and Effects	Nursing Considerations
Unfractionated Heparin			
Heparin	Binds to antithrombin; inactivates clotting factors XII, Xa; half-life of 60–90 min	Prevent extension of thrombus Prevent development of new thrombus	Can be administered subcutaneously or intermittently or continuous intravenously (IV); IV dosing is weight based Administer continuous IV infusions using an electronic infusion device Requires monitoring of aPTT and platelet count; monitor platelet counts for HIT Assess patient for bleeding Administer protamine sulfate for overdose or to reverse effects, as prescribed; monitor patient for hypotension and bradycardia if administered
Low-Molecular-Weight Heparin (LMWH)			
Dalteparin Enoxaparin	Inhibit factor Xa	Prevent extension of thrombus Prevent development of new thrombus	Can be administered subcutaneously once daily or twice a day Associated with fewer bleeding complications than unfractionated heparin Has lower risk of HIT Administer protamine sulfate for overdose or to reverse effects, as prescribed; monitor patient for hypotension and bradycardia if administered; protamine sulfate is less effective in reversing LMWH compared to unfractionated heparin Can be used in pregnancy if clearly indicated; however, patients should be monitored closely for bleeding
Oral Anticoagulant			
Warfarin	Vitamin K	Has narrow	Administer once a day at the

	antagonist inhibits synthesis of vitamin K–dependent clotting factors: II, VII, IX, X Inhibits synthesis of vitamin K–dependent proteins: protein C and protein S	therapeutic window Has slow onset of action Anticoagulant effect occurs 12–24 h after first dose Antithrombotic effect occurs 2–7 days after first dose	same time each day Requires routine monitoring of PT with goal of 1.5–2 times normal; and INR with goal of 2.0–3.0 Requires administration with heparin during drug initiation until desired anticoagulation is achieved Monitor for food and drug–drug interactions (see Chart 26-10) Assess patient for bleeding Administer vitamin K, fresh-frozen plasma, or prothrombin complex concentrate as prescribed for overdose or to reverse effects Requires periprocedural bridging (i.e., giving a short-acting anticoagulant, usually heparin or LMWH, if warfarin needs to be temporarily discontinued) Contraindicated in pregnancy
Factor Xa Inhibitor			
Fondaparinux	Selective inhibitor of factor Xa	Prevent DVT or PE in patients undergoing orthopedic surgery (e.g., hip or knee arthroplasty) Treatment of DVT or PE Excreted unchanged via kidneys Does not affect aPTT or ACT	Administer subcutaneously once daily Use with caution in patients with renal insufficiency Monitor creatinine Routine coagulation tests are not necessary
Oral Direct Factor Xa Inhibitor			
Rivaroxaban	Direct inhibitor of factor Xa	Fixed-dose regimen for	Administer once or twice daily as prescribed based on indication

		treatment of DVT and PE Fixed-dose regimen to prevent recurrent DVT and PE Not indicated for patients with creatinine clearance less than 30 mL/min	Assess renal function Alter dose in individuals with obesity May require periprocedural bridging Administer andexanet alfa or activated charcoal as prescribed for overdose or to reverse effects
Apixaban		Fixed-dose regimen for treatment of DVT and PE Fixed-dose regimen to prevent recurrent DVT and PE Not indicated for patients with creatinine clearance less than 25 mL/min.	Administer twice a day Assess renal function Alter dose in patients 80 yrs of age or older and weight ≤60 kg Administer andexanet alfa or activated charcoal as prescribed for overdose or to reverse effects
Edoxaban		Fixed-dose regimen for treatment of DVT and PE	Administer once daily Assess renal function Alter dose for patients who weigh ≤60 kg
Betrixaban		Prevent DVT and PE in adults hospitalized for acute medical illness	Administer once daily Assess renal function No antidote available to reverse effects
Direct Thrombin Inhibitor			
Argatroban Lepirudin	Reversibly binds to thrombin active site, inhibiting thrombin-	Prevention and treatment of thrombosis in patients with HIT or at risk	Administer as an IV bolus followed by a continuous infusion Assess hepatic function Monitor aPTT and ACT

	mediated stimulation of coagulation factors	for HIT during PCI	
Oral Direct Thrombin Inhibitor			
Dabigatran	Reversibly binds to thrombin active site, inhibiting thrombin-mediated stimulation of coagulation factors	Fixed-dose regimen for treatment of DVT Fixed-dose regimen to prevent recurrent DVT Not indicated for patients with creatinine clearance <30 mL/min	Administer twice a day Assess renal function Routine coagulation tests are not necessary; however if measured, aPTT levels may be prolonged 1.5–2 times normal Administer idarucizumab as prescribed to reverse effects
Thrombolytic			
Alteplase Reteplase Tenecteplase Urokinase	Binds to fibrin within the thrombus converting plasminogen to plasmin. Plasmin degrades fibrin, fibrinogen, and factors V, VIII, and XII.	Lyse and dissolve existing thrombus	Monitor lab values prior to initiation: CBC, platelets, aPTT; repeat during and post therapy Monitor for bleeding and hemorrhage Contraindicated with active bleeding

ACT, activated clotting time; aPTT, activated partial thromboplastin time; CBC, complete blood count; DVT, deep vein thrombosis; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; PCI, percutaneous coronary intervention; PE, pulmonary emboli; PT, prothrombin time; PTT, partial thromboplastin time.

Chart 26-10 **PATIENT EDUCATION**

Taking Anticoagulant Medications

The nurse instructs the patient as follows:

- Take anticoagulation medication as prescribed.
- Do not stop taking your anticoagulation medication unless directed.
- If prescribed warfarin, take at the same time each day.
- Wear or carry identification indicating anticoagulant medication being taken.
- Keep all scheduled appointments for blood tests.
- Be aware that other medications may affect the action of the anticoagulant medication; if taking warfarin, consult with your health care provider before taking any of the following medications or supplements: vitamins, cold medicines, antihistamines, antibiotics, aspirin, laxatives, and anti-inflammatory agents, such as ibuprofen, and similar medications or herbal or nutritional supplements. Your primary provider should be contacted before taking any over-the-counter drugs.
- Avoid alcohol if taking warfarin because it may change the body's response to the warfarin. There are no interactions with the oral factor Xa inhibitors (e.g., rivaroxaban, apixaban, edoxaban) and alcohol.
- Avoid marked changes in eating habits, especially involving foods high in vitamin K, such as green leafy vegetables, which can reduce anticoagulation effectiveness if taking warfarin; dietary habits have no interactions with the oral factor Xa inhibitors.
- When seeking treatment from any health care provider, be sure to inform them that you are taking an anticoagulant medication.
- Contact your provider who manages your anticoagulation therapy before having dental work or surgery.
- Describe potential side effects of coagulation, such as bruising and bleeding, and identify ways to prevent bleeding.
  - Avoid the use of sharps (razors, knives, etc.) to prevent cuts; shave with an electric shaver.
  - Use a toothbrush with soft bristles to prevent gum injury.
  - Avoid contact sports or activities that may result in an injury that causes bleeding.
- If taking warfarin, report the following immediately to your primary provider:
  - Any bleeding—for example, cuts that do not stop bleeding

- Bruises that enlarge, nosebleeds, or unusual bleeding from any part of the body
- Reddish or brownish urine
- Red or black bowel movements

- *For women:* Notify your primary provider and obstetrical provider if you suspect pregnancy.

Promoting Home, Community-Based, and Transitional Care

In addition to instructing the patient on how to apply graduated compression stockings as indicated (see later discussion) and explaining the importance of elevating the legs and exercising adequately, the nurse provides education about the prescribed anticoagulant, its purpose, and the need to take the correct amount at the specific times, especially if warfarin is prescribed (see Chart 26-10). The patient should also be aware that if warfarin is prescribed, periodic blood tests are necessary to determine if a change in medication or dosage is required. If the patient fails to adhere to the therapeutic regimen, continuation of the medication therapy should be questioned. In patients with liver disease, the potential for bleeding may be exacerbated by anticoagulant therapy.

Pulmonary Embolism

Pulmonary embolism (PE) refers to the obstruction of the pulmonary artery or one of its branches by a thrombus (or thrombi) that originate(s) somewhere in the venous system or in the right side of the heart.

Pathophysiology

Most commonly, PE is due to a dislodged or fragmented DVT (see previous pathophysiology discussion in DVT). However, there are other types of emboli that may be implicated: air, fat, amniotic fluid, and septic (from bacterial invasion of the thrombus) (Norris, 2019).

A PE is described as an occlusion of the outflow tract of the main pulmonary artery or of the bifurcation of the pulmonary arteries. Multiple small emboli can lodge in the terminal pulmonary arterioles, producing multiple small infarctions of the lungs. A pulmonary infarction causes ischemic necrosis of part of the lung (Thompson & Kabrhel, 2020).

When a thrombus completely or partially obstructs a pulmonary artery or its branches, the alveolar dead space is increased. The area, although continuing to be ventilated, receives little or no blood flow. Therefore, gas exchange is impaired or absent in this area. In addition, various substances are released from the clot and surrounding area that cause regional blood vessels and bronchioles to constrict. This results in an increase in pulmonary vascular resistance—a reaction that compounds the ventilation–perfusion (V./Q.) imbalance that ensues.

The hemodynamic consequences are increased pulmonary vascular resistance due to the regional vasoconstriction and reduced size of the pulmonary vascular bed. In severe instances, this may result in an increase in pulmonary arterial pressure and, in turn, an increase in right ventricular work to maintain pulmonary blood flow. When the work requirements of the right ventricle exceed its capacity, right ventricular failure occurs, leading to a decrease in cardiac output followed by a decrease in systemic blood pressure and the development of shock (Norris, 2019).

Clinical Manifestations

Symptoms of PE depend on the size of the thrombus and the area of the pulmonary artery occluded by the thrombus; they may be nonspecific. Dyspnea is the most frequent symptom; the duration and intensity of the dyspnea depend on the extent of embolization. Chest pain is common and is usually sudden and pleuritic in origin; however, it may be substernal and may mimic angina (Thompson & Kabrhel, 2020). Other symptoms include anxiety, fever, tachycardia, apprehension, cough, diaphoresis, hemoptysis, and syncope. The most frequent sign is tachypnea (rapid respiratory rate) (De Palo, 2020).

In many instances, PE causes few signs and symptoms, whereas in other instances, it mimics various other cardiopulmonary disorders (e.g., pneumonia, heart failure). Obstruction of the pulmonary artery can result in pronounced dyspnea, sudden substernal pain, rapid and weak pulse, shock, syncope, and sudden death (Thompson & Kabrhel, 2020).

Assessment and Diagnostic Findings

Because the symptoms of PE can vary from few to severe, a diagnostic workup is performed to rule out other diseases. The initial diagnostic workup may include chest x-ray, ECG, pulse oximetry, arterial blood gas

analysis, D-dimer assay and MDCTA or pulmonary arteriogram or V./Q. scan. The chest x-ray is usually normal but may show infiltrates, atelectasis, elevation of the diaphragm on the affected side, or a pleural effusion. The chest x-ray is most helpful in excluding other possible causes. In addition to sinus tachycardia, the most frequent ECG abnormality is nonspecific ST-T wave abnormalities. If an arterial blood gas analysis is performed, it may show hypoxemia and hypocapnia (from tachypnea); however, arterial blood gas measurements may be normal even in the presence of PE (De Palo, 2020).

MDCTA is the criterion standard for diagnosing PE. The MDCTA can be performed quickly and provides the advantage of high-quality visualization of the lung parenchyma (Weinberger, Cockrill, & Mandel, 2019). If MDCTA is not available, pulmonary angiography is considered a reasonable alternative diagnostic method (Ouellette, 2019). The pulmonary angiogram allows for direct visualization under fluoroscopy of the arterial obstruction and accurate assessment of the perfusion deficit. A specially trained team must be available to perform the procedure, in which a catheter is threaded through the vena cava to the right side of the heart to inject dye, similar to a cardiac catheterization.

The V./Q. scan continues to be used to diagnose PE, especially in facilities that do not use pulmonary angiography or do not have access to MDCTA. The V./Q. scan is minimally invasive and requires IV administration of a contrast agent. This scan evaluates different regions of the lung (upper, middle, lower) and allows comparisons of the percentage of V./Q. in each area. This test has a high sensitivity but is not as accurate as an MDCTA or pulmonary angiogram (De Palo, 2020).

Medical Management

Medical management of the patient with PE revolves around whether the patient is diagnosed with a hemodynamically unstable PE (also called a *massive PE*) or a stable PE. The patient with a hemodynamically unstable PE, which comprises a life-threatening emergency, may evidence hypotension, tachycardia, confusion, and cardiovascular collapse.

Medical Management of Unstable Pulmonary Embolism

The immediate objective is to stabilize the cardiopulmonary system in the patient with a hemodynamically unstable PE. A sudden increase in

pulmonary resistance increases the work of the right ventricle, which can cause acute right-sided heart failure with cardiogenic shock. Emergent measures are initiated to improve respiratory and cardiovascular status (see Chapter 11 for discussion of management of the patient in shock).

After emergency measures have been initiated, the treatment goal is to lyse (dissolve) the existing embolus and prevent new ones from forming. Thrombolytic therapy with t-PA or other agents such as reteplase (see Table 26-2) is used in treating unstable PE, particularly in patients who are severely compromised (e.g., those who are hypotensive and have significant hypoxemia despite oxygen supplementation) (Ouellette, 2019). Thrombolytic therapy lyses the thrombi or emboli quickly and restores hemodynamic functioning of the pulmonary circulation, thereby reducing pulmonary hypertension and improving perfusion, oxygenation, and cardiac output. However, the risk of bleeding is significant. Contraindications to thrombolytic therapy include having had a stroke within the past 2 months, other active intracranial processes, active bleeding, surgery within 10 days of the thrombotic event, recent labor and delivery, trauma, or severe hypertension. Consequently, thrombolytic agents are advocated only for PE affecting a significant area of blood flow to the lung and causing hemodynamic instability (Tapson & Weinberg, 2020).

Before thrombolytic therapy is started, INR, aPTT, hematocrit, and platelet counts are obtained. Any anticoagulant is stopped prior to administration of a thrombolytic agent. During therapy, all but essential invasive procedures are avoided because of potential bleeding. After the thrombolytic infusion is completed (which varies in duration according to the agent used), maintenance anticoagulation therapy is initiated.

A surgical embolectomy is rarely performed but may be indicated if there are contraindications to thrombolytic therapy. Embolectomy can be performed using catheters or surgically. Surgical removal must be performed by a cardiovascular surgical team with the patient on cardiopulmonary bypass (Ouellette, 2019).

For patients who have recurrent PE despite therapeutic anticoagulation, an inferior vena cava (IVC) filter may be inserted (Tapson, 2019). IVC filters are not recommended for the initial treatment of patients with PE and should not be used in patients receiving anticoagulants. The IVC filter provides a screen in the IVC, allowing blood to flow unobstructed while large emboli from the pelvis or lower extremities are blocked or fragmented before reaching the lung.

Numerous devices have been developed since the introduction of the original Greenfield filter (see Fig. 26-14).

Medical Management of Stable Pulmonary Embolism

In patients with PE who do not demonstrate any cardiopulmonary instability (e.g., normotensive, no evidence of hypoxemia) immediate anticoagulation is indicated to prevent recurrence or extension of the thrombus and may continue for 10 days (Tapson, 2019). Long-term anticoagulation is also indicated up to 6 months following the PE and is critical in preventing recurrence of VTE. This duration may be extended indefinitely in patients who are at high risk for recurrence (Weinberger et al., 2019).

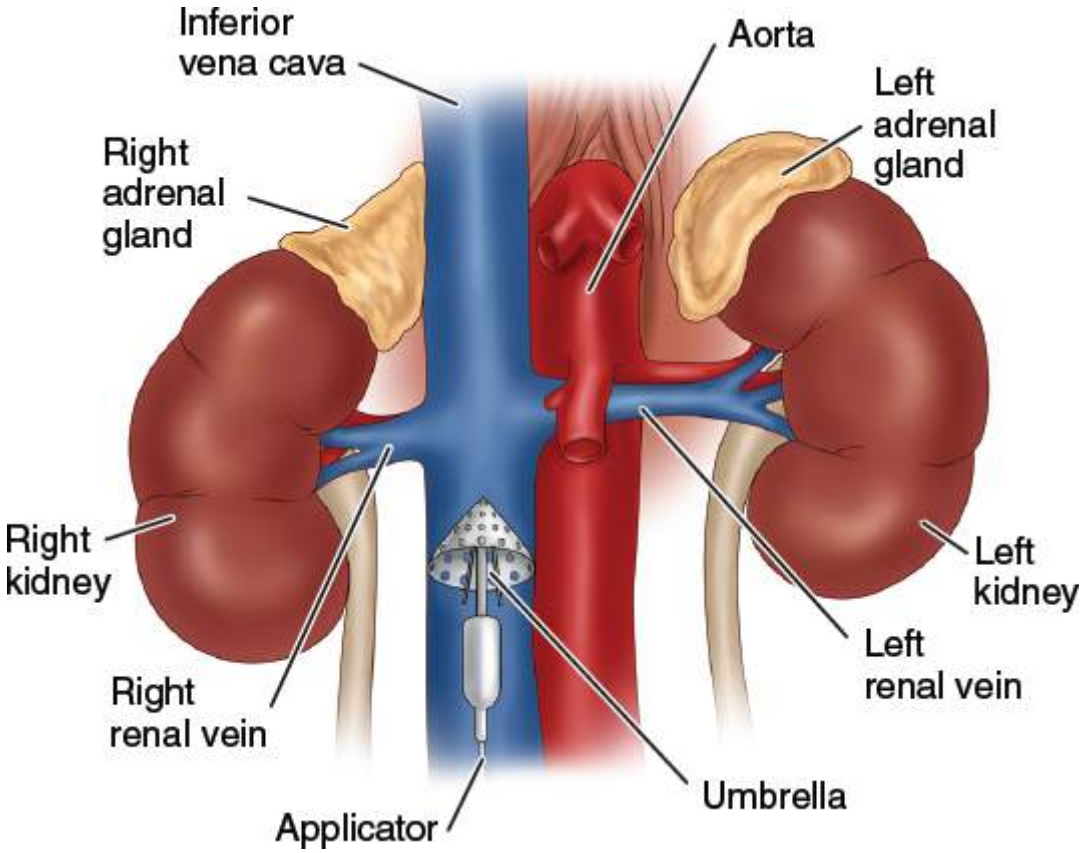

Figure 26-14 • An umbrella filter is in place in the inferior vena cava to prevent PE. The filter (compressed within an applicator catheter) is inserted through an incision in the right internal jugular vein. The applicator is withdrawn when the filter fixes itself to the wall of the inferior vena cava after ejection from the applicator.

In patients with stable PE, the initial anticoagulant selected may include an LMWH (e.g., enoxaparin), unfractionated heparin, or a direct oral anticoagulant (DOAC), such as a direct thrombin inhibitor (e.g., dabigatran), or a factor Xa inhibitor (e.g., fondaparinux, rivaroxaban, apixaban, edoxaban) (Tapson & Weinberg, 2020) (see Table 26-2).

In select patients with PE who are hemodynamically stable, outpatient therapy can be started by administering the first dose in the emergency department or urgent care center and the remaining doses given at home. Although there are not specific selection criteria for outpatient treatment, the patient is usually at low risk of death, has no respiratory or hemodynamic compromise, does not require opioids for pain control, has no risk factors for bleeding, has no serious comorbid conditions, and has stable baseline mental status with a good understanding of the benefits and risks of treatment (Tapson, 2019). The ideal agent for outpatient administration is not empirically confirmed, although the DOACs are often prescribed.

Long-term treatment options include warfarin and the DOACs. An LMWH may also be selected but is usually not prescribed for long-term therapy since it is given via a subcutaneous injection. Warfarin dosing requires regular blood draws for INR monitoring and has a higher bleeding risk, but it has long been the standard of care prior to the development of DOACs. An antidote (vitamin K) is available if the INR is high and there is a risk of bleeding. Warfarin does have interactions with several medications (see Chart 26-10) and has dietary restrictions. DOACs do not require regular blood test monitoring; however, they are more costly than warfarin. The choice of warfarin versus a DOAC is dependent upon risk of bleeding, cost, presence of comorbidities, and provider preference (The Joint Commission [TJC], 2019).

Nursing Management

Monitoring Thrombolytic Therapy

The nurse is responsible for monitoring the patient's response to thrombolytic and anticoagulant therapy. During the thrombolytic infusion, while the patient remains on bed rest, vital signs are frequently assessed and invasive procedures are avoided. Tests to determine INR or aPTT are performed 3 to 4 hours after the thrombolytic infusion is started to confirm that the fibrinolytic systems have been activated.

Quality and Safety Nursing Alert

Because of the prolonged clotting time, only essential arterial punctures or venipunctures are performed in patients who have received thrombolytics, and manual pressure is applied to any puncture site for at least 30 minutes. Pulse oximetry is used to monitor changes in oxygenation. The thrombolytic infusion is discontinued immediately if uncontrolled bleeding occurs.

Managing Pain

Chest pain, if present, is usually pleuritic rather than cardiac in origin. A semi-Fowler position provides a more comfortable position for breathing. However, the nurse must continue to turn patients frequently and reposition them to improve V./Q.. The nurse administers opioid analgesic agents as prescribed for severe pain.

Managing Oxygen Therapy

Careful attention is given to the proper use of oxygen. The patient must understand the need for continuous oxygen therapy. The nurse assesses the patient frequently for signs of hypoxemia and monitors the pulse oximetry values to evaluate the effectiveness of the oxygen therapy. Deep breathing and incentive spirometry are indicated for all patients to minimize or prevent atelectasis and improve ventilation (see Chapter 19 for discussion of incentive spirometry). Nebulizer therapy or percussion and postural drainage may be used for management of secretions.

Relieving Anxiety

The nurse encourages the patient who is stabilized to talk about any fears or concerns related to this frightening episode, answers the patient's and family's questions concisely and accurately, explains the therapy, and describes how to recognize untoward effects early.

Monitoring for Complications

When caring for a patient who has had PE, the nurse must be alert for the potential complication of cardiogenic shock or right ventricular failure subsequent to the effect of PE on the cardiovascular system. (Nursing

activities for managing shock are found in Chapter 11; see Chapter 25 for nursing management of right ventricular failure.)

Providing Postoperative Nursing Care

If the patient has undergone surgical embolectomy, the nurse measures the patient's pulmonary arterial pressure and urinary output. The nurse also assesses the insertion site of the arterial catheter for hematoma formation and infection. Maintaining the blood pressure at a level that supports perfusion of vital organs is crucial. To prevent peripheral venous stasis and edema of the lower extremities, the nurse elevates the foot of the bed and encourages isometric exercises, the use of intermittent pneumatic compression devices, and walking when the patient is permitted out of bed. Sitting for long periods is discouraged, because hip flexion compresses the large veins in the legs.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Before hospital discharge and at follow-up visits to the clinic, the nurse educates the patient about preventing recurrence and reporting signs and symptoms. Patient education instructions, presented in Chart 26-11, are intended to help prevent recurrences and side effects of treatment.

Chart 26-11 **HOME CARE CHECKLIST**

Prevention of Recurrent Pulmonary Embolism

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of pulmonary embolism (PE) on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in lifestyle (e.g., diet, activity) necessary to restore health.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Name the anticoagulant prescribed and describe relevant patient education related to taking anticoagulants described in Chart 26-10.
- Describe the importance of follow-up appointments with providers.
- Describe strategies to prevent recurrent deep venous thrombosis and pulmonary emboli:
  - Continue to wear anti-embolism stockings (compression hose) as long as directed.
  - Avoid sitting with legs crossed or sitting for prolonged periods of time.
  - When traveling, change position regularly, walk occasionally, and do active exercises of moving the legs and ankles while sitting.
  - Drink fluids, especially while traveling and in warm weather, to avoid hemoconcentration due to fluid deficit.
- Describe the signs and symptoms of lower extremity circulatory compromise and potential deep venous thrombosis: calf or leg pain, swelling, pedal edema.
- Describe the signs and symptoms of pulmonary compromise related to recurrent PE (e.g., dyspnea, chest pain, anxiety, fever, tachycardia, apprehension, cough, syncope, diaphoresis, hemoptysis).
- Describe how and when to contact the primary provider if symptoms of circulatory compromise or pulmonary compromise are identified.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Continuing and Transitional Care

During follow-up or home visits, the nurse monitors the patient's adherence to the prescribed management plan and reinforces previous instructions. The nurse also monitors the patient for residual effects of the PE and recovery. The patient is reminded about the importance of keeping follow-up appointments for coagulation tests, if indicated, and appointments with the primary provider.

Chronic Venous Insufficiency/Postthrombotic Syndrome

Venous insufficiency results from obstruction of the venous valves in the legs or a reflux of blood through the valves. Superficial and deep leg veins can be involved. Resultant venous hypertension can occur whenever there has been a prolonged increase in venous pressure, such as occurs with DVT. Because the walls of veins are thinner and more elastic than the walls of arteries, they distend readily when venous pressure is consistently elevated. In this state, leaflets of the venous valves are stretched and prevented from closing completely, causing a backflow or reflux of blood in the veins. Duplex ultrasonography confirms the obstruction and identifies the level of valvular incompetence. Twenty percent to 50% of patients who have had a DVT develop deep vein incompetence leading to postthrombotic syndrome (Sidawy & Perler, 2019) (see Fig. 26-15).

Clinical Manifestations

Postthrombotic syndrome is characterized by chronic venous stasis, resulting in edema, altered pigmentation, pain, and stasis dermatitis. The patient may notice the symptoms less in the morning and more in the evening. Obstruction or poor calf muscle pumping in addition to valvular reflux must be present for the development of severe postthrombotic syndrome and stasis ulcers. Superficial veins may be dilated. The disorder is long-standing, difficult to treat, and often disabling (Kahn, Galanaud, Vedantham, et al., 2016).

Stasis ulcers develop as a result of the rupture of small skin veins and subsequent ulcerations. When these vessels rupture, red blood cells escape into surrounding tissues and then degenerate, leaving a brownish discoloration of the tissues, called *hemosiderin staining*. The pigmentation and ulcerations usually occur in the lower part of the extremity, in the area of the medial malleolus of the ankle. The skin becomes dry, cracks, and itches; subcutaneous tissues fibrose and atrophy. The risk of injury and infection of the extremities is increased.

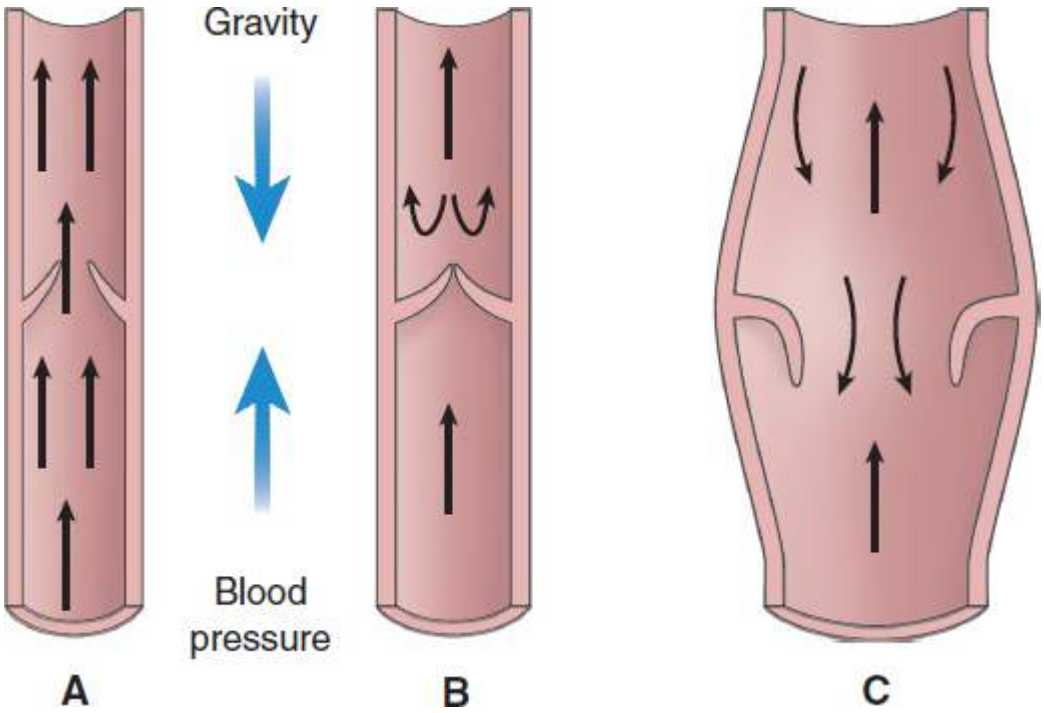

Figure 26-15 • Competent valves showing blood flow patterns when the valve is open (**A**) and closed (**B**), allowing blood to flow against gravity. **C**. With faulty or incompetent valves, the blood cannot move toward the heart.

Complications

Venous ulceration is the most serious complication of chronic venous insufficiency and can be associated with other conditions affecting the circulation of the lower extremities. Cellulitis or dermatitis may complicate the care of chronic venous insufficiency and venous ulcerations.

Management

Management of the patient with venous insufficiency is directed at reducing venous stasis and preventing ulcerations. Extremities with venous insufficiency must be carefully protected from trauma; the skin is kept clean, dry, and soft. Signs of ulceration are immediately reported to the primary provider for treatment and follow-up. Measures that increase venous blood flow are antigravity activities, such as elevating the leg, and compression of superficial veins with graduated compression stockings and other compression therapies.

Elevating the legs decreases edema, promotes venous return, and provides symptomatic relief. The legs should be elevated frequently throughout the day (at least 15 to 20 minutes four times daily). At night, the patient should sleep with the foot of the bed elevated about 15 cm (6 inches). Prolonged sitting or standing in one position is detrimental; walking should be encouraged. When sitting, the patient should avoid placing pressure on the popliteal spaces, as occurs when crossing the legs or sitting with the legs dangling over the side of the bed. Constricting garments, especially socks that are tight at the top or that leave marks on the skin, should be avoided.

Compression of the legs with graduated compression stockings reduces the pooling of venous blood, enhances venous return to the heart, and is recommended for people with venous insufficiency.

Providing Compression Therapy

Stockings

Graduated compression stockings usually are prescribed for patients with venous disease as soon as possible after diagnosis (Bjork & Ehmann, 2019). The amount of pressure gradient is determined by the amount and severity of venous disease. For example, a pressure gradient of 20 to 30 mm Hg is prescribed for patients with asymptomatic varicose veins, whereas at least a pressure gradient of 30 to 40 mm Hg at the ankle is recommended for patients with venous stasis ulceration (Bjork & Ehmann, 2019). Compression stockings with at least 30 to 40 mm Hg pressure can be used during the 6 months post DVT to decrease symptoms and reduce the development of postthrombotic syndrome (Zierler & Dawson, 2016). These stockings should not be confused with anti-embolism stockings (i.e., thromboembolic deterrent [TED] stockings) that provide less compression (12 to 20 mm Hg at the ankle). Graduated compression stockings are designed to apply 100% of the prescribed pressure gradient at the ankle and then decrease along the

length of the stocking, reducing the caliber of the superficial veins in the leg and increasing flow in the deep veins. Each stocking should fit so that pressure is greater at the foot and ankle and then gradually declines to a lesser pressure at the knee or groin. These stockings may be knee high, thigh high, or pantyhose. Several colors, fabrics, and styles are available to promote patient adherence. Stockings should be applied after the legs have been elevated for a period, when the amount of blood in the leg veins is at its lowest.

Quality and Safety Nursing Alert

Any type of stocking can inadvertently become a tourniquet if applied incorrectly (i.e., rolled tightly at the top). In such instances, the stockings produce—rather than prevent—venous stasis. For ambulatory patients, graduated compression stockings can be removed at night and reapplied before the legs are lowered from the bed to the floor in the morning.

When the stockings are off, the skin is inspected for signs of irritation, and the calves are examined for tenderness. Any skin changes or signs of tenderness are reported. Stockings are contraindicated in patients with severe PAD, epifascial arterial bypass, severe cardiac insufficiency, allergy to compression material, and severe diabetic neuropathy with sensory loss or microangiopathy (Rabe, Partsch, Morrison, et al., 2020).

Gerontologic Considerations

Older patients have decreased strength and manual dexterity and may be unable to apply graduated compression stockings. If this is the case, a family member or friend should be taught to assist the patient to apply the stockings so that they do not cause excessive pressure on any part of the feet or legs. Frames and other devices have been designed to assist patients with applying stockings, and if there is any concern regarding patients' physical abilities, they should be referred to an occupational therapist who can provide examples of and training in the use of stocking assistance devices (Balcombe, Miller, & McGuiness, 2017).

External Compression Devices and Bandages

Short-stretch elastic bandages may be applied from the toes to the knee in a 50% spiral overlap. These bandages are available in a two-layer

system, which includes an inner layer of soft padding. These bandages have extension indicators that are rectangular and become squares when extended correctly, which reduces the possibility of bandaging a leg too loosely or too tightly. Three- and four-layer systems are also available (e.g., Profore, Dyna-Care), but these may be used only once compared with the two-layer system, which can be used multiple times.

Other types of compression are available. The Unna boot, which consists of a paste bandage impregnated with zinc oxide, glycerin, gelatin, and sometimes calamine, is applied without tension in a circular fashion from the base of the toes to the tibial tuberosity with a 50% spiral overlap. The foot must remain dorsiflexed at a 90-degree angle to the leg, thus avoiding excess pressure or trauma to the anterior ankle area. Once the bandage dries, it provides a constant and consistent compression to the venous system. This type of compression may remain in place for as long as 1 week, although it may be too heavy for patients who are too frail to tolerate. The Unna boot is more commonly used with venous insufficiency.

The CircAid, a nonelastic leg wrap with a series of overlapping, interlocking Velcro straps, augments the effect of muscle while the patient is walking. The CircAid is usually worn during the day. Patients may find the CircAid easier to apply and wear than the Unna boot because it is lighter, can be removed to shower, and is adjustable. However, its adjustability may also be problematic; if patients loosen the straps, the compression achieved may not be adequate.

Intermittent Pneumatic Compression Devices

Intermittent pneumatic compression devices can be used in conjunction with elastic bandages or graduated compression stockings to support venous circulation and prevent DVT. Compression devices consist of an electric controller that is attached by air hoses to either knee-high or thigh-high sleeves. The sleeves are divided into compartments, which sequentially fill to apply pressure to the ankle, calf, and thigh at variable pressures from 30 to 70 mm Hg. Intermittent pneumatic compression devices can increase blood velocity beyond that produced by elastic bandages or stockings. Intermittent pneumatic compression devices are prescribed for patients who are not physically able to apply compression bandages or wraps, or don a pair of stockings (Nicolaides, 2020). Nursing measures in caring for patients who use these devices include ensuring that sleeves are properly encircling the extremity and the

prescribed pressures are set and not exceeded, assessing for patient comfort, and ensuring adherence to therapy.

Leg Ulcers

A leg ulcer is an excavation of the skin surface that occurs when inflamed necrotic tissue sloughs off. In the United States the most common lower extremity ulcerations have a venous etiology (estimated between 80% and 90%), with PAD the second leading cause. The coexistence of both venous and arterial disease is estimated to be present in 26% of patients with leg ulcers (Singer, Tassiopoulos, & Kirsner, 2017).

Pathophysiology

Inadequate exchange of oxygen and other nutrients in the tissue is the metabolic abnormality that underlies the development of leg ulcers. When cellular metabolism cannot maintain energy balance, cell necrosis (death) results. Alterations in blood vessels at the arterial, capillary, and venous levels may affect cellular processes and lead to the formation of ulcers.

Clinical Manifestations

The characteristics of leg ulcers are determined by the cause of the ulcer (Ermer-Selton, 2016). Most ulcers, especially in older patients, have more than one cause. The symptoms depend on whether the problem is arterial or venous in origin (see Table 26-1). The severity of the symptoms depends on the extent and duration of the vascular insufficiency. The ulcer itself appears as an open, inflamed sore. The area may be exuding or covered by eschar (dark, hard crust).

Figure 26-16 • **A.** Ulcers resulting from arterial emboli. **B.** Gangrene of the toes resulting from severe arterial ischemia. **C.** Ulcer from venous stasis.

Arterial Ulcers

Chronic arterial disease is characterized by intermittent claudication. The patient may also complain of digital or forefoot pain at rest. If the onset of arterial occlusion is acute, ischemic pain is unrelenting and rarely relieved even with opioids. Typically, arterial ulcers are small, circular, deep ulcerations on the tips of toes or in the web spaces between the toes. Ulcers often occur on the medial side of the hallux or lateral fifth toe and may be caused by a combination of ischemia and pressure (see Fig. 26-16).

Venous Ulcers

Chronic venous insufficiency is characterized by pain described as aching or heavy. The foot and ankle may be edematous. Ulcerations are in the area of the medial or lateral malleolus (gaiter area) and are typically large, superficial, and highly exudative. Venous hypertension causes extravasation of blood, which discolors the area (see Fig. 26-16). Studies report the average venous ulcer requires as long as 6 to 12 months to heal completely and in patients who do not adhere to compression therapy (see discussion later in the chapter), the recurrence rate is nearly 100% within 36 months (Nicolaides, 2020). Patients with neuropathy (e.g., a common occurrence in patients with diabetes) frequently have ulcerations on the side of the foot over the metatarsal heads. These ulcers are painless and are described in further detail in Chapter 46.

Assessment and Diagnostic Findings

The cause of each ulcer needs to be identified so that appropriate therapy can be prescribed. The history of the condition is important in determining arterial or venous insufficiency. The pulses of the lower extremities (femoral, popliteal, posterior tibial, and dorsalis pedis) are carefully examined. More conclusive diagnostic aids include Doppler and duplex ultrasound studies, arteriography, and venography. Cultures of the ulcer bed may be necessary to determine whether an infection is contributing to tissue destruction.

Medical Management

Patients with ulcers can be effectively managed by advanced practice nurses or wound-ostomy-continence nurses in collaboration with the

patients' primary provider. All ulcers have the potential to become infected.

Pharmacologic Therapy

Antiseptic agents, such as povidone–iodine, cadexomer iodine, and silver, inhibit growth and development of most microbes, are broad spectrum, generate relatively little antimicrobial resistance, and can be used for short periods of time. Once a wound is infected (e.g., erythema, induration, exudate, edema, wound breakdown, malodor), a systemic antibiotic is necessary (Swanson, Angel, Sussman, et al., 2016). The specific antibiotic agent selected is based on culture and sensitivity test results. Oral antibiotics usually are prescribed because topical antibiotics have not proven to be effective for leg ulcers and promote antimicrobial resistance (Swanson et al., 2016).

Pharmacologic therapy also is important in the management of wound-related pain.

Compression Therapy

After the circulatory status of the patient is assessed and an absolute ankle pressure of greater than 60 mm Hg and an ABI that exceeds 0.80 are confirmed, compression therapy can be used up to 40 mm Hg without impeding arterial perfusion (Singer et al., 2017). See the discussion on compression therapy in the Chronic Venous Insufficiency section.

Cleansing and Débridement

To promote healing, the wound bed is prepared by removing excessive wound exudate and nonviable tissue. The usual cleansing method is to flush the area with water or normal saline solution or clean it with a noncytotoxic wound-cleansing agent (Saf-Clens™, Biolex™, Restore™). If this is unsuccessful, therapeutic wound cleansing and/or débridement may be necessary (Swanson et al., 2016).

Therapeutic wound cleansing includes mechanical cleaning with a cleansing solution or gel such as:

- Polyhexamethylene biguanide (PHMB)
- Octenidine dihydrochloride
- Superoxidised solution with hypochlorous acid (HOCL) and sodium hypochlorite (NaOCL)
- Povidone–iodine

Many older antiseptics are no longer recommended due to the risk of tissue damage associated with their use. However, these agents may still be used for wound management in low-resource settings, where alternative, contemporary antiseptics are not always available. Solutions not recommended include:

- Hydrogen peroxide
- High-concentration sodium hypochlorite (EUSOL™, Milton, Dakin's solution)
- Chlorhexidine gluconate
- Chlorhexidine gluconate and cetrimide (Savlon™)
- High-concentration acetic acid
- Antibiotics for systemic administration
- High-concentration potassium permanganate

Débridement is the removal of nonviable tissue from wounds. Removing nonviable tissue is important, particularly for infection and biofilms (i.e., the microorganisms that grow on the surface of the wound). Biofilms have now been established as an important factor in wound healing and the need for serial débridement is important to disrupt the biofilm and allow the penetration of topical and systemic antimicrobial agent (Swanson et al., 2016).

Débridement can be accomplished by several different methods:

- Surgical débridement is the fastest method and can be performed by a primary provider under aseptic conditions using instruments to excise nonviable tissue. It is usually performed in the operating room with access to anesthesia and hemostasis.
- Conservative sharp wound débridement can be performed at the bedside or in a clinic by a primary provider, skilled advanced practice nurse or wound-ostomy-continence nurse in collaboration with the primary provider or advanced practice nurse. Instruments are used to remove loose, avascular, and insensate nonviable tissue and topical anesthetics may be used to manage procedural pain.
- Chemical débridement involves the application of chemical agents (e.g., cadexomer iodine, hypertonic saline) for the controlled removal of nonviable tissue. There may be some cytotoxic effects to healthy cells in the wound.
- Ultrasonic débridement uses ultrasonography to disrupt the attachment of the nonviable tissue.

- Hydrosurgical débridement uses a water-jet–powered wound débridement tool to cut nonviable tissue.
- Biologic débridement, or larval therapy, involves the deliberate infestation of disinfected fly larvae that secrete a proteolytic enzyme which liquifies and ingests nonviable tissues.
- Enzymatic débridement involves the application of ointments containing enzymes. The ointment is applied to the ulcer but not to surrounding skin. Most enzymatic ointments are covered with a secondary dressing that will not soak up the ointment. The enzymatic ointment is discontinued when the nonviable tissue has been débrided, and an appropriate wound dressing is applied.
- Autolytic débridement is achieved through the application of dressings that allow the lysozymes in wound exudate to naturally break down the nonviable tissue. These include calcium alginate dressings (e.g., Kaltostat™, Sorbsan™) or gelling fiber dressings (e.g., Aquacel Hydrofiber™) and may be used for débridement when absorption of exudate is needed. These dressings are changed when the exudate seeps through the secondary dressing, or at least every 7 days. Calcium alginate dressings can be used on areas that are bleeding after débriding, because the material helps stop the bleeding. As the dry fibers absorb exudate, they become a gel that can be painlessly removed from the ulcer bed. Calcium alginate and gelling fiber dressings should not be used on dry or nonexudative wounds.

Nonselective débridement by applying and removing saline dressings of fine mesh gauze (wet to dry) are not recommended for vascular wounds because of the risk of removing viable tissue and wound-related pain. Preprocedural pain management is usually necessary.

Arterial insufficiency may result in gangrene of the toe(s), or digital gangrene, which is usually caused by trauma. The toe is stubbed and then turns black (see Fig. 26-16). Usually, patients with this problem are older people without adequate circulation. Débridement is contraindicated in these instances. Although the toe is gangrenous, it is dry. Managing dry gangrene is preferable to débriding the toe and causing an open wound that will not heal because of insufficient circulation. If the toe were to be amputated, the lack of adequate circulation would prevent healing and might make higher-level amputation necessary—a below- or an above-

knee amputation. A higher-level amputation in an older adult could result in a loss of independence and possibly the need for institutional care. Dry gangrene of the toe in an older adult with poor circulation is usually left undisturbed. The nurse keeps the toe clean and dry, if it is stable, until it autoamputates or separates (without creating an open wound).

Topical Therapy

A variety of topical agents can be used in conjunction with cleansing and débridement to promote healing of leg ulcers. The goals of treatment are to remove nonviable tissue and biofilm, and keep the ulcer clean and moist while healing takes place. The treatment should not destroy developing tissue. For topical treatments to be successful, adequate nutrition must be maintained.

Wound Dressing

Semiocclusive or occlusive wound dressings prevent evaporative fluid loss from the wound and retain warmth; these factors favor healing. When determining the appropriate dressing to apply, the following should be considered: simplicity of application, frequency of required dressing changes, ability to absorb wound exudate, expense, and patient comfort (see Chapter 56 for further discussion of wound dressings).

Knowledge deficit, frustration, fear, anxiety, and depression can decrease the patient's and family's adherence with the prescribed therapy; therefore, patient and family education is necessary before beginning and throughout the wound care program.

Stimulated Healing

Tissue-engineered human skin equivalent (e.g., Apligraf™ [Graftskin™]) is a skin product cultured from human dermal fibroblasts and keratinocytes used in combination with therapeutic compression. When applied, it interacts with the patient's cells within the wound to stimulate the production of growth factors. Application is not difficult, no suturing is involved, and the procedure is painless. A dermal repair scaffold (e.g., PriMatrix™) is a bioactive and regenerative extracellular matrix that binds with the patient's own cells and growth factors. PriMatrix™ has been used successfully for tunneling wounds, as well as wounds with exposed tendon and bone, in which Apligraf™ cannot be used.

Dermagraft™, which is a human fibroblast–derived dermal replacement, demonstrates efficacy similar to Apligraf™ (Nicolaides, 2020).

Hyperbaric Oxygenation

Hyperbaric oxygenation (HBO) may be beneficial as an adjunct treatment in patients with diabetes with no signs of wound healing after 30 days of standard wound treatment. HBO is accomplished by placing the patient into a chamber that increases barometric pressure while the patient is breathing 100% oxygen. Treatment regimens vary from 90 to 120 minutes once daily for 30 to 90 sessions. The process by which HBO is thought to work involves several mechanisms. The edema in the wound area is decreased because high oxygen tension facilitates vasoconstriction and enhances the ability of leukocytes to phagocytize and kill microbes. In addition, HBO is thought to increase diffusion of oxygen to the hypoxic wound, thereby enhancing epithelial migration and improving collagen production. The two most common adverse effects of HBO are middle-ear barotrauma and confinement anxiety. The benefit from this therapy on wound healing in patients without diabetes is unclear (Bonifant & Holloway, 2019).

Negative Pressure Wound Therapy

Research suggests that negative pressure wound therapy (NPWT) using vacuum-assisted closure (e.g., VAC™) devices decreases time to healing in complex wounds that have not healed in a 3-week period. Groin incisions, common in vascular surgery, may be complicated by wound dehiscence, lymphatic fistula, or infections in 5% to 10% of patients. NPWT has been found to be effective in treating patients who develop postoperative groin wound infections, decreasing hospital lengths of stay, rates of graft infection, and likelihood of limb loss (Apelqvist, Willy, Fagerdahl, et al., 2017). Patients who are ambulatory may be given small, portable NPWT devices, giving them the freedom to perform their ADLs (Harding, Chrysostomou, Mohamud, et al., 2017). Additional features such as instillation therapy (Veraflow™) are now available. This therapy facilitates cleansing via instillation of fluid followed by a negative pressure cycle. Research to evaluate the microbial load and changes in the bacterial spectrum in wounds while using a growing number of NPWT devices is ongoing (Kim, Applewhite, Dardano, et al., 2018).

NURSING PROCESS

The Patient with Leg Ulcers

Assessment

A focused nursing history and assessment are important. The extent and type of pain are carefully assessed, as are the appearance and temperature of the skin of both legs. The quality of all peripheral pulses is assessed, and the pulses in both legs are compared. The legs are checked for edema. If the extremity is edematous, the degree of edema is determined. Any limitation of mobility and activity that results from vascular insufficiency is identified. The patient's nutritional status is assessed, and a history of diabetes, collagen disease, or varicose veins is obtained.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include:

- Impaired skin integrity associated with vascular insufficiency
- Impaired mobility associated with activity restrictions of the therapeutic regimen and pain
- Impaired nutritional status associated with increased need for nutrients that promote wound healing

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Potential complications may include the following:

- Infection
- Gangrene

Planning and Goals

The major goals for the patient may include restoration of skin integrity, improved physical mobility, adequate nutrition, and absence of complications.

Nursing Interventions

Caring for these patients can be challenging, whether the patient is in the hospital, in a long-term care facility, or at home. Leg ulcers are often long term and disabling causing a substantial drain on the patient's physical, emotional, and economic resources.

RESTORING SKIN INTEGRITY

To promote wound healing, measures are used to keep the area clean. Cleansing requires very gentle handling, a neutral skin cleanser, and lukewarm water. Positioning of the legs depends on whether the ulcer is of arterial or venous origin. If there is arterial insufficiency, the patient should be referred for evaluation of vascular reconstruction. If there is venous insufficiency, dependent edema can be avoided by elevating the lower extremities and initiating graduated compression therapy. A decrease in edema promotes the exchange of cellular nutrients and waste products in the area of the ulcer, promoting healing.

Avoiding trauma to the lower extremities is imperative in promoting skin integrity. Heel suspension devices such as protective boots may be used (e.g., Rooke vascular boots, Prevalon); they are soft and provide warmth and protection from injury and displace tissue pressure to prevent pressure injury. If the patient is on bed rest or has reduced mobility, it is important to relieve pressure on the heels to prevent heel pressure injuries. When the patient is in bed, a bed cradle can be used to relieve pressure from bed linens and to prevent anything from touching the legs. When the patient is ambulatory, all obstacles are moved from the patient's path so that the patient's legs are not bumped. Heating pads, hot-water bottles, or hot baths are avoided, because they increase the oxygen demands and thus the blood flow demands of the already compromised tissue. The patient with diabetes and neuropathy has decreased sensation; therefore, heating pads may cause a burn without the patient noticing.

IMPROVING PHYSICAL MOBILITY

Generally, physical activity is initially restricted to promote wound healing. When infection resolves and healing begins, ambulation should resume gradually and progressively. Activity promotes arterial blood flow and venous return and is encouraged after the acute phase of the ulcer process. Until full activity is resumed, the patient is advised to move about when in bed, to turn from side to side frequently, and to exercise the upper extremities to maintain muscle tone and strength. Meanwhile, diversional activities are encouraged. Consultation with an occupational therapist and physical therapist may be helpful if prolonged immobility and inactivity are anticipated.

If pain limits the patient's activity, analgesic agents may be prescribed. The wound-related pain is typically chronic and often

disabling. Analgesic agents may be taken before scheduled activities to help the patient participate more comfortably.

PROMOTING ADEQUATE NUTRITION

Nutritional deficiencies are common, requiring dietary alterations to remedy them. There is conflicting evidence that dietary supplementation aids in healing of ulcerations. Comorbidities that may contribute to ulceration may also cause ongoing inflammation, disuse atrophy, and other metabolic disturbances; these may have a greater effect on wound healing than nutritional intake. Further research is needed; however, eating a diet that is high in protein, vitamins C and A, iron, and zinc is encouraged to promote healing (Bonifant & Holloway, 2019). Particular consideration should be given to iron intake, because many patients are older adults who are at risk for iron deficiency anemia. After a dietary plan has been developed that meets the patient's nutritional needs and promotes healing, dietary instruction is provided to the patient and family.

PROMOTING HOME, COMMUNITY-BASED, AND TRANSITIONAL CARE

The self-care program is planned with the patient so that activities that promote arterial and venous circulation, relieve pain, and promote tissue integrity are encouraged. Reasons for each aspect of the program are explained to the patient and family. Leg ulcers are often chronic and difficult to heal; they frequently recur, even when the patient follows the plan of care. Long-term care of the feet and legs to promote healing of wounds and prevent recurrence of ulcerations is the primary goal. Leg ulcers increase the patient's risk of infection, may be painful, and may limit mobility, necessitating lifestyle changes. Participation of family members and home health care providers may be necessary for treatments such as dressing changes, reassessments, reinforcement of instruction, and evaluation of the effectiveness of the plan of care. Regular follow-up with a primary provider is necessary.

Evaluation

Expected patient outcomes may include:

1. Demonstrates restored skin integrity
    a. Exhibits absence of inflammation
    b. Exhibits absence of drainage
    c. Has negative wound culture
    d. Avoids trauma to the legs

2. Increases physical mobility
   a. Progresses gradually to optimal level of activity
   b. Reports that pain does not impede activity
3. Attains adequate nutrition
   a. Selects foods high in protein, vitamins C and A, iron, and zinc
   b. Discusses with family members dietary modifications that need to be made at home
   c. Plans, with the family, a diet that is nutritionally sound

Varicose Veins

Varicose veins (varicosities) are abnormally dilated, tortuous, superficial veins caused by incompetent venous valves (see Fig. 26-15). Most commonly, this condition occurs in the lower extremities, the saphenous veins, or the lower trunk, but it can occur elsewhere in the body, such as the esophagus (e.g., esophageal varices; see Chapter 43).

It is estimated that varicose veins occur in 23% of American adults, and if spider telangiectasias and reticular veins are included in these statistics, the prevalence increases to 80% of men and 85% of women (Sidawy & Perler, 2019). The condition is most common in people whose occupations require prolonged standing, such as salespeople, hairstylists, teachers, nurses and ancillary medical personnel, and construction workers. A hereditary weakness of the vein wall may contribute to the development of varicosities, and it commonly occurs in several members of the same family. Varicose veins are rare before puberty. Pregnancy may cause varicosities because of hormonal effects related to decreased venous outflow, increased pressure by the gravid uterus, and increased blood volume (Della Torre, Sutherland, & Digiovanni, 2019).

Pathophysiology

Varicose veins may be primary (without involvement of deep veins) or secondary (resulting from obstruction of deep veins). A reflux of venous blood results in venous stasis. If only the superficial veins are affected, the person may have no symptoms but may be concerned by the appearance of the veins.

Clinical Manifestations

Symptoms, if present, may include dull aches, muscle cramps, increased muscle fatigue in the lower legs, ankle edema, and a feeling of heaviness of the legs. Nocturnal cramps are common. When deep venous obstruction results in varicose veins, the patient may develop the signs and symptoms of chronic venous insufficiency: edema, pain, pigmentation, and ulcerations. Susceptibility to injury and infection is increased, thus increasing risk for ulceration.

Assessment and Diagnostic Findings

Diagnostic tests for varicose veins include the duplex ultrasound scan, which documents the anatomic site of reflux and provides a quantitative measure of the severity of valvular reflux. These scans are typically performed in a reverse Trendelenburg position or with the patient standing. Venography is now rarely performed due to the availability of ultrasound. However, when it is used, it involves injecting a radiopaque contrast agent into the leg veins so that the vein anatomy can be visualized by x-ray studies during various leg movements. CT venography can be helpful, especially if the pelvic venous structures are involved.

Prevention and Medical Management

The patient should avoid activities that cause venous stasis, such as wearing socks that are too tight at the top or that leave marks on the skin, crossing the legs at the thighs, and sitting or standing for long periods. Changing position frequently, elevating the legs 3 to 6 inches higher than heart level when they are tired, and getting up to walk for several minutes of every hour promote circulation. The patient is encouraged to walk 30 minutes each day if there are no contraindications. Walking up the stairs rather than using the elevator or escalator is helpful, and swimming is good exercise.

Graduated compression stockings, especially knee-high stockings, are useful. The patient who is overweight should be encouraged to begin a weight reduction plan.

The most common treatment options for venous insufficiency and varicose veins are thermal ablation with radiofrequency and laser therapy, micro (stab) phlebectomy, and foam sclerotherapy. Surgical

ligation and stripping are reserved for select cases not amenable to other treatment options.

Thermal Ablation

Thermal ablation is a nonsurgical approach using thermal energy. Radiofrequency ablation uses an electrical contact inside the vein. As the device is withdrawn, the vein is sealed. Laser ablation uses a laser fiber tip that seals the vein (decompressed). Topical gel may be used first to numb the skin along the course of the saphenous vein. To protect the surrounding tissue, several small punctures are made along the vein, and 100 to 200 mL of dilute lidocaine is delivered to the perivenous space using ultrasound guidance. The goal of this tumescent anesthesia (i.e., anesthesia that causes localized swelling) is to provide analgesia, thermal protection (the cuff of fluid surrounds the veins and accompanying nerves), and extrinsic compression of the vein (Poder, Fisette, Bédard, et al., 2018). The saphenous vein is entered percutaneously near the knee using ultrasound guidance. A catheter is introduced into the saphenous vein and advanced to the saphenofemoral junction. The device is then activated and withdrawn, sealing the vein. Bandages or graduated compression stockings are applied after the procedure. A simultaneous microphlebectomy of branch varicosities may be performed; this is associated with a lower incidence of thrombophlebitis. This is also associated with quality of life improvements such as decreased leg swelling, pain, skin changes and healing of ulcerations, because all symptomatic veins may be treated at one time (Berti-Hearn & Elliott, 2019).

Cyanoacrylate embolization is approved for the treatment of an incompetent greater saphenous vein. Cyanoacrylate adhesive has been used for the treatment of arteriovenous malformations and a modified cyanoacrylate adhesive was developed that has rapid polymerization on contact with blood and tissue, flexibility sufficient to tolerate dynamic movements in the legs without generation of symptoms or be perceptible by the patient, and has a high viscosity to decrease the risk of propagation or embolization into the deep veins (Sidawy & Perler, 2019). During this procedure, a sheath is placed into the greater saphenous vein (guided by ultrasound). A catheter is advanced to the proximal saphenous vein and injections of cyanoacrylate are given, followed by local compression, and then repeated injections with repeated compression until the entire length of the target vein segment is

treated. Cyanoacrylate embolization has been associated with less procedural ecchymosis because heat is not needed during this procedure.

Microphlebectomy

If there are superficial varicose veins that are close to the surface, a microphlebectomy may be performed. This procedure involves removal of a superficial varicosity using anywhere from one to 20 small incisions. There can be extensive bruising and risk of infection with this procedure (Sidawy & Perler, 2019).

Sclerotherapy

Sclerotherapy involves injection of an irritating chemical into a vein to produce localized phlebitis and fibrosis, thereby obliterating the lumen of the vein. This treatment may be performed alone for small varicosities or may follow vein ablation, ligation, or stripping. Sclerotherapy is typically performed in a procedure room and does not require sedation. After the sclerosing agent is injected, graduated compression stockings are applied to the leg and are worn for approximately 1 week after the procedure. Ultrasound-guided foam sclerotherapy has been found to be more effective in achieving closure of the branch veins. It is also associated with decreased symptoms of leg aching, itching, and edema, less skin changes and ulcerations, and increased patient satisfaction (Berti-Hearn & Elliott, 2019). After sclerotherapy, walking is encouraged to activate the calf muscle pump and maintain blood flow in the leg.

Ligation and Stripping

Surgery for symptomatic varicose veins requires that the deep veins be patent and functional. The saphenous vein is ligated high in the groin, where the saphenous vein meets the femoral vein. In addition, the vein may be stripped (removed). After the vein is ligated, an incision is made 2 to 3 cm below the knee, and a metal or plastic wire is passed the full length of the vein to the point of ligation. The wire is then withdrawn, pulling (stripping) the vein as it is removed. Pressure and elevation minimize bleeding during surgery.

Nursing Management

Thermal ablation is performed in an outpatient or clinic setting. The patient is advised to maintain compression on the affected limb for at least 24 hours and then wear compression stockings while ambulatory for at least 1 week post procedure. Patients have no activity restrictions, but are advised to avoid strenuous exercise, such as weight lifting, bicycle riding, or swimming for 2 weeks. The patient is informed that bruising may occur along the course of the saphenous vein and that they may experience leg cramps for a few days and may find it difficult to straighten the knee for up to 1.5 weeks. Nonsteroidal anti-inflammatory medications such as ibuprofen and cool compresses are used as needed for pain.

Ligation and stripping can be performed in an outpatient setting, or the patient may be admitted to the hospital on the day of surgery and discharged the same or next day if a bilateral procedure is to be performed or the patient is at high risk for postoperative complications. If the procedure is performed in an outpatient setting, nursing measures are the same as if the patient were hospitalized. Bed rest is discouraged, and the patient is encouraged to ambulate as soon as sedation has worn off. The patient is instructed to walk every hour for 5 to 10 minutes while awake for the first 24 hours if they can tolerate the discomfort, and then to increase walking and activity as tolerated. Graduated compression stockings are worn continuously for about 1 week after vein stripping. The nurse assists the patient to perform exercises and move the legs. The foot of the bed should be elevated. Standing and sitting are discouraged.

Promoting Comfort and Understanding

Analgesic agents are prescribed to help the patient move the affected extremities more comfortably. Dressings are inspected for bleeding, particularly in the groin, where the risk of bleeding is greatest. The nurse is alert for reported sensations of “pins and needles.” Hypersensitivity to touch in the involved extremity may indicate a temporary or permanent nerve injury resulting from surgery, because the saphenous vein and nerve are close to each other in the leg. Any of these signs or symptoms should be reported to the primary provider.

Usually, the patient may shower after 24 hours. A clean towel is used to gently pat dry, not rub, the incisions. Application of skin lotion is avoided until the incisions are completely healed to avoid infection. The patient is instructed to apply sunscreen to the incisional area prior to sun

exposure; otherwise, hyperpigmentation of the incision, scarring, or both may occur.

If the patient has undergone sclerotherapy, a burning sensation in the injected leg may be experienced for 1 to 2 days. The nurse encourages the use of a mild analgesic medication as prescribed and walking to provide relief.

Promoting Home, Community-Based, and Transitional Care

Long-term venous compression is essential after discharge, and the patient needs to obtain adequate supplies of graduated compression stockings or elastic bandages. Exercise of the legs is necessary; the development of an individualized plan requires consultation with the patient and the health care team.

LYMPHATIC DISORDERS

The lymphatic system consists of a set of vessels that spread throughout most of the body, as described previously in this chapter. The fluid drained from the interstitial space by the lymphatic system is called *lymph*. The flow of lymph depends on the intrinsic contractions of the lymph vessels, the contraction of muscles, respiratory movements, and gravity. The lymphatic system of the abdominal cavity maintains a steady flow of chyle (digested fatty food) from the intestinal mucosa to the thoracic duct. In other parts of the body, the lymphatic system's function is regional; the lymphatic vessels of the head, for example, empty into clusters of lymph nodes located in the neck, and those of the extremities empty into nodes of the axillae and the groin.

Lymphangitis and Lymphadenitis

Lymphangitis is an acute inflammation of the lymphatic channels. It arises most commonly from a focal area of infection in an extremity. Usually, the infectious organism is a *hemolytic streptococcus*. The characteristic red streaks that extend up the arm or the leg from an infected wound outline the course of the lymphatic vessels as they drain.

The lymph nodes located along the course of the lymphatic channels also become enlarged, red, and tender; this is referred to as acute lymphadenitis. They can also become necrotic and form an abscess, called suppurative lymphadenitis. The nodes involved most often are those in the groin, axilla, or cervical region.

Because these infections are nearly always caused by organisms that are sensitive to antibiotics, it is unusual to see abscess formation. Recurrent episodes of lymphangitis are often associated with progressive lymphedema. After acute attacks, a graduated compression stocking should be worn on the affected extremity for several months to prevent long-term edema.

Lymphedema

Lymphedema may be primary (congenital malformations) or secondary (acquired obstructions). Tissue swelling occurs in the extremities because of an increased quantity of lymph that results from obstruction of lymphatic vessels. It is especially marked when the extremity is in a dependent position. Initially, the edema is soft and pitting. As the condition progresses, the edema becomes firm, nonpitting, and unresponsive to treatment. The most common type is congenital lymphedema, known as lymphedema praecox, which is caused by hypoplasia of the lymphatic system of the lower extremity. This disorder is usually seen in women and first appears before age 35 (Dayan, Ly, Kataru, et al., 2018).

The obstruction may be in the lymph nodes and the lymphatic vessels. Sometimes, it is seen in the arm after an axillary node dissection (e.g., for breast cancer) and in the leg in association with varicose veins or chronic thrombophlebitis. In the latter case, the lymphatic obstruction usually is caused by chronic lymphangitis. Lymphatic obstruction caused by a parasite (filaria) is most frequently seen in the tropics. When chronic swelling is present, there may be frequent bouts of acute infection characterized by high fever and chills and increased residual edema once the inflammation has resolved. These changes can lead to chronic fibrosis, thickening of the subcutaneous tissues, and hypertrophy of the skin. This specific type of lymphedema, in which chronic swelling of the extremity recedes only slightly with elevation, is referred to as elephantiasis. There are an estimated 120 million people in the world infected by lymph-dwelling filarial parasites; of these, 40 million have lymphedema and secondary infections, creating an enormous global burden (King, Suamani, Sanuku, et al., 2018).

Medical Management

The goal of therapy is to reduce and control the edema and prevent infection. Active and passive exercises assist in moving lymphatic fluid into the bloodstream. External compression devices milk the fluid proximally from the foot to the hip or from the hand to the axilla. When the patient is ambulatory, custom-fitted graduated compression stockings or sleeves are worn; those with the highest compression strength (exceeding 40 mm Hg) are suggested; however, many patients cannot tolerate these pressures. When the leg is affected, continuous bed rest with the leg elevated may aid in mobilizing the fluids but is not practical long term. Manual lymphatic drainage performed by specially trained therapists is designed to direct or shift the congested lymph through functioning lymphatics that have preserved drainage. Manual lymphatic drainage is performed with light touch (as opposed to deep massage) to the proximal then distal lymphatic channels. Manual lymphatic drainage is incorporated in a sequential treatment approach used in combination with multilayer compression bandages, stockings or wraps, exercises, skin care, pressure gradient sleeves, and pneumatic pumps, depending on the severity and stage of the lymphedema (Patullo & Rajagopalan, 2017).

Pharmacologic Therapy

As initial therapy, the diuretic furosemide may be prescribed to prevent fluid overload due to mobilization of extracellular fluid. Diuretics have also been used along with elevation of the leg and the use of graduated compression stockings or sleeves. The use of diuretics alone has little benefit because their main action is to limit capillary filtration by decreasing the circulating blood volume. If lymphangitis or cellulitis is present, antibiotic therapy is initiated. Lymphedema significantly increases the risk for cellulitis; therefore, the patient is taught to provide meticulous skin care and inspect the skin for evidence of infection.

Surgical Management

Surgery is performed if the edema is severe and uncontrolled by medical therapy, if mobility is severely compromised, or if infection persists. One surgical approach involves the excision of the affected subcutaneous tissue and fascia, with skin grafting to cover the defect. Another procedure involves the surgical relocation of superficial lymphatic vessels into the deep lymphatic system, also known as lymph node transfer, by means of a buried dermal flap to provide a conduit for lymphatic drainage (Pappalardo, Patel, & Cheng, 2018).

Lymphaticovenous bypasses also are performed with anastomosing the end of the lymphatic vessels to the side of veins to reduce lymphatic flow in the limbs (Gallagher, Marulanda, & Gray, 2018).

Nursing Management

After surgery, antibiotics may be prescribed for 3 to 7 days (Pappalardo et al., 2018). Constant elevation of the affected extremity and observation for complications are essential. Complications may include flap necrosis, hematoma or abscess under the flap, and cellulitis. The nurse instructs the patient or caregiver to inspect the dressing daily. Unusual drainage or any inflammation around the wound margin suggests infection and should be reported to the surgeon. The patient is informed that there may be a loss of sensation in the surgical area. The patient is also instructed to avoid the application of heating pads or exposure to sun to prevent burns or trauma to the area.

CELLULITIS

Cellulitis is the most common infectious cause of limb swelling. Cellulitis can occur as a single isolated event or a series of recurrent events. It is sometimes misdiagnosed as recurrent thrombophlebitis or chronic venous insufficiency.

Pathophysiology

Cellulitis occurs when an entry point through broken skin allows microbes to enter and release their toxins in the subcutaneous tissues. The etiologic pathogen of cellulitis is typically either *Streptococcus* species or *Staphylococcus aureus* (Bystritsky & Chambers, 2018).

Clinical Manifestations

The onset of swelling, localized redness, warmth, and pain is frequently associated with systemic signs of fever, chills, and sweating. The redness may not be uniform and often skips areas and eventually develops a pitting “orange peel” appearance. Regional lymph nodes may also be tender and enlarged (Bystritsky & Chambers, 2018).

Concept Mastery Alert

Cellulitis needs to be differentiated from lymphangitis. With cellulitis, the swelling and redness is localized and anatomically nonspecific. With lymphangitis, characteristic red streaks appear denoting the outline of the lymphatic vessels that are affected.

Medical Management

Mild cases of cellulitis can be treated on an outpatient basis with oral antibiotic therapy. If the cellulitis is severe, the patient is treated with IV antibiotics. The key to preventing recurrent episodes of cellulitis lies in adequate antibiotic therapy for the initial event and in identifying the site of microbial entry. Cracks and fissures that occur in the skin between the toes must be examined as potential sites of microbial entry. Other locations include drug use injection sites, contusions, abrasions, ulceration, ingrown toenails, and hangnails. Prophylactic compression therapy to reduce the risk of recurrence may be indicated in some cases (Webb, Neeman, Bowden, et al., 2020).

Nursing Management

The patient is instructed to elevate the affected area 3 to 6 inches above heart level and apply cool packs to the site every 2 to 4 hours until the inflammation has resolved, and then transition to warm packs. Patients with sensory and circulatory deficits, such as those caused by diabetes and paralysis, should use caution when applying warm packs because burns may occur; it is advisable to use a thermometer or have a caregiver ensure that the temperature is not more than lukewarm. Education should focus on preventing a recurrent episode. The patient with peripheral vascular disease or diabetes should receive education or reinforcement about skin and foot care.

CRITICAL THINKING EXERCISES

1 pq A 27-year-old male with Marfan syndrome presents to the emergency department where you work complaining of a sudden onset of chest pain with dyspnea and left leg weakness. You are unable to palpate pulses in his left foot. The patient's laboratory findings indicate a decline in renal function. How would you triage and prioritize your initial nursing care for this patient? The provider orders an urgent CT angiogram, which reveals a dissection of the aorta and obstructed flow to the left kidney and left leg. What are the ongoing priorities for managing this patient's care?

2 ebp A 32-year-old woman presents to the primary care clinic where you work with leg pain. She has recently been on a long airplane flight and has had some unilateral leg swelling with calf tightness and pain. Her only medication is an oral contraceptive agent; she is generally healthy. What are her risk factors for venous thromboembolism (VTE)? What further diagnostic studies should be considered and what evidence-based practice recommendations will guide the management of her care? What pharmacologic options might be considered for anticoagulation and what therapies are indicated to manage her leg edema?

3 ipc A 70-year-old male presents to a preadmission center where you work to prepare for surgical repair of an abdominal aortic aneurysm. His aneurysm is 5.8 cm which is an increase of 1 cm in the last 6 months. His hypertension is well controlled, and he has had no further angina since coronary artery bypass grafts (CABGs) 2 years ago. He has good exercise tolerance and his weight is within a normal range. What preoperative assessments are required? The patient asks what he should do if he experiences increasing abdominal, back, or flank pain before surgery. How will you respond? How will the interprofessional team manage his postoperative care and coordinate a safe discharge?

27 Assessment and Management of Patients with Hypertension

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Compare and contrast normal blood pressure and various stages of hypertension.
2. Identify pathophysiologic processes implicated in the progression of hypertension.
3. Demonstrate the proper techniques to perform an assessment and discriminate between normal and abnormal findings identified in the patient with hypertension.
4. Discuss risk factors and treatment approaches for hypertension, including lifestyle modifications and medication therapy.
5. Use the nursing process as a framework for care of the patient with hypertension.
6. Describe hypertensive crises and their treatments.

NURSING CONCEPTS

Assessment
Perfusion

GLOSSARY

hypertensive emergency: an emergent situation in which blood pressure is severely elevated and there is evidence of actual or probable target organ damage

hypertensive urgency: an urgent situation in which blood pressure is severely elevated but there is no evidence of impending or progressive target organ damage

isolated systolic hypertension: a disorder most commonly seen in the older adult in which the systolic pressure is greater than 140 mm Hg and the diastolic pressure is less than 80 mm Hg

masked hypertension: blood pressure that is typically suggestive of a diagnosis of hypertension that is paradoxically normal in health care settings

primary hypertension: high blood pressure with no identifiable cause (*synonym:* essential hypertension)

rebound hypertension: blood pressure in a patient with hypertension that is controlled with medication and becomes abnormally high with the abrupt discontinuation of that medication

resistant hypertension: high blood pressure treated with three or more antihypertensive medications of different classes; one of these must be a diuretic agent

secondary hypertension: high blood pressure from an identified cause, such as chronic kidney disease

target organ damage: manifestations of pathophysiologic changes in various organs as a consequence of hypertension

white coat hypertension: blood pressure that increases to hypertensive readings in health care settings that is paradoxically within the normal ranges in other settings

Hypertension is the most common chronic disease among adults in the United States and in the world (Whelton, Carey, Aronow, et al., 2017*)*. It is identified as the leading risk factor for premature death, disability, and overall disease burden worldwide because it may lead to cardiovascular disease (CVD), stroke, and chronic kidney disease (CKD) when not appropriately treated (Caillon, Paradis, & Schiffrin, 2019; DePalma, Himmelfarb, MacLaughlin, et al., 2018). The overall risk of developing these CVDs, strokes, and renal disorders is low among patients with blood pressures that are consistently stable around 115/75 mm Hg; however, each increase of 20 mm Hg in the systolic blood pressure (SBP) or 10 mm Hg increase in the diastolic blood pressure (DBP) doubles the risk of death from stroke or heart disease (Lee, Kim, Kang, et al., 2018). And yet, most patients with hypertension could lower their blood pressure through lifestyle changes (e.g., diet, exercise, medication adherence, smoking cessation) and lower these associated morbid risks

(Whelton et al., 2017). This chapter presents an overview of hypertension and how it is defined and managed so that nurses may appropriately assess, monitor, educate, and intervene with patients with hypertension.

Hypertension

For many years, patients were diagnosed with hypertension if they had chronically elevated SBPs of 140 mm Hg or higher or DBPs of 90 mm Hg or higher. These parameters, which also specified that the diagnosis of hypertension must be based on an average of two or more accurate readings taken one to 4 weeks apart, were endorsed by the *Seventh Report of the Joint National Committee on prevention, detection, evaluation, and treatment of high blood pressure* (JNC 7) (Chobanian, Bakris, Black, et al., 2003), as well as the *Eighth Joint National Committee* (JNC 8) (James, Oparil, Carter, et al., 2014), and the *American Society of Hypertension* (ASH) and the *International Society of Hypertension* (ISH) (Weber, Schiffrin, White, et al., 2014). However, these parameters for diagnosing hypertension recently changed to less permissive parameters, and patients with average SBPs that are 130 mm Hg or higher or with average DBPs 80 mm Hg or higher may be diagnosed with hypertension, according to the *American College of Cardiology (ACC)/American Heart Association (AHA) Task Force* (Whelton et al., 2017).

The classification system for hypertension has been further revised by the ACC/AHA (Whelton et al., 2017) to include elevated, stage 1, and stage 2 categories, as displayed in Table 27-1. Table 27-1 compares this classification system to previous JNC 7 and JNC 8 guidelines classification systems, which are no longer followed (DePalma et al., 2018). The blood pressure categories emphasize the direct relationship between the SBP and DBP risks of morbidity, all-cause mortality, and specifically, cardiovascular mortality. Of particular note, the ACC/AHA guideline (Whelton et al., 2017) changed the previously labeled *prehypertension* category to *elevated blood pressure* category. The rationale for this change in terminology is to highlight the association between any elevated blood pressure and increased cardiovascular risk. The blood pressure readings should use the average of two or more valid, reproducible measurements obtained on more than two occasions, in most instances (see later discussion under Assessment and Diagnostic Findings).

The prevalence of hypertension among adults in the United States is substantially higher when the definition of the ACC/AHA guideline is used versus the JNC 7 or JNC 8 definition (46% vs. 32%) (Whelton et al., 2017). However, since nonpharmacologic treatment (i.e., lifestyle changes) is recommended for most adults whose blood pressures are within the elevated hypertension category, the newer guidelines that define hypertension have resulted in only a small increase in antihypertensive medication prescriptions,

overall. Indeed, it has been asserted that the greatest benefit of the ACC/AHA (2017) guideline is its greater emphasis on lifestyle interventions, which include weight loss, healthy diet, physical exercise, reduced sodium intake, increased potassium intake, and decreased alcohol intake (Ioannidis, 2018).

The prevalence of hypertension increases as people age or have other cardiovascular risk factors. Of all adults with hypertension, it is estimated that 35.3% do not know that they have this disorder. Furthermore, approximately 45.4% of people with hypertension do not have their blood pressure under control (Benjamin, Muntner, Alonso, et al., 2019). The prevalence of hypertension varies by ethnicity and gender, and is estimated at approximately 48.2% among Caucasian men, 41.3% among Caucasian women, 58.6% among African American men, 56% among African American women, 47.4% among Hispanic men, 40.8% among Hispanic women, 46.4% among Asian American men, and 36.4% among Asian American women. The prevalence of hypertension among African Americans is among the highest in the world (Benjamin et al., 2019). Moreover, African Americans tend to develop hypertension at younger ages than Caucasian Americans (Spikes, Higgins, Quyyumi, et al., 2019). Chart 27-1 displays risk factors for hypertension.

Findings from the National Health and Nutrition Examination Survey (NHANES) have shown better hypertension control rates in women, in Caucasians than in African Americans and Hispanics, and in older versus younger patients. Additionally, adults of higher socioeconomic status have better control of their blood pressures compared to adults of lower socioeconomic status. Hypertension is most prevalent among adults 75 years of age and older, affecting 80% of men and 85.6% of women (Benjamin et al., 2019).

TABLE 27-1 Comparing Blood Pressure Classifications by Key Guidelines for Adults Age 18 and Older

Systolic BP (mm Hg)		Diastolic BP (mm Hg)	ACC/AHA (2017) Guideline*	JNC 7* and JNC 8* Guidelines
<120	-and-	<80	Normal	Normal
120–129	-and-	<80	Elevated	Prehypertension
130–139	-or-	80–89	Stage 1 hypertension	Prehypertension
140–159	-or-	90–99	Stage 2 hypertension	Stage 1 hypertension
≥160	-or-	≥100	Stage 2 hypertension	Stage 2 hypertension

Note: For each guideline, if the patient's systolic and diastolic BPs fall into different categories, then the patient is classified according to the higher category.
BP, blood pressure.

Chart 27-1 **RISK FACTORS**

Hypertension

Risk Factors

- Advancing adult age
- African American
- Chronic kidney disease
- Diabetes
- Drinking too much alcohol (i.e., more than two drinks per day for men and more than one drink per day for women)
- Family history
- Gender-related:
  - Men have greater risk until 64 y of age
  - Women have greater risk at 65 y of age and later
- Hypercholesterolemia
- Overweight/obesity
- Poor diet habits, particularly if it includes too much salt, as well as limited intake of vegetables, fiber, fish fats, and potassium
- Sedentary lifestyle
- Use of tobacco and nicotine products (e.g., cigarettes, e-cigarettes) and exposure to secondhand smoke
- Stress
- Sleep apnea

Adapted from American Heart Association (AHA). (2019). Know your risk factors for high blood pressure. Retrieved on 10/17/2019 at: www.heart.org/en/health-topics/high-blood-pressure/why-high-blood-pressure-is-a-silent-killer/know-your-risk-factors-for-high-blood-pressure; Whelton, P. K., Carey, R. M., Aronow, W. S., et al. (2017). 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: A report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Hypertension, 71*(6), e13–e115.

Hypertension is categorized as either primary hypertension or secondary hypertension. **Primary hypertension** (also called *essential hypertension*) is diagnosed when there is no identifiable cause (Alexander, 2019). Approximately 90% to 95% of adults with hypertension have primary hypertension.

Secondary hypertension is defined as high blood pressure from an identifiable underlying cause. Between 5% and 10% of all adults with hypertension have secondary hypertension. Screening for secondary hypertension is indicated for new-onset, poorly controlled hypertension, in hypertension resistant to treatment with three or more drugs, with hypertension of an abrupt onset, or in patients younger than 30 years of age. In addition, a new diagnosis of hypertension with associated excessive target organ damage, such as cerebral vascular disease, retinopathy, left ventricular hypertrophy (LVH), heart failure with preserved ejection fraction, coronary artery disease, CKD, or peripheral arterial disease, could suggest secondary hypertension. Chart 27-2 displays some common underlying causes of secondary hypertension.

Pathophysiology

Blood pressure is the product of cardiac output multiplied by peripheral resistance. Cardiac output is the product of the heart rate multiplied by the stroke volume. Each time the heart contracts, pressure is transferred from the contraction of the myocardium to the blood and then pressure is exerted by the blood as it flows through the blood vessels. Hypertension can result from increases in cardiac output, increases in peripheral resistance (constriction of the blood vessels), or both. Increases in cardiac output are often related to an expansion in vascular volume. Although no precise cause can be identified for most cases of hypertension, it is understood that hypertension is a multifactorial condition. Because hypertension can be a sign, it is most likely to have many causes, just as fever has many causes (Norris, 2019). For hypertension to occur there must be a change in one or more factors affecting peripheral resistance or cardiac output. In addition, there must also be a problem with the body's control systems that monitor or regulate pressure (Fig. 27-1).

Chart 27-2

Common Causes of Secondary Hypertension

Chronic kidney disease
Coarctation of the aorta
Cushing's syndrome
Hyperaldosteronism (primary or secondary)
Hyperparathyroidism
Hypo- or hyperthyroidism
Medication abuse (nonsteroidal anti-inflammatory drugs [NSAIDs]) or substance abuse disorder (alcohol, cocaine, amphetamines)
Obstructive sleep apnea
Pheochromocytoma
Preeclampsia
Polycystic kidney disease
Prostatism
Renal artery stenosis

Adapted from Whelton, P. K., Carey, R. M., Aronow, W. S., et al. (2017). 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: A report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Hypertension, 71*(6), e13–e115.

Hypertension is thought to occur as a result of a complex interaction between behavioral–social–environmental risks and genetics (Zilbermint, Gaye, Berthon, et al., 2019). Behavioral–social–environmental risks may include dietary habits, including limited consumption of vegetables, fiber, fish fats, and potassium, and excessive intake of sodium; obesity; poor physical fitness; and excessive alcohol intake (Whelton et al., 2017).

Although single-gene mutations associated with hypertension have been identified, most types of hypertension are thought to be polygenic (i.e., mutations in more than one gene) (Whelton et al., 2017). The tendency to develop hypertension can be inherited; however, genetic profiles alone cannot predict who will and will not develop hypertension. The role of genetics in hypertension is complex and not fully understood at the present time.

To date, over 1000 genetic variants have been identified that may contribute to hypertension; however, collectively they explain only about 6% of the trait variance (Zilbermint et al., 2019).

Many physiologic precedents that can lead to hypertension have been identified (Caillon, Mian, Fraulob-Aquino, et al., 2017; Caillon et al., 2019; Norris, 2019):

- Increased sympathetic nervous system activity related to dysfunction of the autonomic nervous system

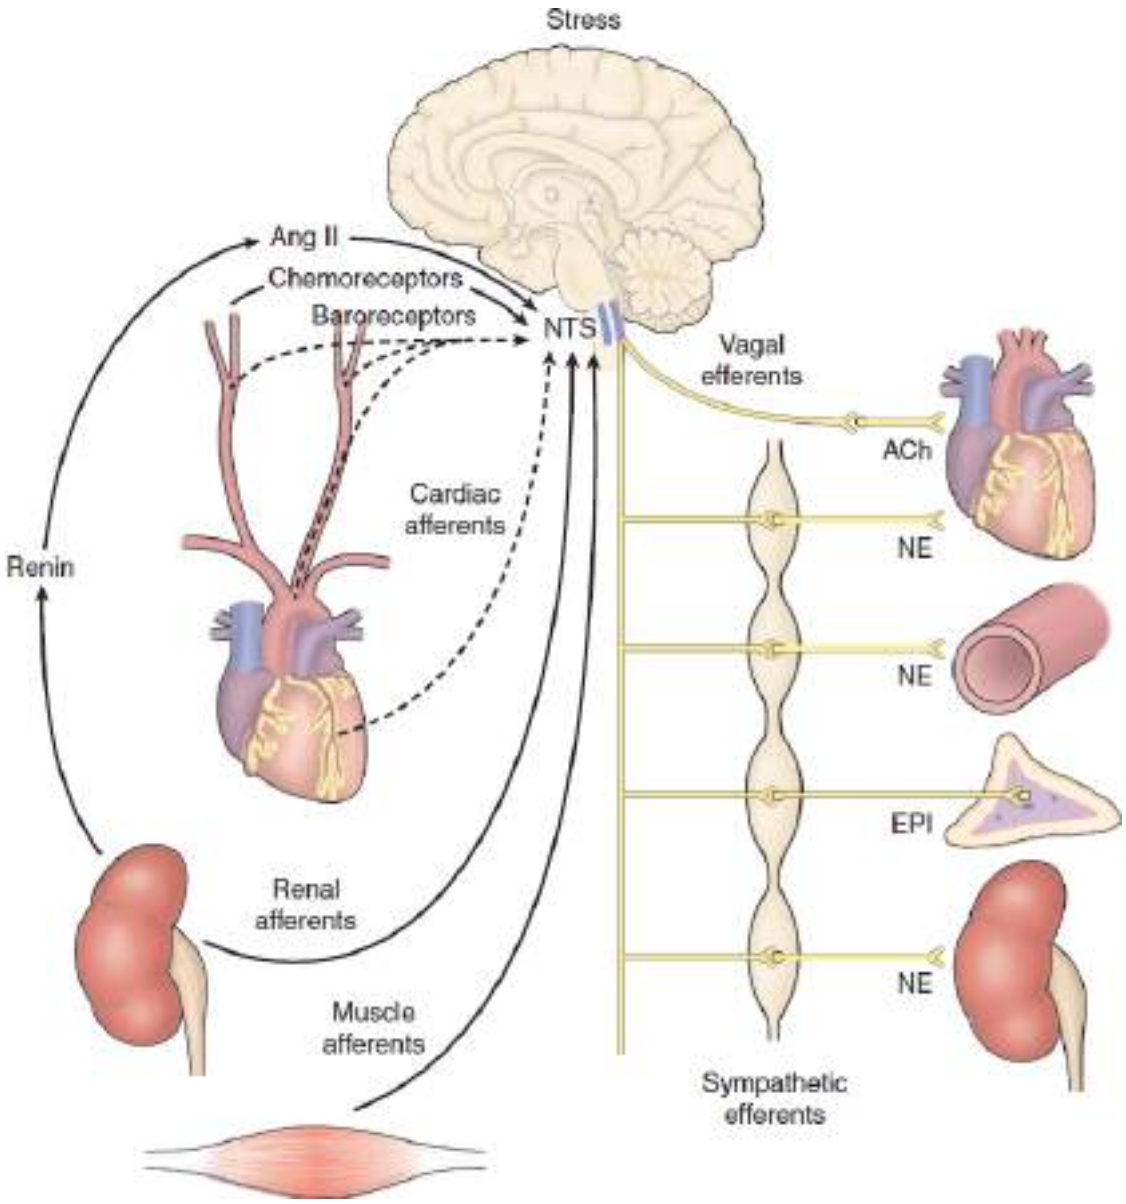

Figure 27-1 • Central and reflex mechanisms involved in the neural control of blood pressure. *Dotted arrows* represent inhibitory neural influences, and *solid arrows* represent excitatory neural influences on sympathetic outflow. ACH, acetylcholine; Ang II, angiotensin II; EPI, epinephrine; NE, norepinephrine; NTS, nucleus tractus solitarius. Adapted from Kaplan, N. M., & Victor, R. G. (2015). *Kaplan's clinical hypertension* (11th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

- Increased renal reabsorption of sodium, chloride, and water related to a genetic variation in the pathways by which the kidneys handle sodium
- Increased activity of the renin–angiotensin–aldosterone system, resulting in expansion of extracellular fluid volume and increased systemic vascular resistance

- Decreased vasodilation of the arterioles related to dysfunction of the vascular endothelium
- Resistance to insulin action, which may be a common factor linking hypertension, type 2 diabetes, hypertriglyceridemia, obesity, and glucose intolerance
- Activation of the innate and adaptive components of the immune response that contribute to vascular inflammation and dysfunction

Gerontologic Considerations

Structural and functional changes in the heart, blood vessels, and kidneys contribute to increases in blood pressure that occur with aging. These changes include accumulation of atherosclerotic plaque, fragmentation of arterial elastins, increased collagen deposits, impaired vasodilation, and renal dysfunction. The result of these changes is decreased elasticity or stiffening of the major blood vessels, particularly the aorta, and volume expansion (Eliopoulos, 2018; Fajemiroye, da Cunha, Saavedra-Rodríguez, et al., 2018). Hence, both SBP and DBP increase linearly up to the sixth decade of life. At that time, among most adults, DBP gradually decreases while SBP continues to rise. Thus, **isolated systolic hypertension** is the predominant form of hypertension in older people (Whelton et al., 2017). Results from randomized controlled studies have demonstrated that lowering blood pressure in older adults with isolated systolic hypertension is effective in reducing the incidence of adverse cardiovascular events and death (Whelton et al., 2017).

Clinical Manifestations

Physical examination may reveal no abnormalities other than elevated blood pressure. People with hypertension may be asymptomatic and remain so for many years. Hypertension is known as the “silent killer” because it typically has no warning signs or symptoms, and many people do not know they have it. However, when specific signs and symptoms appear, they usually indicate vascular damage, with specific manifestations related to the organs served by the involved vessels. These specific manifestations of pathophysiologic changes in various organs as a consequence of hypertension are referred to as **target organ damage**. Retinal changes such as hemorrhages, exudates (fluid accumulation), arteriolar narrowing, and cotton-wool spots (small infarctions) may occur. In severe hypertension, papilledema (swelling of the optic disc) may be seen (Weber & Kelley, 2018). Coronary artery disease with angina and myocardial infarction (MI) are common consequences of hypertension. LVH occurs in response to the increased workload placed on the ventricle as it contracts against higher systemic pressure. When heart damage is extensive, heart failure follows. Pathologic changes in the kidneys (indicated by

increased blood urea nitrogen [BUN] and serum creatinine levels) may manifest as nocturia. Cerebrovascular involvement may lead to a transient ischemic attack (TIA) or stroke, manifested by alterations in vision or speech, dizziness, weakness, a sudden fall, or transient or permanent hemiplegia (paralysis on one side). Cerebral infarctions account for most of the strokes in patients with hypertension (Norris, 2019).

Assessment and Diagnostic Findings

The first step of diagnosis is an accurate blood pressure measurement (see Chart 27-3 for an overview of appropriate BP measurement equipment, instructions, and interpretation for both the patient and the clinician). It is important to use an average of at least two blood pressure readings on at least two occasions to confirm the diagnosis of hypertension for most patients. The notable exception is when a patient's average BP is greater than or equal to 160/100 mm Hg, confirmed by at least two accurate readings on one occasion (see later discussion) (Muntner, Shimbo, Carey, et al., 2019; Whelton et al., 2017).

Blood pressure measurement within a clinical setting is often not an accurate reading; therefore, home blood pressure measurement (HBPM) or ambulatory blood pressure measurement (ABPM) are considered more accurate reflections of the blood pressure status. HBPM and ABPM are used not only to confirm the diagnosis of hypertension in most cases, but also to evaluate whether success has been achieved with treatments, such as lifestyle modifications and prescription medications (see later discussion) (Whelton et al., 2017).

Utilizing HBPM and ABPM measurements have led to recognizing other manifestations of blood pressure. Examples of these alternative manifestations of hypertension include masked hypertension and white coat hypertension. Patients with **masked hypertension** exhibit elevated blood pressure at levels typically consistent with hypertension in settings outside the hospital or clinic, while their blood pressure is seemingly normal in health care settings. In contrast, patients with **white coat hypertension** have blood pressure readings that would suggest a diagnosis of hypertension when they are in health care settings (e.g., clinics), but are within the normal ranges in other settings. If untreated, the patient with masked hypertension can go on to experience adverse cardiovascular events (e.g., MI, strokes) and mortality. On the other hand, the patient with white coat hypertension may receive treatment that is not warranted (Cohen, Lotito, Trivedi, et al., 2019).

Chart 27-3

Measuring Blood Pressure

Equipment

For the Patient at Home

- Automatic or semiautomatic upper-arm electronic device with digital display of readings

For the Practitioner

- Preferably, a validated electronic oscillometric device; if not available, a recently calibrated aneroid sphygmomanometer
- Appropriately sized arm cuff

Instructions for the Patient

- Avoid eating, smoking, drinking caffeinated beverages, and physical activity for 30 min before blood pressure (BP) is measured.
- Empty bladder.
- Sit quietly for 5 min before the measurement.
- Sit comfortably, with back supported, with the forearm supported at heart level on a firm surface, with both feet on the ground; avoid talking while the measurement is being taken.

Instructions for the Practitioner

- Select the size of the cuff based on the size of the patient. (The cuff size should have a bladder width of at least 40% of limb circumference and length 80–100% of limb circumference.) Small adult cuffs are 12 cm wide and 22 cm long, average adult cuffs are 16 cm wide and 30 cm long, large adult cuffs are 16 cm wide and 36 cm long, and extra-large adult cuffs are 16 cm wide and 42 cm long. Using a cuff that is too small will give a higher BP measurement, and using a cuff that is too large results in a lower BP measurement compared to one taken with a properly sized cuff.
- Wrap the cuff firmly around the arm. Center the cuff bladder directly over the brachial artery.
- Position the patient's arm at the level of the heart.
- If an aneroid sphygmomanometer is used, palpate the systolic pressure before auscultating. This technique helps to detect the presence of an auscultatory gap more readily.
- Ask the patient to sit quietly while the BP is measured, because the BP can increase when the patient is engaged in conversation.
- Initially, record BP results of both arms and take subsequent measurements from the arm with the higher BP. Normally, the BP should vary by no more than 5 mm Hg between arms.
- Take two readings 1–2 min apart and use the average of these measurements.

- Record the site where the BP was measured and the position of the patient (i.e., right arm).
- Inform the patient of their BP value and what it means. Emphasize the need for periodic reassessment, and encourage patients who measure BP at home to keep a written record of readings.

Interpretation

Assessment is based on the average of at least two readings. (If two readings differ by more than 5 mm Hg, additional readings are taken and an average reading is calculated from the results.)

Adapted from Muntner, P., Shimbo, D., Carey, R. M., et al. (2019). Measurement of blood pressure in humans: A scientific statement from the American Heart Association. *Hypertension, 73(*5), e35–e66; Padwal, R., Campbell, N. R. C., Schutte, A. E., et al. (2019). Optimizing observer performance of clinic blood pressure measurement: A position statement from the Lancet Commission on Hypertension Group. *Journal of Hypertension, 37*(9), 1737–1745.

A thorough health history and physical examination are necessary to ensure successful diagnosis and treatment. The onset of high blood pressure and the patient's health history can be used to determine whether the patient might have primary hypertension or secondary hypertension (see Chart 27-2).

Abnormal findings from the physical examination could suggest either target organ damage or secondary hypertension. The physical examination should include palpation of all peripheral pulses. Absent, weak, or delayed femoral pulses could suggest coarctation of the aorta or severe peripheral vascular disease. The neck should be examined for carotid bruits, distended veins, or an enlarged thyroid gland. The upper abdomen should be auscultated for the presence of a renal artery bruit that could be suggestive of renal artery stenosis. A careful cardiac examination is also needed to evaluate for signs of LVH. LVH signs include displacement of the apex, a sustained and enlarged apical impulse, and the presence of an S_4 cardiac sound (see Chapter 21) (Weber & Kelley, 2018).

Occasionally, signs of hypertension can be discovered during a fundoscopic eye examination manifested as hypertensive retinopathy (e.g., retinal hemorrhages, microaneurysms, cotton-wool spots, papilledema); these findings are associated with an increased cardiovascular risk (e.g., stroke). Acute or chronic ocular changes can be the initial finding in asymptomatic patients and typically require a referral to an ophthalmologist. Long-standing, untreated hypertension can cause heart failure, CKD (elevated BUN and creatinine), and increased risk for cerebrovascular disease (e.g., TIAs, strokes) (Weber & Kelley, 2018).

Laboratory tests are also performed to assess for possible target organ damage and to screen for primary hypertension or secondary hypertension.

These typically include urinalysis, blood chemistry (i.e., analysis of sodium, potassium, creatinine, fasting glucose, cholesterol levels), and a 12-lead electrocardiogram. LVH can be assessed by echocardiography. Renal damage may be suggested by elevations in BUN and creatinine levels or by microalbuminuria or macroalbuminuria. Additional studies, such as creatinine clearance, renin level, urine tests, and 24-hour urine protein, may be performed. Optional testing may include uric acid and urine albumin to creatinine ratio (Whelton et al., 2017).

Medical Management

The goal of hypertension treatment is to prevent complications (i.e., target organ damage) and death by maintaining a blood pressure lower than 130/80 mm Hg. Findings from a systematic review and meta-analysis demonstrated that hypertension treatment that effectively achieves the aim of BP control to normal levels is associated with lower mortality and lower rates of CVD (Brunstrom & Carlberg, 2018). The optimal treatment plan is one that is inexpensive, simple, and causes the least possible disruption in the patient's life.

The ACC/AHA Guidelines (Whelton et al., 2017) have developed a series of recommendations for prevention, treatment, and management of hypertension. In addition, these guidelines specify that a diagnosis of hypertension must be made based on accurate blood pressure measurements (see Chart 27-3). As noted previously, an average of at least two blood pressure readings on at least two occasions should be used to confirm the diagnosis of hypertension for most patients. After having the BP measured to screen for hypertension, a patient not previously diagnosed with hypertension and with a normal BP (i.e., SBP less than 120 mm Hg and DBP less than 80 mm Hg) can be advised to have the BP reevaluated in 1 year. A patient without a prior diagnosis of hypertension with an elevated BP (i.e., SBP 120 to 129 mm Hg and DBP less than 80 mm Hg) should be advised to follow up with additional BP readings within 3 to 6 months. A patient with a BP that could be consistent with hypertension; that is, with an SBP greater than or equal to 130 mm Hg or a DBP greater than or equal to 80 mm Hg should follow-up with additional BP readings within 1 month's time to either confirm or rule out the diagnosis (Muntner et al., 2019; Whelton et al., 2017). So that patients with suspected white coat hypertension or masked hypertension may be accurately diagnosed, blood pressure readings should be based on HBPM or ABPM. Patients not instructed to follow up with additional BP readings to confirm a diagnosis of hypertension are patients with average BP readings greater than or equal to 160/100 mm Hg on one occasion; these patients are diagnosed with hypertension and begin treatment with antihypertensive medications (Muntner et al., 2019; Whelton et al., 2017).

All patients who report lifestyle choices that may put them at risk for hypertension should be counseled to adopt lifestyle changes, as appropriate. These lifestyle changes could include weight loss, dietary changes, physical activity modifications, decreased alcohol consumption, and smoking cessation (Table 27-2). In particular, the *Dietary Approach to Stop Hypertension* (DASH) diet has been one of the most effective diets in lowering BP; if used in conjunction with weight loss, this diet can lower SBP by 11 to 16 mm Hg (Campbell, 2017) (Table 27-3). In addition to this dietary advice, patients should be counseled to incorporate a low sodium (less than 2 g/day), high potassium (3500 to 5000 mg/day) diet; this dietary combination is more effective than following either a lone low sodium or high potassium diet (Perez & Chang, 2014). A high potassium diet must be avoided in patients with CKD, however.

Patients suspected to have secondary hypertension must be accurately screened and the disorder that caused the high blood pressure must be properly treated in order to bring the patient's blood pressure into normal parameters (see Chart 27-2). The recommended treatment for patients with elevated blood pressure but who are not diagnosed with hypertension is lifestyle changes, not antihypertensive medications, with follow-up in 3 to 6 months, as noted previously, to not only reevaluate the blood pressure but to see if it has responded positively to lifestyle modifications (Whelton et al., 2017).

The primary provider is advised by the ACC/AHA Guidelines (Whelton et al., 2017) to screen the patient diagnosed with Stage 1 hypertension for risk of having adverse cardiac events (e.g., stroke, MI) within the next 10 years by using the online *ASCVD Risk Estimator Plus.* This tool is published by the ACC and is free to use (links to this tool are provided in the Resources section at the end of this chapter). This tool screens patients based on factors that include blood pressure readings, age, gender, lipid panel results, use of medications, smoking status, and whether or not they have concomitant diabetes. The risk of having an adverse cardiac event is then determined as low, borderline, or high. Those patients with a score of 10 or higher (consistent with mid-borderline risk) should be prescribed an antihypertensive medication, as should any patient diagnosed with stage 2 hypertension. All patients should be advised to institute relevant lifestyle changes, regardless of stage and use of antihypertensive medications.

TABLE 27-2 Lifestyle Modifications to Prevent and Manage Hypertension[a]

Modification	Recommendation	Impact on SBP Reduction[b] Patients without Hypertension	Impact on SBP Reduction[b] Patients with Hypertension
Weight reduction	Maintain normal body weight (body mass index 18.5–24.9 kg/m^2). Ideal body weight is best goal; but aim for at least 1 kg (2.2 lb) weight loss. Expect ~ 1 mm Hg SBP decrease per 1 kg reduction in weight.	−2–3 mm Hg	−5 mm Hg
Adopt DASH eating plan	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat.	−3 mm Hg	−11 mm Hg
Dietary sodium reduction	Sodium <2 g/day is optimal goal; but aim for at least 1000 mg/day reduction. Check sodium amount on food labels.	−2–3 mm Hg	−5–6 mm Hg
Dietary potassium increase	Preferred potassium intake is 3500–5000 mg/day. Choose high potassium foods; check potassium amount on food labels.	−2 mm Hg	−4–5 mm Hg
Physical activity	Engage in: Regular aerobic physical activity such as brisk walking 90–150 min weekly Regular dynamic resistance training 90–150 min weekly Regular isometric resistance training at least three times weekly	−2–4 mm Hg −2 mm Hg −4 mm Hg	−5–8 mm Hg −4 mm Hg −5 mm Hg
Moderation of alcohol consumption	Limit consumption to ≤2 drinks (e.g., 24-oz beer, 10-oz wine, or 3-oz 80-proof whiskey) per day in most men and to ≤1 drink per day in women.	−3 mm Hg	−4 mm Hg

[a]For overall cardiovascular risk reduction, stop smoking.

[b]The effects of implementing these modifications are dose and time dependent and could be greater for some individuals.

DASH, dietary approaches to stop hypertension; SBP, systolic blood pressure.

Adapted from Whelton, P. K., Carey, R. M., Aronow, W. S., et al. (2017). 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: A

report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Hypertension*, *71*(6), e13–e115.

Pharmacologic Therapy

Research findings have demonstrated that appropriately prescribing antihypertensive pharmacologic agents lowers BP, and reduces the risk of CVD, cerebrovascular disease, and death (Whelton et al., 2017). Many classes of medications are available for hypertension management (Table 27-4). The medications that have been shown to prevent CVD are recommended as first-line agents for most patients. This first-line group includes thiazide or thiazide-type diuretics, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and calcium channel blockers (CCBs). African American patients with hypertension and without heart failure or CKD should be prescribed either a thiazide diuretic or a CCB as a first-line agent (not an ACE inhibitor or an ARB). The recommended first-line antihypertensive agents for patients with select comorbid disorders or who are pregnant are displayed in Table 27-5.

TABLE 27-3 The DASH (Dietary Approaches to Stop Hypertension) Diet

Food Group	Number of Servings Daily
Grains and grain products	7 or 8
Vegetables	4 or 5
Fruits	4 or 5
Low-fat or fat-free dairy foods	2 or 3
Lean meat, fish, and poultry	≤2
Nuts, seeds, and dry beans	4 or 5 servings weekly

Note: The diet is based on 2000 calories/day.

Adapted from U.S. Department of Health and Human Services. (2003). Your guide to lowering your blood pressure with DASH: DASH eating plan. Retrieved on 9/27//2019 at: www.nhlbi.nih.gov/health/public/heart/hbp/dash/new_dash/pdf

Patients are first prescribed low doses of medication. If blood pressure does not fall to less than 130/80 mm Hg, the dose is increased gradually and additional medications are included as necessary to achieve control. The simplest treatment schedule possible is ideal as it promotes adherence to the regimen (e.g., one pill once each day, two or more agents combined into a single pill).

Resistant hypertension is diagnosed when a patient takes at least three antihypertensive medications from different classes (including a diuretic) and the blood pressure is still not controlled (i.e., not less than 130/80 mm Hg). A patient with controlled blood pressure but who requires at least four antihypertensive medications in order to maintain that control is also

considered to have resistant hypertension (Whelton et al., 2017). Risk factors for resistant hypertension include older age, being African American, and having obesity, CKD, or diabetes. Treatment of patients with suspected resistant hypertension first revolves around ensuring that they are indeed adhering to their prescribed medication regimen, including ensuring that their finances do not preclude them from purchasing their prescriptions, that they understand the purpose of the medications, and that medication side effects are tolerable. Patients with suspected resistant hypertension should also be evaluated for possible secondary hypertension (Whelton et al., 2017).

TABLE 27-4 Oral Medication Therapy for Hypertension

Medications	Major Actions	Advantages and Contraindications	Effects and Nursing Considerations
First-Line Antihypertensive Agents			
Thiazide or Thiazide-Type Diuretics			
chlorthalidone[a] hydrochlorothiazide indapamide metolazone [a]*preferred agent for its long half-life.*	Decrease of blood volume, renal blood flow, and cardiac output. Depletion of extracellular fluid. Negative sodium balance (from natriuresis), mild hypokalemia. Directly affect vascular smooth muscle.	Relatively inexpensive. Effective orally. Effective during long-term administration. Mild side effects. Enhance other antihypertensive medications. Counter sodium retention effects of other antihypertensive medications. *Contraindications:* Gout, known sensitivity to sulfonamide-derived medications, severely impaired kidney function, and history of hyponatremia.	Side effects include dry mouth, thirst, weakness, drowsiness, lethargy, muscle aches, muscular fatigue, tachycardia, GI disturbance. Orthostatic hypotension may be potentiated by alcohol, barbiturates, opioids, or hot weather. Because thiazides cause loss of sodium, potassium, and magnesium, and increase in uric acid and calcium, monitor for signs of electrolyte imbalance. Encourage intake of potassium-rich foods. *Gerontologic considerations:* Risk of orthostatic hypotension.
ACE Inhibitors			
benazepril captopril enalapril fosinopril lisinopril moexipril perindopril quinapril	Inhibit conversion of angiotensin I to angiotensin II. Lower total peripheral resistance.	Angioedema is a rare but potentially life-threatening complication. *Contraindications:* Concomitant use of an ARB or a renin inhibitor or a	Can cause hyperkalemia. Side effect can include cough. *Gerontologic considerations:* Require reduced dosages and the

ramipril trandolapril		potassium-sparing diuretic or potassium supplements; bilateral renal artery stenosis, pregnancy; history of angioedema with prior use of an ACE inhibitor.	addition of loop diuretics when there is renal dysfunction. May cause upregulation of ACE2 receptors, making patients more susceptible to infection with SARS-CoV-2; however, may also mitigate deleterious effects of COVID-19.
Angiotensin Receptor Blockers			
azilsartan candesartan eprosartan irbesartan losartan olmesartan telmisartan valsartan	Block the effects of angiotensin II at the receptor. Reduce peripheral resistance.	Minimal side effects. *Contraindications:* Concomitant use of an ACE inhibitor or a renin inhibitor or a potassium-sparing diuretic or potassium supplements; bilateral renal artery stenosis; history of angioedema with prior use of an ARB; pregnancy, lactation, renovascular disease.	Monitor for hyperkalemia. Can be prescribed for patients with a history of angioedema from ACE inhibitor; however, must wait 6 wks to take after ACE inhibitor stopped. May cause upregulation of ACE2 receptors, making patients more susceptible to infection with SARS-CoV-2; however, may also mitigate deleterious effects of COVID-19.
Calcium Channel Blockers—Dihydropyridines			
amlodipine felodipine isradipine nicardipine SR nifedipine LA nisoldipine	Inhibit calcium ion influx across membranes. Vasodilatory effects on coronary arteries and	Rapid action. Effective by oral or sublingual route. No tendency to slow SA nodal activity or prolong AV node conduction.	Can cause pedal edema, which is more common in women. Administer on empty stomach; recommend

	peripheral arterioles. Decrease cardiac work and energy consumption, increase delivery of oxygen to myocardium.	Useful drug in treating isolated systolic hypertension. *Contraindication:* HFrEF (but can use amlodipine or felodipine, if necessary).	eating small, frequent meals if complaint of nausea. Use with caution in patients with diabetes. Muscle cramps, joint stiffness, sexual dysfunction may disappear if dose decreased. Report irregular heartbeat, constipation, shortness of breath, edema. May cause dizziness.
Calcium Channel Blockers—Nondihydropyridines			
diltiazem ER verapamil IR verapamil SR verapamil—delayed-onset ER	Inhibit calcium ion influx. Reduce cardiac afterload. Slow velocity of conduction of cardiac impulse.	Avoid concomitant dosing with beta-blockers. *Contraindications:* HFrEF; sinus node dysfunction, AV block.	Do not discontinue suddenly. Observe for hypotension. Report irregular heartbeat, dizziness, edema. Instruct on regular dental care because of potential gingivitis. Metabolized via cytochrome p450 system; therefore, many potential drug interactions.
Second-Line Antihypertensive Agents			
Diuretics—Loop			
bumetanide furosemide torsemide	Volume depletion. Block reabsorption of sodium, chloride, and water in renal tubules.	Preferred diuretics for patients with symptomatic HF and for patients with moderate to severe CKD.	Risk of volume and electrolyte depletion; monitor for hypokalemia. *Gerontologic considerations:*

		Contraindications: Same as for thiazide diuretics.	Risk for orthostatic hypotension.
Diuretics—Potassium-Sparing			
amiloride triamterene	Block sodium reabsorption. Act on distal tubule independently of aldosterone.	Not particularly effective antihypertensive drugs when prescribed as lone agents; can be effective when prescribed with a thiazide diuretic in patients with hypokalemia; causes potassium retention. *Contraindications:* Significant CKD, severe hepatic disease, hyperkalemia.	Drowsiness, lethargy, headache. Monitor for hyperkalemia if given with ACE inhibitor or ARB. Diarrhea and other GI symptoms—administer medication after meals.
Diuretics—Aldosterone Antagonists			
eplerenone spironolactone	Competitive inhibitors of aldosterone binding.	Indicated for patients with primary aldosteronism and resistant hypertension. *Contraindications:* Hyperkalemia and impaired renal function.	Drowsiness, lethargy, headache. Monitor for hyperkalemia if given with ACE inhibitor or ARB. Diarrhea and other GI symptoms—administer medication after meals. Avoid the use of potassium supplements or salt substitutes. Spironolactone may cause gynecomastia.
Beta-Blockers—Cardioselective			
atenolol betaxolol bisoprolol metoprolol tartrate metoprolol succinate	Selectively block the beta-1 adrenergic receptors of the sympathetic nervous system, slowing the heart rate and lowering	Not recommended as first-line antihypertensive agents unless the patient has HF or CAD. Bisoprolol or metoprolol succinate preferred	Avoid sudden discontinuation. Side effects may include insomnia, lassitude, weakness, fatigue and

	the blood pressure.	agents for patients with HFrEF. These agents are preferred over noncardioselective beta-blockers if patient has asthma, reactive airway disease, or COPD. *Contraindications:* Heart block, symptomatic bradycardia.	occasionally nausea, vomiting, and epigastric distress.
Beta-Blockers—Cardioselective and Vasodilatory			
nebivolol	Blocks beta-1 adrenergic receptors and induces nitric oxide vasodilation.	Similar to other beta-blockers with additional capacity for vasodilation. *Contraindications:* Similar to beta-blockers but with greater risk of severe bradycardia, heart block, cardiogenic shock, decompensated cardiac failure, sinus node dysfunction.	Avoid sudden discontinuation. Side-effect profile similar to other beta-blockers.
Beta-Blockers—Noncardioselective			
nadolol propranolol propranolol LA timolol	Nonselectively block the beta-adrenergic receptors of the sympathetic nervous system with intended effects of slowing the heart rate and lowering the blood pressure.	*Contraindications:* Asthma, reactive airway disease, COPD, heart block, symptomatic bradycardia.	Avoid sudden discontinuation. Side effects may include insomnia, lassitude, weakness, fatigue and occasionally nausea, vomiting, and epigastric distress.
Beta-Blockers—Intrinsic Sympathomimetic Activity			
acebutolol penbutolol pindolol	Block both beta-1 and beta-2 receptors. Also has antiarrhythmic activity by slowing	*Contraindications:* Avoid use in patients with HFrEF.	Avoid sudden discontinuation. Side-effect profile similar to other beta-blockers.

	atrioventricular conduction.		
Beta-Blockers—Combined Alpha- and Beta-Receptor Blockers			
carvedilol carvedilol phosphate CR labetalol	Block alpha- and beta-adrenergic receptors. Cause peripheral dilation and decrease peripheral vascular resistance.	Carvedilol is a preferred agent for patient with HFrEF. *Contraindications:* Asthma, reactive airway disease, COPD, heart block, symptomatic bradycardia, cardiogenic shock, severe tachycardia.	Avoid sudden discontinuation. Side-effect profile similar to other beta-blockers.
Direct Renin Inhibitor			
Aliskiren	Blocks the conversion of angiotensinogen to angiotensin I by inhibiting the activity of the enzyme renin.	Cannot be given in combination with ACE inhibitors or ARBs. Very long acting. Contraindicated in pregnancy.	Monitor for hyperkalemia, especially for patients with CKD, or patients taking potassium supplements.
Alpha-1 Blockers			
doxazosin prazosin terazosin	Peripheral vasodilator acting directly on the blood vessel; action similar to direct vasodilators.	May be second-line agent in men with BPH. *Contraindication:* CAD.	Associated with orthostasis, especially in older adults.
Central Alpha$_2$-Agonists and Other Centrally Acting Drugs			
clonidine clonidine patch guanfacine methyldopa	clonidine: Exact mode of action is not understood, but acts through the central nervous system, apparently through centrally mediated alpha-adrenergic stimulation in the brain, producing blood pressure reduction. guanfacine:	Generally last-line agents—sometimes can be effective when other medications fail to lower blood pressure. Methyldopa may be drug of choice during pregnancy. *Contraindication:* Severe coronary artery disease.	Dry mouth, drowsiness, sedation, and occasional headaches and fatigue. Anorexia, malaise, and vomiting with mild disturbance of liver function have been reported. Rebound hypertension or hypertensive

	Stimulates central alpha$_2$-adrenergic receptors. methyldopa: Dopa decarboxylase inhibitor; displaces norepinephrine from storage sites.		crisis is relatively common with withdrawal of clonidine; medication dosage should be tapered down when discontinuing clonidine and BP monitored carefully.
Direct Vasodilators			
hydralazine minoxidil	Direct vasodilatory action on smooth muscle of blood vessels, causing decreased peripheral vascular resistance.	Typically used in combination with other medications (diuretics, beta-blockers). Used also in pregnancy-induced hypertension. *Contraindications:* Angina or coronary disease, heart failure, hypersensitivity.	Sodium and fluid retention and reflex tachycardia are common effects; headache, flushing, and dyspnea may occur. Hydralazine may produce lupus erythematosus–like syndrome. Minoxidil may cause hirsutism.

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; AV, atrioventricular; BP, blood pressure; BPH, benign prostatic hyperplasia; CAD, coronary artery disease; CKD, chronic kidney disease; COPD, chronic obstructive pulmonary disease; COVID-19, coronavirus disease 2019; CR, controlled release; ER, extended release; GI, gastrointestinal; HF, heart failure; HFrEF, heart failure with reduced ejection fraction; IR, intermediate release; LA, long acting; SA, sinoatrial; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2; SR, sustained release.

Heart Association Task Force on Clinical Practice Guidelines. *Hypertension*, *71*(6), e13–e115.

TABLE 27-5 Oral Antihypertensive Medications for Patients with Select Comorbid Diseases or Who Are Pregnant

Comorbid Disease or Special Patient Group	First-Line Antihypertensive Agents	Second-Line Antihypertensive Agents Comments
Stable coronary artery disease (e.g., myocardial infarction, angina) without heart failure	Beta-blockers, specifically carvedilol, metoprolol tartrate, metoprolol succinate, nadolol, bisoprolol, propranolol, or timolol; or ACE inhibitors; or ARBs.	Dihydropyridine calcium channel blockers may be prescribed if BP goal is not met and patient has continued angina. Dihydropyridine calcium channel blockers, thiazide diuretics, or aldosterone receptor antagonist diuretics may be prescribed if BP goal is not met.
Heart failure with reduced ejection fraction (HFrEF)	ACE inhibitors; ARBs; angiotensin receptor-neprilysin inhibitor (i.e., sacubitril-valsartan); aldosterone receptor antagonist diuretics; other diuretics; or beta-blockers, specifically carvedilol, metoprolol succinate, or bisoprolol.	Nondihydropyridine calcium channel blockers are NOT recommended. ACE inhibitors and ARBs should not be prescribed concomitantly.
Heart failure with preserved ejection fraction (HFpEF)	Diuretics should be prescribed to control hypertension when volume overload is present.	Nondihydropyridine calcium channel blockers are NOT recommended.
Chronic kidney disease (CKD) or kidney transplant	ACE inhibitors.	ARBs may be prescribed if patient is intolerant of ACE inhibitors. ACE inhibitors and ARBs should not be prescribed concomitantly.
Diabetes	Diuretics, calcium channel blockers, ACE inhibitors, or ARBs.	ACE inhibitors or ARBs are preferred if albuminuria is present.
History of atrial fibrillation	ARBs can prevent recurrence of atrial fibrillation and achieve BP control.	
Metabolic syndrome	The best first-line antihypertensive agent is not clear.	Caution with prescriptions of thiazide diuretics because they are associated with increased insulin resistance, dyslipidemia, increased uric

		acid and progression to diabetes.
Pregnancy	Stop ACE inhibitors, ARBs, and/or direct renin inhibitors due to teratogenic effects. Transition to methyldopa, nifedipine, and/or labetalol.	Beta-blockers or calcium channel blockers appear superior to other options for preventing preeclampsia.

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure.

COVID-19 Considerations

The coronavirus disease 2019 (COVID-19) pandemic began in Wuhan, China, in late 2019. Since that time, several risks for both severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection and pathogenesis to coronavirus disease (COVID-19) have been posed. Epidemiologic findings from early data in China suggest that having a history of hypertension could be an important risk factor for becoming infected with SARS-CoV-2 as well as for being hospitalized to manage COVID-19 (Guo, Huang, Lin, et al., 2020; Sommerstein, Kochen, Messerli, et al., 2020; Vaduganathan, Vardeny, Michel, et al., 2020; Yang, Tan, Zhou, et al., 2020).

Because it is a virus, the SARS-CoV-2 pathogen must replicate within host cells. SARS-CoV-2 gains entry into host cells through the ACE2 cellular surface receptors, which are key to regulating the renin–angiotensin–aldosterone system (Fig. 27-2). ACE2 converts angiotensin II to angiotensin 1–7. ACE2 receptors are particularly abundant in type II alveolar cells (also called type II pneumocytes), vascular endothelial cells, and central nervous system tissue cells.

Patients who take ACE inhibitors or ARBs to manage hypertension tend to have an upregulation of ACE2 receptors (i.e., an increase in numbers of ACE2 receptors). Therefore, it is hypothesized that having an abundance of ACE2 receptors makes individuals with hypertension who take these medications more susceptible to SARS-CoV-2 infection; this hypothesis seems to explain the prevalence of patients with hypertension who also have COVID-19. However, it has also been found that, once infected with SARS-CoV-2, host cells will then downregulate ACE2 receptors, interfering with conversion of angiotensin II to angiotensin 1–7 (Vaduganathan et al., 2020). Angiotensin II

and angiotensin 1–7 have opposing effects. While angiotensin II causes vasoconstriction, high blood pressure, thrombosis, fibrosis, and inflammation, angiotensin 1–7 causes vasodilation, lower blood pressure, antithrombosis, and anti-apoptosis, and has anti-inflammatory effects (Guo et al., 2020). Thus, once infected with SARS-CoV-2, patients who take ACE inhibitors or ARBs might have a protective advantage over patients who do not take these medications, as patients who take ACE inhibitors or ARBs theoretically should have more ACE2 receptors (Sommerstein et al., 2020).

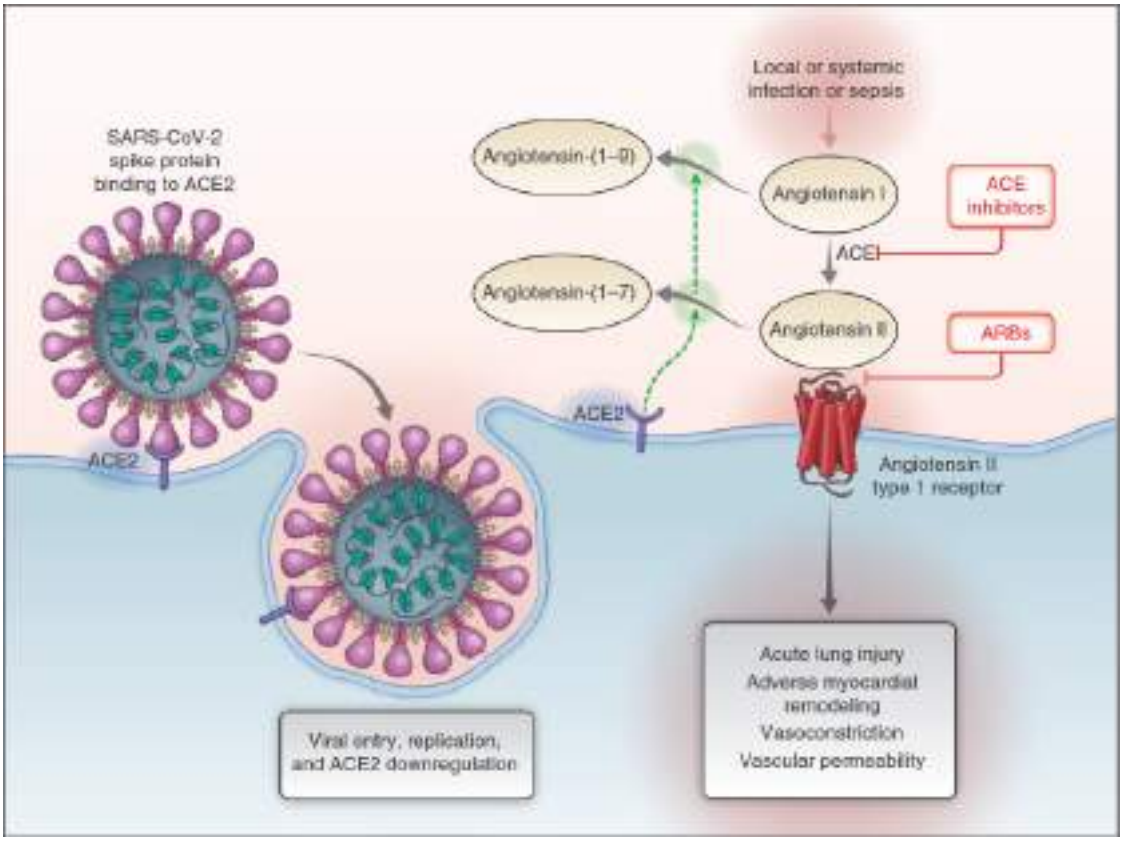

Figure 27-2 • Interaction between SARS-CoV-2 and the renin–angiotensin–aldosterone system. Shown is the initial entry of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) into cells, primarily type II pneumocytes, after binding to its functional receptor, angiotensin-converting enzyme 2 (ACE2). After endocytosis of the viral complex, surface ACE2 is further downregulated, resulting in unopposed angiotensin II accumulation. Local activation of the renin–angiotensin–aldosterone system may mediate lung injury responses to viral insults. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker. Reprinted with permission from Vaduganathan, M., Vardeny, O., Michel, T., et al. (2020). Renin-angiotensin-aldosterone system inhibitors in patients with COVID-19. *The New England Journal of Medicine, 382*(17), 1653–1659.

Findings from a retrospective, single center study of patients hospitalized with COVID-19 in Wuhan, China, support the hypothesis that the use of ACE inhibitors or ARBs has a protective effect on patients with hypertension. In particular, patients with COVID-19 and hypertension who took these medications had significantly lower concentrations of C-reactive protein and procalcitonin (i.e., both are measures of inflammation) than patients with COVID-19 and hypertension who did not take these medications. In addition, fewer patients who took ACE inhibitors or ARBs were critically ill, and they had a lower mortality rate (Yang et al., 2020). Data to date supports continued use of both ACE inhibitors and ARBs in patients with hypertension during the COVID-19 pandemic (Guo et al., 2020; Sommerstein et al., 2020; Vaduganathan et al., 2020).

Gerontologic Considerations

The target blood pressure for all adults with hypertension is less than 130/80 mm Hg, regardless of age, including older adults (Whelton et al., 2017). There is a caveat, however, that community-dwelling, ambulatory older adults should be carefully monitored for adverse effects of prescribed antihypertensive medications, which can include falls, orthostatic hypotension, and reduced renal function. The usual adage for older adults commencing antihypertensive medications is to *start low and go slow;* that is, the medication regimen starts with a low medication dosage that is slowly increased over time as needed. For older adults with multiple comorbidities and limited life expectancy, advanced cognitive impairment, or who have had frequent falls, a less aggressive blood pressure target may be reasonable based on clinical judgment and patient preference (DePalma et al., 2018). Nonetheless, the *American College of Physicians (ACP)* and *American Academy of Family Physicians (AAFP)* recommend antihypertensive pharmacologic treatment of patients 60 years and older with a history of having had a stroke or a TIA to target SBP less than 140 mm Hg to reduce the risk of recurrent stroke (Qaseem, Wilt, Rich, et al., 2017).

NURSING PROCESS

The Patient with Hypertension

Assessment

Nurse-led hypertension management has demonstrated greater rates of blood pressure control than when nurses are not leading these management efforts (Himmelfarb, Commodore-Mensah, & Hill, 2016). In many health care settings, nurses provide the BP assessment, the education, and the counseling while actively engaging the patient to promote adherence to the treatment plan (Himmelfarb et al., 2016). Assessment includes BP assessment using the equipment, instructions, and interpretive guidelines displayed in Chart 27-3, and reviewing the patient's ambulatory or home blood pressure measurement technique and verifying its accuracy.

A complete history is obtained to assess for other cardiovascular risk factors and for signs and symptoms that indicate target organ damage (i.e., whether specific tissues are damaged by the elevated blood pressure). Manifestations of target organ damage may include angina; shortness of breath; alterations in speech, vision, or balance; nosebleeds; headaches; dizziness; or nocturia. The patient's partner may be helpful in identifying whether the patient may be experiencing obstructive sleep apnea (OSA), if the patient does not report being diagnosed or treated for OSA.

During the physical examination, the nurse must also pay specific attention to the rate, rhythm, and character of the apical and peripheral pulses to detect the effects of hypertension on the heart and blood vessels. A thorough assessment can yield valuable information about the extent to which the hypertension has affected the body and any other personal, social, or financial factors. For example, a patient's ability to adhere to an antihypertensive medication regimen may be influenced by the patient's financial resources to buy the medication and also by limited health insurance. Findings from research suggest that health beliefs, the presence of depressive symptoms, social support, and the presence of concomitant comorbidities might be associated with adherence to antihypertensive medication prescriptions (Spikes et al., 2019) (see the Nursing Research Profile in Chart 27-4).

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, nursing diagnoses may include the following:

- Lack of knowledge regarding the relation between the treatment regimen and control of the disease process

- Impaired ability to manage regime as evidenced by difficulty adhering to prescribed regimen (e.g., lifestyle changes, antihypertensive medication prescriptions)

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Potential complications may include the following:

- Left ventricular hypertrophy
- Myocardial infarction

Chart 27-4 NURSING RESEARCH PROFILE

Medication Adherence among African Americans with Hypertension

Spikes, T., Higgins, M., Quyyumi, A., et al. (2019). The relationship among health beliefs, depressive symptoms, medication adherence, and social support in African Americans with hypertension. *Journal of Cardiovascular Nursing*, *34*(1), 44–51.

Purpose

African American adults are disproportionately affected by hypertension. Not only is the prevalence of hypertension greater among African Americans than among Americans of other ethnic groups, African Americans tend to become hypertensive at earlier ages. They also tend to be at higher risk of having complications from hypertension earlier in life, including cardiovascular diseases such as strokes and heart failure, and chronic kidney disease. Evidence from previous research suggests that many African Americans hold different beliefs about the causes and consequences of hypertension than do patients with hypertension from other ethnic groups. These health beliefs are thought to affect adherence to prescribed antihypertensive medications. Furthermore, previous research suggests that depressive symptoms and social support may also affect adherence to prescribed medications. Therefore, the purpose of this study was to find associations between hypertension beliefs, depressive symptoms, social support, and medication adherence among African Americans with hypertension.

Design

This was a cross-sectional study that sampled African Americans with metabolic syndrome and hypertension managed with prescription antihypertensive medications (N = 120). Participants completed a series of surveys, including the medication taking subscale of the Hill-Bone Compliance to High Blood Pressure Therapy Scale, three select subscales of the Beliefs related to High Blood Pressure in African Americans Scale, the Beck Depression Index, and the Enhancing Recovery in Coronary Heart Disease Social Support Inventory.

Findings

Participants were mostly female (77%), with a mean age of 49.9 (±8.6) y. Slightly more than half of participants (54%) reported another comorbid condition in addition to having hypertension and metabolic syndrome. Approximately 37.5% of participants (n = 45) were deemed nonadherent to their prescribed antihypertensive regimen. Beliefs about high blood pressure, depressive symptoms, and social support were not found to correlate with antihypertensive medication adherence. However, participants with other comorbidities were found to have 2.63 times greater odds of adhering to their prescribed antihypertensive medications.

Nursing Implications

Findings from this study suggest that African Americans with hypertension may be more likely to adhere to their prescribed therapy if they have other comorbidities. The role of comorbidities among patients with hypertension needs to be further explored to determine how and why it might affect medication adherence. Nurses who manage the care of patients with hypertension should be cognizant that those without comorbidities might be at greater risk for nonadherence than those with multiple concomitant health disorders.

- Heart failure
- Cerebrovascular disease (TIA or stroke)
- Chronic kidney disease/end-stage renal disease
- Retinal hemorrhage

Planning and Goals

The major goals for the patient include understanding of the disease process and its treatment, participation in a self-care health management program, and absence of complications.

Nursing Interventions

The objective of nursing care for patients with hypertension focuses on lowering and controlling the blood pressure without adverse effects or undue cost. To achieve these goals, the nurse's role is to support and educate the patient about the treatment regimen, including making lifestyle changes, taking medications as prescribed, and scheduling regular follow-up appointments with the patient's primary provider to monitor progress or identify and treat any complications of disease or therapy.

Increasing Knowledge

The patient needs to understand the disease process and how lifestyle changes and medications can control hypertension. The nurse needs to emphasize the concept of controlling hypertension rather than curing it. The nurse can encourage the patient to consult a dietitian to help develop a plan for improving nutrient intake or for weight loss. Explaining that it takes 2–3 mo for the taste buds to adapt to changes in salt intake may help the patient adjust to reduced salt intake and consider herbs and seasonings that add flavor without adding salt. The patient should be advised to limit alcohol intake, and tobacco and nicotine should be avoided because anyone with high blood pressure is already at risk for heart disease, and use of cigarettes and electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars, amplifies this risk.

Promoting Effective Health Management

Deviating from the therapeutic health management program is a significant problem for people with hypertension and other chronic conditions requiring lifetime management. Blood pressure control is achieved by only 54% of patients (Whelton et al., 2017). Rates of blood pressure control are lowest among Mexican American men, at only 39% overall (Himmelfarb et al., 2016). Effective health management is more likely, however, when patients actively participate in self-care, including self-monitoring of blood pressure and diet, possibly because patients receive immediate feedback and have a greater sense of control. Nurse-led wellness programs that are tailored to the patients' behaviors and eating and exercise practices are more effective than generic programs. Patients with hypertension must make considerable effort to adhere to recommended lifestyle modifications (see Table 27-2) and to take regularly prescribed medications. The effort needed to follow the therapeutic plan may seem unreasonable to some, particularly when they have no symptoms without medications but do have side effects with medications. Continued education and encouragement are usually needed to enable patients to formulate an acceptable plan that helps them live with their hypertension and adhere to the treatment plans. Compromises may have to be made about some aspects of therapy to achieve higher-priority goals.

The nurse can assist with behavior change by supporting patients in making small changes with each visit that moves them toward their goals. Another important factor is following up at each visit to see how the patient has progressed with the plans made at the prior visit. If the patient has had difficulty with the plan, the patient and nurse should work together to develop an alternative or modification that the patient believes will be more successful. Support groups for weight control, smoking cessation, and stress reduction may be beneficial for some patients; others can benefit from the support of family and friends. The nurse assists the patient to develop and adhere to an appropriate exercise regimen, because regular activity is a significant factor in reducing blood pressure (Himmelfarb et al., 2016).

Promoting Home, Community-Based, and Transitional Care

If asked to participate in a blood pressure screening program, the nurse should ensure that proper blood pressure measurement technique is being used (see Chart 27-3), that validated electronic devices are used or, if aneroid sphygmomanometers are used, that they are properly calibrated, and that provision has been made to provide follow-up for any person identified as having an elevated blood pressure level. Adequate time should also be allowed to educate each person screened about what the blood pressure numbers mean. Each person should be given a written record of their blood pressure at the screening.

Educating Patients About Self-Care. The therapeutic regimen is the responsibility of the patient in collaboration with the primary provider. The nurse can help the patient achieve blood pressure control through education about managing blood pressure (see earlier discussion), setting goal blood pressures, and providing assistance with social support. Involving family members in education programs enables them to support the patient's efforts to control hypertension. The American Heart Association and the National Heart, Lung, and Blood Institute both provide printed and electronic patient education materials (see Resources section).

Providing written information about the expected effects and side effects of medications is important. When side effects occur, patients need to understand the importance of reporting them and to whom they should be reported. Patients need to be informed that **rebound hypertension** can occur. This phenomenon is characterized by a pathologically high blood pressure exhibited by patients who suddenly stop taking prescribed antihypertensive medications. Thus, patients should be advised to have an adequate supply of medication, particularly when traveling and in case of emergencies such as natural disasters. If traveling by airplane, patients should pack the medication in their carry-on luggage. All patients should be informed that some medications, such as beta-blockers, might cause sexual dysfunction and that other medications are available if problems with sexual function or satisfaction occur. The nurse can encourage and educate patients to measure their blood pressure at home. This practice involves patients in their own care and emphasizes that failing to take medications may result in an identifiable rise in blood pressure. Patients need to know that blood pressure varies continuously and that the range within which their pressure varies should be monitored.

Gerontologic Considerations. Adherence to the therapeutic program may be more difficult for the older adult. The medication regimen may be difficult to remember, and the expense can be a challenge. Simplification of the medication regimen to treatment with a single antihypertensive medication, if possible, is helpful. Many older adults are taking other prescription and over-the-counter medications, and verifying that there are no medication interactions is important. As noted previously, community-dwelling, ambulatory older adults should be carefully monitored for adverse effects of prescribed antihypertensive medications, which can include falls, orthostatic hypotension, and reduced renal function (e.g., the nurse should assess patient's urinary output and weight for changes from baseline). Special care must be taken to ensure the older patient understands the medication regimen, can see and read the instructions, open the medication container, and can get the prescription

refilled. The older adult's family or caregivers should be included in the educational program so that they understand the patient's needs, can encourage adherence to the treatment plan, and know when and whom to call if problems arise or further information is needed.

Continuing and Transitional Care. Regular follow-up care is imperative so that blood pressure control can be achieved. A history and physical examination should be completed at each clinic visit. The history should include all data pertaining to any potential problem, specifically medication-related problems such as orthostatic hypotension (experienced as dizziness or lightheadedness on standing). The patient should also bring a home blood pressure log and their own home blood pressure machine to verify accuracy and technique of home blood pressure monitor use. Patients and caregivers should also be given updated information at each visit on blood pressure medication, side effects, and important side effects to report immediately, such as low blood pressure or orthostatic hypotension. Low blood pressure readings can be due to impaired cardiovascular reflexes brought on by diuretics and other medication interactions.

Quality and Safety Nursing Alert

The patient and caregivers should be cautioned that antihypertensive medications might cause hypotension. Low blood pressure or orthostatic hypotension should be reported immediately. Older adults have impaired cardiovascular reflexes and thus are more sensitive to the extracellular volume depletion caused by diuretics and to the sympathetic inhibition caused by adrenergic antagonists. The nurse educates patients to change positions slowly when moving from a lying or sitting position to a standing position. The nurse also counsels older adult patients to use supportive devices such as hand rails and walkers as necessary to prevent falls that could result from dizziness.

Monitoring and Managing Potential Complications

Target organ damage is a potential adverse effect of long standing or poorly controlled hypertension. When the patient returns for follow-up care, all body systems must be assessed to detect any evidence of vascular damage. An eye examination with an ophthalmoscope is particularly important because retinal blood vessel damage indicates similar damage elsewhere in the vascular system. The patient is questioned about blurred vision, spots in front of the eyes, and diminished visual acuity. The heart, nervous system, and kidneys are also carefully assessed. Any significant findings are promptly reported to determine whether additional diagnostic studies are

required. Based on the findings, medications may be changed to improve blood pressure control.

Evaluation

Expected patient outcomes may include:

1. Reports knowledge of disease management sufficient to maintain adequate tissue perfusion
   a. Maintains blood pressure at less than 130/80 mm Hg with lifestyle modifications, medications, or both
   b. Demonstrates no symptoms of angina, palpitations, or vision changes
   c. Has stable BUN and serum creatinine levels
   d. Has palpable peripheral pulses
2. Effectively manages health program
   a. Adheres to the dietary regimen as prescribed: reduces calorie, sodium, and fat intake; increases fruit and vegetable intake
   b. Exercises regularly
   c. Takes medications as prescribed and reports any side effects
   d. Measures blood pressure routinely
   e. Abstains from tobacco, nicotine, and excessive alcohol intake
   f. Keeps follow-up appointments
3. Has no complications
   a. Reports no changes in vision
   b. Exhibits no retinal damage on vision testing
   c. Maintains pulse rate and rhythm and respiratory rate within normal ranges
   d. Reports no dyspnea or edema
   e. Maintains urine output consistent with intake
   f. Has renal function test results within normal range
   g. Demonstrates no motor, speech, or sensory deficits
   h. Reports no headaches, dizziness, weakness, changes in gait, or falls

Hypertensive Crises

Two classes of hypertensive crisis that require immediate intervention include hypertensive emergency and hypertensive urgency, which occur when the SBP exceeds 180 mm Hg or the DBP exceeds 120 mm Hg. Hypertensive emergencies and urgencies may occur in patients with secondary hypertension, and in those whose hypertension has been poorly controlled, whose hypertension has been undiagnosed, or in those who have abruptly

discontinued their medications (i.e., rebound hypertension). Once the hypertensive crisis has been managed, a complete evaluation is performed to review the patient's ongoing treatment plan, and strategies to prevent the occurrence of subsequent hypertensive crises are implemented (Whelton et al., 2017).

Hypertensive Emergency

Hypertensive emergency is severe BP elevation (SBP greater than 180 mm Hg or DBP greater than 120 mm Hg) with new or worsening target organ damage. Some examples of target organ damage that may occur include hypertensive encephalopathy, ischemic stroke, MI, heart failure with pulmonary edema, dissecting aortic aneurysm, and renal failure. The 1-year mortality rate is more than 79% and median survival is 10.4 months if left untreated (Whelton et al., 2017). The patient needs to be admitted to the intensive care unit for continuous monitoring of BP and parenteral administration of an appropriate antihypertensive medication (Whelton et al., 2017).

A rapid and focused assessment is necessary to determine possible causes and target organ involvement. For patients with suspected aortic dissection, the management goal is to reduce the SBP to less than 120 mm Hg within the first hour of treatment (Fukui, 2018; Whelton et al., 2017). For those patients with suspected severe preeclampsia/eclampsia or pheochromocytoma crises, the management goal is to reduce the SBP to less than 140 mm Hg within the first hour of treatment (Lim, 2018; Whelton et al., 2017). The treatment management goal for other patients with hypertensive emergencies is to reduce the SBP by no more than 25% within the first hour of treatment, and then, if the patient is stable, to 160/100 mm Hg within the next 2 to 6 hours with an eventual goal of a normal, controlled blood pressure within 24 to 48 hours of when treatment commenced (Whelton et al., 2017). The antihypertensive medications of choice are those that have immediate onsets of action, and can include intravenous drugs such as nicardipine, clevidipine, labetalol, esmolol, nitroglycerin, and nitroprusside (Whelton et al., 2017). To date, there is a dearth of research findings that demonstrate the superiority of any antihypertensive medications in treating hypertensive emergencies (Whelton et al., 2017).

Hypertensive Urgency

Hypertensive urgency is severe BP elevation (SBP greater than 180 mm Hg or DBP greater than 120 mm Hg) in stable patients without target organ damage as evidenced based on clinical examination and results of laboratory

studies. Many times, patients with a hypertensive urgency are nonadherent with antihypertensive therapy, resulting in rebound hypertension. The underlying reason for nonadherence should be explored (e.g., finances, anxiety, misunderstandings, miscommunication, drug side effects, or recreational drug use) and the team approach used and resources mobilized to prevent nonadherence from continuing or recurring. Restarting antihypertensive medication therapy or increasing dosages are indicated in treating these patients (Whelton et al., 2017).

Extremely close monitoring of the patient's blood pressure and cardiovascular status is required during treatment of hypertensive emergencies and urgencies (see Chapter 21 for discussion of cardiovascular assessment). The exact frequency of monitoring is a matter of clinical judgment and varies with the patient's condition. Taking vital signs every 5 minutes is appropriate if the blood pressure is changing rapidly; taking vital signs at 15- or 30-minute intervals in a more stable situation may be sufficient. A precipitous drop in blood pressure can occur that would require immediate action to restore blood pressure to an acceptable level.

CRITICAL THINKING EXERCISES

1 pq You are working as a nurse in a clinic that serves both an assisted living and a skilled nursing facility. One of your patients is an 80-year-old woman who is a new resident at the assisted living facility. When you take her blood pressure, you note that it is 110/70 mm Hg. While talking with her, you find that she reports episodes of dizziness and has fallen twice in the past 2 weeks. She tells you that she takes her medications as prescribed and has had no other concerns. What additional assessment data do you need to obtain? What is your priority plan of action?

2 ipc You are employed as an occupational health nurse in a manufacturing facility. A 32-year-old man who operates a forklift presents to be treated after injuring his forearm at work. During your assessment, he reports that he takes a beta-blocker for his hypertension and his blood pressure is 108/77 mm Hg. He also tells you that he is dedicated to staying healthy, has no underlying cardiac disease, and routinely exercises at the gym. He has noted that he cannot get his heart rate up no matter how long he works out and feels tired all the time. What further follow-up would you recommend and with whom?

3 ebp You are working in a clinic and a 50-year-old man presents for his annual examination. He takes no medications at present but reports that last year he was told that his blood pressure was elevated and that he needed to start taking an antihypertensive medication. He never filled that prescription because he had no symptoms and thought that if he had high blood pressure, he would feel bad. His blood pressure is 140/90 mm Hg and the rest of his examination is unremarkable. What education would you provide for him? What is the strength of the evidence that supports your education plan and follow-up with this patient?

UNIT 6

Hematologic Function

Case Study

EVALUATING COMPLICATIONS OF CHEMOTHERAPY

A 66-year-old woman is receiving a course of chemotherapy for non-Hodgkin lymphoma in the infusion center where you work. You note that upon arrival the patient is short of breath, her SpO_2 is 88% on room air, and her heart rate is regular at 104 bpm. Her chemotherapy infusion is placed on hold and laboratory tests reveal she has anemia. Upon initiation of chemotherapy, all patients receive education about strategies to help avoid complications such as anemia, bleeding, and infection. Earlier in the week another patient had their chemotherapy held due to an infection. You wonder if you should consider a different type of intervention aimed at decreasing complications of chemotherapy.

QSEN Competency Focus: **Quality Improvement**

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Quality Improvement Definition: Use data to monitor the outcomes of care processes and use improvement methods to design and test changes to continuously improve the quality and safety of health care systems.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Explain the importance of variation and measurement in assessing quality of care	How can you verify the observations made about increased complication rates among patients receiving chemotherapy? Identify the sources of data that could be accessed to demonstrate the need for a change in the processes of care.
Skills	
Use quality measures to understand performance	Specify the main objective that you hope to achieve with this population of patients receiving chemotherapy. Specify measurable, time-oriented expected outcomes. Might there be an opportunity for you to do a pilot test of change in the infusion center? If so, how would you go about designing this type of project? Who else from the infusion center team might you need to be involved in this type of project?
Attitudes	
Value measurement and its role in good patient care	Reflect on your attitudes toward patients with cancer receiving chemotherapy. Do you tend to think that anemia and infection are unavoidable in patients with cancer receiving treatment?

28 Assessment of Hematologic Function and Treatment Modalities

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe hematopoiesis and the processes involved in maintaining hemostasis.
2. Discuss the significance of the health history to the assessment of hematologic health and specify the appropriate techniques utilized to perform a comprehensive physical assessment of hematologic function.
3. Explain the diagnostic tests and related nursing implications used to evaluate hematologic function.
4. Identify therapies for blood disorders, including nursing implications for the administration of blood components.

NURSING CONCEPTS

Assessment
Clotting

GLOSSARY

anemia: decreased red blood cell (RBC) count

band cell: slightly immature neutrophil

blast cell: primitive white blood cell (WBC)

cytokines: proteins produced by leukocytes that are vital to regulation of hematopoiesis, apoptosis, and immune responses

differentiation: development of functions and characteristics that are different from those of the parent stem cell

erythrocyte: a cellular component of blood involved in the transport of oxygen and carbon dioxide (*synonym:* red blood cell [RBC])

erythropoiesis: process of the formation of RBCs

erythropoietin: hormone produced primarily by the kidney; necessary for erythropoiesis

fibrin: filamentous protein; basis of thrombus and blood clot

fibrinogen: protein converted into fibrin to form thrombus and clot

fibrinolysis: process of breakdown of fibrin clot

granulocyte: granulated WBC (i.e., neutrophil, eosinophil, basophil)

hematocrit: percentage of total blood volume consisting of RBCs

hematopoiesis: complex process of the formation and maturation of blood cells

hemoglobin: iron-containing protein of RBCs; delivers oxygen to tissues

hemostasis: intricate balance between clot formation and clot dissolution

leukocyte: one of several cellular components of blood involved in defense of the body; subtypes include neutrophils, eosinophils, basophils, monocytes, and lymphocytes (*synonym:* white blood cell [WBC])

leukopenia: less-than-normal amount of WBCs in circulation

lymphocyte: form of WBC involved in immune functions

lymphoid: pertaining to lymphocytes

macrophage: reticuloendothelial cells capable of phagocytosis

monocyte: large WBC that becomes a macrophage when it leaves the circulation and moves into body tissues

myeloid: pertaining to nonlymphoid blood cells that differentiate into RBCs, platelets, macrophages, mast cells, and various WBCs

myelopoiesis: formation and maturation of cells derived from myeloid stem cell

natural killer (NK) cells: lymphocytes that defend against microorganisms and malignant cells

neutrophil: fully mature WBC capable of phagocytosis; primary defense against bacterial infection

oxyhemoglobin: combined form of oxygen and hemoglobin; primarily found in arterial blood

phagocytosis: process of cellular ingestion and digestion of foreign bodies

plasma: liquid portion of blood

plasminogen: protein converted to plasmin to dissolve thrombi and clots

platelet: a cellular component of blood involved in blood coagulation (*synonym:* thrombocyte)

red blood cell (RBC): a cellular component of blood involved in the transport of oxygen and carbon dioxide (*synonym:* erythrocyte)

reticulocytes: slightly immature RBCs, usually only 1% of total circulating RBCs

reticuloendothelial system: complex system of cells throughout the body capable of phagocytosis

serum: portion of blood remaining after coagulation occurs

stem cell: primitive cell, capable of self-replication and differentiation into myeloid or lymphoid stem cell

stroma: component of the bone marrow not directly related to hematopoiesis but serves important supportive roles in this process

thrombocyte: a cellular component of blood involved in blood coagulation (*synonym:* platelet)

white blood cell (WBC): one of several cellular components of blood involved in defense of the body; subtypes include neutrophils, eosinophils, basophils, monocytes, and lymphocytes (*synonym:* leukocyte)

Unlike many other body systems, the hematologic system encompasses the entire human body. Patients with hematologic disorders often have significant abnormalities in blood tests but few or no symptoms. Therefore, the nurse must have a good understanding of the pathophysiology of the patient's condition and the ability to make a thorough assessment that relies heavily on the interpretation of laboratory tests. It is equally important for the nurse to anticipate potential patient needs and to target nursing interventions accordingly. Because it is so important to the understanding of most hematologic diseases, a basic appreciation of blood cells and bone marrow function is necessary.

Anatomic and Physiologic Overview

The hematologic system consists of the blood and the sites where blood is produced, including the bone marrow and the reticuloendothelial system (RES). Blood is a specialized organ that differs from other organs in that it exists in a fluid state. Blood is composed of plasma and various types of cells which account for 7% to 9% of total blood volume (Jouria, 2018). **Plasma** is the fluid portion of blood; it contains various proteins, such as albumin, globulin, **fibrinogen**, and other factors necessary for clotting, as well as electrolytes, waste products, and nutrients. About 55% of whole blood volume is plasma (American Society of Hematology, 2020).

Bone Marrow

The bone marrow is the site of hematopoiesis, or blood cell formation. In adults, blood cell formation is usually limited to the pelvis, ribs, vertebrae, and sternum. Marrow is one of the largest organs of the body, making up 4% to 5% of total body weight. It consists of islands of cellular components (red marrow) separated by fat (yellow marrow). As people age, the proportion of active marrow is gradually replaced by fat; however, in healthy adults, the fat can again be replaced by active marrow when more blood cell production is required. In adults with disease that causes marrow destruction, fibrosis, or scarring, the liver and spleen can also resume production of blood cells by a process known as extramedullary hematopoiesis.

The marrow is vascular. Within it are primitive cells called **stem cells**. The stem cells have the ability to self-replicate, thereby ensuring a continuous supply of stem cells throughout the life cycle. When stimulated to do so, stem cells can begin a process called **differentiation**, and develop into either **myeloid** or **lymphoid** stem cells (see Fig. 28-1). These stem cells are committed to produce specific types of blood cells. Lymphoid stem cells produce either T or B **lymphocytes**, cells that have specific immune functions that will be described in more detail later. Myeloid stem cells differentiate into three broad cell types: erythrocytes, leukocytes, and platelets. Thus, with the exception of lymphocytes, all blood cells are derived from myeloid stem cells. A defect in a myeloid stem cell can cause problems with erythrocyte, leukocyte, and platelet production. In contrast, a defect in the lymphoid stem cell can cause problems with T or B lymphocytes, plasma cells (a more differentiated form of B lymphocyte), or natural killer (NK) (see Chapter 31 for additional information) (Wimberly, 2019).

The **stroma** of the marrow refers to all tissue within the marrow that is not directly involved in hematopoiesis. However, the stroma is important in an indirect manner, in that it produces the colony-stimulating factors needed for hematopoiesis. The yellow marrow is the largest component of the stroma.

Other cells comprising the stroma include fibroblasts (reticular connective tissue), osteoclasts, osteoblasts (both needed for remodeling of skeletal bone), and endothelial cells.

Blood

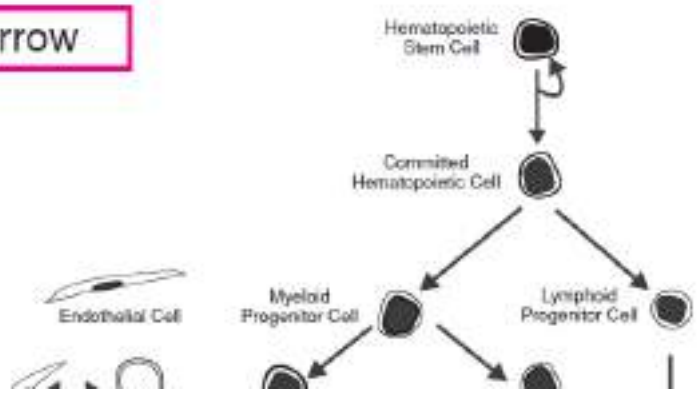
The cellular component of blood consists of three primary cell types (see Table 28-1): **erythrocytes (red blood cells [RBCs], red cells), leukocytes (white blood cells [WBCs]**), and **thrombocytes (platelets)**. These cellular components of blood normally make up 40% to 45% of the blood volume (American Society of Hematology, 2020). Because most blood cells have a short lifespan, the need for the body to replenish its supply of cells is continuous; this process is termed **hematopoiesis**. The primary site for hematopoiesis is the bone marrow. During embryonic development and in other conditions, the liver and spleen may also be involved.

Under normal conditions, the adult bone marrow produces about 175 billion erythrocytes, 70 billion **neutrophils** (a mature type of WBC), and 175 billion platelets each day. When the body needs more blood cells, as in infection (when neutrophils are needed to fight the invading pathogen) or in bleeding (when more RBCs are required), the marrow increases its production of the cells required. Thus, under normal conditions, the marrow responds to increased demand and releases adequate numbers of cells into the circulation.

Blood makes up approximately 7% to 9% of the normal body weight and amounts to 5 to 6 L of volume for men and 4 to 5 L of volume for women (Nair, 2017). Circulating through the vascular system and serving as a link between body organs, blood carries oxygen absorbed from the lungs and nutrients absorbed from the gastrointestinal (GI) tract to the body cells for cellular metabolism. Blood also carries hormones, antibodies, and other substances to their sites of action or use. In addition, blood carries waste products produced by cellular metabolism to the lungs, skin, liver, and kidneys, where they are transformed and eliminated from the body.

Physiology/Pathophysiology

Bone Marrow



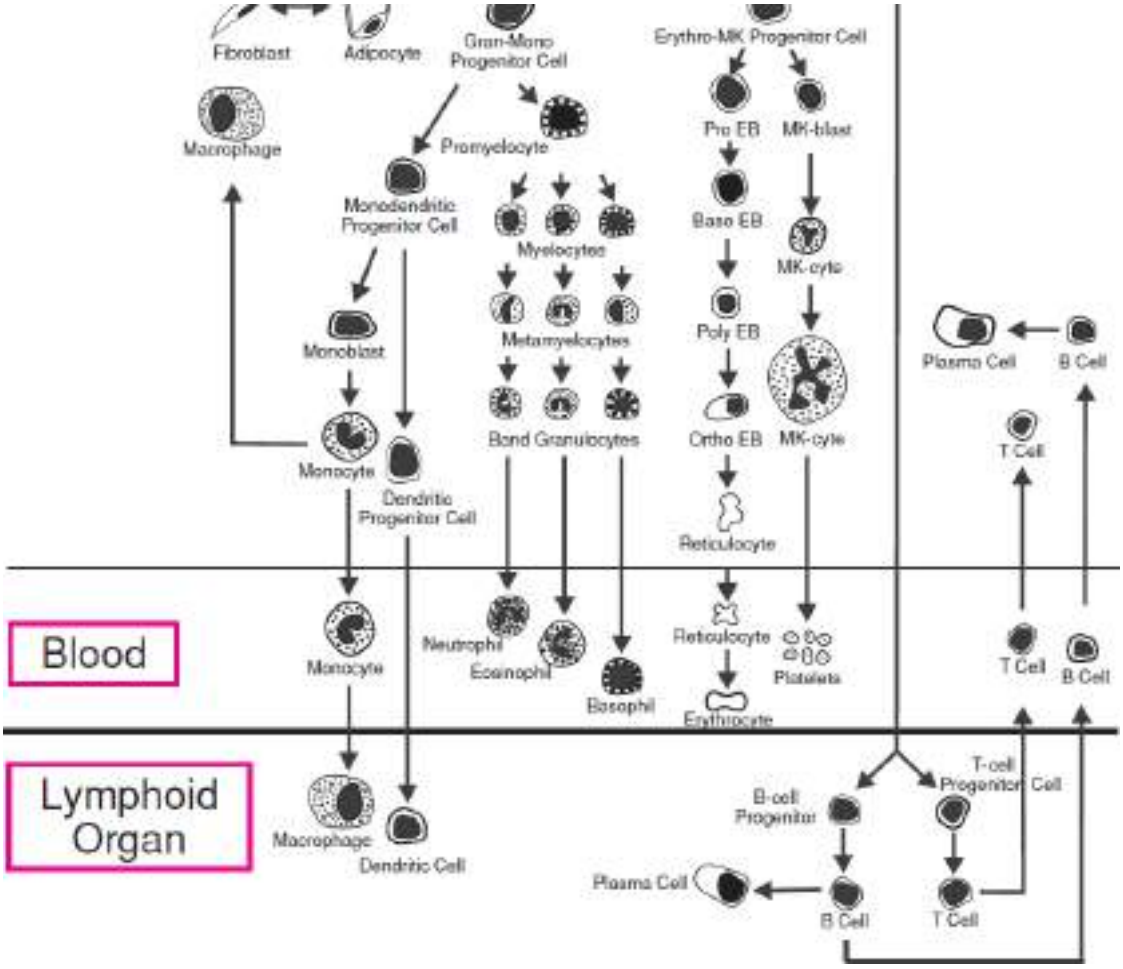


Figure 28-1 • Hematopoiesis and stromal stem cell differentiation. Uncommitted (pluripotent) stem cells can differentiate into myeloid or lymphoid stem cells. These stem cells then undergo a complex process of differentiation and maturation into normal cells that are released into the circulation. The myeloid stem cell is responsible not only for all nonlymphoid white blood cells but also for the production of red blood cells (RBCs) and platelets. Each step of the differentiation process depends in part on the presence of specific growth factors for each cell type. When the stem cells are dysfunctional, they may respond inadequately to the need for more cells, or they may respond excessively, and sometimes uncontrollably, as in leukemia. Reprinted with permission from Koury, M., Mahmud, N., & Rhodes, M. (2009). Origin and development of blood cells. In J. P. Greer, J. Foerster, G. M. Rodgers (Eds.). *Wintrobe's clinical hematology* (12th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

TABLE 28-1 Blood Cells

Cell Type	Major Function
WBC (Leukocyte)	Fights infection
Neutrophil	Essential in preventing or limiting bacterial infection via phagocytosis
Monocyte	Enters tissue as macrophage; highly phagocytic, especially against fungus; immune surveillance
Eosinophil	Involved in allergic reactions (neutralizes histamine); digests foreign proteins
Basophil	Contains histamine; integral part of hypersensitivity reactions
Lymphocyte	Integral component of immune system
T lymphocyte	Responsible for cell-mediated immunity; recognizes material as "foreign" (surveillance system)
B lymphocyte	Responsible for humoral immunity; many mature into plasma cells to form antibodies
Plasma cell	Secretes immunoglobulin (antibody); most mature form of B lymphocyte
RBC (Erythrocyte)	Carries hemoglobin to provide oxygen to tissues; average lifespan is 120 days
Platelet (Thrombocyte)	Fragment of megakaryocyte; provides basis for coagulation to occur; maintains hemostasis; average lifespan is 10 days

WBC, white blood cell; RBC, red blood cell.

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health state* (10th ed.). Philadelphia, PA: Wolters Kluwer.

The danger that trauma can lead to excess blood loss always exists. To prevent this, an intricate clotting mechanism is activated when necessary to seal any leak in the blood vessels. Excessive clotting is equally dangerous, because it can obstruct blood flow to vital tissues. To prevent this, the body has a fibrinolytic mechanism that eventually dissolves clots (thrombi) formed within blood vessels. The balance between these two systems—clot (thrombus) formation and clot dissolution or **fibrinolysis**—is called **hemostasis**.

Erythrocytes (Red Blood Cells)

The normal erythrocyte is a biconcave disc that resembles a soft ball compressed between two fingers (see Fig. 28-2). It has a diameter of about 8 μm and is so flexible that it can pass easily through capillaries that may be as small as 2.8 μm in diameter. The membrane of the red cell is very thin so that gases, such as oxygen and carbon dioxide, can easily diffuse across it; the disc

shape provides a large surface area that facilitates the absorption and release of oxygen molecules.

Mature erythrocytes consist primarily of **hemoglobin**, which contains iron and protein and makes up 95% of the cell mass. Mature erythrocytes have no nuclei, and they have many fewer metabolic enzymes than do most other cells. The presence of a large amount of hemoglobin enables the red cell to perform its principal function, which is the transport of oxygen between the lungs and tissues. Occasionally, the marrow releases slightly immature forms of erythrocytes, called **reticulocytes**, into the circulation. This occurs as a normal response to an increased demand for erythrocytes (as in bleeding) or in some disease states.

The oxygen-carrying hemoglobin molecule is made up of four subunits, each containing a heme portion attached to a globin chain. Iron is present in the heme component of the molecule. An important property of heme is its ability to bind to oxygen loosely and reversibly. Oxygen readily binds to hemoglobin in the lungs and is carried as **oxyhemoglobin** in arterial blood. Oxyhemoglobin is a brighter red than hemoglobin that does not contain oxygen (reduced hemoglobin); thus, arterial blood is a brighter red than venous blood. The oxygen readily dissociates (detaches) from hemoglobin in the tissues, where the oxygen is needed for cellular metabolism. In venous blood, hemoglobin combines with hydrogen ions produced by cellular metabolism and thus buffers excessive acid. Whole blood normally contains about 15 g of hemoglobin per 100 mL of blood (Fischbach & Fischbach, 2018).

Erythropoiesis

Erythroblasts arise from the primitive myeloid stem cells in bone marrow. The erythroblast is an immature nucleated cell that gradually loses its nucleus. At this stage, the cell is known as a reticulocyte. Further maturation into an erythrocyte entails the loss of the dark-staining material within the cell and slight shrinkage. The mature erythrocyte is then released into the circulation. Under conditions of rapid **erythropoiesis** (i.e., erythrocyte production), reticulocytes and other immature cells may be released prematurely into the circulation. This is often seen when the liver or spleen takes over as the site of erythropoiesis and more nucleated red cells appear within the circulation.

Differentiation of the primitive myeloid stem cell into an erythroblast is stimulated by **erythropoietin**, a hormone produced primarily by the kidney. If the kidney detects low levels of oxygen, as occurs when fewer red cells are available to bind oxygen (i.e., **anemia**), or with people living at high altitudes with lower atmospheric oxygen concentrations, erythropoietin levels increase. The increased erythropoietin then stimulates the marrow to increase the production of erythrocytes. The entire process of erythropoiesis occurs over 1 week (Wimberly, 2019). For normal erythrocyte production, the bone marrow also requires iron, vitamin B_{12}, folate, pyridoxine (vitamin B_6), protein, and

other factors. A deficiency of these factors during erythropoiesis can result in decreased red cell production and anemia.

Iron Stores and Metabolism

The rate of iron absorption is regulated by the amount of iron already stored in the body and by the rate of erythrocyte production. Daily dietary iron requirements vary based on age, gender, and health status. For example, pregnant women require up to 30 mg of iron daily, while adult men require up to 12 mg and children up to 10 mg of iron daily (Trevithick, 2019). Additional amounts of iron, up to 2 mg daily, must be absorbed by women of childbearing age to replace that lost during menstruation. Total body iron content in the average adult is approximately 3 g, most of which is present in hemoglobin or in one of its breakdown products. Iron is stored as ferritin and when required, the iron is released into the plasma, binds to transferrin, and is transported into the membranes of the normoblasts (erythrocyte precursor cells) within the marrow, where it is incorporated into hemoglobin. Iron is lost in the feces, either in bile, blood, or mucosal cells from the intestine.

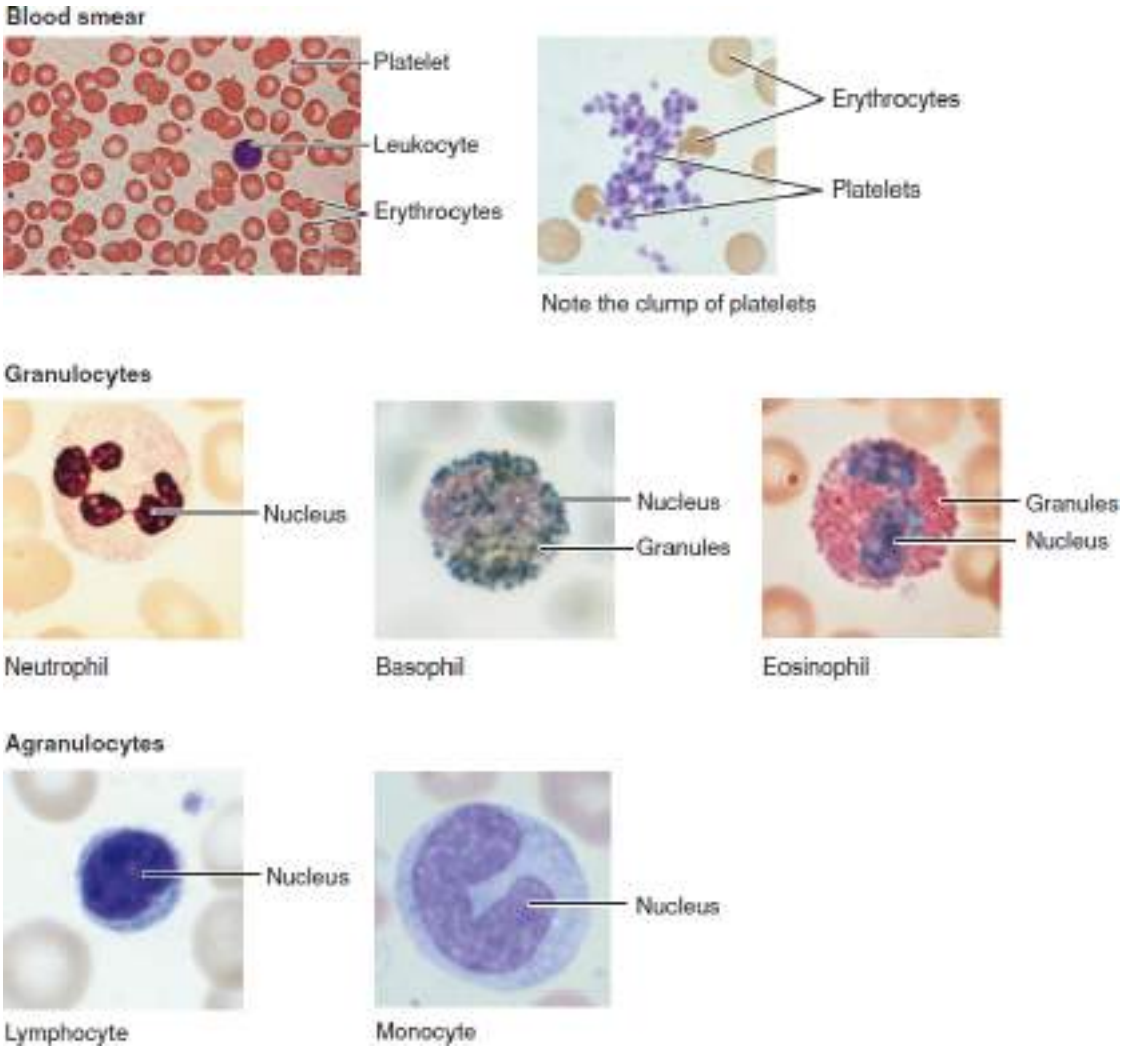

Figure 28-2 • Normal types of blood cells. Reprinted with permission from Cohen, B. J. (2005). *Memmler's the human body in health and disease* (10th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

The normal findings for concentration of iron in blood can range from 50 to 250 µg/dL depending on age and gender (Fischbach & Fischbach, 2018). With iron deficiency, bone marrow iron stores are rapidly depleted; hemoglobin synthesis is depressed, and the erythrocytes produced by the marrow are small and low in hemoglobin. Iron deficiency in the adult generally indicates blood loss (e.g., from bleeding in the GI tract or heavy menstrual flow). Lack of dietary iron is rarely the sole cause of iron deficiency anemia in adults. The source of iron deficiency should be investigated promptly, because iron deficiency in an adult may be a sign of bleeding in the GI tract or colon cancer.

Vitamin B_{12} and Folate Metabolism

Vitamin B_{12} and folate are required for the synthesis of deoxyribonucleic acid (DNA) in RBCs. Both vitamin B_{12} and folate are derived from the diet. Folate

is absorbed in the proximal small intestine, but only small amounts are stored within the body. If the diet is deficient in folate, stores within the body quickly become depleted. Because vitamin B_{12} is found only in foods of animal origin, strict vegetarians may ingest little vitamin B_{12}. Vitamin B_{12} combines with intrinsic factor produced in the stomach. The vitamin B_{12}–intrinsic factor complex is absorbed in the distal ileum. People who have had a partial or total gastrectomy may have limited amounts of intrinsic factor, and therefore the absorption of vitamin B_{12} may be diminished. The effects of either decreased absorption or decreased intake of vitamin B_{12} are not apparent for 2 to 4 years.

Vitamin B_{12} and folate deficiencies are characterized by the production of abnormally large erythrocytes called *megaloblasts*. Because these cells are abnormal, many are sequestered (trapped) while still in the bone marrow, and their rate of release is decreased. Some of these cells actually die in the marrow before they can be released into the circulation. This results in megaloblastic anemia.

Red Blood Cell Destruction

The average lifespan of a normal circulating erythrocyte is 120 days. Often, older erythrocytes lose elasticity and become trapped in small blood vessels and the spleen. These older erythrocytes are removed from the blood by the reticuloendothelial cells, particularly in the liver and the spleen. As the erythrocytes are destroyed, most of their hemoglobin is recycled. Some hemoglobin also breaks down to form bilirubin and is secreted in the bile. Most of the iron is recycled to form new hemoglobin molecules within the bone marrow; small amounts are lost daily in the feces and urine and monthly in menstrual flow.

Leukocytes (White Blood Cells)

Leukocytes are divided into two general categories: granulocytes and lymphocytes. In normal blood, the total leukocyte count is 4000 to 11,000 cells/mm^3. Of these, approximately 60% to 80% are granulocytes and 20% to 40% are lymphocytes. Both of these types of leukocytes primarily protect the body against infection and tissue injury.

Granulocytes

Granulocytes are defined by the presence of granules in the cytoplasm of the cell. Granulocytes are divided into three main subgroups—eosinophils, basophils, and neutrophils—that are characterized by the staining properties of these granules (see Fig. 28-2). Eosinophils have bright-red granules in their cytoplasm, whereas the granules in basophils stain deep blue. The third and most numerous cell in this class is the neutrophil, with granules that stain a

pink to violet hue. Neutrophils are also called *polymorphonuclear neutrophils* (PMNs, or polys) or *segmented neutrophils* (segs).

The nucleus of the mature neutrophil has multiple lobes (usually two to five) that are connected by thin filaments of nuclear material, or a "segmented" nucleus; it is usually two times the size of an erythrocyte. The somewhat less mature granulocyte has a single-lobed, elongated nucleus and is called a **band cell**. Ordinarily, band cells account for only a small percentage of circulating granulocytes, although their percentage can increase greatly under conditions in which neutrophil production increases, such as infection. The increased number of band cells is sometimes called a left shift or shift to the left. (Traditionally, the diagram of neutrophil maturation showed the myeloid stem cell on the left with progressive maturation stages toward the right, ending with a fully mature neutrophil on the far right side. A shift to the left indicates that more immature cells are present in the blood than normal.)

Fully mature neutrophils result from the gradual differentiation of myeloid stem cells, specifically myeloid **blast cells** (i.e., immature white blood cells). The process, called **myelopoiesis**, is highly complex and depends on many factors. These factors, including specific **cytokines** (i.e., regulatory proteins produced by leukocytes) such as growth factors, are normally present within the marrow itself. As the blast cell matures, the cytoplasm of the cell changes in color (from blue to violet) and granules begin to form with the cytoplasm. The shape of the nucleus also changes. The entire process of maturation and differentiation takes about 10 days (see Fig. 28-1). Once the neutrophil is released into the circulation from the marrow, it stays there for only about 6 hours before it migrates into the body tissues to perform its function of **phagocytosis** (ingestion and digestion of foreign bodies, such as bacteria). Neutrophils die here within 1 to 2 days. The number of circulating granulocytes found in the healthy person is relatively constant; however, in infection, large numbers of these cells are rapidly released into the circulation.

Agranulocytes

Monocytes

Monocytes (also called *mononuclear leukocytes*) are leukocytes with a single-lobed nucleus and a granule-free cytoplasm—hence the term *agranulocyte* (see Fig. 28-2). In normal adult blood, monocytes account for approximately 5% of the total leukocytes. Monocytes are the largest of the leukocytes. Produced by the bone marrow, they remain in the circulation for a short time before entering the tissues and transforming into **macrophages**. Macrophages are particularly active in the spleen, liver, peritoneum, and alveoli; they remove debris from these areas and phagocytize bacteria within the tissues.

Lymphocytes

Mature **lymphocytes** are small cells with scanty cytoplasm (see Fig. 28-2). Immature lymphocytes are produced in the marrow from the lymphoid stem cells. A second major source of production for lymphocytes is the thymus. Cells derived from the thymus are known as T lymphocytes (or T cells); those derived from the marrow can also be T cells but are more commonly B lymphocytes (or B cells). Lymphocytes complete their differentiation and maturation primarily in the lymph nodes and in the lymphoid tissue of the intestine and spleen after exposure to a specific antigen. Mature lymphocytes are the principal cells of the immune system, producing antibodies and identifying other cells and organisms as "foreign." **Natural killer (NK) cells** serve an important role in the body's immune defense system. Like other lymphocytes, NK cells accumulate in the lymphoid tissues (especially spleen, lymph nodes, and tonsils), where they mature. When activated, they serve as potent killers of virus-infected and cancer cells. They also secrete cytokines to mobilize the T and B cells into action.

Function of Leukocytes

Leukocytes protect the body from invasion by bacteria and other foreign entities. The major function of neutrophils is phagocytosis. Neutrophils arrive at a given site within 1 hour after the onset of an inflammatory reaction and initiate phagocytosis, but they are short-lived. An influx of monocytes follows; these cells continue their phagocytic activities for long periods as macrophages. This process constitutes a second line of defense for the body against inflammation and infection. Although neutrophils can often work adequately against bacteria without the help of macrophages, macrophages are particularly effective against fungi and viruses. Macrophages also digest senescent (aging or aged) blood cells, primarily within the spleen.

The primary function of lymphocytes is to attack foreign material. One group of lymphocytes (T lymphocytes) kills foreign cells directly or releases lymphokines, substances that enhance the activity of phagocytic cells. T lymphocytes are responsible for delayed allergic reactions, rejection of foreign tissue (e.g., transplanted organs), and destruction of tumor cells. This process is known as *cellular immunity.* The other group of lymphocytes (B lymphocytes) is capable of differentiating into plasma cells. Plasma cells, in turn, produce antibodies called *immunoglobulins* (Igs), which are protein molecules that destroy foreign material by several mechanisms. This process is known as humoral immunity.

Eosinophils and basophils function in hypersensitivity reactions. Eosinophils are important in the phagocytosis of parasites. The increase in eosinophil levels in allergic states indicates that these cells are involved in the hypersensitivity reaction; they neutralize histamine. Basophils produce and store histamine as well as other substances involved in hypersensitivity

reactions. The release of these substances provokes allergic reactions. See Chapter 31 for further information on the immune response.

Platelets (Thrombocytes)

Platelets, or thrombocytes, are not technically cells; rather, they are granular fragments of giant cells in the bone marrow called *megakaryocytes* (see Fig. 28-2). Platelet production in the marrow is regulated in part by the hormone thrombopoietin, which stimulates the production and differentiation of megakaryocytes from the myeloid stem cell. Each megakaryocyte has the capacity to produce approximately 2000 platelets; 80% of these platelets are active in the circulation and 20% are stored in the spleen (Ciesla, 2019a).

Platelets play an essential role in the control of bleeding. They circulate freely in the blood in an inactive state, where they nurture the endothelium of the blood vessels, maintaining the integrity of the vessel. When vascular injury occurs, platelets collect at the site and are activated. They adhere to the site of injury and to each other, forming a platelet plug that temporarily stops bleeding. Substances released from platelet granules activate coagulation factors in the blood plasma and initiate the formation of a stable clot composed of **fibrin**, a filamentous protein. Platelets have a normal lifespan of 7 to 10 days (Ciesla, 2019b).

Plasma and Plasma Proteins

After cellular elements are removed from blood, the remaining liquid portion is called *plasma.* More than 90% of plasma is water. The remainder consists primarily of plasma proteins; clotting factors (particularly fibrinogen); and small amounts of other substances, such as nutrients, enzymes, waste products, and gases. If plasma is allowed to clot, the remaining fluid is called **serum**. Serum has essentially the same composition as plasma, except that fibrinogen and several clotting factors have been removed during the clotting process.

Plasma proteins consist primarily of albumin and globulins. The globulins can be separated into three main fractions (alpha, beta, and gamma), each of which consists of distinct proteins that have different functions. Important proteins in the alpha and beta fractions are the transport globulins and the clotting factors that are made in the liver. The transport globulins carry various substances in bound form in the circulation. For example, thyroid-binding globulin carries thyroxin, and transferrin carries iron. The clotting factors, including fibrinogen, remain in an inactive form in the blood plasma until activated by the clotting cascade. The gamma-globulin fraction refers to the Igs, or antibodies. These proteins are produced by well-differentiated B lymphocytes and plasma cells. The actual fractionation of the globulins can be seen on a specific laboratory test (serum protein electrophoresis).

Albumin is particularly important for the maintenance of fluid balance within the vascular system. Capillary walls are impermeable to albumin, so its presence in the plasma creates an osmotic force that keeps fluid within the vascular space. Albumin, which is produced by the liver, has the capacity to bind to several substances that are transported in plasma (e.g., certain medications, bilirubin, and some hormones). People with impaired hepatic function may have low concentrations of albumin, with a resultant decrease in osmotic pressure and the development of edema.

Reticuloendothelial System (RES)

The **reticuloendothelial system (RES)** is composed of special tissue macrophages. When released from the marrow, monocytes spend a short time in the circulation (about 24 hours) and then enter the body tissues. Within the tissues, the monocytes continue to differentiate into macrophages, which can survive for months or years. Macrophages have a variety of important functions. They defend the body against foreign invaders (i.e., bacteria and other pathogens) via phagocytosis. They remove old or damaged cells from the circulation. They stimulate the inflammatory process and present antigens to the immune system (Banaski, 2019). Macrophages give rise to tissue histiocytes, phagocytic cells that are present in loose connective tissue. These include Kupffer cells of the liver, peritoneal macrophages, alveolar macrophages, and other components of the RES. Thus, the RES is a component of many other organs within the body, particularly the spleen, lymph nodes, lungs, and liver.

The spleen is the site of activity for most macrophages. Most of the spleen (75%) is made of red pulp; here, the blood enters the venous sinuses through capillaries that are surrounded by macrophages. Within the red pulp are tiny aggregates of white pulp, consisting of B and T lymphocytes. The spleen sequesters newly formed reticulocytes from the marrow, removing nuclear fragments and other materials (e.g., damaged or defective hemoglobin, iron) before the now fully mature erythrocyte returns to the circulation. If the spleen is enlarged, a greater number of red cells and platelets can be sequestered. The spleen is a major source of hematopoiesis in fetal life. It can resume hematopoiesis later in adulthood if necessary, particularly when marrow function is compromised (e.g., in bone marrow fibrosis). The spleen has important immunologic functions as well. It forms substances called *opsonins* that promote the phagocytosis of neutrophils; it also forms the antibody immunoglobulin M (IgM) after exposure to an antigen.

Hemostasis

Hemostasis is the process of preventing blood loss from intact vessels and of stopping bleeding from a severed vessel, which requires adequate numbers of functional platelets. Platelets nurture the endothelium and thereby maintain the structural integrity of the vessel wall. Two processes are involved in arresting bleeding: primary and secondary hemostasis (see Fig. 28-3).

In primary hemostasis, the severed blood vessel constricts. Circulating platelets aggregate at the site and adhere to the vessel and to one another. An unstable hemostatic plug is formed. For the coagulation process to be correctly activated, circulating inactive coagulation factors must be converted to active forms. This process occurs on the surface of the aggregated platelets at the site of vessel injury.

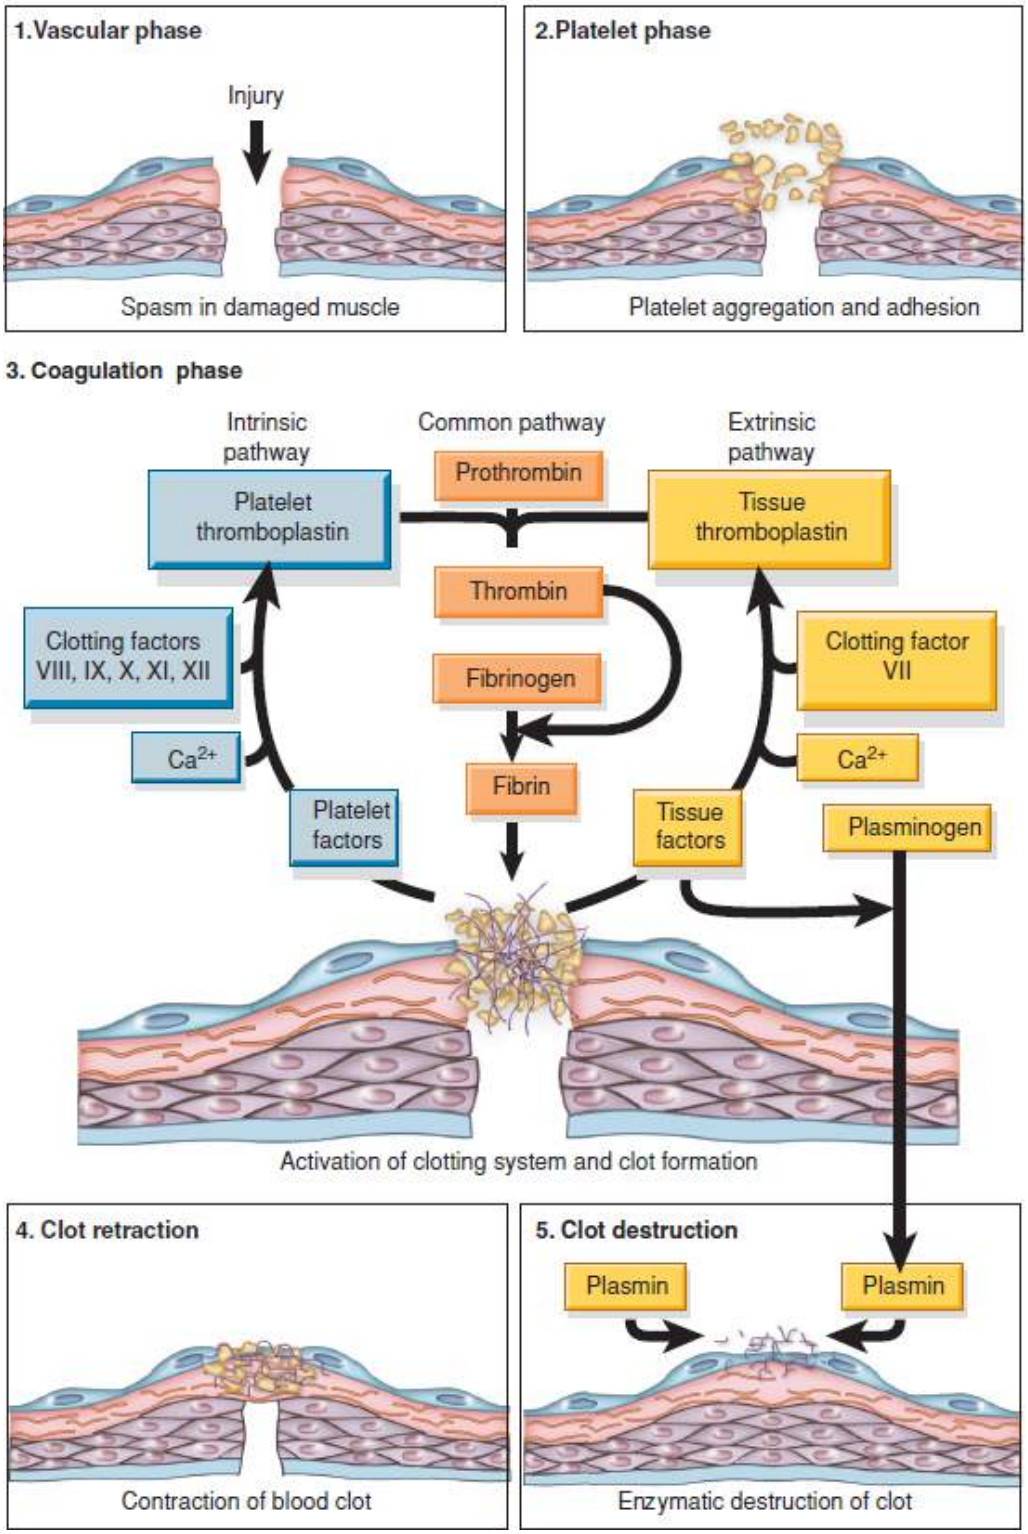

Figure 28-3 • Hemostasis. When the endothelial surface of a blood vessel is injured, several processes occur. In primary hemostasis, platelets within the circulation are attracted to the exposed layer of collagen at the site of injury. They adhere to the site of injury, releasing factors that stimulate other platelets to aggregate at the

site, forming an unstable platelet plug. In secondary hemostasis, based on the type of stimulus, one of two clotting pathways is initiated—the intrinsic or extrinsic pathway—and the clotting factors within that pathway are activated. The end result from either pathway is the conversion of prothrombin to thrombin. Thrombin is necessary for fibrinogen to be converted into fibrin, the stabilizing protein that anchors the fragile platelet plug to the site of injury to prevent further bleeding and permit the injured vessel or site to heal. Modified from www.irvingcrowley.com/cls/clotting.gif

The end result is the formation of fibrin, which reinforces the platelet plug and anchors it to the injury site. This process is referred to as secondary hemostasis. Blood coagulation is highly complex. It can be activated by the extrinsic pathway (also known as the tissue factor pathway) or the intrinsic pathway (also known as the contact activation pathway). Both pathways are needed for maintenance of normal hemostasis. Many factors are involved in the reaction cascade that forms fibrin. When tissue is injured, the extrinsic pathway is activated by the release of thromboplastin from the tissue. As the result of a series of reactions, prothrombin is converted to thrombin, which in turn catalyzes the conversion of fibrinogen to fibrin. Clotting by the intrinsic or contact activation pathway is activated when the collagen that lines blood vessels is exposed. Clotting factors are activated sequentially until, as with the extrinsic pathway, fibrin is ultimately formed (Rockwell, 2019). The intrinsic pathway is slower, and this sequence is less often responsible for clotting in response to tissue injury. However, it is important if a noninjured vessel wall comes into contact with lipoproteins (e.g., atherosclerosis) or with bacteria, resulting in a clot that is formed for purposes other than protection from trauma or bleeding.

As the injured vessel is repaired and again covered with endothelial cells, the fibrin clot is no longer needed. The fibrin is digested via two systems: the plasma fibrinolytic system and the cellular fibrinolytic system. The protein **plasminogen** is required to lyse (break down) the fibrin. Plasminogen, which is present in all body fluids, circulates with fibrinogen and is therefore incorporated into the fibrin clot as it forms. When the clot is no longer needed (e.g., after an injured blood vessel has healed), the plasminogen is activated to form plasmin. Plasmin digests the fibrinogen and fibrin. The breakdown particles of the clot, called *fibrin degradation products,* are released into the circulation. Through this system, clots are dissolved as tissue is repaired, and the vascular system returns to its normal baseline state.

Gerontologic Considerations

In older adults, the bone marrow's ability to respond to the body's need for blood cells (erythrocytes, leukocytes, and platelets) may be decreased, resulting in **leukopenia** (a decreased number of circulating leukocytes) or anemia. This decreased ability is a result of many factors, including diminished production of the growth factors necessary for hematopoiesis by stromal cells within the marrow or a diminished response to the growth factors (in the case of erythropoietin). Over time, stem cells within the marrow acquire damage to their DNA, which compromises their function. T- and B-cell development is also decreased. This age-related decrease in immune system response due to diminished production and function of blood cells designed to protect the body is called immunosenescence (Yeager, 2019).

Assessment

Health History

A careful health history and physical assessment can provide important information related to a patient's known or potential hematologic diagnosis. Because many hematologic disorders are more prevalent in certain ethnic groups, assessments of ethnicity and family history are useful (see Chart 28-1). Similarly, obtaining a nutritional history and assessing the use of prescription and over-the-counter medications, as well as herbal supplements, are important to note, because several conditions can result from nutritional deficiencies, or from the use of certain herbs or medications. Careful attention to the onset of a symptom or finding (e.g., rapid vs. gradual; persistent vs. intermittent), its severity, and any contributing factors can further differentiate potential causes. Of equal importance is assessing the impact of these findings on the patient's functional ability, manifestations of distress, and coping mechanisms.

Chart 28-1 **GENETICS IN NURSING PRACTICE**

Hematologic Disorders

Hematologic disorders are marked by aberrations in the structure or function of the blood cells or the blood clotting mechanism. Some examples of genetic hematologic disorders are:

Autosomal Dominant:

- Factor V Leiden
- Familial hypercholesterolemia
- Hereditary angioedema
- Hereditary spherocytosis
- von Willebrand disease

Autosomal Recessive:

- Hemochromatosis
- Sickle cell disease
- Thalassemia

X-Linked:

- Hemophilia

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Hematologic Disorders

- Collect family history information on maternal and paternal relatives from three generations of the family.
- Assess family history for other family members with histories of blood disorders or episodes of abnormal bleeding.
- If a family history or personal risk is suspected, the person should be carefully screened for bleeding disorders prior to surgical procedures.

Patient Assessment Specific to Hematologic Disorders

- Assess for specific symptoms of hematologic diseases:
  - Extreme fatigue (the most common symptom of hematologic disorders)
  - Delayed clotting of blood
  - Easy or deep bruising

- Abnormal bleeding (e.g., frequent nosebleeds)
- Abdominal pain (hemochromatosis) or joint pain (sickle cell disease)

- Review blood cell counts for abnormalities.
- Assess for presence of illness despite low risk for the illness (e.g., a young adult with a blood clot)

Physical Assessment

The physical assessment should be comprehensive and include careful attention to the skin, oral cavity, lymph nodes, and spleen (see Fig. 28-4). Table 28-2 highlights a general approach to the physical assessment findings in hematologic disorders (more specific findings are presented in Chapters 29 and 30).

Diagnostic Evaluation

Most hematologic diseases reflect a defect in the hematopoietic, hemostatic, or reticuloendothelial systems. The defect can be quantitative (e.g., increased or decreased production of cells), qualitative (e.g., the cells that are produced are defective in their expected functional capacity), or both. Initially, many hematologic conditions cause few symptoms, and extensive laboratory tests are often required to establish a diagnosis. For most hematologic conditions, continued monitoring via specific blood tests is required because it is very important to assess for changes in test results over time. In general, it is important to assess trends in test results because these trends help the clinician decide whether the patient is responding appropriately to interventions.

Hematologic Studies

The most common tests used are the complete blood count (CBC) and the peripheral blood smear. The CBC identifies the total number of blood cells (leukocytes, erythrocytes, and platelets) as well as the hemoglobin, **hematocrit** (percentage of blood volume consisting of erythrocytes), and RBC indices. Because cellular morphology (shape and appearance of the cells) is

particularly important in accurately diagnosing most hematologic disorders, the blood cells involved must be examined. This process is referred to as the manual examination of the peripheral smear, which may be part of the CBC. In this test, a drop of blood is spread on a glass slide, stained, and examined under a microscope. The shape and size of the erythrocytes and platelets, as well as the actual appearance of the leukocytes, provide useful information in identifying hematologic conditions. Blood for the CBC is typically obtained by venipuncture (Fischbach & Fischbach, 2018).

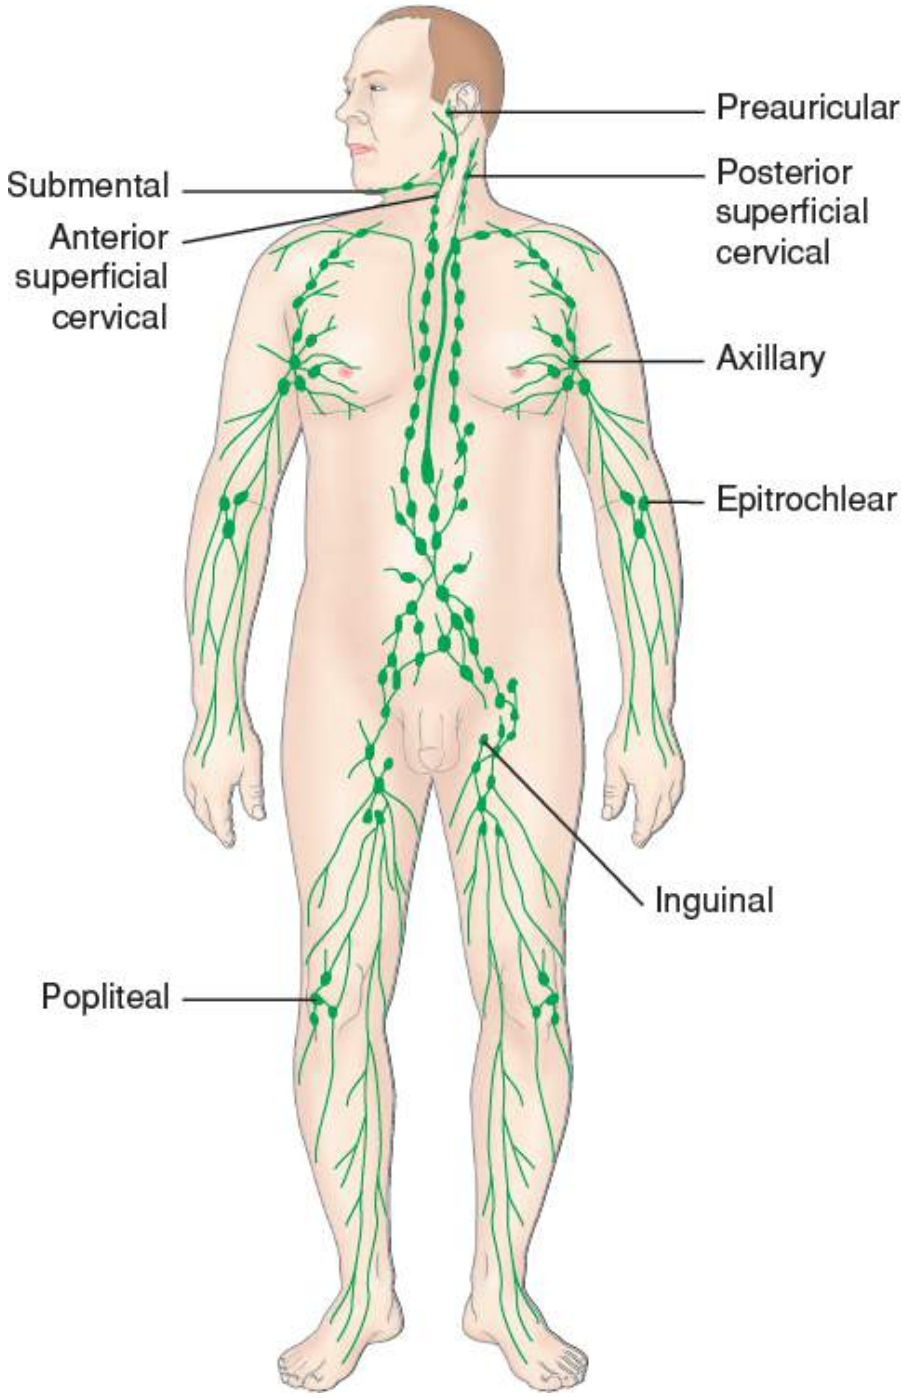

Figure 28-4 • Lymphatic system. Sites where lymph nodes are accessible for palpation. Developed by Thomas, M., & Morrow, K. (2011). Veterans Administration Palo Alto Health Care System.

TABLE 28-2 Health History and Physical Assessment in Hematologic Disorders[a]

	Findings	Potential Indications of Hematologic Disorder
Health History	Prior episodes of bleeding (epistaxis, tooth, gum, hematuria, menorrhagia, hematochezia, gastrointestinal bleeding and/or ulcers)	Thrombocytopenia, coagulopathy, anemia
	Prior blood clots, pulmonary emboli, miscarriages	Thrombotic disorder
	Fatigue and weakness	Anemia, infection, malignancy, clonal disorders
	Dyspnea, particularly dyspnea on exertion, orthopnea, shortness of breath	Anemia, infection
	Prior radiation therapy (especially pelvic irradiation)	Anemia, pancytopenia, myelodysplastic syndrome, leukemia
	Prior chemotherapy	Myelodysplastic syndrome, leukemia
	Hobbies/occupational/military exposure history (especially benzene, Agent Orange)	Myelodysplastic syndrome, leukemia, myeloma, lymphoma
	Diet history	Anemia (due to vitamin B_{12}, folate, iron deficiency)
	Alcohol consumption	Anemia (effect on hematopoiesis, nutritional deficiency)
	Use of herbal supplements	Platelet dysfunction
	Concurrent medications	Neutropenia, anemia, hemolysis, thrombocytopenia
	Family history/ethnicity	Some hematologic disorders have a higher prevalence in certain ethnic groups and families (see Chart 28-1)
Physical Assessment		
Skin	Gray-tan or bronze skin color (especially genitalia, scars, exposed areas)	Hemochromatosis (primary or secondary)
	Ruddy complexion (face, conjunctiva, hands, feet)	Polycythemia
	Ecchymoses (i.e., bruises)	Thrombocytopenia, coagulopathy
	Petechiae (i.e., pinpoint hemorrhagic	Severe thrombocytopenia

	lesions, usually more prominent on trunk or anterior aspects of lower extremities)	
	Rash	Variable; if pruritic, may indicate polycythemia, other non–hematologic-related disorders (see Chapter 56)
	Bleeding (including around vascular lines, tubes)	Thrombocytopenia, coagulopathy
	Conjunctival hemorrhage	Severe thrombocytopenia, coagulopathy
	Pallor, especially in mucous membranes (including conjunctiva), nail beds	Anemia
	Jaundice in mucous membranes (including conjunctiva), nail beds, palate	Hemolysis
Oral cavity	Petechiae in the buccal mucosa, gingiva, hard palate	Severe thrombocytopenia
	Ulceration of oral mucosa	Infection, leukemia
	Tongue: Smooth	Pernicious anemia
	Beefy red	Vitamin B_{12}/folate deficiency
	Enlarged	Amyloidosis
	Angular cheilosis (ulceration at corners of mouth)	Anemia
	Enlarged gums: hyperplasia	Leukemia
Lymph nodes	Enlarged size, firm and fixed vs. mobile and tender	Leukemia, lymphoma
Respiratory	Increased rate and depth of respirations; adventitious breath sounds	Anemia; infection
Cardiovascular	Distended neck veins, edema, chest pain on exertion, murmurs, gallops	Severe anemia
	Hypotension (below baseline)	Polycythemia
	Hypertension (above baseline)	
Genitourinary	Hematuria	Hemolysis, thrombocytopenia
	Proteinuria	Myeloma
Musculoskeletal	Rib/sternal tenderness to palpation	Leukemia, myeloma
	Back pain; tenderness to palpation over spine, loss of height, kyphosis	Myeloma
	Pain/swelling in knees, wrists, hands	Hemophilia, sickle cell disease
Abdominal	Enlarged spleen	Leukemia, myelofibrosis
	Enlarged liver	Myelofibrosis

	Stool positive for occult blood	Anemia, thrombocytopenia
Central nervous system	Cranial nerve dysfunction	Vitamin B_{12} deficiency
	Peripheral nerve dysfunction (especially sensory) Visual changes, headache, alteration in mental status	Vitamin B_{12} deficiency, amyloidosis, myeloma Severe thrombocytopenia
Gynecologic	Menorrhagia	Thrombocytopenia, coagulopathy
Constitutional	Fever, chills, sweats, asthenia	Leukemia, lymphoma; infection

[a]Common findings (obtained via health history and physical assessment) that occur in patients with hematologic disorders. Note that signs and symptoms are not disease specific but are useful in guiding the nurse to establishing an etiology for the findings noted.

Adapted from Bickley, L. S. (2016). *Bates' guide to physical examination and history taking* (12th ed.). Philadelphia, PA: Lippincott Williams & Wilkins; Weber, J. W., & Kelley, J. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

Other common tests of coagulation are the prothrombin time (PT), typically replaced by the standardized test, international normalized ratio (INR), and the activated partial thromboplastin time (aPTT). The INR and aPTT serve as useful screening tools for evaluating a patient's clotting ability and monitoring the therapeutic effectiveness of anticoagulant medications. In both tests, specific reagents are mixed into the plasma sample, and the time taken to form a clot is measured. For these tests to be accurate, the test tube must be filled with the correct amount of the patient's blood; either excess or inadequate blood volume within the tube can render the results inaccurate.

Bone Marrow Aspiration and Biopsy

Bone marrow aspiration and biopsy are crucial when additional information is needed to assess how a patient's blood cells are being formed and to assess the quantity and quality of each type of cell produced within the marrow. Also, results of these tests can be used to document infection or tumor within the marrow. Other specialized tests can be performed on the marrow aspirate, such as cytogenetic analysis or immunophenotyping (i.e., identifying specific proteins expressed by cells), and are useful to identify certain malignant conditions and form a prognosis.

Normal bone marrow is in a semifluid state and can be aspirated through a special large needle. In adults, bone marrow is usually aspirated from the iliac crest and occasionally from the sternum. The bone marrow aspirate provides a sample of cells from the more fluid part of the bone marrow and may not be adequate for evaluating certain conditions, such as anemia. When more

information is required, a bone marrow biopsy is performed, which examines a solid part of the bone marrow. Biopsy samples are taken from the posterior iliac crest; although occasionally, an anterior approach is required. A marrow biopsy shows the architecture of the bone marrow as well as its degree of cellularity.

Patient preparation includes a careful explanation of the procedure, which may be done at the patient's bedside (for a patient who is hospitalized) or in the outpatient setting. Some patients may be anxious, thus an anxiolytic agent may be prescribed. It is essential the physician or nurse explain the procedure, including risks, benefits and alternatives, and describe sensations the patient may experience. A signed informed consent is required for a bone marrow aspiration and biopsy.

Before aspiration, the skin is cleansed using aseptic technique. Next, a small area is anesthetized with a local anesthetic agent through the skin and subcutaneous tissue to the periosteum of the bone; it is not possible to anesthetize the bone itself. The bone marrow needle is introduced with a stylet in place. When the needle moves through the outer cortex of bone and enters the marrow cavity, the stylet is removed, and a syringe is attached. A small volume (5 mL) of blood and marrow is then aspirated. Patients typically feel a pressure sensation as the needle is advanced into position. The actual aspiration always causes sharp but brief pain, resulting from the suction exerted as the marrow is aspirated into the syringe. Taking deep breaths or using relaxation techniques often helps ease the discomfort (see Fig. 28-5).

A bone marrow biopsy is most often performed with a bone marrow aspiration and is called a bone marrow exam (Mayo Clinic, 2018a). The bone marrow aspirate is used to determine types and numbers of cells present in the bone marrow. The bone marrow biopsy consists of an actual tissue sample used to study the architecture of the bone marrow and confirm diagnoses (Wimberly, 2019). For a bone marrow biopsy, a special biopsy needle is used. Because these needles are large, the skin may be punctured first with a surgical blade to make a 3- to 4-mm incision. The biopsy needle is advanced well into the marrow cavity. When the needle is properly positioned, a portion of marrow is cored out. The patient feels a pressure sensation but should not feel actual pain. The nurse should assist the patient in maintaining a comfortable position and encourage relaxation and deep breathing throughout the procedure. The patient should be instructed to inform the physician if pain occurs so that an additional anesthetic agent can be given.

Potential complications of either bone marrow aspiration or biopsy include bleeding and infection. The risk of bleeding is somewhat increased if the patient's platelet count is low or if the patient has been taking a medication that alters platelet function (e.g., aspirin). After the marrow sample is obtained, pressure is applied to the site for several minutes. The site is then covered with a sterile dressing. Most patients have no discomfort after a bone marrow

aspiration, but the site of a biopsy may ache for 1 or 2 days. Warm tub baths and a mild analgesic agent (e.g., acetaminophen) may be useful. Aspirin-containing analgesic agents should be avoided in the immediate postprocedure period because they can aggravate or potentiate bleeding. Also, no rigorous activity or exercise for 1 to 2 days is recommended (Mayo Clinic, 2018a).

Unfolding Patient Stories: Lloyd Bennett • Part 1

Lloyd Bennett is a 76-year-old male who fell while working outdoors. He presents to the emergency department with a hip fracture. What physical assessment and laboratory data can assist the nurse in evaluation for possible internal blood loss from the fracture or indications that the patient is at higher risk of bleeding? (Lloyd Bennett's story continues in Chapter 47.)

Care for Lloyd and other patients in a realistic virtual environment: vSim(**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

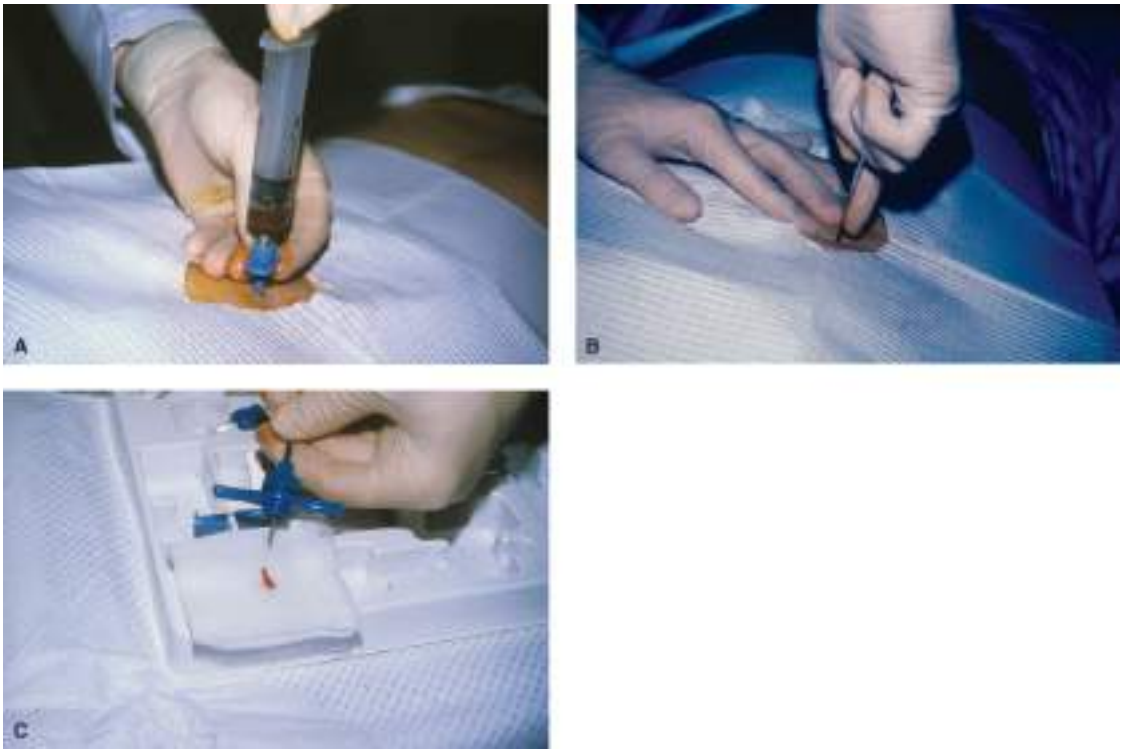

Figure 28-5 • Bone marrow aspiration procedure. The posterior superior iliac crest is the preferred site for bone marrow aspiration and biopsy because no vital organs or vessels are nearby. The patient is placed either in the lateral position with one leg flexed or in the prone position. The anterior iliac crest or sternum may also be used. Note that the sternum cannot be used for a marrow biopsy. **A.** Bone marrow aspiration. **B.** Inserting a Jamshidi biopsy needle. **C.** Dispensing the bone marrow core. Therapeutic Approaches to Hematologic Disorders

Splenectomy

The surgical removal of the spleen, called splenectomy, is a possible treatment for some hematologic disorders. For example, an enlarged spleen may be the site of excessive destruction of blood cells. In addition, some patients with grossly enlarged spleens develop severe thrombocytopenia as a result of platelets being sequestered in the spleen. Splenectomy removes the "trap," and platelet counts may normalize over time.

Laparoscopic splenectomy is associated with decreased postoperative morbidity compared to open splenectomy. Acute risks associated with a splenectomy include hemorrhage, increased clotting, and injury to surrounding

organs and tissues. Long-term risks post splenectomy includes greater likelihood to develop life-threatening infections. Patients should be vaccinated for pneumonia before undergoing splenectomy, if possible. The patient is instructed to seek prompt medical attention for even minor symptoms of infection. The Centers for Disease Control and Prevention (CDC, 2020) recommends patients without spleens receive vaccines for influenza, pneumonia, and meningococci. Also, if a patient has other conditions that increase risk of serious infection in addition to a history of splenectomy, they may need antibiotic prophylaxis (Mayo Clinic, 2018b).

Therapeutic Apheresis

Apheresis is a Greek word meaning "separation." In therapeutic apheresis (or pheresis), blood is taken from the patient and passed through a centrifuge, where a specific component is separated from the blood, removed (see Table 28-3), and the remaining blood is returned to the patient. The entire system is closed, so the risk of bacterial contamination is low. When platelets or leukocytes are removed, the decrease in these cells within the circulation is temporary. Platelet donors can have their platelets apheresed as often as every 14 days. Leukocytes can be obtained similarly, typically after the donor has received growth factors (granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor) to stimulate the formation of additional leukocytes and thereby increase the leukocyte count. The use of these growth factors also stimulates the release of stem cells within the circulation. Apheresis is used to harvest these stem cells (typically over a period of several days) for use in peripheral blood stem cell transplant (Padmanabhan, Smith, Aqui, et al., 2019). Sometimes plasma is removed rather than blood cells, and this process is called plasmapheresis. Indications for plasmapheresis include obtaining plasma for transfusion and removing dangerous substances such as immune complexes and autoantibodies (Sarode, 2018).

Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation (HSCT) is a therapeutic modality that offers the possibility of cure for some patients with hematologic disorders such as severe aplastic anemia, some forms of leukemia, and thalassemia. It can also provide longer remission from disease even when cure is not possible, such as in multiple myeloma. Hematopoietic stem cells may be transplanted from either allogeneic or autologous donors. For most hematologic diseases, allogeneic transplant is more effective (Bazinet & Popradi, 2019); here, stem cells are obtained from a donor whose cells match those of the patient. In contrast, the patient's own stem cells are harvested and then used in autologous transplant. (See Chapter 12 for a detailed discussion of HSCT.)

TABLE 28-3 Types of Apheresis[a]

Procedure	Purpose	Examples of Clinical Use
Plateletpheresis	Remove platelets	Extreme thrombocytosis, essential thrombocythemia (temporary measure); single-donor platelet transfusion
Leukapheresis	Remove WBCs (can be specific to neutrophils or lymphocytes)	Extreme leukocytosis (e.g., AML, CML) (very temporary measure); harvest WBCs for transfusion
Erythrocytapheresis (RBC exchange)	Remove RBCs	RBC dyscrasias (e.g., sickle cell disease); RBCs replaced via transfusion
Plasmapheresis (plasma exchange)	Remove plasma proteins	Hyperviscosity syndromes; treatment for some renal and neurologic diseases (e.g., Goodpasture syndrome, TTP, Guillain–Barré, myasthenia gravis)
Stem cell harvest	Remove circulating stem cells	Transplantation (donor harvest or autologous)

[a]Therapeutic apheresis can be used to treat a wide variety of conditions. When it is used to treat a disease that causes an increase in a specific cell type with a short life in circulation (i.e., WBCs, platelets), the reduction in those cells is temporary. However, this temporary reduction permits a margin of safety while waiting for a longer-lasting treatment modality (e.g., chemotherapy) to take effect. Apheresis can also be used to obtain stem cells for transplantation, either from a matched donor (allogeneic) or from the patient (autologous).

AML, acute myeloid leukemia; CML, chronic myeloid leukemia; RBC, red blood cell; TTP, thrombotic thrombocytopenic purpura; WBCs, white blood cells.

Adapted from Padmanabhan, A., Smith, L., Aqui, N., et al. (2019). Guidelines on the use of therapeutic apheresis in clinical practice—evidence-based approach from the Writing Committee of the American Society for Apheresis: The eighth special issue. *Journal of Clinical Apheresis*, *34*(3), 171–354.

Therapeutic Phlebotomy

Therapeutic phlebotomy is the removal of a certain amount of blood under controlled conditions. Patients with elevated hematocrits (e.g., those with polycythemia vera) or excessive iron absorption (e.g., hemochromatosis) can usually be managed by periodically removing 1 unit (about 500 mL) of whole blood. Over time, this process can produce iron deficiency, leaving the patient unable to produce as many erythrocytes. The actual procedure for therapeutic phlebotomy is similar to that for blood donation (see later discussion).

Blood Component Therapy

A single unit of whole blood contains 450 mL of blood and 50 mL of an anticoagulant, which can be processed and dispensed for administration.

However, it is more appropriate, economical, and practical to separate that unit of whole blood into its primary components: erythrocytes, platelets, and plasma (leukocytes are rarely used; see later discussion).

Each component must be processed and stored differently to maximize the longevity of the viable cells and factors within it; thus, each individual blood component has a different storage life. Because the plasma is removed, a unit of packed red blood cells (PRBCs) is very concentrated (hematocrit approximately 70%) (Butterworth, Mackey, &Wasnick, 2018). PRBCs are stored at 4°C (39.2°F). With special preservatives, they can be stored safely for up to 42 days before they must be discarded (American Red Cross, 2020a).

In contrast, platelets must be stored at room temperature because they cannot withstand cold temperatures, and they last for only 5 days before they must be discarded. To prevent clumping, platelets are gently agitated while stored. Plasma is immediately frozen to maintain the activity of the clotting factors within; it lasts for 1 year if it remains frozen. Alternatively, plasma can be further pooled and processed into blood derivatives, such as albumin, immune globulin, factor VIII, and factor IX. Table 28-4 describes each blood component and how it is commonly used.

Special Preparations

Factor VIII concentrate (antihemophilic factor) is a lyophilized, freeze-dried concentrate of pooled fractionated human plasma used in treating hemophilia A. Factor IX concentrate (prothrombin complex) is similarly prepared and contains factors II, VII, IX, and X. It is used primarily for the treatment of factor IX deficiency (hemophilia B). Factor IX concentrate is also useful in treating congenital factor VII and factor X deficiencies. Recombinant forms of factor VIII, such as Humate-P or Alphanate, are also useful. Because they contain von Willebrand factor, these agents are used in von Willebrand disease as well as in hemophilia A, particularly when patients develop factor VIII inhibitors.

Plasma albumin is a large protein molecule that usually stays within vessels and is a major contributor to plasma oncotic pressure. This protein is used to expand the blood volume of patients in hypovolemic shock and, rarely, to increase the concentration of circulating albumin in patients with hypoalbuminemia.

Immune globulin is a concentrated solution of the antibody immunoglobulin G (IgG), prepared from large pools of plasma. It contains very little immunoglobulin A (IgA) or IgM. Intravenous immunoglobulin (IVIG) is used in various clinical situations to replace inadequate amounts of IgG in patients who are at risk for recurrent bacterial infection (e.g., those with chronic lymphocytic leukemia, those receiving HSCT). It is also used in certain autoimmune disorders, such as idiopathic thrombocytopenic purpura (ITP). Albumin, antihemophilic factors, and IVIG, in contrast to all other

fractions of human blood, cells, or plasma, can survive being subjected to heating at 60°C (140°F) for 10 hours to free them of the viral contaminants that may be present.

TABLE 28-4 Blood and Blood Components Commonly Used in Transfusion Therapy[a]

Component	Composition	Indications and Considerations
Whole blood	Cells and plasma, hematocrit about 40%	Volume replacement and oxygen-carrying capacity; usually used only in significant bleeding (>25% blood volume lost)
PRBCs	RBCs with little plasma (hematocrit about 75%); some platelets and WBCs remain	↑ RBC mass; symptomatic anemia: • Platelets within the unit are not functional • WBCs within the unit may cause reaction and are not functional
Platelets—random	Platelets (5.5×10^{10} platelets/unit), plasma; some RBCs, WBCs	Bleeding due to severe ↓ platelets Prevent bleeding when platelets <5,000–10,000/mm^3 Survival ↓ in presence of fever, chills, infection Repeated treatment leads to ↓ survival due to alloimmunization
Platelets—single donor	Platelets (3×10^{11} platelets/unit) 1 unit is equivalent to 6–8 units of random platelets	Used for repeated treatment: • darr; alloimmunization risk by limiting exposure to multiple donors
Plasma	Plasma; all coagulation factors Complement	Bleeding in patients with coagulation factor deficiencies; plasmapheresis
Granulocytes	Neutrophils (>1×10^{10}/unit); some lymphocytes, RBCs, and platelets will remain within the unit	Severe neutropenia in select patients; controversial
Lymphocytes	Lymphocytes (number varies)	Stimulate graft-vs.-host disease effect
Cryoprecipitate	Fibrinogen ≥150 mg/bag, AHF (VIII:C) 80–110 units/bag, von Willebrand factor; fibronectin	von Willebrand disease Hypofibrinogenemia Hemophilia A
AHF	Factor VIII	Hemophilia A
Factor IX concentrate	Factor IX	Hemophilia B (Christmas disease)
Factor IX complex	Factors II, VII, IX, X	Hereditary factor VII, IX, X deficiency; hemophilia A with factor VII inhibitors
Albumin	Albumin 5%, 25%	Hypoproteinemia; burns; volume expansion by 5% to ↑ blood volume; 25% leads to ↓ hematocrit
IV gamma-globulin	Immunoglobulin G antibodies	Hypogammaglobulinemia (in CLL, recurrent infections); ITP; primary

		immunodeficiency states
Antithrombin III concentrate (AT III)	AT III (trace amounts of other plasma proteins)	AT III deficiency with or at risk for thrombosis

[a]The composition of each type of blood component is described as well as the most common indications for using a given blood component. RBCs, platelets, and fresh-frozen plasma are the blood products most commonly used. When transfusing these blood products, it is important to realize that the individual product is always "contaminated" with very small amounts of other blood products (e.g., WBCs mixed in a unit of platelets). This contamination can cause some difficulties, particularly isosensitization, in certain patients.

↑, increased; ↓, decreased; AHF, antihemophilic factor; CLL, chronic lymphocytic leukemia; ITP, idiopathic thrombocytopenic purpura; IV, intravenous; PRBCs, packed red blood cells; RBCs, red blood cells; WBCs, white blood cells.

Transfusion medicine. In M. Laposata (Ed.). *Laboratory medicine: Diagnosis of disease in the clinical laboratory* (3rd ed., pp. 321–348). New York: McGraw-Hill.

Procuring Blood and Blood Products

The process of procuring blood and blood products includes donation and processing.

Blood Donation

To protect both the donor and the recipients, all prospective donors are examined and interviewed before they are allowed to donate their blood. The intent of the interview is to assess the general health status of the donor and to identify risk factors that might harm a recipient of the donor's blood. There is no upper age limit to donation. The American Red Cross (2020c) requires that donors be in good health and meet specific eligibility criteria related to medications and vaccinations, medical conditions and treatments, travel outside the United States, lifestyle and life events, and so on. Detailed information about these criteria is available on the American Red Cross Web site (see the Resources section). Examples of these minimal requirements include (American Red Cross, 2020a, 2020d):

- Body weight should be at least 50 kg (110 lb) for a standard 450-mL donation.
- Donors must wait at least 8 weeks between whole blood (standard) donations.
- People younger than 17 years require parental consent in some states.
- The oral temperature should not exceed 37.5°C (99.6°F).

- The systolic arterial blood pressure should be 80 to 180 mm Hg, and the diastolic pressure should be 50 to 100 mm Hg.
- The hemoglobin level should be at least 12.5 g/dL.
- The destinations of people who traveled outside the United States and Canada within the past 3 years are reviewed; a waiting period maybe required before a donation is accepted.
- Prospective donors who received a blood transfusion must wait 12 months before a donation is accepted.
- Men who have sexual relations with men must wait 3 months from their last sexual encounter before a donation is accepted.

The American Red Cross follows the U.S. Food and Drug Administration (FDA) policy for donors who are lesbian, gay, bisexual, transgender, or queer (LGBTQ) and provides support for these individuals through the American Red Cross LGBTQ+ Team Member Resource Group (see Resources section at the end of the chapter).

Directed Donation

At times, friends and family of a patient wish to donate blood for that person. These blood donations are referred to as directed donations. These donations are not any safer than those provided by random donors, because directed donors may not be as willing to identify themselves as having a history of any of the risk factors that disqualify a person from donating blood. Therefore, many blood centers no longer accept directed donations.

Standard Donation

Phlebotomy consists of venipuncture and blood withdrawal. Standard precautions are used. Donors are placed in a semirecumbent position. The skin over the antecubital fossa is carefully cleansed with an antiseptic preparation, a tourniquet is applied, and venipuncture is performed. Withdrawal of 450 mL of blood usually takes less than 15 minutes. After the needle is removed, donors are asked to hold the involved arm straight up, and firm pressure is applied with sterile gauze for 2 to 3 minutes. A firm bandage is then applied. The donor remains recumbent until they feel able to sit up, usually within a few minutes. Donors who experience weakness or faintness should rest for a longer period. The donor then receives food and fluids and is asked to remain another 15 minutes.

The donor is instructed to leave the dressing on and to avoid heavy lifting for several hours, to avoid smoking for 1 hour, to avoid drinking alcoholic beverages for 3 hours, to increase fluid intake for 2 days, and to eat healthy meals for at least 2 weeks. Specimens from the donated blood are tested to

detect infections and to identify the specific blood type (see later discussion under Blood Processing).

Autologous Donation

A patient's own blood may be collected for future transfusion; this method is useful for many elective surgeries where the potential need for transfusion is high (e.g., orthopedic surgery). Preoperative donations are ideally collected 4 to 6 weeks before surgery. Iron supplements are prescribed during this period to prevent depletion of iron stores. Typically, 1 unit of blood is drawn each week; the number of units obtained varies with the type of surgical procedure to be performed (i.e., the amount of blood anticipated to be transfused). Phlebotomies are not performed within 72 hours of surgery. Individual blood components can also be collected.

The primary advantage of autologous transfusions is the prevention of viral infections from another person's blood. Other advantages include safe transfusion for patients with a history of transfusion reactions, prevention of alloimmunization, and avoidance of complications in patients with alloantibodies. It is the policy of the American Red Cross that autologous blood is transfused only to the donor. If the blood is not required, it is discarded. The blood is never returned to the general donor supply of blood products to be used by another person (American Red Cross, 2020a).

Needless autologous donation (i.e., performed when the likelihood of transfusion is small) is discouraged because it is expensive, takes time, and uses resources inappropriately. Moreover, in an emergency situation, the autologous units available may be inadequate, and the patient may still require additional units from the general donor supply. Furthermore, although autologous transfusion can eliminate the risk of viral contamination, the risk of bacterial contamination is the same as that in transfusion from random donors (Stowell, 2019).

Contraindications to donation of blood for autologous transfusion are acute infection, severely debilitating chronic disease, hemoglobin level less than 11 g/dL, unstable angina, and acute cardiovascular or cerebrovascular disease. A history of poorly controlled epilepsy may be considered a contraindication in some centers.

Intraoperative Blood Salvage

This transfusion method provides replacement for patients who cannot donate blood before surgery and for those undergoing vascular, orthopedic, or thoracic surgery. During a surgical procedure, blood lost into a sterile cavity (e.g., hip joint) is suctioned into a cell-saver machine. The whole blood or PRBCs are washed, often with saline solution; filtered; and then returned to the patient as

an IV infusion. Salvaged blood cannot be stored, because bacteria cannot be completely removed from the blood and thus cannot be used when it is contaminated with bacteria. The use of intraoperative blood salvage has decreased the need for autologous blood donation but has not affected the need for allogeneic blood products (Sikorski, Rizkalla, Yang, et al., 2017).

Hemodilution

This transfusion method may be initiated before or after induction of anesthesia. About 1 to 2 units of blood are removed from the patient through a venous or arterial line and simultaneously replaced with a colloid or crystalloid solution. The blood obtained is then reinfused after surgery. The advantage of this method is that the patient loses fewer erythrocytes during surgery, because the added IV solutions dilute the concentration of erythrocytes and lower the hematocrit. However, patients who are at risk for myocardial injury should not be further stressed by hemodilution. Hemodilution has been associated with adverse outcomes in patients having cardiopulmonary bypass; it has also been linked to tissue ischemia, particularly in the kidneys (Hare, Han, Leshchyshyn, et al., 2018).

Complications of Blood Donation

Excessive bleeding at the donor's venipuncture site is sometimes caused by a bleeding disorder but more often results from a technique error: laceration of the vein, excessive tourniquet pressure, or failure to apply enough pressure after the needle is withdrawn.

Fainting may occur after blood donation and may be related to emotional factors, a vasovagal reaction, or prolonged fasting before donation. Because of the loss of blood volume, hypotension and syncope may occur when the donor assumes an erect position (John, Theodora, Gloria, et al., 2017). A donor who appears pale or complains of faintness should immediately lie down or sit with the head lowered below the knees. The donor should be observed for another 30 minutes.

Anginal chest pain may be precipitated in patients with unsuspected coronary artery disease. Seizures can occur in donors with epilepsy, although the incidence is very low. Both angina and seizures require further medical evaluation and treatment.

Blood Processing

Samples of the unit of blood are always taken immediately after donation so that the blood can be typed and tested. Each donation is tested for antibodies to human immune deficiency virus (HIV) types 1 and 2, hepatitis B core antibody

(anti-HBc), hepatitis C virus (HCV), human T-cell lymphotropic virus type I (anti-HTLV-I/II), hepatitis B surface antigen (HbsAG), and syphilis. Negative reactions are required for the blood to be used, and each unit of blood is labeled to certify the results. Nucleic acid amplification testing has increased the ability to detect the presence of HCV, HIV, and West Nile virus infections, because it directly tests for genomic nucleic acids of the viruses rather than for the presence of antibodies to the viruses. This testing significantly shortens the "window" of inability to detect HIV and HCV from a donated unit, further ensuring the safety of the blood; the risk of transmission of HIV or HCV is now estimated at 1 in 2 million units and 1 in 1.6 million units of blood donated, respectively (American Cancer Society, 2017). Blood is also screened for cytomegalovirus (CMV). If it tests positive for CMV, it can still be used, except in recipients who are negative for CMV and who are severely immunocompromised; any components are labeled as CMV positive.

Equally important is accurate determination of the blood type. More than 200 antigens have been identified on the surface of RBC membranes. Of these, the most important for safe transfusion are the ABO and Rh systems. The ABO system identifies which sugars are present on the membrane of a person's erythrocytes: A, B, both A and B, or neither A nor B (type O). To prevent a significant reaction, the same type of PRBCs should be transfused. Previously, it was thought that in an emergency situation in which the patient's blood type was not known, type O blood could be safely transfused. This practice is no longer recommended.

The Rh antigen (also referred to as D) is present on the surface of erythrocytes in 85% of the population (Rh positive). Those who lack the D antigen are referred to as being Rh negative. PRBCs are routinely tested for the D antigen as well as ABO. Patients should receive PRBCs with a compatible Rh type.

The majority of transfusion reactions are due to clerical errors, including mislabeling, inaccuracy transcribing orders and incorrect verification of product and patient. When these errors occur, the patient is transfused an incompatible unit of blood product (Stubbs, 2018). Reactions (other than those due to procedural error) are most frequently due to the presence of donor leukocytes within the blood component unit (PRBCs or platelets); the recipient may form antibodies to the antigens present on these leukocytes. PRBC components typically have 1 to 3×10^9 leukocytes remaining in each unit. Leukocytes from the blood product are frequently filtered to diminish the likelihood of developing reactions and refractoriness to transfusions, particularly in patients who have long-term transfusion needs. The process of leukocyte filtration renders the blood component "leukocyte poor" (i.e., leukopoor). Filtration can occur at the time the unit is collected from the donor and processed, which achieves better results but is more expensive, or at the time the blood component is transfused by attaching a leukocyte filter to the

blood administration tubing. Many centers advocate routinely using leukopoor filtered blood components for people who have or are likely to develop long-term transfusion requirements.

When a patient is immunocompromised, as in the case following stem cell transplant, any donor lymphocytes must be removed from the blood components. In this situation, the blood component is exposed to low amounts of radiation (25 Gy) that kill any lymphocytes within the blood component. Irradiated blood products are highly effective in preventing transfusion-associated graft-versus-host disease, which is fatal in most cases. Irradiated blood products have a shorter shelf life.

Transfusion

Administration of blood and blood components requires knowledge of correct administration techniques and possible complications. It is very important to be familiar with the agency's policies and procedures for transfusion therapy.

Most blood transfusions are performed in the acute care setting, and sometimes must be done emergently. Patients with long-term transfusion requirements (i.e., patients who require transfusions on an ongoing, periodic basis) often can receive transfusions in other settings. Freestanding infusion centers, ambulatory care clinics, physicians' offices, and even patients' homes may be appropriate settings for transfusion. Typically, patients who need long-term transfusions but are otherwise stable physically are appropriate candidates for outpatient therapy. Verification and administration of the blood product are performed as in a hospital setting. Although most blood products can be transfused in the outpatient setting, the home is typically limited to transfusions of PRBCs and factor components (e.g., factor VIII for patients with hemophilia).

Pretransfusion Assessment

Patient History

The patient history is an important component of the pretransfusion assessment to determine the history of previous transfusions as well as previous reactions to transfusion. The history should include the type of reaction, its manifestations, the interventions required, and whether any preventive interventions were used in subsequent transfusions. The nurse assesses the number of pregnancies a woman has had, because a high number can increase her risk of reaction due to antibodies developed from exposure to fetal circulation. Other concurrent health problems should be noted, with careful

attention to cardiac, pulmonary, and vascular disease. Informed consent must be obtained preprocedure (see Chart 28-2).

Physical Assessment

A systematic physical assessment and measurement of baseline vital signs and fluid status are important before transfusing any blood product. The respiratory system should be assessed, including careful auscultation of the lungs and the patient's use of accessory muscles. Cardiac system assessment should include careful inspection for any edema as well as other signs of heart failure (e.g., jugular venous distention; see Chapter 25). The skin should be observed for rashes, petechiae, and ecchymoses. The sclera should be examined for icterus. In the event of a transfusion reaction, a comparison of findings can help differentiate between types of reactions.

Chart 28-2 **ETHICAL DILEMMA**

Can Surrogates Refuse Life-Saving Treatment?

Case Scenario

L.C. is a 34-year-old woman who was an unrestrained front-seat passenger in a motor vehicle crash 2 days ago. She sustained multiple trauma, including a fractured skull, traumatic brain injury, several fractured ribs, a pulmonary contusion, and a fractured right femur. After stabilization in the emergency department, she was admitted to the intensive care unit (ICU) endotracheally intubated and mechanically ventilated. You are a staff nurse in the ICU and have been assigned as L.C.'s nurse since her admission. You have come to know her family members, including her parents and her boyfriend, whom she has lived with for the past 10 months. During interdisciplinary rounds, L.C.'s trauma surgeon notes that her hemoglobin continues to drop since admission, and is now 7.7 g/dL; he asserts that she must receive blood transfusions. L.C.'s parents and her boyfriend are present during these rounds. L.C.'s parents tell the trauma surgeon that they are Jehovah's Witnesses, and that receiving blood transfusions is against their religious beliefs. L.C.'s boyfriend notes that she no longer adheres to the tenets of Jehovah's Witnesses and does not attend any religious meetings or services. L.C.'s parents become angry and tell her boyfriend that they are the ones to make decisions on L.C.'s behalf. L.C. does not have an advance directive or a power-of-attorney for health care.

Discussion

Whenever a patient lacks capacity to make their own health care decisions, those decisions are made by a legally identified surrogate. Had L.C. identified who that surrogate should be in a power-of-attorney for health care document, that person would have the rights and responsibilities to make those decisions. Since that document does not exist, and since L.C. does not have a spouse, her parents are her legal surrogates and authorized to make those decisions on her behalf.

Had L.C. written an advance directive and specified whether or not she would wish to receive blood transfusions for life-threatening contingencies, that specification would be legally binding. For instance, had she noted in an advance directive that she would *not* wish to receive blood transfusions, even if that meant that she would die, that would be a legally binding decision, even if her parents wished for her to receive blood transfusions.

However, L.C.'s parents and her boyfriend disagree about what they believe L.C. would want to be done in this situation. Surrogates are charged with making decisions on behalf of patients who lack capacity. However, that charge is predicated on the belief that surrogates know which decision is consistent with what the patient would have wanted when the patient could have made a reasoned decision. It is noteworthy that L.C.'s parents insist that she not be transfused since it is against *their* religious beliefs. However, they do not note that their beliefs are also consistent with L.C.'s beliefs.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Is it possible to preserve L.C.'s autonomy, given that she lacks capacity at this time, and given the conflict between her family members?
- There is a conflict between legal rights and moral decisions in this case. Are there situations where the decision that a legal surrogate makes for a patient who lacks capacity could and should be overturned?
- What if a family meeting is called to try to resolve the conflict between L.C.'s parents and her boyfriend, and her boyfriend is able to provide evidence that L.C. does not adhere to the tenets of the Jehovah's Witness faith? By contrast, what if her parents are able to provide evidence that L.C. has been faithfully attending Jehovah's Witnesses meetings for the past 10 months and that she has explicitly told her parents that she would not ever wish to have blood transfusions? Finally, what if L.C.'s parents and her boyfriend each express that none of them are certain what decision L.C. would make in this situation? Would the trauma surgeon be justified in then upholding the principle of beneficence and prescribe blood transfusions for L.C., despite her parents' objections? If those transfusions were prescribed, would you administer the blood transfusions or would you object?
- What resources might be mobilized to be of assistance to L.C.'s family and the health care team so that the decision that best respects L.C.'s wishes might be made?

Resources

See Chapter 1, Chart 1-10, for Steps of an Ethical Analysis and Ethics Resources.

Patient Education

Reviewing the signs and symptoms of a transfusion reaction is crucial with all patients, including those who have and have not received a previous transfusion. Signs and symptoms of a reaction include fever, chills, respiratory distress, low back pain, nausea, pain at the IV site, or anything "unusual." Although a thorough review is very important, the nurse also reassures the patient that the blood is carefully tested against the patient's own blood (cross-

matched) to diminish the likelihood of any untoward reaction. Similarly, the patient can be reassured about the very low possibility of contracting HIV from the transfusion; this fear persists among many people.

Transfusion Procedures

Methods for transfusing blood components and the role of the nurse in assessing patients before, during, and after these procedures are described in Charts 28-3 and 28-4.

Complications

Any patient who receives a blood transfusion is at risk for developing complications from the transfusion. Nursing management is directed toward preventing complications, promptly recognizing complications if they develop, and promptly initiating measures to control complications. Nurses assess patients' vital signs before, during, and after a blood transfusion is complete to screen for any adverse reactions; however, the optimal frequency for assessing these vital signs during the transfusion is not well established (Cortez-Gann, Gilmore, Foley, et al., 2017) (see the Nursing Research Profile in Chart 28-5). The following sections describe the most common or potentially severe transfusion-related complications.

Febrile Nonhemolytic Reaction

A febrile nonhemolytic reaction is caused by antibodies to donor leukocytes that remain in the unit of blood or blood component; it is the most common type of transfusion reaction (Stubbs, 2018). It occurs more frequently in patients who have had previous transfusions (exposure to multiple antigens from previous blood products) and in Rh-negative women who have borne Rh-positive children (exposure to an Rh-positive fetus raises antibody levels in the untreated mother).

Chart 28-3

Transfusion of Packed Red Blood Cells

Preprocedure

1. Confirm that the transfusion has been prescribed.
2. Check that patient's blood has been typed and cross-matched.
3. Verify that patient has signed a written consent form per institution or agency policy and agrees to procedure.
4. Explain procedure to patient. Educate patient about signs and symptoms of transfusion reaction (itching, hives, swelling, shortness of breath, fever, chills).
5. Take patient's temperature, pulse, respiration, blood pressure, and assess fluid volume status (e.g., auscultate lungs, assess for jugular venous distention) to serve as a baseline for comparison during transfusion.
6. Note if signs of increased fluid overload present (e.g., heart failure, see Chapter 25), contact primary provider to discuss potential need for a prescription for diuretic, as warranted.
7. Use hand hygiene and wear gloves in accordance with standard precautions.
8. Use appropriately sized intravenous cannula for insertion in a peripheral vein.[a] Use special tubing that contains a blood filter to screen out fibrin clots and other particulate matter. Do not vent blood container.

Procedure

1. Obtain packed red blood cells (PRBCs) from the blood bank *after* the IV line is started. (Institution policy may limit release to only 1 unit at a time.)
2. Double-check labels with another nurse or physician to ensure that the ABO group and Rh type agree with the compatibility record. Check to see that number and type on donor blood label and on patient's medical record are correct. Confirm patient's identification by asking the patient's name and checking the identification wristband.
3. Check blood for gas bubbles and any unusual color or cloudiness. (Gas bubbles may indicate bacterial growth. Abnormal color or cloudiness may be a sign of hemolysis.)
4. Make sure that PRBC transfusion is initiated within 30 minutes after removal of PRBCs from blood bank refrigerator.
5. For the first 15 minutes, run the transfusion slowly—no faster than 5 mL/min. Observe patient carefully for adverse effects. If no adverse effects occur during the first 15 minutes, increase the flow rate unless patient is at high risk for circulatory overload.
6. Monitor closely for 15 to 30 minutes to detect signs of reaction. Monitor vital signs at regular intervals per institution or agency policy; compare results with baseline measurements. Increase frequency of measurements based on patient's condition. Observe patient frequently throughout the

transfusion for any signs of adverse reaction, including restlessness, hives, nausea, vomiting, torso or back pain, shortness of breath, flushing, hematuria, fever, or chills. Should any adverse reaction occur, stop infusion immediately, notify primary provider, and follow the agency's transfusion reaction standard.

7. Note that administration time does not exceed 4 hours because of increased risk of bacterial proliferation.
8. Be alert for signs of adverse reactions: circulatory overload, sepsis, febrile reaction, allergic reaction, and acute hemolytic reaction.
9. Change blood tubing after every 2 units transfused to decrease chance of bacterial contamination.

Postprocedure

1. Obtain vital signs and breath sounds; compare with baseline measurements. If signs of increased fluid overload present (e.g., heart failure), consider obtaining prescription for diuretic as warranted.
2. Dispose of used materials properly.
3. Document procedure in patient's medical record, including patient assessment findings and tolerance to procedure.
4. Monitor patient for response to and effectiveness of procedure. If patient is at risk, monitor for at least 6 hours for signs of transfusion-associated circulatory overload (TACO); also monitor for signs of delayed hemolytic reaction.

Note: Never add medications to blood or blood products; if blood is too thick to run freely, normal saline may be added to the unit. If blood must be warmed, use an in-line blood warmer with a monitoring system.

[a]The size of the peripheral cannula used in a blood transfusion depends on two factors, size and integrity of the vein and desired speed for transfusion.

Adapted from Robinson, S., New, H., Shackleton, T., et al. (2018). The administration of blood components: A British Society for Haematology Guideline. *Transfusion Medicine, 28*(1), 3–21.

Chart 28-4

Transfusion of Platelets or Fresh-Frozen Plasma

Preprocedure

1. Confirm that the transfusion has been prescribed.
2. Verify that patient has signed a written consent form per institution or agency policy and agrees to procedure.
3. Explain procedure to patient. Educate patient about signs and symptoms of transfusion reaction (itching, hives, swelling, shortness of breath, fever, chills).
4. Take patient's temperature, pulse, respiration, blood pressure, and assess fluid status, and auscultate breath sounds to establish a baseline for comparison during transfusion.
5. Note if signs of increased fluid overload present (e.g., heart failure, see Chapter 25), contact primary provider to discuss potential need for a prescription for diuretic, as warranted; this is particularly important when plasma is also infused.
6. Use hand hygiene and wear gloves in accordance with standard precautions.
7. Use a 22-gauge or larger needle or catheter for placement in a large vein, if possible. Use appropriate tubing per institution policy (platelets often require different tubing from that used for other blood products).

Procedure

1. Obtain platelets or fresh-frozen plasma (FFP) from the blood bank (only *after* the IV line is started.)
2. Double-check labels with another nurse or physician to ensure that the ABO group matches the compatibility record (not usually necessary for platelets; here only if compatible platelets are ordered). Check to see that the number and type on donor blood label and on patient's medical record are correct. Confirm patient's identification by asking the patient's name and checking the identification wristband.
3. Check blood product for any unusual color or clumps (excessive redness indicates contamination with larger amounts of red blood cells).
4. Make sure that platelets or FFP units are given immediately after they are obtained.
5. Infuse each unit of FFP over 30 to 60 minutes per patient tolerance; be prepared to infuse at a significantly lower rate in the context of fluid overload. Infuse each unit of platelets as fast as patient can tolerate to diminish platelet clumping during administration. Observe patient carefully for adverse effects, especially circulatory overload. Decrease rate of infusion if necessary.
6. Observe patient closely throughout transfusion for any signs of adverse reaction, including restlessness, hives, nausea, vomiting, torso or back pain, shortness of breath, flushing, hematuria, fever, or chills. Should any adverse reaction occur, stop infusion immediately, notify primary provider, and follow the agency's transfusion reaction standard.

7. Monitor vital signs at the end of transfusion per institution policy; compare results with baseline measurements.
8. Flush line with saline after transfusion to remove blood component from tubing.

Postprocedure

1. Obtain vital signs and auscultate breath sounds; compare with baseline measurements. If signs of increased fluid overload present, consider obtaining prescription for diuretic, as warranted.
2. Dispose of used materials properly.
3. Document procedure in patient's medical record, including patient assessment findings and tolerance to procedure.
4. Monitor patient for response to and effectiveness of procedure. A platelet count may be ordered 1 hour after platelet transfusion to facilitate this evaluation.
5. If patient is at risk for transfusion-associated circulatory overload (TACO), monitor closely for 6 hours after transfusion if possible.

Note: FFP requires ABO but not Rh compatibility. Platelets are not typically cross-matched for ABO compatibility. Never add medications to blood or blood products.

Adapted from Robinson, S., New, H., Shackleton, T., et al. (2018). The administration of blood components: A British Society for Haematology Guideline. *Transfusion Medicine, 28*(1), 3–21.

The diagnosis of a febrile nonhemolytic reaction is made by excluding other potential causes, such as a hemolytic reaction or bacterial contamination of the blood product. The signs and symptoms of a febrile nonhemolytic transfusion reaction are chills (minimal to severe) followed by fever (more than 1°C elevation). The fever typically begins within 2 hours after the transfusion has begun. Although the reaction is not life threatening, the fever, and particularly the chills and muscle stiffness, can be frightening to the patient.

This reaction can be diminished, even prevented, by further depleting the blood component of donor leukocytes; this is accomplished by a leukocyte reduction filter. Antipyretic agents can be given to prevent fever; however, routine premedication is not advised because it can mask the beginning of a more serious transfusion reaction.

Acute Hemolytic Reaction

The most dangerous, and potentially life-threatening, type of transfusion reaction occurs when the donor blood is incompatible with that of the recipient (i.e., type II hypersensitivity reaction). Antibodies already present in the recipient's plasma rapidly combine with antigens on donor erythrocytes, and the erythrocytes are destroyed in the circulation (i.e., intravascular hemolysis).

The most rapid hemolysis occurs in ABO incompatibility. Rh incompatibility often causes a less severe reaction. This reaction can occur after transfusion of as little as 10 mL of PRBCs. Although the overall incidence of such reactions is not high (1:20,000 to 1:40,000 units transfused) (Robinson, New, Shackleton, et al., 2018), they are largely preventable. The most common causes of acute hemolytic reaction are errors in blood component labeling, a type of clerical error, and errors in patient identification that result in the administration of an ABO-incompatible transfusion.

Symptoms consist of fever, chills, low back pain, nausea, chest tightness, dyspnea, and anxiety. As the erythrocytes are destroyed, the hemoglobin is released from the cells and excreted by the kidneys; therefore, hemoglobin appears in the urine (hemoglobinuria). Hypotension, bronchospasm, and vascular collapse may result. Diminished renal perfusion results in acute kidney injury, and disseminated intravascular coagulation may also occur. The reaction must be recognized promptly and the transfusion discontinued immediately (see the Nursing Management of Transfusion Reactions section).

Chart 28-5 **NURSING RESEARCH PROFILE**

Blood Transfusions and Vital Sign Frequency

Cortez-Gann, J., Gilmore, K. D., Foley, K. W., et al. (2017). Blood transfusion vital sign frequency: What does the evidence say? *MEDSURG Nursing, 26*(2), 89–92.

Purpose

Nurses are responsible for assuring patient safety during a blood transfusion through effective monitoring of vital signs. When and how often to take vital signs varies, based upon institutional protocols. There are no evidence-based research findings that provide direction regarding optimal timing and frequency of vital sign monitoring for patients who receive blood transfusions. Therefore, the purpose of this research was to discover the relationship between vital sign findings and blood transfusion-associated adverse events in order to find patterns suggestive of optimal vital sign timing and frequency for patients receiving blood transfusions.

Design

A retrospective descriptive study was conducted in a 921-bed hospital where approximately 77,800 units of blood products were transfused during 2008 through 2012. Of those patients transfused during this time, 116 experienced a blood transfusion reaction. Using a medical record data collection tool, information from these 116 patients was collected including demographics, type of blood product administered, transfusion start and stop times, vital signs before, during, and after transfusion, symptomatology and treatment protocol for the transfusion reaction, and patient outcomes.

Findings

Packed red blood cells were the most commonly transfused product. Of the 116 sampled patients who experienced a transfusion reaction, 67% were over 60 years of age. The most common changes among vital signs were an increase in temperature, blood pressure, and heart rate. Six of the 116 patients with transfusion reactions experienced severe life-threatening complications from the blood transfusion, but none died from them. The average time from the start of transfusion to an adverse reaction was approximately 92 minutes, with the quickest documented response occurring 5 minutes after initiation of the transfusion and the most delayed reaction taking place 2 hours and 30 minutes after the start of the transfusion.

Nursing Implications

Hospitals endorse different protocols that dictate when and how often nurses take vital signs for patients who receive blood products. While it is commonly believed that the most likely time for a patient to experience a transfusion reaction is within the first 15 minutes after the start of a transfusion, findings from this study established an average time to the reaction of 1.5 hours, with the most severe reaction occurring 2 hours after initiation of the transfusion. Only one severe reaction in this study occurred during the first 15 minutes of

the transfusion period. Findings from this study suggest that nurses should take vital signs of patients receiving blood transfusions at periodic intervals during the entire timeframe that a patient receives a blood transfusion.

Acute hemolytic transfusion reactions are preventable. Meticulous attention to detail in labeling blood samples and blood components and accurately identifying the recipient cannot be overemphasized. Bar coding methods can be useful safeguards in matching a patient's wristband with the label on the blood component; however, these methods are not fail proof and do not reduce the nurse's responsibility to ensure the correct blood component is transfused to the correct patient (Robinson et al., 2018).

Allergic Reaction

Some patients develop urticaria (hives) or generalized itching during a transfusion; the cause is thought to be a sensitivity reaction to a plasma protein within the blood component being transfused. Symptoms of an allergic reaction are urticaria, itching, and flushing. The reactions are usually mild and respond to antihistamines. If the symptoms resolve after administration of an antihistamine (e.g., diphenhydramine), the transfusion may be resumed. Rarely, the allergic reaction is severe, with bronchospasm, laryngeal edema, and shock. These reactions are managed with epinephrine, corticosteroids, and vasopressor support, if necessary.

Giving the patient antihistamines or corticosteroids before the transfusion may prevent future reactions. For severe reactions, future blood components are washed to remove any remaining plasma proteins. Leukocyte filters are not useful to prevent such reactions, because the offending plasma proteins can pass through the filter.

Transfusion-Associated Circulatory Overload (TACO)

If too much blood is infused too quickly, hypervolemia can occur. This condition, known as transfusion-associated circulatory overload (TACO), can be aggravated in patients who already have increased circulatory volume (e.g., those with heart failure, renal dysfunction, advanced age, acute myocardial infarction) (Carman, Uhlenbrock, & McClintock, 2018). A careful assessment for signs of circulatory overload or positive fluid status prior to initiating the transfusion is required, particularly in patients at risk for developing transfusion-related acute lung injury (TRALI) (see discussion below). PRBCs are safer to use than whole blood. If the administration rate is sufficiently slow, circulatory overload may be prevented. For patients who are at risk for, or already in, circulatory overload, diuretics are given prior to the transfusion or between units of PRBCs. Patients receiving fresh-frozen plasma or even platelets may also develop circulatory overload. The infusion rate of these blood components must also be titrated to the patient's tolerance. Rates of

transfusion may need to decrease to less than 100 to 120 mL/h (Henneman, 2017).

Signs of circulatory overload include dyspnea, orthopnea, tachycardia, an increase in blood pressure, and sudden anxiety. Jugular vein distention, crackles at the base of the lungs, and hypoxemia will also develop. Pulmonary edema can quickly develop, as manifested by severe dyspnea and coughing of pink, frothy sputum.

If fluid overload is mild, the transfusion can often be continued after slowing the rate of infusion and administering diuretics. However, if the overload is severe, the patient is placed upright with the feet in a dependent position, the transfusion is discontinued, and the primary provider is notified. The IV line is kept patent with a very slow infusion of normal saline solution or a saline lock device to maintain access to the vein in case IV medications are necessary. Oxygen and morphine may be needed to treat severe dyspnea (see Chapter 25).

TACO can develop as late as 6 hours after transfusion (Henneman, 2017). Therefore, patients need close monitoring after the transfusion is completed, particularly those who are at higher risk for developing this complication (e.g., older adults, those with a positive fluid balance prior to transfusion, patients with renal dysfunction, patients with left ventricular dysfunction). Monitoring vital signs, auscultating breath sounds, and assessing for jugular venous distention should be included in patient monitoring.

Bacterial Contamination

The incidence of bacterial contamination of blood components is very low; however, administration of contaminated products puts the patient at great risk. Contamination can occur at any point during procurement or processing but often results from organisms on the donor's skin. Many bacteria cannot survive in the cold temperatures used to store PRBCs, but some organisms can. Platelets are at greater risk of contamination because they are stored at room temperature. In response to this, blood centers have developed rapid methods of culturing platelet units, thereby diminishing the risk of using a contaminated platelet unit for transfusion (CDC, 2019).

Preventive measures include meticulous care in the procurement and processing of blood components. When PRBCs or whole blood is transfused, it should be given within a 4-hour period, because warm room temperatures promote bacterial growth. A contaminated unit of blood product may appear normal, or it may have an abnormal color.

The signs of bacterial contamination are fever, chills, and hypotension. These manifestations may not occur until the transfusion is complete, and occasionally not until several hours after the transfusion. As soon as the reaction is recognized, any remaining transfusion is discontinued (see the Nursing Management of Transfusion Reactions section). If the condition is not

treated immediately with fluids and broad-spectrum antibiotics, sepsis can occur. Sepsis is treated with IV fluids and antibiotics; corticosteroids and vasopressors are often also necessary (see Chapter 11).

Transfusion-Related Acute Lung Injury (TRALI)

TRALI is a potentially fatal, idiosyncratic reaction that is defined as the development of acute lung injury occurring within 6 hours after the blood transfusion. All blood components have been implicated in TRALI, including IVIG, cryoprecipitate, and stem cells. TRALI is the most common cause of transfusion-related death (Heering & Karakashian, 2017).

The underlying pathophysiologic mechanism for TRALI is unknown but is thought to involve specific human leukocyte antigen (HLA) or human neutrophil antigen (HNA) antibodies in the donor's plasma that react to the leukocytes in the recipient's blood. Occasionally, the reverse occurs, and antibodies present in the recipient's plasma agglutinate the antigens on the few remaining leukocytes in the blood component being transfused. Another theory suggests that an initial insult to the patient's vascular endothelium can predispose the neutrophils to aggregate at the injured endothelium. Various substances within the transfused blood component (lipids, cytokines) then activate these neutrophils. Each of these pathophysiologic mechanisms can contribute to the process. The end result of this process is interstitial and intra-alveolar edema, as well as extensive sequestration of WBCs within the pulmonary capillaries (Heering & Karakashian, 2017).

Onset is abrupt (usually within 6 hours of transfusion, often within 2 hours). Signs and symptoms include acute shortness of breath, hypoxia (arterial oxygen saturation [SaO_2] less than 90%; partial pressure of arterial oxygen [PaO_2] to fraction of inspired oxygen [FIO_2] ratio of less than 300), hypotension, fever, and eventual pulmonary edema. Diagnostic criteria include hypoxemia, bilateral pulmonary infiltrates (seen on chest x-ray), no evidence of cardiac cause for the pulmonary edema, and no other plausible alternative cause within 6 hours of completing transfusion. Aggressive supportive therapy (e.g., oxygen, intubation, fluid support) may prevent death. Immunologic therapy (e.g., corticosteroids) has not been shown to be effective in this setting; diuretics can worsen the situation (Raja, Rahul, Kumar, et al., 2019).

Although TRALI can occur with the transfusion of any blood component, it is more likely to occur when plasma and, to a lesser extent, platelets are transfused. One commonly used preventive strategy involves limiting the frequency and amount of blood products transfused. Another entails obtaining plasma and possibly platelets only from men because women who have been pregnant may have developed offending antibodies. A third strategy involves screening donors for the presence of these antibodies and discarding any plasma-containing blood products from those donors who screen positive. The

efficacy of these approaches in preventing TRALI remains unclear (Otrock, Liu, & Grossman, 2017).

Delayed Hemolytic Reaction

Delayed hemolytic reactions usually occur within 14 days after transfusion, when the level of antibody has been increased to the extent that a reaction can occur (Siddon, Kenney, Hendrickson, et al., 2018). The hemolysis of the erythrocytes is extravascular via the RES and occurs gradually.

Signs and symptoms of a delayed hemolytic reaction are fever, anemia, increased bilirubin level, decreased or absent haptoglobin, and possibly jaundice. Rarely, there is hemoglobinuria. Generally, these reactions are not dangerous, but it is important to recognize them because subsequent transfusions with blood products containing these antibodies may cause a more severe hemolytic reaction. However, recognition is also difficult because the patient may not be in a health care setting to be tested for this reaction, and even if the patient is hospitalized, the reaction may be too mild to be recognized clinically. Because the amount of antibody present can be too low to detect, it is difficult to prevent delayed hemolytic reactions. Fortunately, the reaction is usually mild and requires no intervention (Siddon et al., 2018).

Disease Acquisition

Despite advances in donor screening and blood testing, certain diseases can still be transmitted by transfusion of blood components (see Chart 28-6).

Chart 28-6

Diseases Potentially Transmitted by Blood Transfusion

Hepatitis (Viral Hepatitis B, C)

- There is greater risk from pooled blood products and blood of paid donors than from volunteer donors.
- A screening test detects most hepatitis B and C.
- Transmittal risk for Hepatitis B is estimated at 1:350,000 donated units.

AIDS (HIV and HTLV)

- Donated blood is screened for antibodies to HIV.
- Transmittal risk is estimated at 1:1.5 million donated units.
- People with high-risk behaviors (multiple sex partners, anal sex, IV/injection drug use) and people with signs and symptoms that suggest AIDS should not donate blood.

Cytomegalovirus (CMV)

- Transmittal risk is greater for premature newborns with CMV antibody–negative mothers and for immunocompromised recipients who are CMV negative (e.g., those with acute leukemia, organ or tissue transplant recipients).
- Blood products rendered "leukocyte reduced" help reduce transmission of virus.

Graft-Versus-Host Disease (GVHD)

- GVHD occurs only in recipients who are severely immunocompromised (e.g., Hodgkin disease, bone marrow transplantation).
- Transfused lymphocytes engraft in recipient and attack host lymphocytes or body tissues; signs and symptoms are fever, diffuse reddened skin rash, nausea, vomiting, and diarrhea.
- Preventive measures include irradiating blood products to inactivate donor lymphocytes (no known radiation risks to transfusion recipient) and processing donor blood with leukocyte reduction filters.

Creutzfeldt–Jakob Disease (CJD)

- CJD is a rare, fatal disease that causes irreversible brain damage.
- There is no evidence of transmittal by transfusion.
- All blood donors must be screened for positive family history of CJD.
- Potential donors who spent a cumulative time of 5 years or more (January 1980 to present) in certain areas of Europe cannot donate blood; blood products from a donor who develops CJD are recalled.

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; HTLV, human T-lymphotropic virus.

Adapted from Katz, L. M., & Dodd, R. Y. (2018). Transfusion-transmitted diseases. In B. H. Shaz, C. D. Hillyer, & M. R. Gil (Eds.). *Transfusion medicine and hemostasis: Clinical and laboratory aspects* (3rd ed.). Cambridge, MA: Elsevier.

Complications of Long-Term Transfusion Therapy

The complications that have been described represent a real risk to any patient any time a blood component is given. However, patients with long-term transfusion requirements (e.g., those with myelodysplastic syndrome, thalassemia, aplastic anemia, sickle cell disease) are at greater risk for infection transmission and for becoming more sensitized to donor antigens, simply because they are exposed to more units of blood and, consequently, more donors. A summary of complications associated with long-term transfusion therapy is given in Table 28-5.

Iron overload is a complication unique to people who have had long-term PRBC transfusions. One unit of PRBCs contains 250 mg of iron. Patients with long-term transfusion requirements can quickly acquire more iron than they can use, leading to iron overload. Over time, the excess iron deposits in body tissues can cause organ damage, particularly in the liver, heart, testes, and pancreas. Promptly initiating a program of iron chelation therapy can prevent end-organ damage from iron toxicity (see Chapter 29, Hereditary Hemochromatosis, Nursing Management, and Chapter 30, Myelodysplastic Syndrome, Nursing Management).

Nursing Management of Transfusion Reactions

If a transfusion reaction is suspected, the transfusion must be stopped immediately, and the primary provider notified. A thorough patient assessment is crucial because many complications have similar signs and symptoms. The following steps are taken to determine the type and severity of the reaction:

TABLE 28-5 Common Complications Resulting from Long-Term Packed Red Blood Cell Transfusion Therapy[a]

Complication	Manifestation	Management
Infection	Hepatitis (B, C)	May immunize against hepatitis B; treat hepatitis C; monitor hepatic function
	CMV	WBC filters to protect against CMV
Iron overload	Heart failure Endocrine failure (diabetes, hypothyroidism, hypoparathyroidism, hypogonadism)	Prevent by chelation therapy
Transfusion reaction	Sensitization	Diminish by RBC phenotyping, using WBC-filtered products
	Febrile reactions	Diminish by using WBC-filtered products

[a]Patients with long-term transfusion therapy requirements are at risk not only for the transfusion reactions discussed in the text but also for the complications noted in the table. In many cases, the use of WBC-filtered (i.e., leukocyte-poor) blood products is standard for patients who receive long-term packed RBC transfusion therapy. An aggressive chelation program initiated early in the course of therapy can prevent problems with iron overload.

CMV, cytomegalovirus; RBC, red blood cell; WBC, white blood cell.

Adapted from Carman, M., Uhlenbrock, J. S., & McClintock, S. M. (2018). CE: A review of current practice in transfusion therapy. *The American Journal of Nursing*, *118*(5), 36–44.

- Stop the transfusion. Maintain the IV line with normal saline solution through new IV tubing, given at a slow rate.
- Assess the patient carefully. Compare the vital signs with baseline, including oxygen saturation. Assess the patient's respiratory status carefully. Note the presence of adventitious breath sounds; the use of accessory muscles; the extent of dyspnea; and changes in mental status, including anxiety and confusion. Note any chills, diaphoresis, jugular vein distention, and reports of back pain or urticaria.
- Notify the primary provider of the assessment findings and implement any treatments prescribed. Continue to monitor the patient's vital signs and respiratory, cardiovascular, and renal status.
- Notify the blood bank that a suspected transfusion reaction has occurred.
- Send the blood container and tubing to the blood bank for repeat typing and culture. The patient's identity and blood component identifying tags and numbers are verified.

If a hemolytic transfusion reaction or bacterial infection is suspected, the nurse does the following:

- Obtains appropriate blood specimens from the patient.
- Collects a urine sample as soon as possible to detect hemoglobin in the urine.
- Documents the reaction according to the institution's policy.

Pharmacologic Alternatives to Blood Transfusions

Pharmacologic agents that stimulate the production of one or more types of blood cells by the marrow are commonly used (see Chart 28-7). Researchers continue to seek a blood substitute that is practical and safe. Manufacturing artificial blood is problematic, given the myriad functions of blood components. Currently, there are two types of products in development: hemoglobin-based oxygen carriers and perfluorocarbons (which can dissolve gases and thus carry oxygen indirectly); none are approved for use in humans, to date (Adams, 2019).

Chart 28-7 **PHARMACOLOGY**

Pharmacologic Alternatives to Blood Transfusions

Growth Factors

Recombinant technology has provided a means to produce hematopoietic growth factors necessary for the production of blood cells within the bone marrow. By increasing the body's production of blood cells, transfusions and complications resulting from diminished blood cells (e.g., infection from neutropenia) may be avoided. However, the successful use of growth factors requires functional bone marrow. Moreover, the safety of these products has been questioned, and the U.S. Food and Drug Administration is limiting their use in some patient populations.

Erythropoietin

Erythropoietin (epoetin alfa; darbopoietin) is an effective alternative treatment for patients with chronic anemia secondary to diminished levels of erythropoietin, as in chronic kidney disease. This medication stimulates erythropoiesis. It also has been used for patients who are anemic from chemotherapy or zidovudine (AZT) therapy and for those who have diseases involving bone marrow suppression, such as myelodysplastic syndrome (MDS). The use of erythropoietin can also enable a patient to donate several units of blood for future use (e.g., preoperative autologous donation). The medication can be administered IV or subcutaneously, although plasma levels are better sustained with the subcutaneous route. Side effects are rare, but erythropoietin can cause or exacerbate hypertension. If the anemia is corrected too quickly or is overcorrected, the elevated hematocrit can cause headache and, potentially, seizures. Thrombosis has been noted in some patients whose hemoglobins were raised to a high level; thus, it is recommended that a target hemoglobin level of less than 12 g/dL be used. These adverse effects are rare except for patients with renal failure. Serial complete blood counts (CBCs) must be performed to evaluate the response to the medication. The dose and frequency of administration are titrated to the hemoglobin level.

Granulocyte Colony-Stimulating Factor (G-CSF)

G-CSF (filgrastim) is a cytokine that stimulates the proliferation and differentiation of myeloid stem cells; a rapid increase in neutrophils is seen within the circulation. G-CSF is effective in improving transient but severe neutropenia after chemotherapy or in some forms of MDS. It is particularly useful in preventing bacterial infections that would be likely to occur with neutropenia. G-CSF is given subcutaneously on a daily basis. The primary side effect is bone pain; this probably reflects the increase in hematopoiesis within the marrow. Serial CBCs should be performed to evaluate the response to the medication and to ensure that the rise in white blood cells is not excessive. The effect of G-CSF on myelopoiesis is short; the neutrophil count drops once the medication is stopped.

Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF)

GM-CSF (sargramostim) is a cytokine that is naturally produced by a variety of cells, including monocytes and endothelial cells. It works either directly or synergistically with other growth factors to stimulate myelopoiesis. GM-CSF is not as specific to neutrophils as is G-CSF; thus, an increase in erythroid (red blood cell) and megakaryocytic (platelet) production may also be seen. GM-CSF serves the same purpose as G-CSF. However, it may have a greater effect on macrophage function and therefore may be more useful against fungal infections, whereas G-CSF may be better used to fight bacterial infections. GM-CSF is also given subcutaneously. Side effects include bone pain, fevers, and myalgias.

Thrombopoietin

Thrombopoietin (TPO) is a cytokine that is necessary for the proliferation of megakaryocytes and subsequent platelet formation. Nonimmunogenic second-generation thrombopoietic growth factors (romiplostim; eltrombopag) are used for the treatment of idiopathic thrombocytopenic purpura. Eltrombopag is also approved for use in certain situations for patients with aplastic anemia and in patients requiring hepatitis C treatment that can cause significant thrombocytopenia.

CRITICAL THINKING EXERCISES

1 pq A 40-year-old female is receiving one unit of packed red blood cells after admission for trauma as a result of an automobile injury. She is alert and responsive but lost a large amount of blood and presented with a hematocrit of 28% and a hemoglobin of 10 mg/dL. The blood has been transfusing for approximately 15 minutes when the patient complains of a headache and feeling "achy." Her pulse is 96 bpm, respirations 20 per minute, blood pressure 128/76, and temperature 37.8°C (100.2°F). A nursing co-worker tells you this is a transfusion reaction, and you should stop the transfusion immediately. How would you respond to the nursing co-worker? What would you prioritize as the first three nursing actions most appropriate for this patient?

2 ebp You are a nurse working in a community health clinic and today during a vaccination health fair a 70-year-old male patient presents for varicella and Td/Tdap vaccines. You notice on his health history that he had a blood transfusion 2 months prior during a total hip replacement procedure. Based on this history, would you advise this patient to accept both vaccinations, varicella only, Td/Tdap only, or no vaccines? What is the strength of the evidence supporting the role of vaccinations in patients who have received blood transfusions? Which interprofessional resources and team members would you consult to help determine the best decision for this patient?

29 Management of Patients with Nonmalignant Hematologic Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Differentiate between hypoproliferative and hemolytic anemias and compare the physiologic mechanisms, clinical manifestations, medical management, and nursing interventions for each.
2. Describe the processes involved in neutropenia and lymphopenia and the principles involved in medical and nursing management of patients with these disorders.
3. Specify the etiologies and the medical and nursing management of patients with secondary polycythemias and bleeding and thrombotic disorders.
4. Use the nursing process as a framework for care of the patient with anemia, with sickle cell disease, or with disseminated intravascular coagulation.

NURSING CONCEPTS

Cellular Regulation
Clotting
Perfusion

GLOSSARY

absolute neutrophil count (ANC): a calculation of the number of circulating neutrophils, derived from the total number of white blood cells (WBCs) and the percentage of neutrophils counted in a microscope's visual field

anemia: decreased red blood cell (RBC) count

aplasia: lack of cellular development (e.g., of cells within the bone marrow)

cytokines: proteins produced by leukocytes that are critical for regulation of hematopoiesis, apoptosis, and immune responses

erythrocyte: a cellular component of blood essential to the transport of oxygen and carbon dioxide (*synonym*: RBC)

erythroid cells: any cell that is or will become a mature RBC

erythropoietin: hormone produced primarily by the kidneys in response to cellular hypoxia that is necessary for erythropoiesis

haptoglobin: blood protein synthesized by the liver; binds free hemoglobin released from erythrocytes which is then removed by the reticuloendothelial system

hemolysis: destruction of RBCs with release of cellular components into the circulation; may occur within or outside the vasculature

hemosiderin: iron-containing pigment derived from the breakdown of hemoglobin

hypochromia: pallor within the RBCs caused by decreased hemoglobin content

leukemia: uncontrolled proliferation of WBCs

lymphopenia: a lymphocyte count less than 1500/mm^3

megaloblastic anemia: a type of anemia characterized by abnormally large, nucleated RBCs

microcytosis: smaller-than normal RBCs

neutropenia: lower-than-normal number of neutrophils

normochromic: normal RBC color, indicating normal amount of hemoglobin

normocytic: normal size of RBC

pancytopenia: abnormal decrease in WBCs, RBCs, and platelets

petechiae: tiny capillary hemorrhages

poikilocytosis: variation in shape of RBCs

polycythemia: excess RBCs

reticulocytes: slightly immature RBCs, usually 1% of total number of circulating RBCs

spherocytes: small, spherically shaped RBCs

thrombocytopenia: lower-than-normal platelet count

thrombocytosis: higher-than-normal platelet count

Hematologic disorders vary widely in their etiologies and manifestations. While some are malignant, most hematologic disorders are benign. Disease processes can be quite complex, so a comprehensive understanding of the processes involved is important so that nurses may effectively assess, intervene, monitor, and educate patients about their conditions.

Anemia

Anemia is a condition characterized by a lower-than-normal hemoglobin concentration. Fewer than the normal number of red blood cells (RBCs), also called **erythrocytes**, are present in the circulation. Subsequently, less oxygen reaches the tissues, causing a variety of signs and symptoms. Rather than a disease state, anemia is a sign of an underlying disorder. It is the most common of all hematologic conditions and is prevalent throughout the world (Bunn, 2017a; Nair, 2018).

Pathophysiology

Anemia is classified in several ways (see Table 29-1). Most often it is classified according to whether the decreased number of erythrocytes is associated with hypoproliferation (decreased production), hemolysis (increased destruction), or loss of cells through bleeding.

Hypoproliferative anemias occur when the bone marrow produces an inadequate number of erythrocytes. Decreased erythrocyte production results in a low or inappropriately normal **reticulocyte** (i.e., immature RBC) count. Causes of hypoproliferative anemia may include bone marrow damage from chemicals (e.g., benzene) or medication (e.g., chloramphenicol), lack of important factors that promote erythrocyte production such as **erythropoietin**, or lack of nutrients, including iron, vitamin B_{12} and folic acid.

In hemolytic anemias, premature destruction of erythrocytes results in the liberation of hemoglobin from the erythrocytes into the plasma; the released hemoglobin is converted in large part to bilirubin and, therefore, the bilirubin concentration rises. The increased erythrocyte destruction leads to tissue hypoxia, which in turn stimulates erythropoietin production. This increased production is reflected in an increased reticulocyte count as the bone marrow responds to the loss of erythrocytes. **Hemolysis** (destruction of RBCs with release of cellular components into the circulation) can result from an abnormality within the erythrocyte itself (e.g., sickle cell disease [SCD], glucose-6-phosphate dehydrogenase [G-6-PD] deficiency), within the plasma

(e.g., immune hemolytic anemias), or from direct injury to the erythrocyte within the circulation (e.g., hemolysis caused by a mechanical heart valve). Chart 29-1 identifies causes of hemolytic anemias.

It is often possible to determine the cause of anemia in each patient based on the following factors:

- The ability of the bone marrow to respond to the decrease in erythrocytes by producing reticulocytes.
- The degree to which immature erythrocytes proliferate in the bone marrow and their ability to mature (as seen in a bone marrow biopsy).

TABLE 29-1 Classification of Anemias

Type of Anemia	Laboratory Findings	
	CBC	Other
Hypoproliferative (Resulting from Defective RBC Production)		
Iron deficiency (microcytic)	↓ MCV, ↓ reticulocytes	↓ Iron, % saturation, ferritin ↑ TIBC
Vitamin B_{12} deficiency (megaloblastic)	↑ MCV	↓ Vitamin B_{12}
Folate deficiency (megaloblastic)	↑ MCV	↓ Folate
Decreased erythropoietin production (e.g., from chronic kidney disease)	Normal MCV	↓ Erythropoietin level ↑ Creatinine ↑ Ferritin, % saturation
Cancer/inflammation	Normal MCV	↓ Iron, TIBC ↓ Erythropoietin level (usually)
Bleeding (Resulting in RBC Loss)		
Bleeding from gastrointestinal tract, epistaxis (nosebleed), trauma, bleeding from genitourinary tract (e.g., menorrhagia)	↓ Hgb and Hct (*Note:* Hgb and Hct may be normal if measured soon after bleeding starts) ↓ MCV (normal MCV initially) ↑ Reticulocytes	↓ Iron, % saturation, ferritin (later)
Hemolytic (Resulting from RBC Destruction)		
Altered erythropoiesis (sickle cell disease, thalassemia, other hemoglobinopathies)	↓ MCV ↑ Reticulocytes Fragmented RBCs (various shapes)	
Hypersplenism (hemolysis)	↑ MCV	
Drug-induced anemia	↑ Presence of spherocytes	
Autoimmune anemia	↑ Presence of spherocytes	
Mechanical heart valve–related anemia	Fragmented red cells	

↓, decreased; ↑, increased; %, percent; CBC, complete blood count; Hct, hematocrit; Hgb, hemoglobin; MCV, mean corpuscular volume; RBC, red blood cell; TIBC, total iron-binding capacity.

Chart 29-1

Causes of Hemolytic Anemias

Inherited Hemolytic Anemia

Sickle cell disease
Thalassemia

Red Blood Cell Membrane Abnormality

Acanthocytosis
Hereditary elliptocytosis
Hereditary spherocytosis
Stomatocytosis

Enzyme Deficiencies

Glucose-6-phosphate dehydrogenase deficiency

Acquired Hemolytic Anemia

Antibody Related

Autoimmune hemolytic anemia
Iso-antibody/transfusion reaction
Cold agglutinin disease

Not Antibody Related

Disseminated intravascular coagulation
Hypersplenism
Infection
  Bacterial
  Parasitic
Liver disease
Mechanical heart valve
Microangiopathic hemolytic anemia
Paroxysmal nocturnal hemoglobinuria
Toxins
Trauma
Uremia

- The presence or absence of end products of erythrocyte destruction in the circulation (e.g., increased bilirubin level, decreased haptoglobin level).

Clinical Manifestations

Several factors influence the development of symptoms associated with anemia. The severity of the anemia, the rapidity with which the anemia developed, the duration (chronicity) of the anemia, metabolic requirements of the patient, the presence of other conditions, such as cardiac or pulmonary disease, and complications or related features of the condition that produced the anemia are some of these factors.

In general, the more quickly the anemia develops, the more severe the symptoms (Bunn, 2017a). An otherwise healthy patient may be able to tolerate as much as a 50% reduction in hemoglobin over several months without pronounced symptoms or significant incapacity; however, a rapid loss of 30% of the hemoglobin over minutes may lead to profound vascular collapse in the same person. A patient who gradually becomes anemic, such as a woman experiencing heavy menses over several months with hemoglobin levels between 9 and 11 g/dL, may have few or no symptoms except for slight tachycardia on exertion or fatigue.

People who are more active or who have significant life demands are more likely to have symptoms than those who are more sedentary. Patients with hypothyroidism with decreased oxygen demands may be asymptomatic without tachycardia or dyspnea with a hemoglobin of 10 g/dL. Similarly, those with co-existing cardiac, vascular, or pulmonary disease may develop pronounced symptoms of anemia (e.g., dyspnea, chest pain, muscle pain, or cramping) with a higher hemoglobin level than those without concurrent health problems. Some anemias, such as SCD, or autoimmune diseases are often complicated by other abnormalities that do not result from the anemia but are inherent with the associated disease. Pain and other symptoms may overshadow those caused by the anemia.

Complications of severe anemia include heart failure, paresthesias, and delirium. Patients with underlying heart disease are more likely to have angina and symptoms associated with heart failure than those without heart disease. Complications of specific types of anemia are included in the description of each type.

Assessment and Diagnostic Findings

A number of studies are performed to determine the type and cause of the anemia. Initial evaluation includes hemoglobin, hematocrit, reticulocyte count, and RBC indices, including mean corpuscular volume (MCV), and red cell distribution width (RDW). Other studies may include iron studies (serum iron level, total iron-binding capacity [TIBC], percent saturation, and ferritin), serum vitamin B_{12}, folate levels, haptoglobin, and erythropoietin levels (Elder, Winland-Brown, & Porter, 2019; Nair, 2018). The remaining complete blood count (CBC) values are also useful in determining if the anemia is an isolated condition or associated with another hematologic condition such as **leukemia**

(i.e., malignancy of the WBCs) or myelodysplastic syndrome (MDS). Bone marrow aspiration may be performed to asses for cellular abnormalities. Additional studies such as colonoscopy or upper endoscopy may be performed to determine if underlying conditions causing the anemia are present. Lesions in the gastrointestinal (GI) tract including ulcers, polyps, or tumors may be sources of blood loss.

Medical Management

Management of anemia is directed toward correcting or controlling the cause of the anemia; if the anemia is severe, the erythrocytes that are lost or destroyed may be replaced with a transfusion of packed red blood cells (PRBCs). Management of the various types of anemia is covered in the discussions that follow.

Gerontologic Considerations

Anemia is the most common hematologic condition affecting older adults, particularly those admitted to hospitals and in long-term care facilities. The overall prevalence of anemia is 17% in older adults, including approximately 10% of community-dwelling older adults, 45% of nursing homes residents, and 40% of those who are hospitalized. Most have mild anemia with hemoglobin level of 11 g/dL or higher, but even mild anemia may be associated with decreased functional ability and increased morbidity and mortality. Mild anemia in older adults is associated with decreased physical performance, decreased mobility, increased frailty, increased depression, increased risk of falls, and delirium (Lanier, Park, & Callahan, 2018). Studies have identified an association between anemia and cognitive decline. Older adults with anemia are more likely to have fatigue, dyspnea, and confusion because of reduced cardiac reserve and inability to respond with an increase in heart rate and increased cardiac output. Those with preexisting renal and cardiac disease and those who have had recent surgery are at increased risk for morbidity and mortality when anemic (Stauder, Valent, & Theurl, 2018).

NURSING PROCESS

The Patient with Anemia

Assessment

The health history and physical examination provide important data about the type of anemia involved, the extent and type of symptoms it produces, and the impact of the symptoms on the patient's life. Weakness, fatigue, and general malaise are common symptoms, and pallor of the skin and mucous membranes (conjunctivae, oral mucosa) are common signs (Fig. 29-1).

Jaundice, angular cheilitis (inflammation and fissures in the corners of the mouth), and brittle, concave, ridged nails may be associated with **megaloblastic anemia** (characterized by abnormally large, nucleated RBCs) or hemolytic anemia. The tongue may be sore and beefy red in megaloblastic anemia, and smooth and red with iron deficiency anemia. Patients with iron deficiency anemia often experience pica, a craving for ice, starch, or dirt (Cadet, 2018). Restless leg syndrome is also common among those with iron deficiency anemia (Van Wyk, 2018). The health history should include a medication history because some medications may depress bone marrow activity, induce hemolysis, interfere with folate metabolism, or cause GI irritation that leads to bleeding. An accurate social history should include alcohol intake, noting the amount consumed and the duration of alcohol use. Family history is also important since some types of anemia are inherited. The nurse should also inquire about athletic endeavors since extreme forms of exercise such as marathon running may influence erythropoiesis and erythrocyte survival (Leung, 2019).

A nutritional assessment is needed because it may indicate deficiencies in essential nutrients such as iron, vitamin B_{12}, and folate. People who follow strict vegetarian diets and do not supplement with vitamin B_{12} are at risk for megaloblastic anemia. Older adults may also have decreased intake of foods rich in vitamin B_{12} or folate.

Cardiac status should be assessed carefully. When hemoglobin levels are low, the heart attempts to compensate by pumping faster and harder to deliver more oxygen to hypoxic tissue. This increased cardiac workload can result in symptoms including tachycardia, palpitations, dizziness, orthopnea, and exertional dyspnea. Heart failure may eventually develop, evidenced by cardiomegaly (an enlarged heart), hepatomegaly (an enlarged liver), and peripheral edema.

GI assessment may reveal complaints of nausea, vomiting (with specific questions regarding the appearance of any emesis [e.g., looks like "coffee grounds"]), melena (dark stools), diarrhea, anorexia, and glossitis (inflammation of the tongue). Stool should be tested for occult blood.

Women should be asked about their menstrual periods (e.g., excessive flow, other vaginal bleeding) and the use of iron and vitamin supplements during pregnancy. Neurologic examination is important because pernicious anemia with vitamin B_{12} deficiency affects the function of the central and peripheral nervous systems (see later discussion). Examination should include assessment for the presence and extent of peripheral numbness and paresthesia, ataxia, impaired coordination, and confusion. Delirium can sometimes result from other types of anemia, particularly in older adults. It is important to monitor relevant laboratory results over time and note any changes (see Chapter 28).

Diagnosis

Nursing Diagnoses

Based on assessment data, major nursing diagnoses may include:

- Fatigue associated with decreased hemoglobin and diminished oxygen-carrying capacity of the blood
- Impaired nutritional status associated with inadequate intake of essential nutrients
- Activity intolerance associated with inadequate hemoglobin and hematocrit
- Impaired ability to manage regime associated with prescribed therapy

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Heart failure
- Paresthesias
- Confusion
- Injury associated with falls

Planning and Goals

The major goals for the patient with anemia include decreased fatigue, attainment or maintenance of adequate nutrition, attainment or maintenance of adequate tissue perfusion, effective management of prescribed treatment plan, and absence of complications.

Nursing Interventions

Managing Fatigue

The most common symptom and complication of anemia is fatigue. Fatigue is often the symptom with the greatest negative impact on the patient's ability to function and subsequent quality of life. Fatigue is often described as overwhelming or oppressive. The sensation of fatigue may be severe even when the anemia is not severe enough to warrant transfusion. Fatigue may interfere with the patient's ability to engage in work as well as pleasurable activities with family and friends. Significant distress can stem from the inability to meet life's demands and responsibilities and the need to rely on others for assistance.

Nursing interventions can focus on assisting the patient to prioritize activities to establish a balance between activity and rest that is acceptable to the patient. Patients with chronic anemia will need assistance in establishing a program of activity and exercise to avoid deconditioning associated with inactivity. It is also important to assess for other conditions that may contribute to fatigue, such as pain, depression, and sleep disturbances.

Maintaining Adequate Nutrition

Inadequate intake of essential nutrients, including iron, vitamin B_{12}, folic acid and protein, can cause some forms of anemia. The symptoms associated with anemia (fatigue, anorexia) can interfere with maintaining adequate nutritional intake. A well-balanced diet should be encouraged. The nurse should advise the patient that alcohol can interfere with utilization of some essential nutrients and recommend limited alcohol intake (Stouten, Riedel, Droogendijk, et al., 2016). Dietary education involving family members when possible should be individualized to address specific needs and include cultural preferences for food preparation and selection (see Chapter 4). Dietary supplements (e.g., vitamins and iron) may be prescribed.

Equally important, the patient and family need to understand the role of nutritional supplements in the proper context. Some forms of anemia are not associated with nutritional deficiency. In some cases, excessive use of supplements will not improve the anemia and may be harmful. For example, patients with anemia who receive long-term transfusion therapy are at risk for iron overload from their transfusions. In this situation chelation therapy is implemented to reduce accumulation of excess iron (Murray, De Gelder, Pringle, et al., 2016; see Chapter 30 for discussion of chelation therapy). The use of oral iron supplements may exacerbate the situation.

Managing Activity Intolerance

Patients with severe anemia, with acute blood loss from hemorrhage or severe hemolysis, may not tolerate decreased blood volume or reduced circulating erythrocytes. Lost volume can be replaced with transfusions or intravenous fluids based on symptoms and laboratory test results. Supplemental oxygen may be needed, especially if there is underlying cardiac or pulmonary disease. Monitoring the patient's vital signs and pulse oximetry, especially with activity, is an important nursing action. Medications, including antihypertensive drugs, may need to be adjusted or withheld based on the patient's vital signs.

Promoting Effective Management of Prescribed Therapy

Medications, including nutritional supplements, are frequently prescribed for patients with anemia. It is important that patients understand the purpose of these therapies, how to take them, and how to manage side effects of treatment. Nurses play an important role in promoting adherence to the prescribed plan by educating patients and family caregivers about ways to incorporate the therapeutic plan in daily activities. For example, side effects of oral iron supplements including GI distress may make adherence to treatment difficult for some patients and may contribute to some patients stopping treatment. Nurses can provide important education

and support to assist patients to cope with side effects. Abrupt cessation of some medications, including high-dose steroids for treatment of hemolytic anemia, can have serious consequences for patients. The cost of some medications, such as hematologic growth factors, can be quite high. Patients requiring these medications may need assistance to find alternative ways to obtain the necessary medication. Nurses may need to collaborate with social workers or other health care team members to assist patients in meeting these needs.

Monitoring and Managing Potential Complications

A significant complication of anemia is heart failure associated with chronic diminished blood volume and the heart's compensatory effort to increase cardiac output. Patients with anemia should be assessed for signs and symptoms of heart failure (see Chapter 25).

In megaloblastic anemias associated with folate or vitamin B_{12} deficiency, there is potential for neurologic complications. Neurologic assessment of patients with megaloblastic anemia should be performed. Patients may complain of paresthesias, often manifested by numbness and, as the anemia progresses, symptoms worsen and other signs become apparent. Position and vibration sense may be diminished. Difficulty maintaining balance and gait disturbances may occur. Mental status changes, beginning with confusion and progressing to more severe memory changes and delirium can occur with severe folate or vitamin B_{12} deficiency (Elder et al., 2019).

Evaluation

Expected patient outcomes may include:

1. Reports less fatigue
    a. Follows a graduated plan of rest, activity, and exercise
    b. Prioritizes activities
    c. Paces activities according to energy level
2. Attains and maintains adequate nutrition
    a. Eats a healthy diet
    b. Develops a meal plan that promotes optimal nutrition
    c. Maintains appropriate amounts of iron, vitamins, and protein from diet and supplements
    d. Adheres to nutritional supplements when prescribed
    e. Verbalizes understanding of rationale for using recommended nutritional supplements when prescribed
    f. Verbalizes understanding of rationale for avoiding nonrecommended nutritional supplements
3. Maintains appropriate activity level

a. Vital signs will be within baseline for patient
b. Pulse oximetry value within normal limits

4. Absence of complications
   a. Avoids or limits activities that trigger dyspnea, palpitations, dizziness, or tachycardia
   b. Uses rest and comfort measures to relieve dyspnea
   c. Has vital signs within baseline for patient
   d. Has no signs of increased fluid retention (e.g., peripheral edema, decreased urine output, neck vein distention)
   e. Remains oriented to time, place, and situation
   f. Verbalizes understanding of importance of serial CBC and other laboratory test measurements
   g. Maintains safe home environment; obtains and uses assistance as necessary

Hypoproliferative Anemias

The hypoproliferative anemias include iron deficiency anemia, anemias in renal disease, anemia of inflammation, aplastic anemia, and megaloblastic anemias.

Iron Deficiency Anemia

Iron deficiency anemia results when the intake of dietary iron is inadequate for synthesis of hemoglobin. The body is able to store about one fourth to one third of its iron requirements, and it is not until those stores are depleted that iron deficiency anemia develops. Iron deficiency anemia may occur when total body iron stores are adequate, but the amount of iron delivered to the erythroid precursors is inadequate. This is referred to as functional iron deficiency (Hashemi, Mashhadi, Mohammadi, et al., 2017). Iron deficiency anemia is the most common type of anemia in all age groups, and it is the most common form of anemia worldwide, affecting as many as one in eight people (Bunn & Heeney, 2017). It is especially prevalent in developing countries where iron stores may be chronically depleted because of lack of sources for iron-rich foods and from blood loss associated with intestinal parasites (Harper, Besa, & Conrad, 2019).

Iron deficiency anemia is also common among adults in the United States, with the most common cause being blood loss. Blood loss should always be considered as the cause of iron deficiency anemia until proven otherwise. The most common cause of this anemia in men and postmenopausal women is GI bleeding from ulcers, gastritis, tumors, or inflammatory bowel disease. The

most common causes of iron deficiency anemia in premenopausal women are menorrhagia (i.e., excessive menstrual bleeding) and pregnancy with inadequate iron intake. Patients with chronic alcohol abuse and patients who take aspirin, steroids, or nonsteroidal anti-inflammatory drugs (NSAIDs) may have chronic blood loss from the GI tract, leading to iron loss and subsequent anemia. Other causes include iron malabsorption, as seen after gastrectomy or bariatric surgery, or from celiac disease and inflammatory bowel diseases (Harper et al., 2019).

Clinical Manifestations

Patients with iron deficiency primarily have symptoms of anemia. If the deficiency is severe or prolonged, they may also have a smooth, red tongue; brittle and ridged nails; and angular cheilosis. These signs subside after iron replacement therapy. The health history may be significant for multiple pregnancies, GI bleeding, and pica (Camaschella, 2019).

Assessment and Diagnostic Findings

The definitive method of establishing the diagnosis of iron deficiency anemia is bone marrow aspiration (see Chapter 28 for further discussion of bone marrow aspiration). The aspirate is stained to detect iron, which is at a low level or even absent. However, few patients with suspected iron deficiency anemia undergo bone marrow aspiration. In many patients, the diagnosis can be established with other tests, particularly in patients with a history of conditions that predispose them to this type of anemia.

A strong correlation exists between laboratory values that measure iron stores and hemoglobin levels. After iron stores are depleted (as reflected by low serum ferritin levels), the hemoglobin level falls. The diminished iron stores cause small erythrocytes to be produced by the marrow. Therefore, as the anemia progresses, the MCV, which measures the size of the erythrocytes, also decreases. Hematocrit and RBC levels are also low in relation to the hemoglobin level. Other laboratory tests that measure iron stores are useful but not as precise as ferritin levels. Typically, patients with iron deficiency anemia have a low serum iron level and an elevated TIBC, which measures the transport protein supplying the marrow with iron as needed (also referred to as transferrin) (Camaschella, 2019). However, other disease states, such as infection and inflammatory conditions, can also cause a low serum iron level and TIBC, as well as an elevated ferritin level. If these are suspected, measuring the soluble transferring receptor can aid in differentiating the cause of anemia. This test result will be increased in the setting of iron deficiency, but not in chronic inflammation (Camaschella, 2019).

Medical Management

Oral iron supplementation is often the primary mode of treatment for iron deficiency anemia. Several oral iron preparations, including ferrous sulfate, ferrous gluconate, and ferrous fumarate, are available. Ferric maltol, another oral preparation, was approved by the U.S. Food and Drug Administration (FDA) in 2019 for use in iron deficiency anemia in those with inflammatory bowel disease. After taking oral iron preparations, hemoglobin typically begins to increase within a few weeks and the anemia may be corrected within a few months. Replenishing iron stores takes several months so it is important that patients continue taking oral iron supplements for 6 to 12 months. If oral iron is poorly absorbed or poorly tolerated, or large amounts of supplemental iron are needed, intravenous (IV) iron may be given in repeated doses (see Chart 29-2). Initial evidence has shown that ferric maltol is not inferior to parenteral iron and may be an alternative for patients who cannot tolerate other oral preparations or do not wish to have parenteral iron; however, it is unknown whether use of ferric maltol will decrease demands for parenteral iron preparations (Harper et al., 2019).

Chart 29-2

Parenteral Iron Formulations

- Older formulations of parenteral iron had a high molecular weight and carried a significant risk for hypersensitivity reactions, including anaphylaxis. Newer formulations have a low molecular weight and a markedly lower risk for anaphylaxis.
- Ferric gluconate: Each 5 mL contains 62.5 mg of elemental iron; 125 mg is diluted in 100-mL normal saline and infused over 1 hour, or 5 mL undiluted is given as a slow IV push injection over 5 minutes. Although the likelihood of an allergic reaction is very low, a test dose is often given prior to the first infusion.
- Iron sucrose: Each 5 mL contains 100 mg of elemental iron; 100 to 200 g can be given, undiluted, as a slow IV push over 2 to 5 minutes. This procedure can be repeated as often as every 3 days for a cumulative dose of 1000 mg within a 2-week period.
- Ferumoxytol injection: The 17 mL vial is diluted in 50 to 200 mL of normal saline or 5% dextrose and water and infused over 15 minutes. Close observation for signs and symptoms of hypersensitivity reaction, including monitoring blood pressure and pulse, is recommended.

Nursing Management

Preventive education is important for women who are menstruating and for those who are pregnant. Food sources rich in iron include organ meats (e.g., beef or calf's liver, chicken liver), other meats, beans (e.g., pinto, black, and garbanzo beans), leafy green vegetables, raisins, and molasses. Eating iron-rich foods with a source of vitamin C (e.g., orange juice) improves iron absorption.

The nurse assists the patient in selecting healthy diet options. Nutritional counseling can be provided for those who have an inadequate diet. Patients with history of strict vegetarian or other diets lacking in essential nutrients should be counseled about how to meet their dietary needs. The nurse also encourages the patient to continue the prescribed therapy for as long as needed to replenish iron stores even when fatigue and other symptoms have resolved.

Oral iron is best absorbed on an empty stomach, making it important for patients to be instructed to take the supplement approximately 1 hour before or 2 hours after meals. The least expensive, standard form of oral iron, ferrous sulfate, is tolerated by most patients. GI side effects, including constipation, cramping, nausea, and vomiting may result in difficulty adhering to the prescribed regimen. Decreasing the frequency of administration or taking iron supplements with food may reduce symptoms but will diminish iron absorption, thus, it may take longer to replete iron stores. Taking iron with vitamin C can enhance absorption, but it may also increase the frequency of side effects (Heffernan, Evans, Holmes, et al., 2017). Some iron formulations have been designed to limit GI side effects by adding stool softeners to reduce constipation or sustained release formulations to reduce gastritis and nausea. However, enteric-coated tablets may be poorly absorbed. Slow release formulations are absorbed beyond the duodenum; however, the duodenum is the site where maximum iron absorption takes place (Auerbach & Adamson, 2016). Educational materials to assist patients with use of iron supplements are available (see Chart 29-3).

Chart 29-3 **PATIENT EDUCATION**

Taking Oral Iron Supplements

The nurse instructs the patient to:

- Take iron on an empty stomach (1 hour before or 2 hours after a meal), preferably with orange juice or other source of vitamin C. Iron absorption is reduced by food, especially dairy products.
- Reduce gastrointestinal distress by using the following schedule when more than one tablet per day is prescribed: Take one tablet per day for the first few days, then increase to two tablets per day, then three tablets per day in divided doses. This allows gradual adjustment to the iron. If unable to tolerate oral supplements due to gastrointestinal distress despite using this intervention, a reduced amount of iron may be used rather than stopping it completely. Reduced doses will require that the treatment duration is extended to adequately replenish iron stores.
- Increase intake of foods rich in vitamin C to enhance iron absorption (citrus fruits and juices, strawberries, tomatoes, broccoli).
- Note that stool will be dark in color and often appear black.
- Eat foods high in fiber to reduce problems with constipation. A stool softener may be needed.
- Be aware that liquid iron preparations may stain the teeth. They may be taken through a straw or by placing the spoon at the back of the mouth. Rinse the mouth thoroughly after each dose.

If taking iron on an empty stomach causes GI distress, the patient may need to take it with meals. However, this may reduce absorption by as much as 40%, therefore increasing the time needed to replenish iron stores. Antacids and dairy products should be avoided with iron as they can greatly diminish its absorption. Polysaccharide iron complex preparations are available. These reduce GI toxicity but are more expensive. Liquid forms of iron that cause less GI distress are also available. Oral iron replacement therapy may change the color of the stool but should not cause a false-positive result for occult blood on stool analysis.

IV supplementation may be used when the patient's iron stores are very low, if the patient cannot tolerate oral forms of iron, or both. The nurse must be aware of the type of parenteral formulation of iron ordered so that risk for anaphylaxis can be determined. High-molecular formulations are associated with a much higher risk for anaphylaxis and are seldom used. Administering a test dose of low-molecular formulations of iron dextran is recommended by many manufacturers. The nurse must assist the patient in understanding the need for repeated doses to replenish iron stores or to maintain iron stores in the setting of chronic blood loss, such as hemodialysis or chronic GI bleeding.

Anemias in Renal Disease

The degree of anemia in patients with chronic kidney disease (CKD) can vary greatly; however, in general, patients do not become severely anemic until the glomerular filtration rate (GFR) is less than 30 mL/min/1.73 m^2 (Fishbane & Spinowitz, 2018). The symptoms of anemia may be the most troubling of the patient's symptoms. In patients with CKD, anemia contributes to increased cardiac output, reduced oxygen utilization, decreased cognition and ability to concentrate, reduced immune responsiveness, and reduced libido. Anemia may be more severe in patients with both CKD and diabetes (Fishbane & Spinowitz, 2018). Anemia in patients with CKD is discussed in Chapter 48.

Anemia of Inflammation

Anemia of inflammation describes anemia associated with chronic diseases including inflammation, infection, and malignancy. This classification was previously known as anemia of chronic disease (Weiss, Ganz, & Goodnough, 2019). This classification also includes anemia of critical illness that can develop within days after the onset of serious illness, and the anemia associated with aging. Many chronic inflammatory diseases are associated with **normochromic**, **normocytic** anemia (i.e., RBCs are of normal color and size). These disorders include rheumatoid arthritis, chronic infections, and many cancers. It is important that the underlying condition be identified so that it can be treated appropriately.

The anemia of inflammation is usually mild to moderate and not progressive. The hemoglobin level does not usually fall below 9 g/dL and bone marrow samples have normal cellularity and normal stores of iron. Erythropoietin levels are low and iron use is blocked by **erythroid cells** (cells that are or will become mature RBCs). Erythrocyte survival may also be shortened.

Many patients with anemia of inflammation have few symptoms related to their anemia and do not require treatment. Treatment of the underlying disorder allows iron stored in the bone marrow to be utilized, promoting increased RBC production and facilitating the rise of hemoglobin levels. Iron supplementation is not beneficial for these patients.

Gerontologic Considerations

Evidence suggests that inflammation may have a significant role in the development of anemia in older adults (Price, 2019). Higher-than-normal levels of inflammatory **cytokines** are found in older adults, and this pro-inflammatory state may predispose older adults to frailty. Frailty is manifested by weight loss, impaired mobility, generalized weakness, and loss of balance

and is strongly associated with anemia of inflammation. Erythropoietin levels may not rise as expected in response to decreased hemoglobin (Price, 2019).

Aplastic Anemia

Aplastic anemia is a rare disease caused by a decrease in or damage to bone marrow stem cells, damage to the microenvironment within the bone marrow, and replacement of marrow with fat. Stem cell damage is caused by the body's T cells, which mediate an attack on the bone marrow resulting in **aplasia** (i.e., markedly reduced hematopoiesis). Therefore, in addition to severe anemia, significant **neutropenia** (i.e., lower-than-normal neutrophil count) and **thrombocytopenia** (i.e., lower-than-normal platelet count) also occur.

Pathophysiology

Aplastic anemia is a life-threatening condition associated with bone marrow failure evidenced by **pancytopenia** (i.e., anemia, neutropenia, and thrombocytopenia; lower-than-normal counts of erythrocytes, neutrophils, and platelets) (Peslak, Olson, & Babushok, 2017). It can be acquired, or in rare cases, congenital, but most cases are idiopathic (i.e., without apparent cause) (Young, 2018). It may also be associated with certain medications, chemicals, or radiation damage. Agents that have been associated with bone marrow aplasia include benzene and benzene derivatives (i.e., airplane glues, paint remover, dry cleaning solutions). Certain toxic materials, including inorganic arsenic, glycol ethers, plutonium, and radon, have also been suggested as possible causes (Young, 2018). Nonviral hepatitis may be a precipitating factor in about 10% of cases (Peslak et al., 2017).

Clinical Manifestations

The onset of symptoms of aplastic anemia is often insidious. Complications stemming from bone marrow failure may occur before the diagnosis is made. Typical complications include infection and symptoms of anemia, including fatigue, pallor, and dyspnea. Purpura (bruising) associated with thrombocytopenia may develop. Any combination of these signs and symptoms should prompt a CBC and hematologic evaluation. Lymphadenopathy and splenomegaly may also occur. Retinal hemorrhages are common.

Assessment and Diagnostic Findings

Aplastic anemia occurs in some situations when a medication or chemical is ingested in toxic amounts; however, it may occur even when medications are

taken at the recommended dosage. This is known as an idiosyncratic reaction in those who are highly susceptible, possibly due to a genetic defect in the biotransformation of the medication or elimination process. The CBC reveals pancytopenia. Patients may have neutrophil counts less than 1,500/mm^3, hemoglobins less than 10 g/dL, and platelet counts less than 50,000/mm^3 (Segel & Lichtman, 2016). A bone marrow biopsy typically reveals an extremely hypoplastic or aplastic bone marrow (i.e., with few or no cells), often replaced with fat.

Medical Management

It is believed that aplastic anemia is an immune-mediated condition in which T lymphocytes attack hematopoietic stem cells with subsequent reduction in production of erythrocytes, leukocytes, and platelets. Aplastic anemia can be successfully treated in many cases. Patients under 60 years of age who are otherwise healthy can often be cured with a hematopoietic stem cell transplant (HSCT) from a compatible donor (see Chapter 12) (Young, 2018). In other situations, treatment with immunosuppressive therapy using antithymocyte globulin (ATG) and androgens or cyclosporine is useful in managing the disease (Young, 2018). ATG is a purified gamma-globulin solution that is obtained from rabbits or horses immunized with human T lymphocytes. Side effects of such therapy include fever and chills. There is risk for anaphylaxis with associated bronchospasm and hypotension requiring emergency treatment. Serum sickness, associated with rash, fever, arthralgias, and pruritus may occur in some patients but can be prevented or reduced in some cases with premedication with corticosteroids (Segel & Lichtman, 2016). Serum sickness resolves slowly, often over a few weeks when it occurs.

Immunosuppressive therapies prevent T cells from destroying stem cells. If relapse does occur, resuming the same immunosuppressive therapy may induce another remission but the response rate is usually reduced (Segel & Lichtman, 2016). Corticosteroids may be beneficial in the short-term; however, in aplastic anemia, long-term use is associated with bony abnormalities including aseptic necrosis and osteopenia.

Supportive therapies play a critical role in the management of aplastic anemia. All potentially offending medications should be discontinued. Transfusions with PRBCs and platelets are frequently required (see Chapter 28 for discussion of transfusions); however, judicious use of blood products is necessary, especially for patients who are candidates for bone marrow transplant because of the risk for alloimmunization (Peslak et al., 2017). Aggressive treatment of infections is necessary. Deaths associated with aplastic anemia are most often caused by bacterial or fungal infection and bleeding.

Prophylaxis against invasive fungal infection is needed for patients who are severely neutropenic. Patients who become lymphopenic after ATG require prophylaxis for pneumocystis pneumonia.

Nursing Management

Patients with aplastic anemia are at high risk for problems associated with deficiencies of erythrocytes, leukocytes, and platelets. Thorough assessment for signs of infection and bleeding are critical (see later sections on Neutropenia and Thrombocytopenia for specific interventions). Nursing care includes monitoring for side effects of therapy, including hypersensitivity reactions while administering ATG. Patients who require long-term cyclosporine therapy should be monitored for long-term effects, including renal and liver dysfunction, hypertension, pruritus, visual changes, tremor, and skin cancer. Education regarding drug–drug interactions between ATG and many other drugs is necessary. Patients should be informed that stopping immunosuppressive therapy abruptly is not recommended.

Megaloblastic Anemias

Anemias associated with vitamin B_{12} or folic acid deficiency cause the same bone marrow and peripheral blood changes because both are needed for normal DNA synthesis. The erythrocytes produced with these nutritional deficiencies are abnormally large, thus they are termed megaloblastic red blood cells. Other cells from the myeloid stem cell lines (nonlymphoid leukocytes and platelets) are also abnormal. Bone marrow analysis shows hyperplasia (an abnormal increase in the number of cells) and the precursor erythroid and myeloid cells are abnormally large and irregular in appearance. Many of these abnormal cells are destroyed within the bone marrow leading to an insufficient number of mature cells entering the peripheral blood. Over time, pancytopenia may develop. Cells that enter the circulation are often irregularly shaped; neutrophils are hypersegmented, and platelets may be abnormally large. Erythrocytes are abnormally shaped and shapes can vary greatly; this is known as **poikilocytosis**. Because erythrocytes are very large, the MCV is very high, often exceeding 110 fL. Megaloblastic anemias usually develop over months, allowing the body to compensate; thus, symptoms do not often occur until the anemia is severe (Green, 2016). In patients with light skin, the skin may develop a pale-yellow color resulting from simultaneous pallor and mild jaundice from red blood cell hemolysis.

Pathophysiology

The pathophysiologic mechanisms that undergird megaloblastic anemias are most commonly because of either a folic acid or vitamin B_{12} deficiency, as noted previously.

Folic Acid Deficiency

Folic acid is stored in the body as compounds known as folates. Folate stores are smaller than those of vitamin B_{12} and can be depleted within months if dietary intake of folate is deficient (Green, 2016). Folate is found in green vegetables and liver. Folate deficiency is rarely seen in patients who consume uncooked vegetables. Alcohol ingestion increases folic acid requirements and it is not uncommon for those with alcohol abuse disorder to have a diet deficient in folate and other nutrients. Folic acid requirements are also higher in those with liver disease, chronic hemolytic anemias, and in women who are pregnant because erythrocyte production is increased with these conditions. Small bowel diseases such as celiac disease may interfere with normal absorption of folic acid (Green, 2016).

Vitamin B_{12} Deficiency

Deficiency of vitamin B_{12} can occur in several ways. Inadequate dietary intake is unusual but sometimes can occur in people who follow a vegan diet and do not consume any meat or dairy products. Impaired absorption from the GI tract is more common, especially in older adults. Nearly 20% of older adults have low vitamin B_{12} levels; 5% to 10% have symptoms related to vitamin B_{12} deficiency (Langan & Goodbred, 2017). Vitamin B_{12} deficiency can occur in patients with disorders such as inflammatory bowel disease, or in patients who have had GI surgery such as ileal resection, bariatric surgery, or gastrectomy. Use of metformin for treatment of type 2 diabetes as well as chronic use of histamine blockers, antacids, and proton pump inhibitors to reduce gastric acid can also inhibit vitamin B_{12} absorption (Lanier et al., 2018).

Absence of intrinsic factor also impairs vitamin B_{12} absorption. When associated with lack of intrinsic factor, the anemia is referred to as pernicious anemia. Intrinsic factor is normally secreted by cells in the gastric mucosa; it binds to vitamin B_{12} and transports it to the ileum where it is absorbed. Without intrinsic factor, vitamin B_{12} taken orally cannot be absorbed and deficiency with associated anemia eventually results. Diseases of the pancreas and ileum may impair absorption even when adequate intrinsic factor and vitamin B_{12} are present. Pernicious anemia tends to run in families. It is typically a disease of adults, especially older adults. The body typically has large stores of vitamin B_{12} so years may pass before deficiency results in anemia. The body is able to compensate over time and the anemia is often severe before the patient becomes symptomatic. Because patients with

pernicious anemia and low vitamin B_{12} levels have an increased incidence of gastric cancer they may benefit from screening for gastric cancer with endoscopy at regular intervals (Miranti, Stolzenberg-Solomon, Weinstein, et al., 2017).

Clinical Manifestations

Symptoms of folic acid and vitamin B_{12} deficiencies are similar, and the two anemias may coexist. However, the neurologic manifestations of vitamin B_{12} deficiency do not occur with folic acid deficiency, and they persist if vitamin B_{12} is not replaced. Therefore, careful distinction between the two anemias must be made.

After the body's stores of vitamin B_{12} are depleted, the patient may begin to show signs and symptoms of the anemia. However, because the onset and progression of the anemia are so gradual, the body can compensate well until the anemia is severe, so the typical manifestations of anemia (weakness, listlessness, fatigue) may not be apparent initially. The hematologic effects of vitamin B_{12} deficiency are accompanied by effects on other organ systems, particularly the GI tract and nervous system. Patients with pernicious anemia develop a smooth, sore, red tongue and mild diarrhea. They are extremely pale, particularly in the mucous membranes. They may become confused; more often, they have paresthesias in the extremities (particularly numbness and tingling in the feet and lower legs). They may have difficulty maintaining their balance because of damage to the spinal cord, and they also lose position sense (proprioception). These symptoms are progressive, although the course of illness may be marked by spontaneous partial remissions and exacerbations. Without treatment, heart failure associated with severe anemia may result, often leading to death several years after onset of symptoms (Leung, 2019).

Assessment and Diagnostic Findings

Serum levels of both folic acid and vitamin B_{12} are analyzed. Small amounts of folate can increase the serum folate level; therefore, measurement of the amount of folate within the red blood cells is a more sensitive test to determine true folate deficiency although it is not commonly performed.

The traditional method of determining the cause of vitamin B_{12} deficiency was the Schilling test, but in recent years this has been replaced by other testing methods. A vitamin B_{12} assay is usually the initial test performed but the reliability of the results is sometimes questionable, when vitamin B_{12} levels are not unequivocally low. Elevated methylmalonic acid and homocysteine levels are more sensitive for the diagnosis of vitamin B_{12} deficiency (Lanier et al., 2018). An intrinsic factor antibody test is often more useful in

determining the presence of pernicious anemia. A positive test indicates that antibodies are present that interfere with the binding of the intrinsic factor–vitamin B_{12} complex to receptors in the ileum, preventing absorption. While not specific for only pernicious anemia, it is useful in helping arrive at the diagnosis.

Medical Management

Folate deficiency is easily treated in most cases by increasing the amount of folic acid in the diet and taking 1 mg of folic acid daily as a supplement. Folic acid can be given intramuscularly to those people with conditions associated with malabsorption. While many multivitamin supplements contain folic acid, the amount may not be enough to replace body stores completely. When folate deficiency is associated with alcohol abuse, supplementation should continue as long as the patient is consuming alcohol.

Vitamin B_{12} deficiency is treated with vitamin B_{12} replacement. People who follow a vegan diet can prevent or treat deficiency with oral supplements with vitamins or fortified soy milk. When deficiency is caused by impaired absorption or absence of intrinsic factor (i.e., pernicious anemia), replacement is typically given by monthly intramuscular injections. It is possible to treat patients with oral preparations in the absence of intrinsic factor but much larger doses are required. Intranasal sprays and gels are also available options to avoid the need for intramuscular injections.

As vitamin B_{12} is replaced, the reticulocyte count rises, often within 1 week, and within 4 to 8 weeks blood counts return to normal (Green, 2016). The tongue begins to feel better and appears less red after several days. Recovery from neurologic symptoms takes more time, and, if the neuropathy is severe, the patient may not fully recover. To prevent a recurrence of pernicious anemia, vitamin B_{12} supplementation must continue for life.

Nursing Management

Assessment of patients who have or are at risk for megaloblastic anemia includes inspection of the skin, tongue, and mucous membranes. Mild jaundice may be evident and is best seen in the sclera with natural lighting. Vitiligo and premature graying of the hair are frequently present in those with pernicious anemia. Careful neurologic assessment is important to identify neurologic complications. Assessment should include tests of position, vibration sense, and cognitive function. The nurse should pay close attention to the patient's gait and stability with ambulation. Safety is a concern when gait, coordination and position sense are affected. Physical and occupational therapy referrals may be needed to assist in obtaining assistive devices and making sure patients

are instructed in their use. When sensation is impaired, patients should be instructed to avoid excessive heat and cold.

Mouth and tongue soreness may impair nutritional intake. The nurse may instruct the patient to choose soft bland foods that are less likely to cause further discomfort.

Promoting Home, Community-Based and Transitional Care

Education for patients with pernicious anemia must include the chronic nature of this condition and the necessity of monthly vitamin B_{12} injections or daily oral vitamin B_{12} supplements even when symptoms have resolved. Patients or a family caregiver can be taught to administer injections. The risk for gastric cancer is increased in patients with gastric atrophy associated with pernicious anemia making it important that patients understand the need for ongoing follow-up care and screening (see Chapter 40 for further discussion on gastric cancer).

Hemolytic Anemias

In hemolytic anemias, the erythrocytes have a shortened lifespan; thus, their number in the circulation is reduced. Fewer erythrocytes result in decreased available oxygen, causing hypoxia, which in turn stimulates an increase in erythropoietin release from the kidney. Erythropoietin then stimulates the bone marrow to compensate by producing new erythrocytes and releasing some of them into the circulation somewhat prematurely as reticulocytes. If the red cell destruction persists, the hemoglobin is broken down excessively; the majority of the heme is converted to bilirubin, conjugated in the liver, and excreted in the bile (Packman, 2016). Hemolytic anemias are far less common than other forms of anemia with approximately 5% of all anemias caused by hemolysis (Schick, 2019).

The mechanisms of erythrocyte breakdown vary, but common laboratory features are characteristic of hemolytic anemia. These include elevated reticulocyte count, increased fraction of indirect (unconjugated) bilirubin, and decreased **haptoglobin** (a binding protein for free hemoglobin) as additional hemoglobin is released from the cells. Anemia worsens if hemolysis persists and the bone marrow is unable to replace the destroyed cells.

Hemolytic anemia is associated with a variety of conditions. Inherited forms include SCD, thalassemias, G-6-PD deficiency, and hereditary spherocytosis. Acquired forms include immune hemolytic anemia, non–immune-mediated paroxysmal nocturnal hemoglobinuria, microangiopathic hemolytic anemia, heart valve–related hemolysis and anemias associated with hypersplenism.

Sickle Cell Disease

SCD is an autosomal recessive disorder caused by inheritance of the sickle hemoglobin (HbS) gene. It is associated with severe hemolytic anemia. The HbS gene results in production of a defective hemoglobin molecule that causes the erythrocyte to change shape when exposed to low oxygen tension. In some circumstances, even the oxygen level in venous blood can cause this change. The erythrocyte usually has a round, biconcave, pliable shape which in SCD can easily become rigid and sickle shaped (see Fig. 29-2). The long, rigid cells can subsequently adhere to the walls of small blood vessels where they accumulate, causing decreased blood flow to the tissues and organs in that region. When blood flow is severely reduced, ischemia or infarction of the tissue can cause severe pain, swelling, and fever referred to as a sickle cell crisis. Because the sickling process takes time, if the patient is exposed to adequate amounts of oxygen, the process can be reversed before the cell membranes become too rigid, allowing the erythrocytes to return to their normal shape. Sickle cell crises are intermittent and can be triggered by cold because of vasoconstriction that slows blood flow.

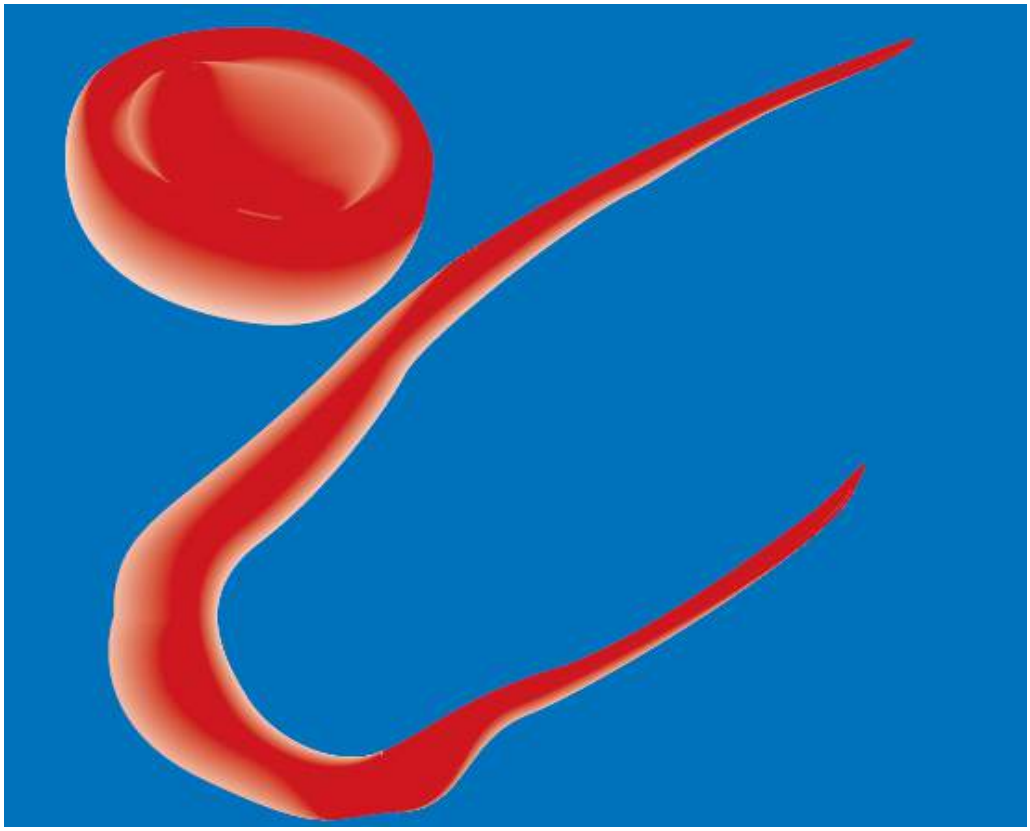

Figure 29-2 • A normal red blood cell (**upper left**) and a sickled red blood cell.

The HbS gene is inherited primarily in people of African descent. It may also be seen to a lesser degree in people of Middle Eastern and Mediterranean descent, and some tribal populations in India (Bunn, 2017b). Sickle cell anemia is the most severe form of SCD and is found in approximately 1 in 365 African Americans (National Heart Lung and Blood Institute, 2014). Other less severe forms of SCD include sickle cell hemoglobin C (SC) disease, sickle cell hemoglobin D (SD) disease, and sickle cell beta-thalassemia. Clinical presentation and treatment for these forms of the disease are the same as for sickle cell anemia.

The term sickle cell trait refers to the carrier state for SCD in which the patient has inherited a sickle gene from one parent and a normal gene from the other parent. Less than 50% of the hemoglobin within the erythrocytes is HbS. Those with sickle cell trait may be unaware that it is present unless severe hypoxia is experienced. Approximately 10% of African Americans have sickle cell trait (Bunn, 2017b). It is important that patients with sickle cell trait understand that if two people with sickle cell trait have children, the children have approximately one in four odds of inheriting two abnormal genes and will manifest SCD (see Chapter 6 for additional discussion of genetic diseases).

Clinical Manifestations

Symptoms of SCD vary and are not solely based on the amount of HbS present. Symptoms and complications are the result of chronic hemolysis and thrombosis. Sickled cells hemolyze rapidly and have a shortened lifespan. Anemia is typically present with hemoglobin values between 5 and 11 g/dL (Natrajan & Kutlar, 2016). Jaundice is often present. The bone marrow expands early in life to compensate for the resulting anemia, sometimes causing enlargement of the bones in the face and skull. Chronic anemia is often associated with tachycardia, cardiac murmurs, and cardiomegaly. Arrhythmias and heart failure may also occur, especially in adults.

Any organ can be affected by thrombosis, but those areas with slower circulation are frequently involved, including the lungs, spleen, and central nervous system (CNS). All tissues and organs can be affected by thrombosis in the microcirculation caused by the sickling process leading to hypoxia and tissue damage and necrosis. Patients with SCD are particularly susceptible to infections, especially pneumonia and osteomyelitis. Additional complications of SCD include stroke, kidney injury, impotence, and pulmonary hypertension (see Table 29-2).

TABLE 29-2 Complications in Sickle Cell Disease[a]

Organ Involved	Mechanisms[a]	Diagnostic Findings	Signs and Symptoms
Spleen	Primary site of sickling → infarctions → ↓ phagocytic function of macrophages	Autosplenectomy; ↑ infection (especially pneumonia, osteomyelitis)	Abdominal pain; fever, other signs of infection
Lungs	Infection	Pulmonary infiltrate	Chest pain; dyspnea
	Infarction → ↑ pulmonary pressure → pulmonary hypertension	↑ $sPLA_2$[b]	Chest pain; dyspnea
Central nervous system	Infarction	Stroke	Weakness; cognitive dysfunction, speech and swallowing dysfunction
Kidney	Sickling → damage to renal medulla	Hematuria; inability to concentrate urine; kidney injury	Dehydration
Heart	Anemia	Tachycardia; cardiomegaly → heart failure	Weakness, fatigue, dyspnea
Bone	↑ Erythroid production	Widening of medullary spaces and cortical thinning	Ache, arthralgias
	Infarction of bone	Osteosclerosis → avascular necrosis	Bone pain, especially hips
Liver	Hemolysis	Jaundice and gallstone formation; hepatomegaly	Abdominal pain
Skin and peripheral vasculature	↑ Viscosity/stasis → infarction → skin ulcers	Skin ulcers; ↓ wound healing	Pain
Eye	Infarction	Scarring, hemorrhage, retinal detachment	↓ Vision; blindness
Penis	Sickling → vascular thrombosis	Priapism → impotence	Pain, impotence

→, leading to; ↓, decreased; ↑, increased; $sPLA_2$, secretory phospholipase A_2.

[a]Problems encountered in sickle cell disease vary and are the result of a variety of mechanisms, as depicted in this table. Common physical findings and symptoms are also variable.

[b]Elevated $sPLA_2$ levels can predict impending acute chest syndrome (see text).

Adapted from Natrajan K., & Kutlar, A. (2016). Disorders of hemoglobin structure: Sickle cell anemia and related abnormalities. In K. Kaushansky, M. A. Lichtman, J. T. Prchal,

et al. (Eds.). *Williams hematology* (9th ed.). New York: McGraw-Hill Medical.

Sickle Cell Crisis

Three types of sickle cell crises affect adults. The most common is *acute vaso-occlusive crisis* (Kim, Brathwaite, & Kim, 2017). This very painful condition is the result of accumulation of erythrocytes and leukocytes in the microcirculation restricting blood flow to the tissue and causing hypoxia, inflammation, and necrosis. Substances released after tissue perfusion is restored include free radicals and free plasma hemoglobin, which cause oxidative damage to the blood vessel. As a result, the endothelial tissues in the vessel become dysfunctional (Bunn, 2017b). *Aplastic crisis* results from infection with the human parvovirus. The hemoglobin level falls rapidly and the marrow cannot compensate, as evidenced by an absence of reticulocytes (Natrajan & Kutlar, 2016). *Sequestration crisis* results when sickled cells are pooled in organs. In young children, the most common site of sequestration is the spleen; however, in many children with SCD over 10 years of age, the spleen has been infarcted and is no longer functional (Natrajan & Kutlar, 2016). In adults, the most common organs involved are the liver and the lungs.

Acute Chest Syndrome

Acute chest syndrome is a frequent complication in those hospitalized with SCD and is associated with significant morbidity and mortality. Acute chest syndrome is most frequently manifested by fever; respiratory distress that is manifested with tachypnea, cough and wheezing; and new infiltrates on the chest x-ray (Jain, Bakshi, & Krishnamurti, 2017). It is a common cause of death in young adults with SCD (Field, 2019). Infection with atypical bacteria including *Chlamydia pneumoniae* and *Mycoplasma pneumoniae* and viruses, including influenza, are often the cause. Other causes of acute chest syndrome include pulmonary thromboembolism, pulmonary fat embolism, bone marrow embolism, and pulmonary infarction. The patient's clinical condition can deteriorate very quickly leading to respiratory failure. Medical management includes blood transfusion, antibiotics, bronchodilators, inhaled nitric oxide, and when respiratory failure occurs, mechanical ventilation. Risk for acute chest syndrome can be reduced through immunization against influenza and pneumococcal pneumonia, and with use of incentive spirometry during vaso-occlusive crises, and with blood transfusion perioperatively (Jain et al., 2017). Prompt recognition and aggressive treatment can result in good outcomes for this potentially life-threatening condition.

Pulmonary Hypertension

Pulmonary hypertension is a common sequela of SCD and is a common cause of death (Natrajan & Kutlar, 2016). The onset of symptoms of pulmonary

hypertension is insidious; diagnosis is difficult in the early stages and is usually delayed until irreversible damage occurs. Symptoms include fatigue, dyspnea on exertion, dizziness, chest pain, or syncope. Pulse oximetry is usually normal and breath sounds are often clear to auscultation until the condition is quite advanced. Pulmonary artery pressures are elevated above baseline but are generally lower than seen with idiopathic or hereditary pulmonary hypertension. Screening of patients with SCD with Doppler echocardiography may be helpful in identifying increased pulmonary artery pressure (Kling & Farber, 2019). High levels of the amino-terminal form of brain natriuretic peptide can be a biomarker for pulmonary hypertension in people with SCD and serve as a predictor of mortality (Kling & Farber, 2019). Computed tomography (CT) scan of the chest frequently reveals microvascular pulmonary occlusion and decreased lung perfusion while chest x-ray may appear normal.

Stroke

Stroke is a catastrophic consequence of SCD that affects approximately 10% of patients under 20 years of age (Natrajan & Kutlar, 2016). Ischemic stroke is most common, especially in young children and older adults, while hemorrhagic stroke is more common in young adults. The mechanisms vary but often result from decreased blood flow due to anemia, hemolysis, and increased hypoxic stress. Silent cerebral infarction occurs in about 40% of patients with SCD who have strokes, resulting in neurocognitive decline (Vichinsky, 2017). Medical management of stroke includes red blood cell transfusion to reduce the amount of hemoglobin S to less than 30% to reduce the risk of cerebral edema (George, 2019).

Reproductive Disorders

The adverse effects of SCD on sexual function have become more evident as patients with the disease are living longer. Hypogonadism with associated low testosterone levels, delayed puberty, low libido, erectile dysfunction, and infertility occur frequently in men with SCD (Huang & Muneyyirci-Delale, 2017). Episodes of priapism (prolonged penile erection, without sexual stimulation) also contribute to significant pain and decreased libido. Over time, repeated episodes lead to permanent damage and erectile dysfunction, thereby making priapism a medical emergency that needs early recognition and treatment to preserve normal sexual function (Field, Vemulakonda, DeBaun, et al., 2019). In addition to physical signs and symptoms, these problems can also lead to embarrassment and depression.

In young women, menarche may be delayed, but menstrual patterns are generally normal. Fertility problems in women are not well described. Contraception is important when hydroxyurea is used in SCD treatment

because of its teratogenic effects. Concerns about infertility may be associated with poor adherence to hydroxyurea therapy. Although most pregnancies complicated by maternal SCD are likely to result in live births, these pregnancies are at increased risk of obstetrical and fetal complications, as well as medical complications of SCD (Vichinsky, 2018).

Assessment and Diagnostic Findings

The patient with sickle cell trait usually has a normal hemoglobin level, normal hematocrit, and normal blood smear. Conversely, the patient with SCD has a low hematocrit and sickled cells on the blood smear. The white blood cell count and platelet count are often elevated as a result of a chronic inflammatory state (Natrajan & Kutlar, 2016). Abnormal hemoglobin is identified by hemoglobin electrophoresis.

Medical Management

Patients with SCD are typically diagnosed in childhood, with anemia often occurring in infancy and crises beginning as early as 1 or 2 years of age. Some children die in the first few years of life as a result of infection; however, outcomes have improved considerably in recent years. Average life expectancy is lower than the general population, rarely exceeding the sixth decade (Field, 2019). Young adults often experience multiple, severe complications from their disease. A subgroup of patients experiences a decrease in symptoms and complications after age 30; however, at present there is no means to predict who will fall into this group. Death is most often caused by cardiac, lung, kidney, or neurologic complications, or from infection (Field, 2019).

Treatment of SCD is the focus of continued research. In addition to aggressive management of symptoms, including pain, and complications, there are a few primary treatment modalities.

Hematopoietic Stem Cell Transplant

HSCT may cure SCD. However, this treatment modality is available to only a small subset of affected patients, either due to a lack of compatible donors or due to severe organ damage (e.g., renal, liver, lung) that may be already present in the patient (see Chapter 12 for further discussion of HSCT).

Pharmacologic Therapy

For patients with SCD, hydroxyurea is a chemotherapeutic agent that is effective in increasing levels of fetal hemoglobin (i.e., hemoglobin F), which in turn decreases the formation of sickled cells. It is the only drug currently approved by the FDA for treatment of SCD. Studies have demonstrated that

patients with SCD who received hydroxyurea experienced fewer episodes of painful crisis, had a lower incidence of acute chest syndrome, and needed fewer transfusions (Matte, Zorzi, & De Franceschi, 2019). Additional studies have shown a 40% decrease in mortality in patients receiving hydroxyurea (Natrajan & Kutlar, 2016). It is unknown whether hydroxyurea can prevent or reverse organ damage. Side effects of the drug include chronic lowering of the leukocyte count, teratogenesis, and potential for later development of a malignancy. Patients' response to the drug can vary widely. The incidence and severity of side effects are variable. Adherence to the prescribed treatment regimen may be difficult for some patients.

Patients with SCD often require daily folic acid supplements to maintain the amount needed for increased erythropoiesis to counteract the effects of hemolysis. Infections are common and should be treated promptly with the appropriate antibiotics. Pneumococcal pneumonia is common in children with SCD while in adults, *Staphylococcus aureus* infection is more common, involving bones and joints (Natrajan & Kutlar, 2016). Patients should be immunized against pneumococcal infection and receive annual influenza vaccines.

Acute chest syndrome is managed by prompt treatment with antibiotics. Incentive spirometry has been shown to significantly reduce the incidence of pulmonary complications. In severe cases, bronchoscopy may be needed to identify the source of acute chest syndrome symptoms. Hydration is important but must be monitored carefully to avoid fluid overload. Corticosteroids may also be helpful. Transfusion can reduce hypoxia. Pulmonary function should be monitored carefully to detect symptoms of pulmonary hypertension as soon as possible so that therapies, including hydroxyurea and HSCT, can be of the greatest benefit.

Transfusion Therapy

RBC transfusions have been shown to be highly effective in several situations: in an acute exacerbation of anemia (e.g., aplastic crisis, severe vaso-occlusive crisis), in the prevention of severe complications from anesthesia and surgery, in improving the response to infection (when it results in exacerbated anemia), in the case of acute chest syndrome and multiple organ dysfunction syndrome (MODS), and in thwarting the cerebral edema from a stroke. Transfusions are also effective in diminishing episodes of sickle cell crisis in pregnant women, although such transfusions do not improve fetal survival. Ongoing transfusion therapy may be effective in preventing or managing complications from SCD by keeping the HbS level to less than 30% (DeBaun, 2018).

Transfusions are not without risks, so it is important to consider the risks of complications versus benefits. Complications include difficulty with venous access, which necessitates placement of a vascular access device, and the concomitant risk for access site infection and thrombosis. Additional risks

include other infections, particularly hepatitis; delayed hemolytic transfusion reactions; and iron overload that requires treatment with chelating agents.

Iron overload is very likely with long-term/ongoing transfusion therapy, causing deposition of iron in vital organs, including the liver, heart, pancreas, kidneys, and pituitary gland. It is sometimes difficult to distinguish organ damage associated with the disease process from damage associated with iron overload. Iron chelation therapy, aimed at keeping iron levels at near normal, reduces complications (see Chapter 30 for further discussion of chelation therapy) (Coates & Wood, 2017). An additional complication of transfusion therapy is increased blood viscosity without reduction in the concentration of hemoglobin S. Exchange transfusion, where some of the patient's blood is removed and replaced by RBC transfusion, may reduce the risk of increasing blood viscosity (Davis, Allard, Qureshi, et al., 2017). Additionally, repeated transfusions may result in development of multiple antibodies to other blood antigens, making cross matching increasingly difficult, and lead to increased risk for hemolytic transfusion reaction. This phenomenon is referred to as alloimmunization (Davis et al., 2017). Some patients who are alloimmunized have an increased risk of avascular necrosis, end-organ damage, and death (Holmes-Maybank, Martin, & Duckett, 2017). Hemolytic transfusion reaction may mimic the signs and symptoms of sickle cell crisis. A distinguishing feature of a hemolytic reaction versus sickle cell crisis is that the patient becomes more anemic after the transfusion than before. Close observation after hemolytic transfusion reaction is needed and further transfusion should be avoided until after the hemolytic process subsides. Patients are supported with corticosteroids, such as prednisone, intravenous immunoglobulins (IVIG) and erythropoietin alfa.

For the procedural guidelines for managing immunoglobulin therapy, go to thepoint.lww.com/Brunner15e.

Supportive Therapy

Supportive care is essential for patients with SCD. Pain management is a significant problem. Acute pain is most often associated with vaso-occlusive crisis and is the frequent reason for hospitalization and emergency department visits in people with SCD. Pain may also be neuropathic in nature stemming from damage or inflammation of nerves as seen with avascular necrosis and leg ulcers (see Fig. 29-3). Chronic non-neuropathic pain may result from CNS dysfunction, including CNS sensitivity to peripheral afferent pain signals, or differences in psychosocial aspects of pain perception (Darbari & Brandow,

2017). Pain severity may interfere with ability to work, even when patients do seek assistance with pain management from health care providers.

The use of medications for acute pain relief is critical and should be appropriate for the etiology of the pain. Aspirin may be useful in patients with mild pain; it decreases inflammation and risk for potential thrombosis (because it inhibits platelet adhesion). NSAIDs are useful for moderate pain or in combination with opioid analgesics. While there is no risk of developing tolerance to NSAIDs there is a "ceiling effect" by which increased doses do not improve analgesia but increase the risk for adverse effects. NSAID use must be monitored carefully because of the risk for renal dysfunction and GI bleeding. Severe acute pain is most often treated with parenteral opioids (Okwerekwu & Skirvin, 2018). Patient-controlled analgesia is frequently used for this purpose in the acute care setting (see Chapter 9 for additional information on pain management). Neuropathic pain can be effectively managed with gabapentinoids, tricyclic antidepressants, and serotonin and norepinephrine reuptake inhibitors (Sharma & Brandow, 2019). With chronic pain management, the principal goal is to maximize functioning; pain may not be completely eliminated without sacrificing function. This concept may be difficult for patients to understand and ongoing education and support is often needed. Nonpharmacologic pain management strategies are important in this setting. Such strategies include physical therapy including heat, massage and exercise; occupational therapy; cognitive and behavioral therapies, including distraction and relaxation techniques; and support groups (Okwerekwu & Skirvin, 2018).

Figure 29-3 • Chronic skin ulcers seen in a patient with sickle cell anemia. Reprinted with permission from Tkachuk, D. C., & Hirschman, J. V. (2007). *Wintrobe's atlas of clinical hematology* (Fig. 1.71, p. 36). Philadelphia, PA: Lippincott Williams & Wilkins.

Hydration is critical during a painful crisis. Oral hydration may be sufficient if the patient is able to maintain adequate intake. IV hydration may be needed if the patient is unable to consume 2 to 3 L of fluid during a crisis episode. Supplemental oxygen may also be needed.

Another significant problem for people with SCD is fatigue. Fatigue can interfere with ability to perform effectively at work and school and reduce quality of life. Its causes, as with pain, may be multifactorial. Fatigue may occur in response to hypoxia associated with low levels of normal hemoglobin and decreased capacity to carry oxygen with sickled cells. Endothelial cells in the blood vessels become inflamed as a result of hypoxia. Inflammatory cytokines are increased in patients with SCD resulting in reduced muscle strength and decreased exercise capacity, increased resting energy expenditure, and sleep disturbances, all exacerbating fatigue. Sleep disturbances and depression are common and contribute to fatigue (Ahmadi, Poormansouri, Beiranvand, et al., 2018).

Working with patients who have multiple episodes of severe pain and fatigue can be challenging. Health care providers must recognize that patients with SCD are confronted with lifelong experiences with severe pain and fatigue that impair physical and social functioning that may be associated with depression and helplessness. Patients without adequate sources of support may have more issues with coping.

NURSING PROCESS

The Patient with Sickle Cell Crisis

Assessment

The patient is asked to identify factors that precipitated previous crises and measures taken to prevent and manage crises. If a sickle cell crisis is suspected, the nurse needs to determine whether the pain currently experienced is the same as or different from the pain typically encountered in crisis. Pain levels should always be assessed (see Chapter 9). A similar assessment should be made of the patient's fatigue, including the impact of fatigue on the current lifestyle, quality of life, and the extent that the fatigue influences pain and interferes with sleep.

Because the sickling process can interrupt circulation in any organ or tissues, a thorough assessment of all body systems is needed. Particular attention should be placed on assessing pain, swelling, and fever. Careful examination of all joints for pain and swelling is necessary. The abdomen is assessed for pain and tenderness because of the possibility of splenic infarction.

The cardiovascular and respiratory systems must also be assessed carefully. These assessments include measurement of oxygen saturation, auscultation of breath sounds, and recognition of signs of cardiac failure, including the presence of dependent edema, increased size of the point of maximum impulse, and cardiomegaly (as seen on a chest x-ray). The patient is assessed for signs and symptoms of dehydration by a history of reduced fluid intake, and careful examination of mucous membranes, skin turgor, urine output, and serum creatinine and blood urea nitrogen levels.

A meticulous neurologic examination is essential to identify symptoms of cerebral hypoxia, but it is also important to recognize that evidence of ischemia may be present on magnetic resonance imaging (MRI) or Doppler studies before becoming evident on the physical examination. MRI or Doppler may be used for early diagnosis resulting in improved patient outcomes because therapy can be initiated promptly. Cognitive dysfunction is often present and may reflect reduced blood flow and oxygenation to the brain. Assessment for neurologic abnormalities is important in identifying silent cerebral ischemia or infarction.

Assessment for the presence of infectious processes is crucial as many patients with SCD are susceptible to infection. Special attention should be paid to examination of the chest, long bones, and femoral head because pneumonia and osteomyelitis are particularly common. Leg ulcers are common, frequently recurrent, occur in as many as 75% of adults with SCD, and may become infected and slow to heal (El Khatib & Hayek, 2016) (see Fig. 29-3).

The degree of anemia and ability of the bone marrow to replenish erythrocytes are assessed with hemoglobin level, hematocrit, and reticulocyte counts, and comparing these to baseline values. The patient's current and past history of medical care must also be obtained, particularly long-term transfusion therapy, hydroxyurea treatment, and prior treatment of infections.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include:

- Acute pain, chronic pain, and fatigue associated with tissue hypoxia due to agglutination of sickled cells within blood vessels
- Risk for infection
- Risk for powerlessness associated with illness-induced helplessness
- Lack of knowledge regarding sickle cell crisis prevention

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Hypoxia, ischemia, and poor wound healing leading to skin breakdown and ulcers
- Dehydration
- Cerebrovascular disease (stroke)
- Anemia
- Acute kidney injury and chronic kidney failure
- Heart failure, pulmonary hypertension, and acute chest syndrome
- Impotence and impaired fertility
- Cognitive dysfunction
- Poor adherence to therapy
- Mutual conflict and distrust between patient and health care providers due to poorly managed acute and chronic pain

Planning and Goals

The major goals for the patient are relief of pain, decreased incidence of crisis, enhanced sense of self-esteem and power, and absence of complications.

Nursing Interventions

Managing Pain

Acute pain during a sickle cell crisis can be unpredictable and severe. The patient's subjective description of pain rating on a pain scale is useful in directing its treatment (see Chapter 9). Swollen joints should be supported and elevated until swelling subsides. Relaxation techniques, breathing exercises, yoga, and self-hypnosis may be helpful to some patients in

coping with pain (DeBaun & Vichinsky, 2019). Following acute pain episodes, aggressive measures should be taken to preserve joint function. Physical therapy, whirlpool baths, and transcutaneous electrical nerve stimulation (TENS) are among modalities that may be used. While heat packs may be helpful, cold packs and ice should be avoided as cold may precipitate sickling (DeBaun & Vichinsky, 2019).

It is not unusual for patients to have difficulty coping with repeated episodes of acute pain and with chronic pain, making adherence to the prescribed treatment regimen difficult. Some patients with SCD develop substance use disorder although the incidence of substance abuse among people with SCD is not unlike that of patients with other chronic conditions (Natrajan & Kutlar, 2016). This can be a result of inadequate treatment of acute pain during episodes of crisis, which then leads to a lack of trust of the health care system and of health care providers. Research findings suggest that prompt treatment of pain during vaso-occlusive crises can improve patient satisfaction with care and also decrease patient length of stay or treatment times (Kim et al., 2017) (see Chart 29-4 Nursing Research Profile: Acute Pain Management for Patients with Sickle Cell Disease).

Managing Fatigue

Fatigue experienced with SCD may be acute or chronic. Assisting the patient to find a balance between activity and rest is important. Patients need to develop strategies to help cope with the demands on their lives while dealing with their fatigue. Maximizing nutrition, hydration, adequate sleep, and tissue perfusion can all help to minimize fatigue. Research is needed to better understand fatigue in this patient population and identify the most effective ways to relieve it. Although there are validated scales that have been used to quantify the extent of fatigue in patients with SCD, such as the PROMIS Fatigue short form®, standards for when to assess fatigue are currently lacking (Aslani, Georgios, & Maria, 2018; Hildenbrand, Quinn, Mara, et al., 2019).

Preventing and Managing Infection

Nursing care focuses on monitoring patients for signs and symptoms of infection. Prescribed antibiotics should be administered as soon as possible. If oral antibiotics are prescribed at home, patients and caregivers must understand the importance of completing the entire course of antibiotics. Patients should be encouraged to seek immunizations per the latest guidelines (see Chapter 3, Table 3-3), particularly the pneumonia and influenza vaccines.

Promoting Coping Skills

SCD may cause patients to feel powerless and lacking in self-worth because of the health problems associated with repeated crises and chronic health conditions. These feelings can be exacerbated when pain and fatigue

are not well controlled. Optimizing management of pain and fatigue are critical in helping patients to cope with their illness. Listening to and advocating for the needs of patients is important for building a therapeutic relationship based on mutual respect and trust. Nursing care that focuses on patients' strengths and not their deficits aids in promoting effective coping. Providing patients with opportunities to make decisions about their care can help foster autonomy and a sense of control. Supportive guidance can help patients understand the importance of adhering to their therapeutic regimen.

Chart 29-4 NURSING RESEARCH PROFILE

Acute Pain Management for Patients with Sickle Cell Disease

Kim, S., Brathwaite, R., & Kim, O. (2017). Evidence-based practice standard care for acute pain management in adults with sickle cell disease in an urgent care center. *Quality Management in Healthcare, 26*(2), 108–115.

Purpose

Vaso-occlusive episodes (VOEs) are the most common reason patients with sickle cell disease (SCD) seek emergency or urgent care services. Evidence-based guidelines specify that patients with SCD who seek urgent care for treatment of VOE should receive analgesics quickly. However, these guidelines are not followed by many clinicians, resulting in poorly managed pain in this patient population. The purpose of this study was to find whether implementing a VOE analgesic care algorithm in an urgent care (UC) center would decrease patient time to receipt of analgesics, improve patient satisfaction with care, and decrease length of treatment time.

Design

The setting for this study was an urban tertiary care UC center. Eligible participants were adults at least 18 years of age who sought care at the UC center for VOE from SCD. A Quality Improvement (QI) best practice VOE analgesic intervention was conducted with UC center staff so that all were educated to follow the algorithm. Data were collected over 6 months. Time to administration of first analgesic medication for participants postintervention (n = 63) was compared with historical controls preintervention (n = 61), as were participant reports of satisfaction with care and their length of stay in the UC center.

Findings

The mean time to administration of analgesics decreased significantly from pre- to postintervention, from 92 minutes to 62 minutes (p = 0.001). Likewise, participant satisfaction with care improved from pre- to postintervention (p = 0.002) and mean time in the UC center decreased significantly from pre- to postintervention, from 283 minutes to 256 minutes (p = 0.01).

Nursing Implications

Findings from this study suggest that administering analgesics quicker to patients with SCD complicated with VOE not only mitigates their pain, but may also improve their satisfaction with care, and decrease their time in treatment. This may indirectly help to foster patient trust of the health care system and of providers. Nurses can leverage findings from this study to replicate this best practice algorithm and improve the care of patients with SCD complicated with VOE.

Minimizing Knowledge Deficits

Patients with SCD benefit greatly from understanding the circumstances that may precipitate a sickle cell crisis and the steps they can take to prevent or diminish the symptoms they may experience during a crisis. Keeping warm, reducing risks for infection, and maintaining adequate hydration can be effective in reducing the occurrence and severity of crises.

When hydroxyurea is prescribed for women of childbearing age, they should be informed that the drug can cause harm to an unborn fetus and advised that pregnancy should be avoided.

Monitoring and Managing Potential Complications

Many of the measures for managing potential complications have already been described. Other measures follow.

Leg Ulcers. Leg ulcers require careful management and protection from trauma and contamination. Referral to a wound-ostomy-continence nurse or other wound care specialist may facilitate healing and promote prevention. If leg ulcers fail to heal, skin grafting may be needed (El Khatib & Hayek, 2016). Meticulous aseptic technique during wound care is needed to reduce risk for hospital-acquired wound infections.

Priapism and Impotence. Male patients may experience sudden, painful erection known as priapism. Initial management can include warm compresses or warm bath, and mild to moderate exercise, oral hydration, and masturbation with ejaculation (Field et al., 2019). If the priapism persists longer than 3 hours the patient should seek medical attention; treatment may consist of IV hydration, administration of analgesics, and possible aspiration of blood from the corpus carvernosa with or without injection of a sympathomimetic drug (Al-Qudah, 2016; Field et al., 2019). Repeated episodes of priapism may lead to extensive vascular damage resulting in impotence.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Because patients with SCD are typically diagnosed during childhood, their parents typically participate in the initial education. As the child ages, educational interventions prepare the child to assume more responsibility for self-care. Most families can learn about vascular access device management and chelation therapy. Nurses in outpatient facilities or home health nurses may need to provide follow-up care for patients with vascular access devices.

Continuing and Transitional Care. The illness trajectory of SCD is highly variable, often with unpredictable episodes of complications or crises. Care is frequently on an emergency basis, especially for some patients with pain management problems. All health care providers who offer services to patients with SCD and their families must communicate regularly with each

other. Alternative methods of care delivery including day hospitals for acute symptom management and patient-centered medical homes, where multidisciplinary care is emphasized, are available in some regions. Nurses play an important role in serving as coordinators and facilitators of care by communicating with health care providers in a variety of settings to optimize the care of patients. Patient education about which parameters are important to monitor and how to monitor them is also a critical role for nurses. Making certain that patients understand when to seek urgent care for acute problems is essential.

Evaluation

Expected patient outcomes may include the following:

1. Control of pain and fatigue
   a. Uses analgesic agents appropriately to relieve pain
   b. Uses nonpharmacologic strategies to help relieve pain and fatigue, such as relaxation techniques, breathing exercises, and guided imagery
2. Absence of infection
   a. Is afebrile
   b. Maintains leukocyte count within normal baseline (4500/mm^3 to 11,000/mm^3)
   c. Identifies importance of completing antibiotics as prescribed
   d. Demonstrates measures to prevent infection (i.e., obtains recommended immunizations)
3. Expresses improved sense of control
   a. Participates in goal setting, planning, and implementing daily activities
   b. Participates in making decisions about care
   c. Adheres to prescribed medical therapy
4. Increases knowledge about disease process
   a. Identifies situations and factors that can precipitate sickle cell crisis
   b. Describes lifestyle changes needed to prevent crisis
   c. Describes the importance of warmth, adequate hydration, and prevention of infection in preventing crisis
5. Absence of complications

Thalassemias

The thalassemias are a group of hereditary anemias characterized by **hypochromia** (an abnormal decrease in the hemoglobin content of erythrocytes), extreme **microcytosis** (smaller than normal size erythrocytes),

hemolysis, and variable degrees of anemia. The thalassemias occur worldwide, but the highest prevalence is found in people of Mediterranean, African, and Southeast Asian ancestry (Weatherall, 2016).

Thalassemias are associated with impaired hemoglobin synthesis so that one or more globulin chains in the hemoglobin molecule are reduced. When this occurs, the imbalance in the configuration of the hemoglobin molecule causes it to precipitate in premature or mature erythrocytes. This increases the rigidity of erythrocytes, leading to premature cell destruction.

Thalassemias are classified into two major groups according to which hemoglobin chain is affected, alpha or beta. The alpha-thalassemias occur mainly in people of Southeast Asian and eastern Mediterranean descent (i.e., Middle Eastern), and the beta-thalassemias are most prevalent in those of African descent. Thalassemias are not limited to any geographic region because of extensive immigration (Weatherall, 2016). Symptoms of the alpha-thalassemias are typically less severe than those of beta-thalassemias. In alpha-thalassemias, erythrocytes are often quite microcytic but anemia, when present, is usually mild.

The severity of beta-thalassemia varies depending on the extent to which the hemoglobin chains are affected. Patients with mild forms have microcytosis and mild anemia. When untreated, severe beta-thalassemia (i.e., thalassemia major or Cooley's anemia) can be fatal within the first few years of life. HSCT offers a chance of cure. When this is not possible, treatment consists of PRBC transfusion and iron chelation therapy, as needed (Fibach & Rachmilewitz, 2017). Patient education for adolescents and young adults should include preconception counseling about the risk of thalassemia major in offspring (see Chapter 6 for discussion about genetic counseling and evaluation services).

Thalassemia major is characterized by severe anemia, profound hemolysis, and ineffective erythropoiesis. With early initiation of regular transfusions with PRBCs, growth and development through childhood is supported. Iron overload that can result from multiple transfusions can lead to organ dysfunction. Regular chelation therapy can reduce complications associated with iron overload and prolong life in those with thalassemia major. Long-term survivors of beta thalassemia may experience neurologic complications including cognitive dysfunction, peripheral neuropathy, and cerebrovascular disease (Fibach & Rachmilewitz, 2017).

Glucose-6-Phosphate Dehydrogenase Deficiency

The Glucose-6-Phosphate Dehydrogenase (G-6-PD) gene is responsible for the abnormality seen in this disorder. The gene produces an enzyme within the erythrocyte that is necessary to stabilize the cell membrane. Some patients produce an enzyme so defective that they have chronic hemolytic anemia;

however, the most common type of defect only results in hemolysis when cells are under certain types of stress, associated with fever and certain types of medications. G-6-PD deficiency is one of the most common X-linked genetic blood disorders in the world, affecting more than 400 million people (see Chapter 6 for discussion of X-linked disorders). However, women may also develop the disease because one of the X chromosomes is inactivated in each cell of the female embryo; thus, a female who is heterozygous for the deficiency would have one half normal red blood cells and one half with the deficiency. While the deficient cells are at risk for hemolysis, symptoms are generally milder in affected women because normal cells are not subject to hemolysis. In the United States, African Americans and people of Mediterranean descent are most likely to be affected with G-6-PD (Anderle, Bancone, Domingo, et al., 2018). The type of deficiency found in person with Mediterranean ancestry is typically more severe than that in African Americans; it results in more hemolysis and sometimes life-threatening hemolytic anemia.

Oxidant drugs have hemolytic effects for people with G-6-PD deficiency, particularly some antibiotics including sulfadiazine, nitrofurantoin, trimethoprim-sulfamethoxazole, moxifloxacin, and chloramphenicol, as well as antimalarial agents including chloroquine, primaquine, and dapsone. Other medications associated with hemolysis include phenazopyridine, rasburicase, methylthioninium, tolonium chloride, tamsulosin, glyburide, nonsteroidal anti-inflammatory drugs, and the street drug amyl nitrate (van Solinge & van Wijk, 2016). A severe hemolytic episode can also occur in affected people after ingesting fava beans, menthol, tonic water, and some Chinese herbs.

Clinical Manifestations

Patients are typically asymptomatic and have normal hemoglobin levels and reticulocyte counts. However, within several days after exposure to an offending agent, pallor, jaundice, and hemoglobinuria develop. The reticulocyte count increases, and symptoms of hemolysis develop. Special stains of peripheral blood often show Heinz bodies (degraded hemoglobin) within the erythrocytes. Hemolysis may be mild and self-limited; however, in more severe cases, usually in the Mediterranean type of the disease, spontaneous recovery does not occur.

Assessment and Diagnostic Findings

The diagnosis is made by a screening test for the deficiency or by quantitative assay of G-6-PD.

Medical Management

Treatment requires discontinuation of the offending agent. Transfusion is not usually necessary unless severe hemolysis is present, as may be seen in the Mediterranean variety of G-6-PD deficiency.

Nursing Management

Patients should be educated about the disease and provided with a list of medications and other substances to be avoided. Patients with G-6-PD deficiency should always seek medical advice before taking any new medication or supplement. The G-6-PD Deficiency organization Web site (see Resources) is an excellent source of information. If hemolysis occurs, nursing interventions are the same as for hemolysis with other conditions. Patients should be advised to wear Medic-Alert bracelets that identify that they have G-6-PD deficiency. Genetic counseling may also be indicated (see Chapter 6).

Immune Hemolytic Anemias

Immune hemolytic anemias can result from exposure of erythrocytes to antibodies. Alloantibodies (antibodies against the host or "self") occur as a result of immunization of a person to foreign antigens (e.g., the immunization of an Rh-negative person with Rh-positive blood). Alloantibodies tend to be of the immunoglobulin G (IgG) type and cause immediate destruction of sensitized erythrocytes either within the blood vessels (intravascular) or the liver. Hemolysis and anemia associated with hemolytic transfusion reaction is an example of alloimmune hemolytic anemia.

Autoantibodies may develop for a number of reasons. In some circumstances, the person's immune system is dysfunctional and falsely identifies its own erythrocytes as foreign and produces antibodies against them. This may be seen in people with chronic lymphocytic leukemia (CLL) (see Chapter 30). Another cause of autoimmune hemolytic anemia is a deficiency of suppressor lymphocytes, which normally prevents antibody production against the patient's own antigens. Erythrocytes are then sequestered in the spleen and destroyed by macrophages outside of blood vessels (extravascular hemolysis) (Phillips & Henderson, 2018).

Autoimmune hemolytic anemias may be classified based on the body temperature involved when the antibodies react with the RBC antigen. Warm-body antibodies are the most common (80%) and bind to erythrocytes most actively in warm-body conditions (37°C [98.6°F]); cold-body antibodies react in cold conditions (0°C [32°F]) (Packman, 2016). Autoimmune hemolytic anemia is associated with other disorders in most cases (e.g., medication exposure, lymphoma, CLL, other malignancies, collagen vascular diseases, autoimmune diseases, infection). In idiopathic autoimmune hemolytic states, the cause for antibody production is unknown. This primary form affects

people of all ages and genders equally, while secondary forms occur more frequently in females and in people over the age of 45 years (Packman, 2016).

Clinical Manifestations

Clinical signs and symptoms vary and often reflect the severity of anemia. The hemolysis may range from very mild, with the patient's bone marrow able to compensate adequately with few or no symptoms, to severe, with life-threatening anemia. Most patients complain of fatigue and dizziness. Splenomegaly, with associated abdominal discomfort, is a common finding; hepatomegaly, lymphadenopathy, and jaundice are also frequently seen.

Assessment and Diagnostic Findings

Laboratory tests show a low hemoglobin level and hematocrit, usually associated with an elevated reticulocyte count. Erythrocytes appear abnormal; **spherocytes** (small, spherically shaped erythrocytes) are often seen on the peripheral blood smear. The serum bilirubin level is elevated, and if the hemolysis is severe, the haptoglobin level is low or absent. The Coombs test (also known as the direct antiglobulin test), which detects antibodies on the surface of the erythrocytes, is typically positive.

Medical Management

Any possible contributing medication should be immediately discontinued. Treatment most often consists of high doses of corticosteroids until hemolysis decreases; this is especially beneficial when treating warm-antibody–induced hemolysis (Packman, 2016). Corticosteroids have several actions including suppressing antibody production, reducing the affinity of antibodies for the erythrocytes, and reducing destruction of erythrocytes by macrophages in the spleen (Go, Winters, & Kay, 2017). If the hemoglobin levels return to normal, often within a few weeks, the corticosteroid dose can be gradually reduced, and in some cases be tapered and eventually discontinued. However, treatment with corticosteroids does not produce lasting effects. In severe cases, transfusions with PRBCs are needed to maintain adequate levels of hemoglobin until the hemolytic process can be reduced. The antibodies may react to donor cells, making careful typing and cross matching essential. Transfusions are given slowly and cautiously with careful monitoring for transfusion reaction. Folic acid supplementation should be given when hemolysis is severe, because the bone marrow will attempt to compensate by increasing hematopoietic activity (Hill, Stamps, Massey, et al., 2017).

If corticosteroids do not result in remission, splenectomy (removal of the spleen) may be necessary to remove a major site of erythrocyte destruction. If

neither corticosteroids nor splenectomy are successful, immunosuppressive medications may be given (Hill et al., 2017). Immunosuppressive drugs used include cyclophosphamide and azathioprine. Cyclophosphamide has a rapid onset of action but is associated with significant toxicity. Azathioprine has a slower onset of action but less toxicity. Danazol, a synthetic androgen, may be beneficial for some patients, especially when used in combination with corticosteroids. Immunosuppressive drugs and corticosteroids must be tapered slowly over several months to avoid a flare of the immune system leading to an exacerbation of hemolysis. Monoclonal antibodies, including rituximab, can be effective in some patients and may offer long-term control of symptoms (Hill et al., 2017).

Quality and Safety Nursing Alert

Cross-matching blood when antibodies are present can be difficult. If imperfectly cross-matched PRBCs must be transfused, the nurse should begin the infusion very slowly (10 to 15 mL over 20 to 30 minutes) and monitor the patient very carefully for signs and symptoms of a hemolytic transfusion reaction.

For patients with cold-antibody hemolytic anemia, no treatment may be needed, other than to advise the patient to keep warm. Relocation to a warmer climate may be advisable in some cases. In other situations, where hemolysis is more severe, more aggressive interventions as previously described may be needed.

Nursing Management

Patients may have difficulty understanding the complex nature of their illness and may need repeated explanations in terms they can understand. Patients who have had splenectomy should receive the pneumococcal pneumonia vaccine and annual influenza vaccine and be informed that they are permanently at increased risk for infection. Patients receiving long-term corticosteroid therapy, particularly those with diabetes or hypertension, need careful monitoring. They must understand the need for their medications and avoid abruptly discontinuing them. A written explanation and a tapering schedule should be provided, emphasizing adjustments based on hemoglobin levels. Similar information should be provided when immunosuppressive agents are used. Corticosteroid therapy is associated with risks and patients should be monitored frequently for complications (see Chapter 45, Table 45-3, Corticosteroid therapy and implications for nursing practice).

Hereditary Hemochromatosis

Hereditary hemochromatosis is a genetic condition characterized by excess iron absorption from the GI tract. Normally, the GI tract absorbs 1 to 2 mg of iron daily, but in those with hereditary hemochromatosis, this rate is significantly increased. The excess iron is deposited in various organs, especially the liver, skin, and pancreas; and less frequently, the heart, testes, and thyroid gland. Eventually, affected organs become dysfunctional. Although hereditary hemochromatosis is diagnosed in 1% to 6% of the U.S. population, the actual prevalence is unknown because it is not always recognized. The genetic defect associated with hemochromatosis is most commonly seen as a specific mutation (C282Y homozygosity) of the *HFE* gene. Despite the high prevalence of the genetic mutation, the actual expression of the disease is much lower; the reason for this discrepancy is not clear. The prevalence of hemochromatosis is lower in Asian Americans, African Americans, Latinos, and Pacific Islanders and higher in people of European descent (Kowdley, Brown, Ahn, et al., 2019). Women are less often affected than men because women lose iron through menses.

Clinical Manifestations

Tissue damage is seldom evident until middle age because the accumulation of iron in body organs occurs gradually. Symptoms of weakness, lethargy, arthralgia, and weight loss are common and occur earlier in the course of the disease. The skin may appear hyperpigmented or bronze in color from melanin deposits and **hemosiderin**, an iron-containing pigment. Cardiac arrhythmias and cardiomyopathy can occur, with resulting dyspnea and edema. Endocrine dysfunction can be manifested as hypothyroidism, diabetes, and hypogonadism with testicular atrophy, diminished libido, and impotence. Cirrhosis is common in later stages of the disease, shortens life expectancy, and is a risk factor for hepatocellular carcinoma (Kowdley et al., 2019).

Assessment and Diagnostic Findings

Diagnostic laboratory findings include an elevated serum ferritin and high serum transferrin saturation. CBC values are often normal. The definitive diagnostic test for hemochromatosis was formerly a liver biopsy but that test has been replaced by testing for the associated genetic mutation. While the prevalence of the genetic mutation is high (1 in 200 to 300 in persons of Northern European descent) few people with the gene will actually develop sufficient iron overload to cause symptoms and organ dysfunction (Bacon, 2019).

Medical Management

Therapy often involves the removal of excess iron with therapeutic phlebotomy (removal of whole blood via venipuncture). Each unit of blood removed results in a decrease of 200 to 250 mg of iron. Initial treatment typically involves weekly removal of one unit of whole blood. As the ferritin level decreases, the frequency of phlebotomy can be decreased. The goal is to maintain an iron saturation between 10% and 50% and a serum ferritin level of less than 100 mcg/L (Ganz, 2016). Evaluation of iron studies should be repeated regularly and phlebotomy resumed when the ferritin level rises. CBCs and iron panel tests should be performed at regular intervals during treatment to ensure that the patient is not becoming anemic. If moderate anemia occurs, a delay in phlebotomy is often adequate to correct the problem. Aggressive removal of excess iron can prevent organ dysfunction and the complications associated with organ damage. Fatigue, skin pigmentation changes, and fibrosis are partially reversed by achieving and maintaining normal ferritin levels. Screening for hepatocellular carcinoma includes monitoring alpha-fetoprotein levels and serial abdominal ultrasounds (Kowdley et al., 2019).

Nursing Management

Patients with hemochromatosis frequently limit their iron intake; however, this is not typically effective as lone therapy. They should be advised to avoid taking additional iron supplements. Vitamin C supplementation should also be limited because it enhances iron absorption. Patients with hemochromatosis must be careful to avoid substances that might impair liver function including excessive alcohol ingestion. Other body systems should be monitored for evidence of organ dysfunction, particularly the endocrine and cardiac systems, so that appropriate interventions can be initiated without delay. Children of patients who are homozygous for the *HFE* gene mutation should be screened for the mutation. Patients who are heterozygous for the gene do not develop the disease but should be advised that they may transmit the gene to their children.

POLYCYTHEMIA

Polycythemia refers to an increased volume of RBCs. The term is used when the hematocrit is elevated (more than 55% in males and 50% in females). Dehydration can cause elevated hematocrit but not usually to the level seen with polycythemia. Polycythemia is classified as either primary or secondary. Primary polycythemia, also known as polycythemia vera, is a myeloproliferative neoplasm that is discussed in Chapter 30.

Secondary Polycythemia

Secondary polycythemia is caused by excessive production of erythropoietin. This may occur in response to a reduced amount of oxygen, which acts as a stimulus for production. Heavy smoking, obstructive sleep apnea (OSA), chronic obstructive pulmonary disease (COPD), severe heart disease, or conditions such as living at high altitudes or exposure to low levels of carbon monoxide may be responsible for increased erythropoietin production. Certain hemoglobinopathies (e.g., hemoglobin Chesapeake), in which the hemoglobin has a high affinity for oxygen, or genetic mutations that cause abnormally high erythropoietin levels may also increase erythropoiesis (Prchal, 2016b). Secondary polycythemia can also occur from certain neoplasms that stimulate erythropoietin production (e.g., renal cell carcinoma), excessive use of exogenous erythropoietin, and androgen use.

Management

When secondary polycythemia is mild, treatment may not be necessary. When treatment is necessary, however, it involves treating the primary condition. If the cause cannot be corrected (e.g., treatment of OSA or improving function with smoking cessation), therapeutic phlebotomy may be needed for symptom management and to reduce blood viscosity and volume. Therapeutic phlebotomy is not indicated when the cause for the elevated RBC count is an appropriate response to tissue hypoxia (Prchal, 2016b).

Neutropenia

Neutropenia is defined as a neutrophil count less than 2,000/mm^3. It is the result of decreased production of neutrophils or increased destruction of cells (see Chart 29-5). Neutrophils are essential in preventing and limiting bacterial infection. A patient with neutropenia is at increased risk for infection from both exogenous and endogenous sources (the GI tract and skin are common endogenous sources). The risk for infection is based not only on the severity of the neutropenia but also on its duration. The actual number of neutrophils, known as the **absolute neutrophil count (ANC)**, is determined by a simple mathematical calculation using information from the CBC and differential (see Chapter 12 for further discussion of the ANC). The risk for infection increases proportionately with a decrease in the neutrophil count. The risk is low when the ANC is greater than 1000/mm^3, and high when less than 500/mm^3 and greatest when less than 100/mm^3 (Dale & Welte, 2016). The duration of neutropenia is another risk factor for developing infection as is the underlying etiology (see Chart 29-6).

Chart 29-5

Causes of Neutropenia

Decreased Production of Neutrophils

- Aplastic anemia, due to medications or toxins
- Chemotherapy
- Metastatic cancer, lymphoma, leukemia
- Myelodysplastic syndromes
- Radiation therapy

Ineffective Granulocytopoiesis

- Megaloblastic anemia

Increased Destruction of Neutrophils

- Bacterial infections
- Hypersplenism
- Immunologic disorders (e.g., systemic lupus erythematosus)
- Medication induced[a]
- Viral disease (e.g., infectious hepatitis, mononucleosis)

[a]Formation of antibody to medication, leading to a rapid decrease in neutrophils.

Adapted from Dale, D. C., & Welte, K. (2016). Neutropenia and neutrophilia. In K. Kaushansky, M. A. Lichtman, J. T. Prchal, et al. (Eds.). *Williams hematology* (9th ed.). New York: McGraw-Hill Medical.

Clinical Manifestations

There are no definite symptoms of neutropenia until the patient develops an infection. A routine CBC with differential can reveal neutropenia before the onset of infection.

Chart 29-6 RISK FACTORS

Development of Infection and Bleeding in Patients with Hematologic Disorders

Risk for Infection	Risk for Bleeding
• *Severity of neutropenia*: Risk for infection is proportional to severity of neutropenia. • *Duration of neutropenia:* Increased duration of neutropenia leads to increased risk for infection. • *Nutritional status:* Decreased protein stores lead to decreased immune response and anergy. • *Deconditioning:* Decreased mobility leads to decreased respiratory effort, leading to increased pooling of secretions. • *Lymphocytopenia; disorders of lymphoid system (chronic lymphocytic leukemia, lymphoma, and myeloma)*: Decreased cell-mediated and humoral immunity. • *Invasive procedures:* Breaks in skin integrity create increased opportunities for organisms to enter blood system. • *Hypogammaglobinemia:* Decreased antibody formation.	• *Severity of thrombocytopenia:* Risk increases when platelet count decreases; usually not a significant risk until platelet count drops below 10,000/mm^3, or less than 50,000/mm^3 with trauma or when an invasion procedure is performed. • *Duration of thrombocytopenia:* Risk increases when duration increases (e.g., risk is less when duration is transient as after chemotherapy than when duration is prolonged as with decreased cell production by bone marrow). • *Sepsis:* Mechanism unclear; appears to cause increased platelet consumption. • *Increased intracranial pressure:* Increased blood pressure leads to rupture of blood vessels. • *Liver dysfunction:* Decreased synthesis of multiple clotting factors. • *Renal dysfunction:* Decreased platelet function. • *Dysproteinemia:* Protein coats surface of platelet, leading to decreased platelet function; protein causes increased blood viscosity, which leads to stretching of capillaries an increased risk for rupture and bleeding. • *Alcohol abuse:* Suppressive effect on bone marrow results in deceased platelet production and impaired platelet function; impaired liver function results in decreased production of clotting factors.

- *Poor hygiene:* Increased organisms on skin and mucous membranes, including perineum.
- *Poor dentition; mucositis*: Decreased endothelial integrity leads to increased opportunity for organisms to enter blood system.
- *Antibiotic therapy*: Increased risk for superinfection, often fungal.
- *Certain medications*: See text.

New York: McGraw-Hill Medical.

Quality and Safety Nursing Alert

Patients with neutropenia do not always exhibit classic signs of infection. Fever is the most common indicator of infection, but is not always present, particularly if the patient is taking corticosteroids or is an older adult.

Medical Management

Treatment of neutropenia varies depending on its etiology. If the neutropenia is medication induced, the offending agent should be discontinued immediately whenever possible. Treatment of an underlying neoplasm can temporarily

make the neutropenia worse, but after bone marrow recovery, treatment may improve it. Corticosteroids may be used if the neutropenia is caused by an immunologic disorder. The use of growth factors such as granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor can be effective in increasing neutrophil production when the cause is reduced cell production. Withholding or reducing the dose of chemotherapy or radiation therapy may be necessary when the neutropenia is caused by these cancer treatments; however, when treatment is potentially curative, administration of growth factors is preferable so that the maximum antitumor effect of the cancer treatment can be achieved (Lyman, 2019).

If the neutropenia is associated with fever, it is assumed that the patient has an infection. Cultures of blood, urine, and sputum, as well as a chest x-ray are obtained. Broad-spectrum antibiotics are initiated immediately after cultures are obtained to ensure adequate treatment of infectious organisms. After culture and sensitivity results are obtained, the antibiotic regimen may be changed.

Nursing Management

Nurses in all settings can play a crucial role in assessing the severity of neutropenia and in preventing and managing complications, which most often include infections. Knowledge of risk factors for developing infection is an integral part of nursing care, particularly for those who work with patients who have cancer. Patient education is equally important, particularly at the time of discharge from the hospital or in the outpatient setting so that the patient can put an appropriate self-care plan into effect, including knowing when to seek medical attention (see Chart 29-7). Patients at risk for neutropenia should have blood drawn for a CBC with differential; the frequency is based on the suspected duration and severity of the neutropenia. To assess the severity of neutropenia and risk for infection, nurses must assess the ANC (see Chapter 12 for formula). Nursing interventions related to neutropenia are delineated in Chapters 12 and 30.

Lymphopenia

Lymphopenia is defined as a lymphocyte count less than 1500/mm^3. It may occur as a result of exposure to ionizing radiation, long-term use of corticosteroids, uremia, infections (particularly viral infections), neoplasms (breast and lung cancer and advanced Hodgkin disease), and some protein-losing enteropathies which may cause lymphocytes from the GI tract to be lost (Vasu & Caligiuri, 2016). When lymphopenia is mild, there are no serious sequelae, but when it is severe, it can result in bacterial infections (due to

reduced B lymphocytes) or in opportunistic infections (due to reduced T lymphocytes). T-lymphocyte depletion is frequently associated with viral infections, including human immune deficiency virus (HIV). Excessive or prolonged use of alcohol can also impair lymphocyte production; lymphocyte counts can improve when alcohol intake is discontinued (Vasu & Caligiuri, 2016).

Bleeding Disorders

The failure of normal hemostatic mechanisms can result in bleeding which may be severe. Bleeding is commonly provoked by trauma; however, in certain circumstances, it can occur spontaneously. The causes of bleeding disorders can be categorized based upon whether there is a deficiency of platelets or a defect in the platelets, or based upon whether there is an inherited or acquired coagulation factor abnormality, or based upon a defect in the vasculature. When the cause is platelet or coagulation factor abnormalities, bleeding can occur anywhere in the body. When the source is a vascular abnormality the site of bleeding is more localized. Some patients may have simultaneous defects in more than one hemostatic mechanism.

Chart 29-7 **HOME CARE CHECKLIST**

The Patient at Risk for Infection

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of alterations in neutrophils, lymphocytes, immunoglobulins on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in lifestyle (e.g., diet, activity) or home environment necessary to decrease risk for infection.
  - Maintain good hand hygiene technique, oral hygiene, total body hygiene, and skin integrity.
  - Avoid cleaning birdcages and litter boxes; consider avoiding garden work (soil) and fresh flowers in stagnant water.
  - Maintain a high-calorie, high-protein diet, with fluid intake of 3000 mL daily (unless fluids are restricted).
  - Avoid people with infections and crowds.
  - Perform deep breathing; use incentive spirometer every 4 hours while awake if mobility is restricted.
  - Provide adequate lubrication with gentle vaginal manipulation during penile-vaginal intercourse; avoid anal intercourse.
- Identify signs and symptoms of infection to report to the primary provider, such as fever; chills; wet or dry cough; breathing problems; white patches in the mouth; swollen glands; nausea; vomiting; persistent abdominal pain; persistent diarrhea; problems with urination or changes in the character of the urine; red, swollen, or draining wounds; sores or lesions on the body; persistent vaginal discharge with or without itching; and severe fatigue.
- Demonstrate how to monitor for signs of infection.
- Describe to whom, how, and when to report signs of infection.
- Describe appropriate actions to take should infection occur.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

The bone marrow may be stimulated to increase platelet production. This can be a reactive response to significant bleeding, or a more general response to increased hematopoiesis, as in iron deficiency anemia. Sometimes an increase in platelets does not result from increased platelet production, but from a loss of platelet pooling in the spleen. The spleen typically holds about one third of circulating platelets at any time. If the spleen is absent (e.g., after splenectomy) the platelet reservoir is lost, and an abnormally high number of platelets enter the circulation. Eventually the rate of platelet production slows to reestablish a more normal platelet level.

Clinical Manifestations

Signs and symptoms of bleeding disorders vary according to the type of defect. A careful history and physical examination can be useful in determining the source of the hemostatic defect. Abnormalities of the vascular system are sources of localized bleeding, usually into the skin. Because platelets are primarily responsible for stopping bleeding from small vessels, patients with decreased platelets develop **petechiae,** often in clusters. These lesions can be seen on the skin and mucous membranes and occur throughout the body (see Fig. 29-4). Bleeding from platelet disorders can be severe, but most often, bleeding from platelet disorders can be controlled when pressure is applied.

In contrast, coagulation factor defects do not tend to cause superficial bleeding because the primary hemostatic mechanisms are still intact. Instead, bleeding occurs deeper within the body (e.g., subcutaneous or intramuscular hematomas, hemorrhage into joint spaces). External bleeding diminishes very slowly when local pressure is applied; it frequently recurs several hours after pressure is removed. An example of this would be severe bleeding that occurs several hours after tooth extraction. Risk factors for bleeding are listed in Chart 29-6.

Figure 29-4 • Petechiae. Reprinted with permission from *Wintrobe's clinical hematology* (10th ed). (1999). Color plate 62.4. Philadelphia, PA: Lippincott Williams & Wilkins.

Medical Management

Management varies based on the underlying bleeding disorder. If bleeding is significant, transfusion of blood products may be indicated. The specific blood product used is determined by the underlying defect and the extent of blood loss. If fibrinolysis is excessive, hemostatic agents such as aminocaproic acid can be useful to inhibit the process, but this agent must be used cautiously because excessive inhibition of fibrinolysis can lead to thrombosis. A patient scheduled for an invasive procedure may need to have transfusions of select blood products to reduce risk for excessive bleeding.

Nursing Management

Patients who have bleeding disorders or who have the potential for development of such disorders as a result of disease or therapeutic agents must be educated to monitor themselves frequently and carefully for signs of bleeding (see Chart 29-8). They should understand the importance of avoiding activities that increase the risk for bleeding, such as contact sports. The skin should be examined for evidence of bleeding, including petechiae and ecchymoses (bruises) and the nose and gums should also be examined for bleeding. When bleeding disorders are severe, patients who are hospitalized are monitored for bleeding by testing all drainage and excreta (feces, urine, emesis, and, gastric drainage) for obvious and occult blood.

Chart 29-8 **HOME CARE CHECKLIST**

The Patient at Risk for Bleeding

At the completion of education, the patient and/or caregiver will be able to:

- Describe the source and function of platelets and clotting factors.
- State the impact of an alteration in platelets on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in lifestyle (e.g., diet, activity) or home environment necessary to decrease risk of bleeding.
  - Avoid the use of suppositories, enemas, and tampons
  - Avoid constipation
  - Avoid vigorous sexual intercourse and anal sex
  - Avoid contact sports
  - Avoid or limit aggressive manual labor
  - Use an electric razor for shaving and a soft-bristled toothbrush for teeth brushing
  - Notify health care professional before having dental work or other invasive procedures
- Identify medications and other substances to avoid (e.g., aspirin-containing medications, alcohol).
- Identify signs and symptoms of bleeding.
- Demonstrate how to monitor for signs of bleeding.
- Describe to whom, how, and when to report signs of bleeding.
- Demonstrate appropriate actions to take should bleeding occur.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

TABLE 29-3 Causes and Management of Thrombocytopenia

Cause	Management
Decreased Platelet Production	
Hematologic malignancy; especially acute leukemia	Treat leukemia, platelet transfusion
MDS	Treat MDS, platelet transfusion
Bone marrow metastases from solid tumors	Treat solid tumor
Aplastic anemia	Treat underlying condition
Megaloblastic anemia	Treat underlying anemia
Toxins	Remove toxin
Medications (e.g., sulfa drugs, methotrexate)	Discontinue medication
Infection (especially sepsis, viral infections, tuberculosis, chronic hepatitis C)	Treat underlying infection
Chronic alcohol abuse	Refrain from alcohol, refer for substance use disorder
Chemotherapy	Delay or decrease dose, platelet transfusion
Chronic liver disease	Treat underlying disorder
Radiation (e.g., pelvic irradiation)	Platelet transfusion
Delayed engraftment after stem cell transplantation	Platelet transfusion
Increased Platelet Destruction	
Due to antibodies:	Treat underlying condition
ITP	
SLE	
Malignant lymphoma	
CLL	Treat CLL and/or treat as ITP
Medications	Discontinue medication
Due to infection: Bacteremia/sepsis; post-viral infection	Treat infection
Sequestration of platelets in spleen	If severe, splenectomy may be needed
Increased Platelet Consumption	
DIC	Treat underlying condition triggering DIC; refer to text for indicated treatments
Major bleeding	Transfusion support, surgery if appropriate
Severe pulmonary embolism/severe thrombosis	Treat clot
Intravascular devices (intra-aortic balloon pump, cardiac assist devices)	Transfusion support as needed
Extracorporeal circulation (hemofiltration, extracorporeal lung assist)	Transfusion support as needed

CLL, chronic lymphocytic leukemia; DIC, disseminated intravascular coagulation; ITP, idiopathic thrombocytic purpura; MDS, myelodysplastic syndrome; SLE, systemic lupus erythromatosus.

Thrombocytopenia

Thrombocytopenia (low platelet level) can result from a variety of factors, including reduced production of platelets in the bone marrow, increased destruction of platelets, or increased consumption of platelets (e.g., the use of platelets for clot formation). Causes and treatments are summarized in Table 29-3.

Clinical Manifestations

Bleeding and petechiae rarely occur with platelet counts greater than 50,000/mm^3, but excessive bleeding can occur after surgery or other trauma. When platelet counts fall to 20,000/mm^3 or less, petechiae may occur. Additionally, nasal and gingival bleeding, excessive menstrual bleeding, and excessive bleeding from surgery or dental extractions can occur. Spontaneous and potentially fatal bleeding in the CNS or GI tract can occur when platelet counts fall to less than 5000/mm^3. If platelet function is abnormal as a result of disease (e.g., MDS) or medications (e.g., aspirin) the risk of bleeding may be much greater even when the platelet count is mildly reduced.

Assessment and Diagnostic Findings

Bone marrow aspiration and biopsy are used to identify platelet deficiency associated with decreased production. A number of genetic causes of thrombocytopenia have been identified. Autosomal dominant, autosomal recessive, and X-linked mutations are among such disorders. When platelet destruction is the cause of thrombocytopenia, the bone marrow shows increased megakaryocytes and normal or increased platelet production as the body attempts to compensate for the decreased platelets in the circulation. Screening for hepatitis B or C, which can cause thrombocytopenia, should be done.

An important cause to exclude is pseudothrombocytopenia. Platelets aggregate and clump in the presence of ethylenediaminetetraacetic acid (EDTA), the anticoagulant present in the tube used for CBC collection. This clumping can be seen 0.8% to 1.25% of the population. Manual examination of the peripheral smear can easily detect platelet clumping as the cause of thrombocytopenia. Redrawing the blood in a tube anticoagulated with citrate rather than EDTA, followed by rapid analysis of the platelet count can provide a more accurate count.

Medical Management

Secondary thrombocytopenia is usually managed with treatment of the underlying disease. If platelet production is impaired, platelet transfusion may be needed to increase the platelet count and stop bleeding or prevent spontaneous hemorrhage. If excessive platelet destruction occurs, transfused platelets may also be destroyed. The most common cause of increased platelet destruction is immune thrombocytopenic purpura (ITP) (see the following discussion). In some circumstances, splenectomy may be a therapeutic intervention, but it is not always feasible. For example, when an enlarged spleen is associated with portal hypertension related to cirrhosis, splenectomy may cause further issues with bleeding.

Nursing Management

When determining nursing interventions, the nurse considers the cause of the thrombocytopenia, the likely duration, and overall condition of the patient. Education is an important intervention to promote safety and should include fall prevention, particularly for older adults and those who are frail. Interventions for patients with secondary thrombocytopenia are the same as those for a patient with cancer who is at risk for bleeding (see Chapter 12).

Immune Thrombocytopenic Purpura

ITP is a condition that affects people of all ages but is most common in children and young women. This disorder is also referred to as idiopathic thrombocytopenic purpura, and immune thrombocytopenia. Primary ITP occurs as an isolated disorder while secondary ITP is associated with other disorders including autoimmune disorders (e.g., antiphospholipid antibody syndrome), viral infections (e.g., hepatitis C, HIV), and some drugs (e.g., cephalosporins, sulfonamides, furosemide). A platelet count less than 100,000/mm^3 with no explicable cause is the primary criterion for the diagnosis (Nomura, 2016).

Pathophysiology

Primary ITP is an acquired immune disorder characterized by thrombocytopenia that results from pathologic antiplatelet antibodies, impaired production of megakaryocytes, and T-cell–mediated destruction of platelets. Secondary ITP is associated with other underlying disorders, including autoimmune disease (systemic lupus erythematosus or rheumatoid arthritis), HIV infection, *Helicobacter pylori* infection, or underlying immune dysregulation syndromes, such as common variable immunodeficiency. The

majority of adults with ITP (approximately 80%) have primary ITP. With both types of ITP, antiplatelet antibodies develop and bind to the patient's platelets. The antibody-bound platelets are then destroyed by the reticuloendothelial system (RES) and tissue macrophages. The body attempts to compensate for the platelet destruction by increasing platelet production within the bone marrow (Lambert & Gernsheimer, 2017).

Clinical Manifestations

ITP is often asymptomatic; the low platelet count frequently is an incidental finding. Platelet counts of less than 30,000/mm^3 are not uncommon. Common signs of thrombocytopenia include easy bruising, heavy menses, and petechiae on the extremities or trunk (see Fig. 29-4). Patients who experience only bruising and petechiae tend to have fewer complications from bleeding than those with bleeding from mucosal surfaces, such as the GI tract and respiratory system (sometimes described as "wet purpura"). Patients with wet purpura have a greater risk of life-threatening bleeding which requires immediate aggressive treatment to reduce complications (Diz-Kucukkaya & Lopez, 2016). Severe thrombocytopenia, characterized by platelet count less than 20,000/mm^3, a prior history of minor bleeding episodes, and advanced age, is a risk factor for severe bleeding. Despite low platelet counts, platelets are typically immature yet very functional, with the ability to adhere to endothelial surfaces and each other. This may explain why spontaneous bleeding does not always occur. Treatment is not necessary unless bleeding becomes severe or if surgery or another invasive procedure is required (Diz-Kucukkaya & Lopez, 2016).

Assessment and Diagnostic Findings

A careful history and physical examination are essential to aid in excluding other causes of thrombocytopenia and identify sites of bleeding. Patients should be tested for hepatitis C and HIV, if not previously done to rule them out as potential causes. Bone marrow aspirate may reveal an increased number of megakaryocytes. The severity of the thrombocytopenia is highly variable.

H. pylori infection is associated with ITP, and treatment to eradicate the infection may improve the platelet count. The correlation between *H. pylori* infection and ITP is not clear; it is postulated that the presence of the *H. pylori* organism may stimulate an autoimmune reaction (Aljarad, Alhamid, Tarabishi, et al., 2018).

Medical Management

The primary goal of treatment is to achieve a platelet count high enough to maintain hemostasis. Because the risk for bleeding does not typically increase until the platelet count is less than 30,000/mm^3, a patient whose platelet count exceeds 30,000/mm^3 to 50,000/mm^3 may be carefully monitored without immediate intervention. However, if the platelet count is less than 30,000/mm^3 or if bleeding occurs, the goal is to improve the patient's platelet count and not to cure the disease. The decision to treat is made based upon the severity of bleeding (if any) and not solely on the platelet count. Potential treatment side effects, the patient's lifestyle, activity level, concurrent use of medications, and treatment preferences are also considered. A person with a sedentary lifestyle can tolerate a low platelet count more safely than a more active person; however, increasing age is also associated with increased risk for bleeding and mortality (Diz-Kucukkaya & Lopez, 2016).

Treatment for ITP usually involves several approaches. If the patient is taking a medication known to be associated with ITP (e.g., quinine, sulfa-containing drugs), then that medication should be discontinued. Transfusions are often ineffective because antiplatelet antibodies bind with transfused platelets, causing them to be destroyed. Platelet counts may drop even further after platelet transfusion. Thus, despite extremely low platelet counts, platelet transfusions may result in catastrophic bleeding in patients with wet purpura. Aminocaproic acid, a fibrinolytic enzyme inhibitor that slows the dissolution of blood clots, may be useful for patients with significant mucosal bleeding that is resistant to other treatments.

The mainstay of short-term therapy is the use of immunosuppressive agents. These agents block the binding receptors on macrophages to reduce platelet destruction. The American Society of Hematology recommends dexamethasone or prednisone in adults with newly diagnosed ITP as the types of corticosteroids that might be selected for initial therapy. Continuous long-term use of corticosteroids is not recommended because of the risk for side effects (Neunert, Terrell, Arnold, et al., 2019). Platelet counts typically begin to rise within a few days after initiating treatment with corticosteroids. The platelet count tends to decrease once the corticosteroid dose is tapered but may remain sufficiently adequate to prevent bleeding.

IVIG is commonly used to treat ITP. It renders its effect by binding to the receptors on macrophages. However, the need for high doses of IVIG and its high cost are disadvantages.

For the procedural guidelines for managing immunoglobulin therapy, go to thepoint.lww.com/Brunner15e.

The effects of treatment are transient in most cases. Another approach to treatment of chronic ITP is the use of anti-D immunoglobulin in patients who are Rh (D) positive. The exact mechanism of action is unknown, but it is theorized that the anti-D binds to the patient's erythrocytes, which are in turn destroyed by the body's macrophages. The receptors in the RES may become flooded with sensitized erythrocytes, which then reduce the number of antibody-coated platelets. This then results in a transient reduction of hematocrit and an increased number of platelets in some patients with ITP (Neunert et al., 2019).

Eventually, the platelet count again declines and additional therapy is needed. Second-line treatment options should take the patient's individual needs and the potential treatment-related side effects into account.

Splenectomy is an alternative treatment and typically results in a sustained increase in platelets. Many patients can maintain a "safe" platelet count of more than 30,000/mm^3 after splenectomy; however, many patients may have a recurrence of thrombocytopenia months or years later (Neunert et al., 2019). Patients who undergo splenectomy are permanently at risk for serious infection and should receive pneumococcal, influenzae, and meningococcal vaccines approximately 2 weeks prior to splenectomy, or 2 to 3 weeks postoperatively if splenectomy is performed emergently (Bonanni, Grazzini, Niccolai, et al., 2017) (see Chapter 19 for information on pneumonia vaccine).

Other management strategies include use of monoclonal antibodies, such as rituximab. Patients may have long lasting effects with increased platelet counts for up to 1 year after treatment. Unfortunately, when the response dwindles, platelets may fall to unsafe levels, making additional treatment necessary (Neunert et al., 2019).

Two thrombopoietin receptor agonists are available for treatment of refractory ITP. These include romiplostim and eltromopag. Romiplostim is given as a weekly subcutaneous injection and eltromopag is given orally. The response varies widely, and treatment must be continued indefinitely (Depré, Aboud, Ringel, et al., 2016).

Nursing Management

Nursing care includes a thorough assessment of the patient's lifestyle to determine risks for bleeding associated with activities. A careful medication history should also be obtained, including use of over-the-counter (OTC) medications, herbs, and nutritional supplements. The nurse must be alert to sulfa-containing medications and others that may interfere with platelet function (e.g., aspirin, NSAIDs). The nurse must assess for a history of recent viral illness and reports of headache, visual disturbances, and other symptoms that may indicate intracranial bleeding. Patients admitted to the hospital with wet purpura and low platelet counts should have neurologic assessment

included with their vital sign measurements. Injections and rectal medications should be avoided. Rectal temperature measurements should also be avoided because they may cause trauma to the rectal mucosa and stimulate bleeding.

There is evidence that patients with ITP experience an increase in fatigue when compared to those without the disease that is not associated with the duration of the disease, corticosteroid use, bleeding, or low platelet counts (Diz-Kucukkaya & Lopez, 2016). Assessment of the extent of the patient's fatigue can be beneficial in helping the patient to identify coping strategies.

Patient and family education should address signs of exacerbation (e.g., petechiae and ecchymoses), how to contact appropriate health care personnel, the name and type of medications inducing ITP (if appropriate) current medical treatment (name of medications, side effects, tapering schedule, if indicated), frequency of monitoring for the platelet count, and follow-up appointments.

The patient should be instructed to avoid all agents that interfere with platelet function, including herbal therapies and OTC medications. The patient should avoid constipation, straining, and vigorous flossing of the teeth. Electric razors should be used for shaving and soft-bristled toothbrushes should be used for dental hygiene. Patients and their partners should be counseled to avoid vigorous sexual intercourse when platelet counts are low. Patients who are receiving long-term corticosteroids should understand that they are at increased risk for complications including osteoporosis, proximal muscle wasting, cataract formation, and dental caries (see Chapter 45, Table 45-3). Bone mineral density should be monitored, and patients may benefit from supplemental calcium, vitamin D, and bisphosphonate to reduce risk for significant bone disease.

Platelet Defects

Quantitative platelet defects (i.e., thrombocytopenia, thrombocytosis) are not uncommon, however qualitative defects may also occur. Despite normal platelet counts, when qualitative defects are present, platelets do not function normally. A platelet function analyzer is used to evaluate platelet function. This technique is valuable for rapid screening. Examination of platelet morphology with the peripheral blood smear in the laboratory can also identify possible qualitative defects. Platelet morphology is frequently hypogranular and pale and may also be larger than normal (Coutre, 2018).

Aspirin may induce a platelet disorder. Even small amounts of aspirin can reduce normal platelet aggregation and increase bleeding time for several days after ingestion. Although this typically does not cause bleeding in most people, patients with thrombocytopenia and coagulation disorders such as hemophilia

can experience significant bleeding after ingestion of aspirin, especially in conjunction with trauma and invasive procedures.

Chart 29-9 PHARMACOLOGY

Medications and Substances That Impair Platelet Function

Medications

- Angiotensin-converting enzyme inhibitors
- Angiotensin receptor blockers
- Antibiotics
- Beta-lactams
- Cephalosporins
- Penicillins
- Beta-blockers
- Calcium channel blockers
- Chemotherapeutic agents
- Mithramycin
- Vincristine
- Diuretics
- Ethacrynic acid
- Furosemide
- HMG-CoA reductase inhibitors (i.e., “statins”)
  - Atorvastatin
  - Simvastatin
- Methylxanthines
  - Aminophylline
  - Theophylline
- Milrinone
- Misoprostol
- Nitrates
  - Isosorbide
  - Nitroglycerin
- Phosphodiesterase inhibitors
- Pentoxyfilline
- Sildanafil
- Tadalafil
- Protease inhibitors
- Ritonavir
- Tipranavir
- Phenytoin
- Selective serotonin reuptake inhibitors
  - Fluoxetine
  - Fluvoxamine
  - Paroxetine
  - Sertraline
- Tricyclic antidepressants
  - Doxepin
  - Imipramine

Tyrosine kinase inhibitors
Dasatinib
Imatanib
Valproic acid

Food and Food Additives

Caffeine
Ethanol (Alcohol)
Fish oils
Garlic
Ginger
Grape juice

Over-the-Counter and Herbal Supplements

Ginkgo biloba
Ginseng
Saw palmetto
Vitamin C
Vitamin E

Congenital and acquired disorders of platelet function. *UpToDate*. Retrieved on 1/1/2020 at: www.uptodate.com/contents/congenital-and-acquired-disorders-of-platelet-function; Nagalla, S., & Bray, P. F. (2017). Hematology: Drug-induced platelet dysfunction. Cancer Therapy Advisor. Retrieved on 1/1/2020 at: www.cancertherapyadvisor.com/home/decision-support-in-medicine/hematology/drug-induced-platelet-dysfunction/

NSAIDs can also impair platelet function, but the effects are not as prolonged as with aspirin (4 days vs. 7 to 10 days). Other causes of platelet dysfunction include end-stage renal disease, MDS, multiple myeloma, cardiopulmonary bypass, herbal remedies, and other medications (see Chart 29-9).

Clinical Manifestations

Bleeding can range from mild to severe. The severity does not necessarily correlate with the platelet count or with tests that measure coagulation (prothrombin time [PT], activated partial thromboplastin time [aPTT]). However, results from these tests may be useful in determining the etiology of the bleeding disorder when abnormalities are present (Levi, Seligsohn, & Kaushansky, 2016). For example, an elevated PT in the setting of a normal aPTT and platelet count may suggest factor VII deficiency, whereas an elevated aPTT in the setting of a normal PT and platelet count is suggestive of

von Willebrand disease (vWD) or hemophilia. Ecchymoses, particularly on the extremities, are frequently evident. Patients with platelet dysfunction are at increased risk for bleeding after trauma or invasive procedures (e.g., dental extraction, biopsy).

Medical Management

Platelet dysfunction that is associated with a medication requires stopping the medication when possible, especially when bleeding occurs. If platelet dysfunction is present, bleeding may be prevented by transfusion of platelets prior to an invasive procedure. Antifibrinolytic agents (e.g., aminocaproic acid) may be needed to prevent significant bleeding after procedures; desmopressin, a synthetic vasopressin analogue, can reduce the duration of bleeding and improve hemostasis for some patients (Levi et al., 2016).

Nursing Management

Patients with platelet dysfunction should be instructed to avoid substances that can interfere with platelet function. These include OTC medications such as aspirin and NSAIDs, as well as some herbal preparations, nutritional supplements, and alcohol. Patients should notify all health care providers, including dentists, of their underlying condition before undergoing any invasive procedure so that measures to reduce risk for bleeding can be implemented. Maintaining good oral hygiene is important to promote good dental health and reduce risk for gingival bleeding.

Inherited Bleeding Disorders

Two of the more commonplace inherited bleeding disorders include hemophilia and vWD. Each of these is discussed in the sections that follow.

Hemophilia

There are two forms of hemophilia: hemophilia A and hemophilia B. Both are clinically similar but are distinguishable by laboratory tests. Hemophilia A is caused by a genetic defect that results in deficient or defective factor VIII. Hemophilia B, also known as Christmas disease, is due to a genetic defect that causes a deficiency or defect in factor IX. Hemophilia is a relatively common disease, with hemophilia A occurring in 1 of every 5000 to 7000 births. Hemophilia A is five times more common than hemophilia B (Escobar & Key, 2016). Both hemophilia A and hemophilia B are inherited as X-linked traits, making both conditions much more common in males than in females.

Females can be carriers of the gene but are typically asymptomatic. It is estimated that one third of cases result from spontaneous mutations rather than familial transmission (National Hemophilia Foundation, 2019).

The tendency for developing bleeding is the basis for the classification of hemophilia (Escobar & Key, 2016):

- Severe disease is defined by a plasma factor activity level of less than 1 IU/dL, or less than 1% normal factor VIII levels.
- Moderate disease reflects a level of 1 to 5 IU/dL or factor VIII level between 1% and 5% of normal.
- Mild disease reflects a level above 5 IU/dL or factor VIII level above 5%.

Hemophilia is often recognized in early childhood, usually in the toddler period. However, patients with mild hemophilia may not be diagnosed until they experience severe trauma or surgery.

Clinical Manifestations

Hemophilia is manifested by hemorrhages into various parts of the body; hemorrhages can be severe and can occur even with minimal trauma. The frequency and severity of bleeding depend on the degree of factor deficiency and the severity of the precipitating trauma. Those with mild factor deficiency rarely develop spontaneous bleeding; hemorrhage is usually associated with trauma. In contrast, spontaneous bleeding, including hemarthroses and hematomas, occur frequently in patients with severe factor deficiency (Escobar & Key, 2016).

About 75% of bleeding in patients with hemophilia occurs in the joints. Joints most frequently affected include the knees, elbows, ankles, shoulders, wrists, and hips. Pain is often noticed prior to the presence of swelling and limitations in movement. Recurrent joint hemorrhages can lead to joint arthropathy that causes ankylosis and chronic pain (see Fig. 29-5). Patients with severe factor deficiency may become disabled due to joint damage early in life. Bleeding may be superficial as hematomas or as deep hemorrhages into muscle and subcutaneous tissue. With severe factor VIII deficiency, hematomas can occur without trauma and extend into the surrounding tissue. Hematomas in the muscles, particularly in the extremities, may cause peripheral nerve compression with impaired sensation. Over time, nerve compression may lead to weakness and atrophy of the affected area.

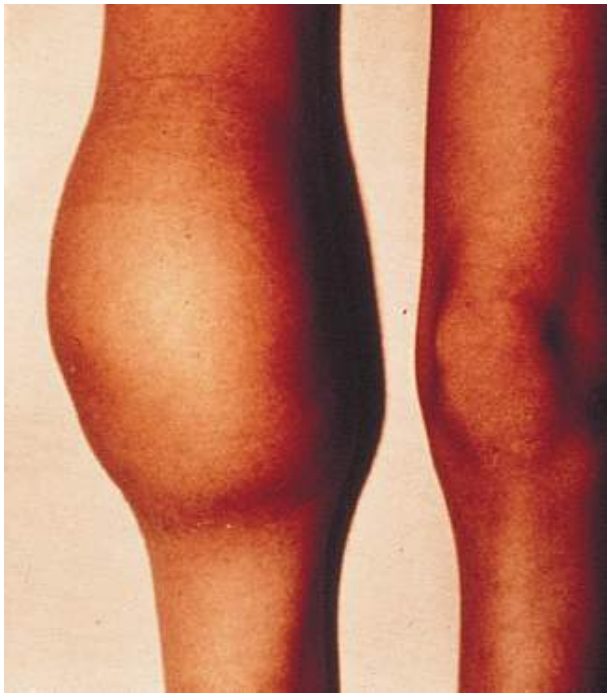

Figure 29-5 • Hemophilic arthropathy: Sequelae of recurrent joint bleeding. Reprinted with permission from *Wintrobe's clinical hematology* (10th ed). (1999). Color plate 68. Philadelphia, PA: Lippincott Williams & Wilkins.

Bleeding is not limited to joints and muscles. Dental procedures, including extractions, are associated with bleeding. Spontaneous hematuria and GI bleeding may also occur. Bleeding is also common in other mucous membranes, including the nasal passages and conjunctivae as well as soft tissue. Falls in adults are particularly dangerous. Intracranial and extracranial hemorrhages are the most serious sites of bleeding. Any head trauma requires immediate evaluation and treatment. Surgical procedures often result in excessive bleeding at the surgical site. Clot formation and wound healing are often poor.

Medical Management

Recombinant forms of factor VIII and IX concentrates are available and decrease the need for using plasma-derived factor concentrates and fresh-frozen plasma. Concentrates are used when patients are actively bleeding; it is important that treatment is initiated as soon as possible to reduce risk for bleeding complications. Factors should be administered prophylactically prior to traumatic procedures to prevent excessive bleeding (Escobar & Key, 2016). Children frequently receive prophylactic treatment three to four times per week to reduce risk for joint complications. The cost and challenges with adhering to the prescribed regimen may limit the effectiveness of this approach

(Thornburg & Duncan, 2017). Initiating prophylactic treatment in adolescents and young adults can also lead to positive outcomes by reducing joint complications, pain, and disability and improving quality of life (Reding, 2018).

Development of neutralizing antibodies (inhibitors) to factor concentrates is a significant complication of factor replacement therapy. Up to 33% of patients with hemophilia A and 3% of patients with hemophilia B develop antibodies to factor concentrates (Reding, 2018). The presence of these inhibitors may be transient; however, the effects may be significant and lead to partial or complete refractoriness to factor replacement, leading to increased risk for bleeding. Ideally, antibody titers should remain low. It is important to identify rising antibody titers as soon as possible. To reduce the impact of inhibitors, inducing immune tolerance is critical. Immunosuppressive therapy in the form of corticosteroids, IVIG or cyclophosphamide may be used to remove inhibitors. Emicizumab is a new bispecific humanized monoclonal antibody that is effective in preventing bleeding in patients with hemophilia A. Initially indicated as effective therapy for patients with inhibitors, it is now also indicated for patients without inhibitors (Franchini, Marano, Pati, et al., 2019; Young, Liesner, Chang, et al., 2019). Patients with severe factor deficiency should be screened for antibodies, particularly prior to invasive procedures, so that appropriate therapy aimed at reducing risk for bleeding complications can be started. Other therapeutic options include administration of recombinant factor VIIa or activated prothrombin complex concentrates (Reding, 2018).

Aminocaproic acid inhibits fibrinolysis and subsequently stabilizes blood clots. It can be very effective as an adjunctive measure to treat mucosal bleeding after oral surgery. Desmopressin induces a significant but short-lived increase in factor VIII levels; the mechanism of this response is unclear. In patients with mild forms of hemophilia A, desmopressin is very useful and can significantly reduce the requirement for blood products (Mannucci, 2018).

Nursing Management

Most adult patients with hemophilia are diagnosed during childhood. They frequently need assistance in coping with the disease because it is chronic and imposes restrictions on their lifestyle. Additionally, the disease is inherited and can be passed to future generations. Helping patients cope with their condition, assisting them to identify positive aspects of their lives, and encouraging independence and self-sufficiency are important nursing activities. This must be balanced with promoting safety and preventing trauma that can result in acute bleeding. As patients mature, they can be encouraged to work through their feelings, progressing toward acceptance, and assuming greater responsibility for maintaining an optimal state of health.

Patients with mild factor deficiency may not be diagnosed until they reach adulthood if they do not have surgery or significant trauma during childhood. The nurse must provide these patients with extensive education to understand activity restrictions and self-care strategies to reduce risk for hemorrhage and complications associated with bleeding. Safety at home and at work should be emphasized.

Patients and family caregivers need to learn how to administer factor concentrate at home at the earliest signs of bleeding to minimize bleeding and reduce complications. Prophylactic factor replacement can be beneficial in reducing morbidity associated with repeated episodes of bleeding. This method requires factor administration several times a week, making adherence to the regimen difficult. Nurses can help patients and families understand the potential benefits of prophylactic therapy while helping them to minimize the disadvantages. Patients with hemophilia are also instructed to avoid agents that can interfere with platelet aggregation that can add additional risk for bleeding. Aspirin, NSAIDs, some herbal and nutritional supplements (e.g., nettle, chamomile, alfalfa), and alcohol should be avoided. Oral hygiene is an important measure to reduce gingival bleeding, and good dental health should be promoted to reduce the need for extractions over the long term. While application of pressure may be helpful in controlling bleeding from minor injuries in patients with factor deficiency, it is inadequate in the presence of severe factor deficiency. Nasal packing for epistaxis should be avoided because bleeding often resumes when packing is removed. Splints and other orthopedic devices may be beneficial in supporting and immobilizing joints and muscles affected by hemorrhage. All injections should be avoided; invasive procedures (e.g., endoscopy, lumbar puncture) should be avoided or performed after administration of appropriate factor replacement. Patients with hemophilia should carry or wear medical identification (e.g., Medic-Alert bracelets). Additionally, patients and families should have a written emergency plan that includes measures to be taken in specific situations along with names and telephone numbers for emergency contacts.

During bleeding episodes, the extent of bleeding must be carefully assessed. Patients at risk for significant complications (e.g., bleeding into the respiratory tract or CNS) require close observation, specifically assessing for respiratory distress and altered levels of consciousness. Patients who have had recent surgery need careful monitoring to assess for bleeding from surgical sites. Frequent monitoring of vital signs, drains, and dressings is necessary to identify postoperative bleeding.

Significant pain requiring analgesics is often associated with hematomas and joint hemorrhage. Warm baths can be helpful in relieving pain, promoting relaxation, and improving mobility. During bleeding episodes, heat should be avoided because it may exacerbate bleeding; applications of cold are more efficacious.

Factor concentrates used since 1985 are free of viruses, including hepatitis C and HIV; however, patients treated prior to that time were exposed to these viruses (Escobar & Key, 2016). Patients who have acquired HIV and other viral infections may need assistance in coping with these additional diagnoses and the consequences of infection.

Genetic testing and counseling should be offered to female carriers so they can make informed decisions regarding childbearing and managing pregnancy (see Chapter 6).

Gerontologic Considerations

Advances in treatment have led to extended lifespans for patients with hemophilia, causing unique challenges for older patients with this disorder. Older adult patients with hemophilia are likely to have been managed with blood component transfusion and plasma-derived clotting factors prior to the advent of universal screening, at least early in life. For this reason, HIV and hepatitis B and C infections are not uncommon in this population; these infections carry significant risk for liver cancer and other liver diseases (Mannucci, 2019). Intracranial hemorrhage is the third most common cause of death after HIV and hepatitis and result from trauma. The likelihood of acquiring inhibitors increases with age.

Cardiovascular disease among adults with hemophilia can be difficult to manage. Antiplatelet therapy (including aspirin) can be challenging for patients with severe hemophilia. Stent placement and coronary artery bypass graft surgery are accompanied by significant risk but aggressive factor replacement therapy can make these therapeutic treatments possible (Kanellopoulou & Nomikou, 2018). Close collaboration and coordination of care with the patient's hematologist are required to improve outcomes.

Arthropathy is a major cause of morbidity in older patients with hemophilia and can result in reduced range of motion, impaired functioning, and chronic pain. However, quality of life can improve with arthroplasty and multidisciplinary rehabilitation tailored to address the special needs of older adults with hemophilia (Mannucci, 2019).

von Willebrand Disease

vWD is an inherited bleeding disorder characterized by a deficiency in von Willebrand factor (vWF), which is necessary for factor VIII activation. The disease is characterized primarily by mucosa-associated bleeding and bleeding following surgery and trauma. vWD is the most common inherited bleeding disorder, affecting up to 1% of the general population. It typically has an autosomal dominant inheritance pattern, affecting both genders equally (Rick, 2019). vWD is divided into types 1, 2, and 3. Type 1 accounts for 70% to 80%

of cases, and is characterized by a quantitative deficiency of vWF. Type 2, accounting for approximately 20% of cases, is caused by dysfunctional vWF. Type 2 is further subdivided on the basis of certain phenotypic characteristics. Type 3 vWD is rare and accounts for fewer than 5% of cases. It is the most severe form, and is caused by the absence of circulating vWF (Leebeek, & Eikenboom, 2016). Figure 29-6 illustrates the differences in clotting found with hemophilia and vWD.

Clinical Manifestations

Bleeding most often involves the mucous membranes. Nosebleeds, heavy menses, easy bruising, and prolonged bleeding from cuts and surgical sites are common. Soft tissue and joint hemorrhages are not seen often, unless the patient has type 3 vWD. As laboratory values fluctuate, so does bleeding. For example, postoperative bleeding may be minor with one procedure but significant with another (Rick, 2019).

Assessment and Diagnostic Findings

vWD may be suspected based upon a personal or family history of bleeding that may then be confirmed by laboratory evidence of abnormalities in vWF, factor VIII, or both. The diagnosis of vWD is based on measurements of vWF antigen; the level of vWF–dependent platelet adhesion, measured with the use of the vWF–ristocetin cofactor activity assay; and the coagulant activity of factor VIII. Type 3 vWD is diagnosed when vWF antigen is undetectable (or the level is less than 5 IU/dL). These results are variable with individual patients over time, making it important to review laboratory values over time and not rely on single measurements (Rick, 2019).

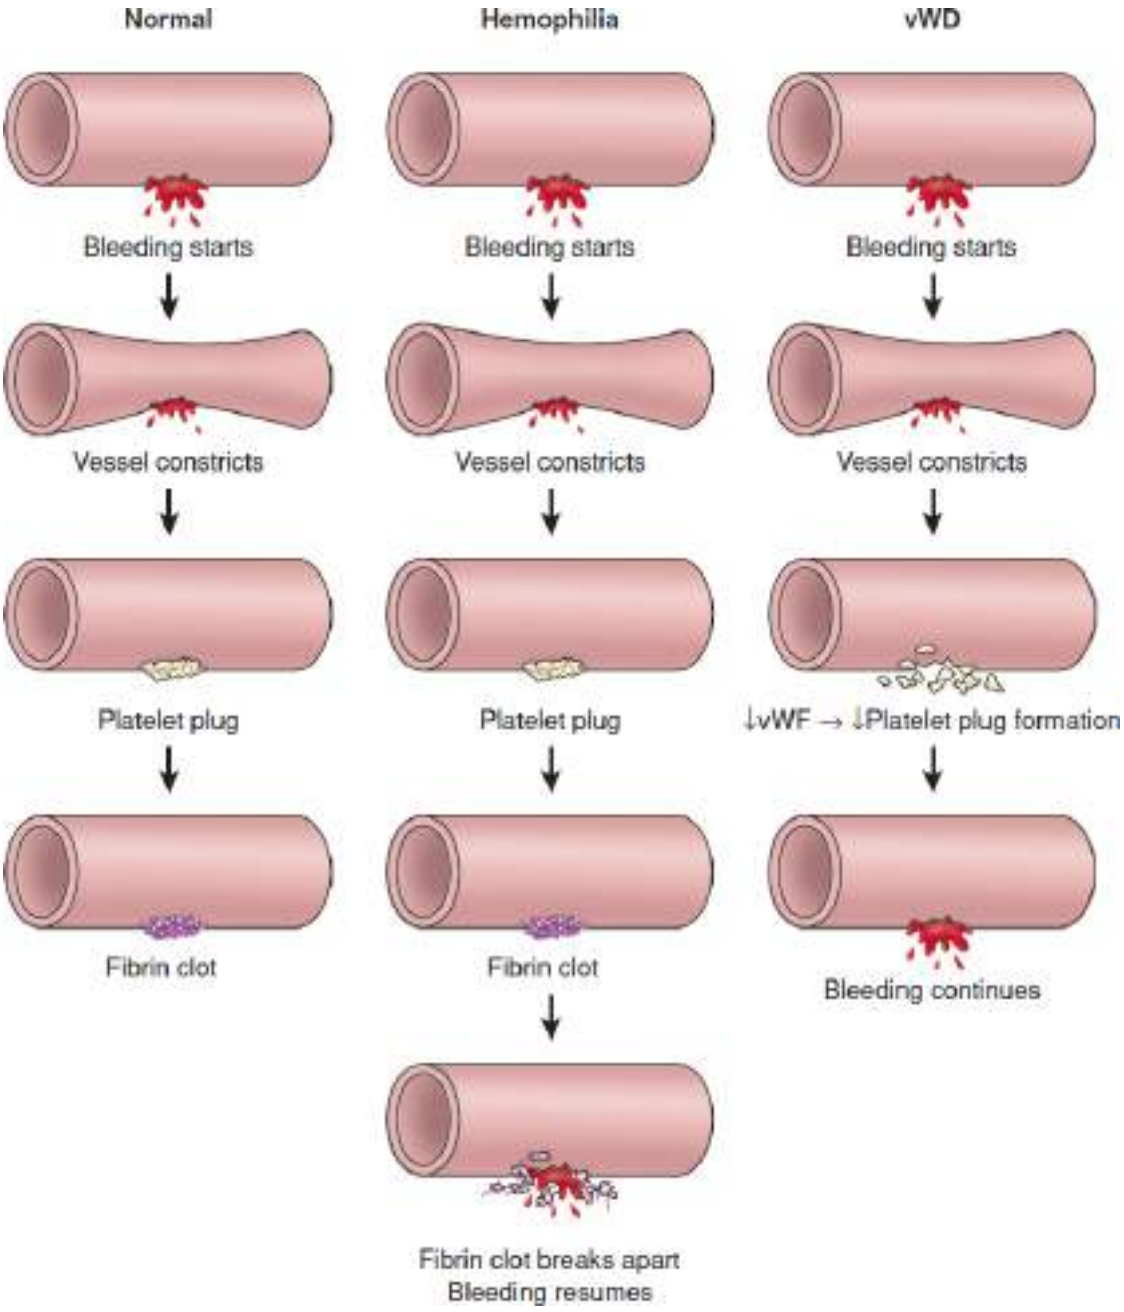

Figure 29-6 • Differences in bleeding. Normal, hemophilia, and von Willebrand disease (vWD). Reprinted with permission from Thomas, M., & Morrow, K. *Veterans Administration Palo Alto Health Care System*. Palo Alto: CA.

Management

The goal of treatment is to replace the deficient protein (e.g., vWF or factor VIII) at the time of spontaneous bleeding or prior to an invasive procedure to prevent subsequent bleeding. Desmopressin is often used to prevent bleeding associated with dental and surgical procedures or to manage mild bleeding after surgery in patients with mild vWD; it is often not effective in treating

those with type 3 vWD (Leebeek, & Eikenboom, 2016). Desmopressin provides a transient increase in factor VIII coagulant activity and may also correct bleeding time. Desmopressin can be given as an IV infusion or intranasally. IV administration is preferred for invasive procedures, including surgery. Hyponatremia and seizures may occur after repeated doses; therefore, treatment longer than 3 consecutive days is not typically indicated.

Factor replacement concentrates of vWF and factor VIII are the treatments of choice for patients with type 3 vWD and most patients with type 2. The dosage and frequency of administration of these agents depend on the patient's factor VIII level and extent of bleeding. Treatment may be needed for up to 7 to 10 days after a surgical procedure and 3 to 4 days postpartum. In patients with type 3 vWD, prophylactic use of replacement agents is often successful in preventing or limiting spontaneous bleeding. Formation of antibodies to these agents is most likely to occur in patients with type 3 vWD receiving high doses.

Other agents are also effective in controlling bleeding. Aminocaproic acid is useful in managing mild mucosal bleeding because it inhibits dissolution of the thrombus at the site of bleeding. Topical agents that augment thrombin formation at the site of application help to achieve hemostasis in dental procedures. Estrogen-progesterone compounds may reduce bleeding associated with menses. Platelet transfusions are useful when there is significant bleeding. Cryoprecipitate, which is rich in vWF and factor VIII, typically is used only in emergencies due to risk for iatrogenic transmission of viruses. Herbs and medications that interfere with platelet function should be avoided (Leebeek & Eikenboom, 2016).

Acquired Bleeding Disorders

There are a plethora of acquired bleeding disorders. Common causes include liver disease, vitamin K deficiency, and heparin-induced thrombocytopenia (HIT).

Liver Disease

Excluding factor VIII, most blood coagulation factors are synthesized in the liver. Therefore, liver dysfunction (due to cirrhosis, hepatitis, and tumor) can lead to reduced amounts of the factors needed for coagulation and hemostasis (see Chapter 43). Prolongation of the PT may indicate severe hepatic dysfunction, unless associated with vitamin K deficiency. Patients may experience minor bleeding (e.g., ecchymoses) but are also at risk for significant bleeding, especially after surgery or trauma. Transfusion of fresh-frozen plasma may be needed to replace clotting factors and prevent or stop

bleeding. Life-threatening hemorrhage associated with peptic ulcer or esophageal varices may occur. In the event of significant hemorrhage, transfusion of fresh-frozen plasma, PRBCs, and platelets is often necessary.

Vitamin K Deficiency

Vitamin K is an essential element for synthesis of many coagulation factors. Vitamin K deficiency is often seen in patients who are malnourished. Prolonged use of some antibiotics can reduce the intestinal flora that produce vitamin K, causing depletion of vitamin K stores. Correction of the deficiency can be achieved with oral or subcutaneous administration of vitamin K (phytonadione). Adequate synthesis of coagulation factors is reflected in normalization of the PT.

Heparin-Induced Thrombocytopenia

HIT is a serious complication of heparin-based therapy, a medication commonly prescribed for its anticoagulant effects (see Chapter 26 for description of indications for heparin). HIT involves the formation of antibodies against the heparin–platelet complex. HIT may occur in as many as 5% of patients receiving heparin (Brien, 2019). The type of heparin used, the duration of therapy (4 to 14 days), and surgery (especially if cardiopulmonary bypass is used) appear to be risk factors for developing HIT. Bovine heparin preparations are more likely to lead to HIT than porcine preparations; even low–molecular-weight heparins (LMWHs) carry risk for HIT. Neither the dose nor the route of administration of heparin is a risk factor. Women appear to be at higher risk and young adults are at low risk for developing this condition. A decline in the platelet count is the hallmark sign that most often develops 5 to 10 days after heparin therapy is initiated; therefore, monitoring the platelet count in patients receiving heparin therapy is essential. The platelet count can drop significantly, typically by 50% of the baseline over a period of 1 to 3 days. Autoantibodies develop that may activate platelets, causing thromboses. After patients with HIT are successfully managed, these autoantibodies typically disappear in 2 to 3 months.

Affected patients are at increased risk for thrombosis, either venous, arterial, or both, with thromboses that may manifest as deep vein thrombosis (DVT), acute coronary syndrome (ACS), stroke, or thrombosis to major vessels in an extremity, leading to amputation. Venous thromboembolism (VTE) is the most common manifestation of thrombosis secondary to HIT (i.e., DVT or pulmonary embolism [PE]) (Brien, 2019).

Treatment for HIT includes immediate cessation of heparin (including heparin-coated catheters) and initiation of another form of anticoagulation. If the heparin is discontinued without providing an alternative form of

anticoagulation, the patient is at increased risk of developing new thrombi. Argatroban, a thrombin inhibitor, is an FDA-approved anticoagulant for the treatment of HIT. Oral anticoagulation with warfarin is contraindicated because it initially promotes thrombosis in the microvasculature by depletion of protein C. This can lead to tissue ischemia and gangrenous limbs, ultimately resulting in amputation if untreated (Arepally, 2017). Patients who develop thrombosis in the presence of HIT should receive anticoagulation for 3 to 6 months; in the absence of thrombosis, treatment may be shorter. Patients must be aware that the condition may be reactivated with re-exposure to heparin, even in small amounts, within 3 to 4 months of the diagnosis (Arepally, 2017).

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a systemic syndrome that is characterized by microthromboses and bleeding. DIC may be precipitated by sepsis, trauma, cancer, shock, abruptio placentae, allergic reactions, and other conditions. Most cases are associated with infection or malignancy (Levi & Seligsohn, 2016). The severity of DIC varies but it is potentially life-threatening.

Pathophysiology

Normal hemostatic mechanisms are altered in DIC. The inflammatory response generated by the underlying disease initiates the process of inflammation and coagulation within the vasculature. The normal anticoagulation pathways in the body are impaired, and fibrinolysis is suppressed allowing numerous small clots to form in the microcirculation. Coagulation time is initially normal; however, when platelets and clotting factors form microthrombi, coagulation fails. The result of these processes leads to both excessive clotting and bleeding (see Fig. 29-7).

The clinical manifestations of DIC are primarily reflected in compromised organ function or failure. Decline in organ function is usually a result of excessive clot formation (with resultant ischemia to all or part of the organ) or, less often, of bleeding. The excessive clotting triggers the fibrinolytic system to release fibrin degradation products, which are potent anticoagulants, furthering the bleeding. The bleeding is characterized by low platelet and fibrinogen levels; prolonged PT, aPTT, and thrombin time; and elevated fibrin degradation products and D-dimers.

The mortality rate can exceed 80% in patients who develop severe DIC with ischemic thrombosis, frank hemorrhage, and MODS. Identification of patients who are at risk for DIC and recognition of the early clinical

manifestations of this syndrome can result in prompt medical intervention, which may improve the prognosis. However, the primary prognostic factor is the ability to treat the underlying condition that precipitated DIC (Levi & Seligsohn, 2016).

Clinical Manifestations

During the initial process of DIC, the patient may have no new symptoms—the only manifestation being a progressive decrease in the platelet count. As the thrombosis becomes more extensive, the patient exhibits signs and symptoms of thrombosis in the organs involved. Then, as the clotting factors and platelets are consumed to form these thrombi, bleeding occurs. Initially, the bleeding is subtle, but it can develop into frank hemorrhage. Signs and symptoms depend on the organs involved and are listed in Chart 29-10. Patients with frank DIC may exhibit bleeding from mucous membranes and venipuncture sites as well as the GI and urinary tracts. Bleeding may range from minimal, occult internal bleeding to copious bleeding from multiple orifices.

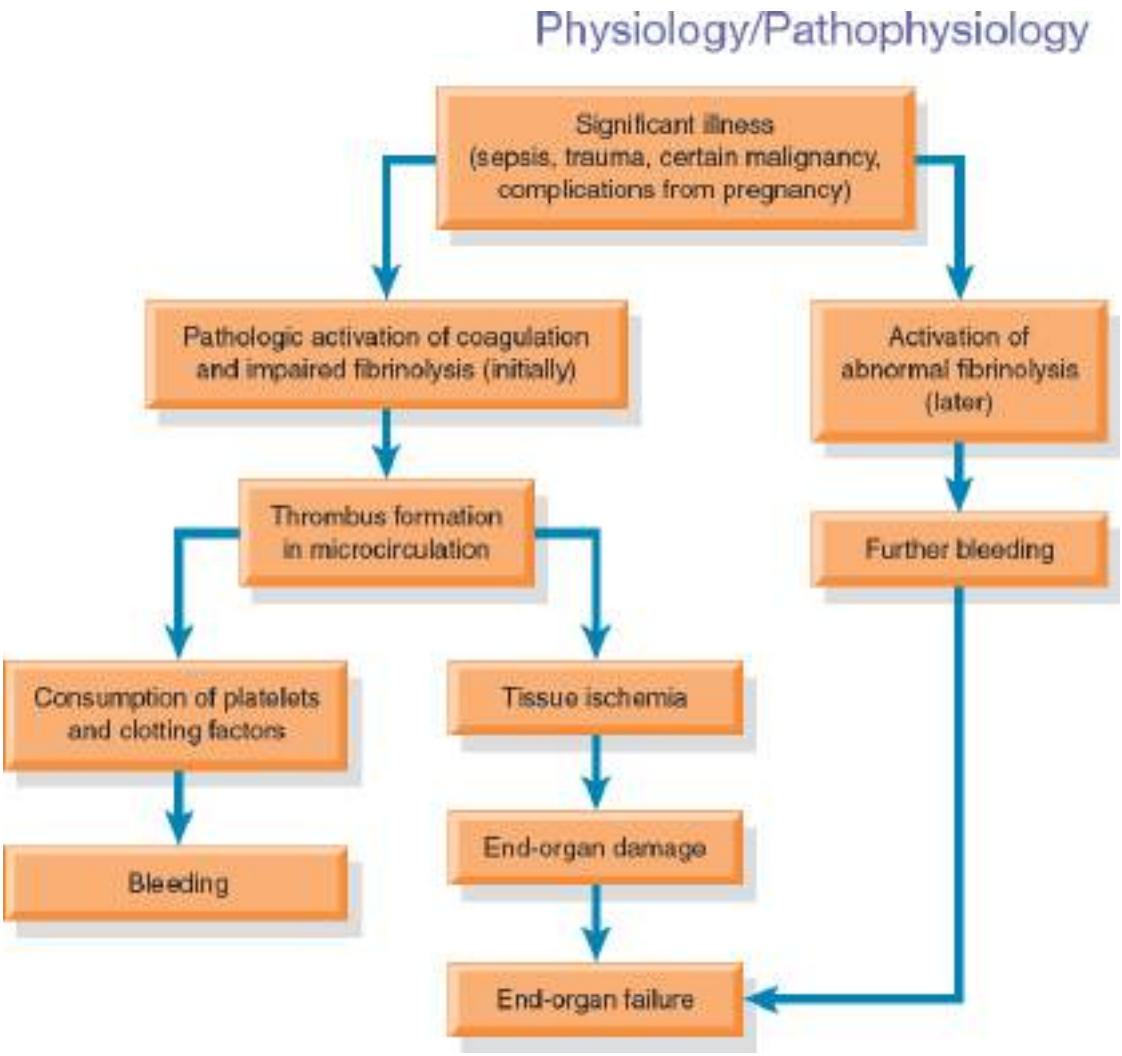

Figure 29-7 • Pathophysiology of disseminated intravascular coagulation.

Chart 29-10 ASSESSMENT

Assessing for Thrombosis and Bleeding in Disseminated Intravascular Coagulation

System	Signs and Symptoms of Microvascular Thrombosis	Signs and Symptoms of Microvascular and Frank Bleeding
Integumentary	↓ Temperature, sensation; ↑ pain; cyanosis in extremities, nose, earlobes; focal ischemia, superficial gangrene	Petechiae, including periorbital and oral mucosa; bleeding: gums, oozing from wounds, previous injection sites, around catheters (IVs, tracheostomies); epistaxis; diffuse ecchymoses; subcutaneous hemorrhage; joint pain
Circulatory	↓ Pulses; capillary filling time >3 seconds	Tachycardia
Respiratory	Hypoxia (secondary to clot in lung); dyspnea; chest pain with deep inspiration; ↓ breath sounds over areas of large embolism	High-pitched bronchial breath sounds; tachypnea; ↑ consolidation; signs and symptoms of acute respiratory distress syndrome
Gastrointestinal	Gastric pain; "heartburn"	Hematemesis (heme⊕ nasogastric output); melena (heme⊕ stools → tarry stools → bright-red blood from rectum); retroperitoneal bleeding (abdomen firm, distended, and tender to palpation; ↑ abdominal girth)
Renal	↓ Urine output; ↑ creatinine, ↑ blood urea nitrogen	Hematuria
Neurologic	↓ Alertness and orientation; ↓ pupillary reaction; ↓ response to commands; ↓ strength and mobility	Anxiety; restlessness; ↓ mentation, altered level of consciousness; headache; visual disturbances; conjunctival hemorrhage

↓, decreased; ↑, increased; heme⊕, positive for hemoglobin; IV, intravenous.

Note: Signs of microvascular thrombosis are the result of an inappropriate activation of the coagulation system, causing thrombotic occlusion of small vessels within all body organs. As the clotting factors and platelets are consumed, signs of microvascular bleeding appear. This bleeding can quickly worsen, becoming frank hemorrhage. Treatment must be aimed at the underlying disorder so that the stimulus for the syndrome is diminished or arrested.

Adapted from Levi, M., & Seligsohn, U. (2016). Disseminated intravascular coagulation. In K. Kaushansky, M. A. Lichtman, J. T. Prchal, et al. (Eds.). *Williams hematology* (9th ed.). New York: McGraw-Hill Medical.

Assessment and Diagnostic Findings

The diagnosis of DIC is frequently made based on laboratory tests that demonstrate the consumption of platelets and clotting factors (see Table 29-4). Although each test is useful in establishing the diagnosis of DIC, the specificity of each individual test is lacking. The International Society of Thrombosis and Haemostasis developed a highly sensitive and specific scoring system using platelet count, fibrin degradation products, PT, and fibrinogen level to diagnose DIC (Levi & Seligsohn, 2016) (see Table 29-5). Additionally, this system is useful in predicting the severity of the disease and subsequent mortality. Additional tests, such as thromboelastography, can be performed at the bedside and can effectively assess platelet function and fibrinolytic activity. Studies suggest that assessment of the status of the coagulation system at the bedside of critically ill patients is more useful than using conventional laboratory tests (Afzal & Syed, 2017).

TABLE 29-4 Laboratory Values Commonly Found in Disseminated Intravascular Coagulation[a]

Test	Function Evaluated	Normal Range	Changes in DIC
Platelet count	Platelet number	150,000–450,000/mm^3	↓
Prothrombin time (PT)	Extrinsic pathway	11–12.5 s	↑
Partial thromboplastin time (activated)(aPTT)	Intrinsic pathway	23–35 s	↑
Thrombin time (TT)	Clot formation	8–11 s	↑
Fibrinogen	Amount available for coagulation	170–340 mg/dL	↓
D-dimer	Local fibrinolysis	0–250 ng/mL	↑
Fibrin degradation products (FDPs)	Fibrinolysis	0–5 mcg/mL	↑
Euglobulin clot lysis	Fibrinolytic activity	≥2 h	≤1 h

[a]Because DIC is a dynamic condition, the laboratory values measured will change over time. Therefore, a progressive increase or decrease in a given laboratory value is likely to be more important than the actual value of a test at a single point in time.

↓, decreased; ↑, increased; DIC, disseminated intravascular coagulation.

Medical Management

The most critical factor in managing DIC is treatment of the underlying cause; until the cause is controlled, DIC will continue. Correcting the secondary effects of tissue ischemia by increasing tissue oxygenation, replacing fluids, correcting electrolyte abnormalities, and administering vasopressor medications is also important. When serious hemorrhage is present, depleted coagulation factors and platelets are replaced to promote normal hemostasis and reduce bleeding. The extent of hemorrhage and need for any invasive procedure are important considerations in determining the decision to provide transfusion support. Cryoprecipitate is given to replace fibrinogen and factors V and VII (Levi & Seligsohn, 2016).

The use of a heparin infusion to interrupt the thrombosis process is a controversial treatment strategy. Heparin may inhibit the formation of microthrombi and allow improved tissue perfusion to vital organs. Traditionally, heparin has been used in patients with predominantly thrombotic manifestations or in those in whom blood component replacement failed to reduce hemorrhage or increased fibrinogen and other clotting levels. When bleeding is absent, LMWH can be used to prevent VTE, while therapeutic doses may be used when severe thrombosis is predominant. Normalization of plasma fibrinogen and diminished signs of bleeding serve as evidence of heparin's effectiveness. Fibrinolytic inhibitors, such as aminocaproic acid, are not routinely used as they block the lysis of fibrin that is necessary to preserve tissue perfusion. If bleeding is profuse and there is evidence of extensive fibrinolysis, fibrinolytic inhibitors are used along with continuous infusion of IV heparin (Levi & Seligsohn, 2016).

Recombinant forms of thrombomodulin were believed to inactivate thrombin, the main culprit in inciting the coagulopathy that undergirds DIC. However, a systematic review of clinical trials found no improvement in mortality rates with patients with DIC who were prescribed recombinant thrombomodulin (Murao & Yamakawa, 2019). All management strategies must be individualized to the specific patient, underlying cause of DIC, and response to interventions.

Nursing Management

Nurses need to identify patients at risk for DIC (see previous discussion on precipitating factors). It is important to assess patients frequently and thoroughly for signs and symptoms of thrombi and bleeding and monitor for progression of these signs (see Chart 29-10). Laboratory values must be monitored frequently to assess for trends over time as well as for changes in values.

Chart 29-11 describes care of the patient with DIC. Assessment and interventions should target potential sites of end-organ damage. As organs become ischemic from microthrombi, organ function diminishes; the kidneys, lungs, brain, and skin are particularly vulnerable. Lack of renal perfusion may result in acute tubular necrosis and kidney injury, sometimes requiring dialysis. Placement of a large-bore dialysis catheter is extremely hazardous for this patient population and should be accompanied by adequate platelet and plasma transfusions. Hepatic dysfunction is also relatively common, reflected in altered liver function tests, depleted albumin stores, and diminished synthesis of clotting factors. Respiratory function warrants careful monitoring and aggressive measures to diminish alveolar compromise. Suctioning should be performed as gently as possible to diminish the risk of additional bleeding. CNS involvement can be manifested as headache, visual changes, and alteration in level of consciousness.

Secondary Thrombocytosis

Increased platelet production is the primary mechanism of secondary or reactive **thrombocytosis**, characterized by an elevation in the platelet count. However, these elevations are rarely above 1 million/mm^3. This is in contrast to essential thrombocytosis which is a chronic myeloproliferative disease (see Chapter 30). In secondary thrombocytosis, platelet function and survival are typically normal; therefore, hemorrhage and thrombosis are rare (Kaushansky, 2016). A number of disorders are associated with a reactive increase in platelets, including infection, iron deficiency anemia, chronic inflammatory disorders, malignancy, acute hemorrhage, and splenectomy. Treatment is directed at the underlying disorder. When managed successfully, the platelet count often returns to normal.

THROMBOTIC DISORDERS

Several conditions can affect the balance of normal hemostasis, causing excessive thrombosis that can alter arterial or venous circulation. Arterial thrombosis is caused by platelet aggregation, while venous thrombosis is a result of accumulation of platelets, red blood cells, and thrombin. Abnormalities that predispose a person to thrombotic events include decreased clotting inhibitors in the circulation, impaired liver function, lack of fibrinolytic enzymes, and vascular abnormalities that promote platelet aggregation. Thrombosis may also occur as the initial manifestation of an occult malignancy or as a complication of a previously diagnosed cancer. In some cases, more than one precipitating factor exists. There are several inherited or acquired disorders, including hyperhomocysteinemia, antithrombin (AT) deficiency, protein C deficiency, protein S deficiency, activated protein C (APC) resistance, and factor V Leiden deficiency that can predispose patients to repeated episodes of thrombosis. These are also referred to as hypercoagulable states or thrombophilia. Inherited disorders should prompt a referral for familial genetic testing. Genetic testing is not indicated with acquired disorders.

Chart 29-11 PLAN OF NURSING CARE

The Patient with Disseminated Intravascular Coagulation

NURSING DIAGNOSIS: Risk for hypovolaemia associated with bleeding
GOAL: Hemodynamic status maintained; urine output ≥0.5 mL/kg/h over 6 hours or <400 mL in 24 hours

Nursing Interventions	Rationale	Expected Outcomes
1. Avoid procedures/activities that can increase intracranial pressure (e.g., coughing, straining to have a bowel movement).	1. Prevents intracranial bleeding	• Level of consciousness (LOC) stable • Central venous pressure 5–12 cm H_2O, systolic blood pressure ≥70 mm Hg • Urine output ≥0.5 mL/kg/h • Decreased bleeding • Decreased oozing • Decreased ecchymoses • Amenorrhea • Absence of oral and bronchial bleeding • Oral mucosa clean, moist, intact
2. Monitor vital signs closely, including neurologic checks: a. Monitor hemodynamics. b. Monitor abdominal girth. c. Monitor urine output.	2. Identifies signs of hemorrhage/shock as soon as possible	
3. Avoid medications that interfere with platelet function if possible (e.g., aspirin, nonsteroidal anti-inflammatory drugs, beta-lactam antibiotics).	3. Decreases problems with platelet aggregation and adhesion	
4. Avoid rectal probes, rectal medications.	4. Decreases risk of rectal bleeding	
5. Avoid intramuscular injections.	5. Decreases risk of intramuscular bleeding	
6. Monitor amount of external bleeding carefully: a. Monitor number of dressings, percentage of dressing saturated; time to saturate a dressing is more	6. a. Provides accurate, objective assessment of extent of bleeding	

objective than "dressing saturated a moderate amount." b. Assess suction output, all excreta for frank or occult blood. c. Monitor pad counts in women with vaginal bleeding. d. Women may receive progesterone to prevent menses. 7. Use low pressure for any necessary suctioning. 8. Administer oral hygiene carefully. a. Avoid lemon-glycerin swabs, hydrogen peroxide, commercial mouthwashes. b. Use sponge-tipped swabs, salt/baking soda (bicarbonate of soda) mouth rinses. 9. Avoid dislodging any clots, including those around IV sites and injection sites.	b. Identifies presence of or quantifies extent of bleeding c. Quantifies extent of bleeding d. Decreases risk of bleeding from gynecologic source 7. Prevents excessive trauma that can cause additional bleeding 8. Prevents excessive trauma that can cause bleeding. Glycerin and alcohol (in commercial mouthwashes) dry the mucosa, increasing risk for bleeding. 9. Reduces risk for excessive bleeding from sites	

NURSING DIAGNOSIS: Risk for impaired skin integrity associated with ischemia or bleeding

GOAL: Skin integrity remains intact; oral mucosa remains intact

Nursing Interventions	Rationale	Expected Outcomes

1. Assess skin, with particular attention to bony prominences, skin folds.	1. Prompt identification of any area of risk for skin breakdown or showing early signs of breakdown can prompt early intervention and reduce complications.	• Skin integrity remains intact; skin is warm, and of normal color. • Oral mucosa is intact, pink, moist, without bleeding.
2. Reposition carefully; use pressure-reducing mattress.	2–4. Meticulous skin care and use of measures to prevent pressure on bony prominences decreases risk of skin trauma.	
3. Perform careful skin care every 2 hours, emphasizing dependent areas, all bony prominences, and perineum.		
4. Use lamb's wool between digits, around ears, as needed.		
5. Use prolonged pressure (at least 5 minutes) after injection or procedure when such measures must be performed.	5. Initial platelet plug is very unstable and can be easily dislodged, which can lead to increased bleeding.	
6. Perform oral hygiene carefully (see previous discussion).	6. Meticulous care is needed to decrease trauma, bleeding, and risk of infection.	

NURSING DIAGNOSIS: Fluid imbalance associated with excessive blood and/or factor component replacement

GOAL: Absence of edema; absence of crackles; intake not greater than output

Nursing Interventions	Rationale	Expected Outcomes
1. Auscultate breath sounds every 2–4 hours.	1. Crackles can develop quickly.	• Breath sounds clear

2. Monitor extent of edema. 3. Monitor volume of IV fluids, blood products; decrease volume of IV medications if indicated. 4. Administer diuretics as prescribed.	Fluid may extend 2. beyond intravascular space. 3. Helps prevent fluid overload 4. Decreases excess fluid volume	• Absence of edema • Intake does not exceed output • Weight stable

NURSING DIAGNOSIS: Risk for injury associated with microthrombi
GOAL: Neurologic status remains intact; absence of hypoxemia; peripheral pulses remain intact; skin integrity remains intact; urine output remains ≥0.5 mL/kg/h over 6 hours and >400 mL in 24 hours

Nursing Interventions	Rationale	Expected Outcomes
1. Assess neurologic, pulmonary, integumentary systems. 2. Monitor response to heparin therapy. 3. Assess extent of bleeding. 4. Monitor fibrinogen levels. 5. Stop aminocaproic acid, if prescribed, if symptoms of thrombosis occur.	1. Initial signs of thrombosis may be subtle. 2. Assure anticoagulation effectiveness that may prevent formation of additional thromboses. 3. Objective measurements of all sites of bleeding are crucial to accurately assess extent of blood loss. 4. Response to heparin is most accurately reflected in fibrinogen level. 5. Aminocaproic acid should be used only in the setting of extensive hemorrhage not	• Arterial blood gases, O_2 saturation, pulse oximetry, LOC within normal limits • Breath sounds clear • Absence of edema • Intake does not exceed output • Weight stable

	responding to replacement therapy.	
NURSING DIAGNOSIS: Anxiety associated with uncertain prognosis and risk for death **GOAL:** Feelings identified/verbalized; realistic hope maintained		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Identify previous coping mechanisms, if possible; encourage patient to use them as appropriate. 2. Explain all procedures and their rationale in terms that the patient and family/significant others can understand. 3. Assist family in supporting patient. 4. Use services from behavioral health, chaplain as needed.	1. Identifying previous stressful situations can aid in recall of successful coping mechanisms. 2. Decreased knowledge and uncertainty can increase anxiety. 3. Family/significant others can be valuable in assisting the patient to use coping strategies and to maintain hope. 4. An interdisciplinary approach may be warranted, particularly when coping strategies are maladaptive or ineffective. The spiritual dimension of care may be especially important in a crisis.	• Previously used coping strategies are identified and utilized, to the extent the patient is able to do so. • Patient and family indicate understanding of procedures as situation permits.

LOC, level of consciousness.

Thrombotic disorders require anticoagulation therapy; the duration of therapy varies with the location and extent of thrombosis, precipitating events (e.g., trauma, immobility), and any concurrent risk factors (e.g., use of oral

contraceptives, obesity, tobacco use, integrity of blood vessels, previous thrombotic events; see Table 29-6). Conditions that may result from thrombosis include ACS (see Chapter 23), ischemic stroke (see Chapter 62), and occlusive peripheral arterial disease (see Chapter 26). With some conditions, or with repeated thrombosis, lifelong anticoagulation may be required.

TABLE 29-6 Risk Factors for Thrombosis

Acquired	Inherited	Mixed/Unknown
Advanced age	Antithrombin deficiency	Activated protein C resistance
Antiphospholipid antibody syndrome	Factor V Leiden	↑ Factor VII
Atrial fibrillation	Factor XII deficiency	↑ Factor VIII
Diabetes	Protein C deficiency	↑ Factor IX
Drugs (e.g., cocaine, ergot)	Protein S deficiency	↑ Factor XI
Estrogen therapy	Prothrombin 20210[a]	↓ Fibrinolytic activity
Hypertension		↑ Homocysteine
Inflammatory bowel disease		
Immobility		
Lupus anticoagulant		
Major surgery		
Myeloproliferative disease		
Nephrotic syndrome		
Obesity		
Paralysis		
Pregnancy/postpartum period		
Prior stroke		
Prior superficial vein thrombosis		
Smoking		
Trauma/fracture		
Vascular access devices		

Note: Risk factors for first, unprovoked venous thromboembolism. Note that the factor levels that are increased are procoagulant proteins.

↑, increased; ↓, decreased.

Adapted from Koupenova, M., Kehrel, B. E., Corkerey, H. A., & Freedman, J. E. (2016). Thrombosis and platelets: An update. *European Heart Journal*, *38*(11), 785–791.

Hyperhomocysteinemia

Homocysteine is known to promote platelet aggregation. When hyperhomocysteinemia is present, the endothelial lining of blood vessels are denuded, which can lead to thrombus formation, specifically VTE (e.g., DVT, PE) and arterial thrombosis (e.g., ischemic stroke, ACS); however, the evidence available does not clearly identify homocysteine as a causal factor.

Research suggests that the mechanisms through which hyperhomocysteinemia causes vascular disease are more complex than an increase in homocysteine alone (Ospina-Romero, Cannegieter, den Heijer, et al., 2018).

Hyperhomocysteinemia can be hereditary but may also occur as a result of folate deficiency, and to a lesser degree, deficiency of vitamins B_6 and B_{12}. These nutrients are cofactors in homocysteine metabolism. Additionally, for reasons that are unclear, older adults and those with kidney injury may also have elevated homocysteine levels without vitamin deficiency (Ostrakhovich & Tabibzadeh, 2019). While a fasting measurement of plasma homocysteine can be useful for screening in some cases, levels may be normal or slightly elevated in people with inherited hyperhomocysteinemia or those with vitamin B_6 deficiency. A more sensitive method of measurement involves obtaining a second measurement 4 hours after consumption of methionine; hyperhomocysteinemia is found more often using this method. Supplemental use of folic acid, vitamin B_{12}, or vitamin B_6 has not been shown to be effective in reducing the recurrence of venous or arterial thromboemboli (Middeldorp & Coppens, 2016). Smoking is associated with reduced levels of vitamin B_6, vitamin $B_{12,}$ and folate, making smoking cessation an important goal for patients with known hyperhomocysteinemia.

Antithrombin Deficiency

AT is a protein that inhibits thrombin and certain coagulation factors. It may also play a role in reducing inflammation within the endothelium of blood vessels. AT deficiency can be acquired by four mechanisms: accelerated consumption of AT (as in DIC); decreased synthesis of AT (as in hepatic dysfunction); increased excretion of AT (as in nephrotic syndrome); and medication induced (e.g., estrogens) (Bunn & Bauer, 2017). However, AT deficiency is most often an inherited condition that can lead to venous thrombosis, especially when AT levels are less than 60% of normal. The most common sites of thrombosis are the deep veins in the legs and within the mesentery. Recurrent thrombosis can occur, particularly as patients age. Patients with AT deficiency may exhibit heparin resistance and therefore require greater doses of heparin to achieve adequate anticoagulation. Patients with AT deficiency should encourage their family members to be tested for the condition.

Protein C Deficiency

Protein C is a vitamin K–dependent enzyme synthesized in the liver that, when activated, inhibits coagulation. When protein C levels are low, the risk for

thrombosis increases and thrombosis may occur spontaneously. People with protein C deficiency are often asymptomatic until they reach adulthood; the risk for thrombosis then increases with age. A rare but important complication for patients with protein C deficiency receiving warfarin for anticoagulation is warfarin-induced skin necrosis. This condition is believed to be a result of progressive thrombosis of capillaries in the skin. The degree of necrosis can be quite extensive (Bunn & Bauer, 2017). Prompt recognition of the problem with immediate cessation of the warfarin, along with treatment with vitamin K, heparin, and fresh-frozen plasma infusions are needed to arrest the pathophysiologic process and reverse the effects of warfarin. Treatment with purified protein C concentrate may be necessary.

Protein S Deficiency

Protein S is another natural anticoagulant normally produced by the liver. APC requires protein S to inactivate certain clotting factors. When the level of protein S is deficient, this inactivation process is diminished and the risk of thrombosis increases. As with protein C deficiency, patients with protein S deficiency have a greater risk for recurrent venous thrombosis early in life, including risk for PE (Bunn & Bauer, 2017).

Thromboses frequently occur in axillary, mesenteric, and cerebral veins. Warfarin-induced skin necrosis is also possible with protein S deficiency. A number of conditions may lead to acquired protein S deficiency including pregnancy, DIC, liver disease, nephritic syndrome, HIV infection, and the use of L-asparaginase.

Activated Protein C Resistance and Factor V Leiden Mutation

APC resistance is a common condition that can occur with other hypercoagulable states. APC is an anticoagulant, and resistance to APC increases risk for venous thrombosis. A defect in the factor V gene has been identified in 90% of patients with APC resistance. This factor V Leiden mutation is the most common cause of inherited hypercoagulability in Caucasians; its incidence appears to be much lower in other ethnic groups (Bunn & Bauer, 2017; Middeldorp & Coppens, 2016). The risk of thrombosis significantly increases when factor V Leiden mutation is paired with other risk factors (e.g., increased age, use of oral contraceptives, hyperhomocysteinemia). People who are homozygous for factor V Leiden mutation are at extreme risk for thrombosis and therefore require lifelong anticoagulation. In contrast, those who are heterozygous for the mutation have

a lower risk for developing a thrombus. The duration of anticoagulation is based on the coexistence of other risk factors for thrombus formation.

Antiphospholipid Antibody Syndrome

Antibodies to phospholipids are common causes of thrombophilia; up to 5% of the general population may have this disorder. These antibodies reduce levels of annexin V, a protein that binds to phospholipids and has anticoagulant activity. The most common of the antiphospholipid antibodies are lupus and anticardiolipin antibodies, or an antibody to beta-2 glycoprotein (Rand & Wolgast, 2016). Antiphospholipid antibody syndromes are classified as primary or secondary, with a reaction secondary to a preexisting autoimmune disease, with systemic lupus erythematosus being most frequently implicated. Primary antiphospholipid antibody syndrome is associated with a number of infections including hepatitis C, HIV, syphilis and malaria as well as certain medications (e.g., antibiotics, quinine, hydralazine, procainamide); a genetic predisposition to this syndrome has been postulated but has not been proven. Antiphospholipid antibodies are associated with multiple miscarriages and are strongly associated with stroke (Heuser & Branch, 2019). Most thromboses are venous, but arterial thrombosis is also possible in up to one third of patients with this syndrome. Recurrent thromboses tend to occur in the same fashion, with recurrent venous thrombosis after an initial venous presentation and recurrent arterial thromboses after an initial arterial thrombosis. Thrombi typically occur in large vessels. Therapy varies depending on the type of syndrome (e.g., secondary forms caused by autoimmune disorders may be treated with immunosuppressive therapy), history of prior thrombosis, and location of the thrombus (venous or arterial). Arterial thrombosis is often treated by adding low-dose aspirin to some form of heparin therapy (see later discussion).

Malignancy

Cancers, particularly stomach, pancreatic, lung, and ovarian cancers, are often associated with thrombophilia with significant risk for VTE. VTE contributes to morbidity and mortality of patients with cancer, with a fatal PE being three times more common in patients with cancer than in those without cancer. Patients with cancer have a five- to sevenfold increased risk of developing VTE, and those who develop VTE at diagnosis of cancer or within a year of diagnosis tend to have a significantly worse prognosis than patients with cancer without VTE. A diagnosis of VTE is a serious complication of cancer that adversely affects a patient's quality of life and reduces overall survival.

Anticoagulation may be difficult to manage and thromboses can progress despite adequate doses of anticoagulants. LMWH may be more effective than warfarin in treating this group of patients (Razak, Jones, Bhandari, et al., 2018).

Medical Management

The primary treatment for thrombotic disorders is anticoagulation. However, when to treat and how long to treat with anticoagulant medications is controversial. Anticoagulation therapy is not without risk, with the most significant risk of bleeding. Anticoagulant medications used to treat a variety of thromboses are discussed in Chapter 26.

Nursing Management

Patients with thrombotic disorders should be counseled to avoid activities that lead to circulatory stasis (e.g., immobility, crossed legs). Exercise, especially ambulation, should be performed frequently throughout the day, especially during long trips by car or plane. Anti-embolism stockings may be prescribed and patients often need instruction in how to use them properly. Surgery increases risk for thrombosis significantly.

Medications that alter platelet aggregation, such as low-dose aspirin or clopidogrel, may be prescribed. Some patients require lifelong anticoagulation therapy.

Patients with thrombotic disorders, particularly those with thrombophilia, should be evaluated for concurrent risk factors for thrombosis and should avoid them whenever possible. For example, products containing tobacco and nicotine should be avoided, blood pressure should be controlled, and alcohol consumption limited. In some instances, younger patients with thrombophilia may not need prophylactic anticoagulation, but when concomitant risk factors (e.g., pregnancy), increasing age, or subsequent thrombotic events are present, prophylactic or long-term anticoagulation therapy may be needed. Being able to provide the health care provider with an accurate health history can be extremely useful and help in guiding the selection of the appropriate interventions. Patients need to be aware of risk factors for thrombosis and how they can be reduced or eliminated, such as avoiding tobacco, using alternative forms of contraception, avoiding immobility, and maintaining a healthy weight. Patients with hereditary disorders should encourage their siblings and children to be tested for the disorder.

When a patient with a thrombotic disorder is hospitalized, frequent assessment should be performed to promote early recognition of signs and symptoms of thrombus formation, particularly in the legs (DVT) and lungs (PE). Ambulation or range-of-motion exercises as well as anti-embolism

stockings or sequential compression devices are used to decrease venous stasis.

CRITICAL THINKING EXERCISES

1 pq A 72-year-old man presents to the emergency department complaining of acute shortness of breath and chest pain. He reports increasing fatigue, exertional dyspnea, dull abdominal pain, and weight loss over the last few months. His CBC reveals a normal WBC count and platelet count; however, the hemoglobin is 7.2 mg/dL and the hematocrit is 22.3%. The MCV is reduced. Iron deficiency anemia is suspected. What are your priority interventions targeted at relieving the patient's symptoms? What other medical interventions do you anticipate might be prescribed? What additional laboratory tests do you anticipate for this patient?

2 ipc A 23-year-old female patient with sickle cell disease tells you during a routine office visit that she would like to become pregnant. Her condition has been well controlled with hydroxyurea. She takes ibuprofen on a regular basis for chronic pain. What additional information should you collect in the patient history? What challenges do you anticipate in caring for this patient? What other members of the interdisciplinary team do you think should be consulted to be part of the patient's prenatal care?

3 ebp Your 44-year-old female neighbor tells you that her brother has been "nagging her" to get tested for hemochromatosis since he was diagnosed with this disease a few months ago. Her brother has periodic therapeutic phlebotomies to treat his disease, and she feels her lifestyle is too busy to support these types of treatments. She tells you that she "feels fine" and wonders how likely it is that she has hemochromatosis, and if she does, whether treatment would be needed. What are the risks for hemochromatosis? If your neighbor does have hemochromatosis, what is the strength of the evidence for best treatment options for her?

30 Management of Patients with Hematologic Neoplasms

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Compare and contrast the different types of leukemias in terms of their incidence, physiologic alterations, clinical manifestations, complications, and medical and nursing management.
2. Use the nursing process as a framework for care of the patient with acute leukemia.
3. Explain the differences between the various myeloproliferative disorders in terms of their incidence, physiologic alterations, clinical manifestations, complications, and medical and nursing management.
4. Compare and contrast Hodgkin and non-Hodgkin lymphomas in terms of their incidence, physiologic alterations, clinical manifestations, complications, and medical and nursing management.
5. Discuss medical and nursing care of the patient with multiple myeloma.

NURSING CONCEPTS

Cellular Regulation
Clotting

GLOSSARY

absolute neutrophil count (ANC): a calculation of the number of circulating neutrophils, derived from the total white blood cells (WBCs) and the percentage of neutrophils counted in a microscope's visual field

angiogenesis: formation of new blood vessels

apoptosis: programmed cell death

blast cells: immature leukocytes

clone: proliferation from same cell of origin so that descendent cells are identical to the cell of origin

cytokines: proteins produced by leukocytes that are vital to regulation of hematopoiesis, apoptosis, and immune responses; also called *biochemical* or *inflammatory mediators*

erythrocyte sedimentation rate (ESR): laboratory test that measures the rate of settling of red blood cells (RBCs); elevation is indicative of inflammation; also called the *sed rate*

erythromelalgia: a burning, painful sensation and erythema in the fingers or toes

hematopoiesis: complex process of the formation and maturation of blood cells

indolent: when in reference to a neoplasm refers to a slow-growing cancer that often remains localized or causes few symptoms

leukemia: uncontrolled proliferation of WBCs, often immature

lymphadenopathy: enlargement of a lymph node or lymph nodes

lymphoid: pertaining to lymphocytes

myeloid: pertaining to nonlymphoid blood cells that differentiate into RBCs, platelets, macrophages, mast cells, and various WBCs

neutropenia: lower-than-normal number of neutrophils

pancytopenia: abnormal decrease in WBCs, RBCs, and platelets

petechiae: tiny capillary hemorrhages

phagocytosis: process of cellular ingestion and digestion of foreign bodies

reticulocytes: slightly immature RBCs, usually only 1% of total circulating RBCs

splenomegaly: enlargement of the spleen

stem cell: primitive cell, capable of self-replication and differentiation into myeloid or lymphoid stem cell

thrombocythemia: higher-than-normal platelet count that occurs without a known cause

thrombocytopenia: lower-than-normal platelet count

thrombocytosis: higher-than-normal platelet count that results because of a disease or disorder

Hematopoiesis is the process by which all blood cells develop, differentiate, and mature. This process starts with the hematopoietic stem cells (HSC) in the bone marrow. As these **stem cells** divide, they are delineated into one of two cell pathways, to become lymphoid or myeloid progenitor cells. The myeloid stem cells then differentiate into red blood cells, white blood cells (WBCs), and platelets, while the lymphoid stem cells differentiate into B and T lymphocytes. Normally, the differentiation of these progenitor cells is regulated according to the body's need. However, when the mechanisms that control the production of these cells is disrupted or impaired, the cells can proliferate uncontrollably, leading to the development of a hematologic malignancy. The pathophysiologic processes for the development of hematologic malignancies are complex. Understanding these processes and the rationale for treatments is important so that nurses may appropriately assess, monitor, educate, and intervene with patients with hematologic neoplasms.

Hematopoietic malignancies are classified by the specific blood cells involved. **Leukemia** is a neoplastic proliferation of a particular cell type (granulocytes, lymphocytes, or infrequently erythrocytes or megakaryocytes). This proliferation leads to an overcrowding in the bone marrow resulting in impaired hematopoietic cell function and can affect other organs in the body (i.e., lymph nodes, skin, and spleen) (Leukemia & Lymphoma Society, 2018b). The defect originates in the HSC, the myeloid, or the lymphoid stem cell. Lymphomas are neoplasms of lymphoid tissue, usually derived from B lymphocytes. Multiple myeloma is a malignancy of the most mature form of B lymphocyte—the plasma cell.

CLONAL STEM CELL DISORDERS

A key feature of hematologic malignancies is the increased proliferation of blood cells from an abnormal single HSC, known as clonal hematopoiesis. Despite this increase in proliferation, the clonal HSCs continue to differentiate, leading to increased myeloid cells, erythroid cells, and platelets in the peripheral blood as well as hyperplasia in the bone marrow (Leukemia & Lymphoma Society, 2018b). Figure 30-1 illustrates how hematopoietic malignancies develop and whether they are derived from the myeloid or lymphoid stem cells (Leukemia & Lymphoma Society, 2019f).

LEUKEMIA

The term *leukocytosis* refers to an increase of leukocytes (WBCs) in the circulation. Typically, only one specific cell type is increased. Because the proportions of several types of leukocytes (e.g., eosinophils, basophils, monocytes) are small, an increase in other types can be great enough to elevate the total leukocyte count, particularly the neutrophils or lymphocytes. Although leukocytosis can be a normal response to increased need (e.g., in acute infection), the elevation in leukocytes should decrease as the physiologic need decreases. A prolonged or progressively increasing elevation in leukocytes is abnormal and should be evaluated. A significant cause of persistent leukocytosis is a hematologic malignancy (i.e., leukemia).

The common feature of the leukemias is an unregulated proliferation of leukocytes in the bone marrow. In acute forms (or late stages of chronic forms), the proliferation of leukemic cells leaves little room for normal cell production. There can also be a proliferation of cells in the liver and spleen (extramedullary hematopoiesis). With acute forms, there can be infiltration of leukemic cells in other organs, such as the meninges, lymph nodes, gums, and skin. The cause of leukemia is not fully known, but exposure to radiation or chemicals, certain genetic disorders, and viral infections are known to be risk factors for certain types of leukemia. Bone marrow damage from pelvic radiation or certain types of chemotherapy drugs can cause acute leukemia, typically occurring years after treatment for another malignancy (Leukemia & Lymphoma Society, 2018b).

The leukemias are commonly classified according to the stem cell line involved, either **lymphoid** (referring to stem cells that produce lymphocytes) or **myeloid** (referring to stem cells that produce nonlymphoid blood cells). They are also classified as either acute or chronic, based on the time it takes for symptoms to evolve and the phase of cell development that is halted (i.e., with few leukocytes differentiating beyond that phase).

In acute leukemia, the onset of symptoms is abrupt, often occurring within a few weeks. Leukocyte development is halted at the blast phase, and thus most leukocytes are undifferentiated cells or blasts. Acute leukemia can progress rapidly, with death occurring within weeks to months without aggressive treatment.

In chronic leukemia, symptoms evolve over a period of months to years, and the majority of leukocytes produced are mature. Chronic leukemia progresses more slowly; the disease trajectory can extend for years.

Acute Myeloid Leukemia

Acute myeloid leukemia (AML) originates due to a series of genetic mutations in the myeloid HSC leading to clonal development of abnormal blast cells (National Comprehensive Cancer Network [NCCN], 2019a). As these **blast**

cells (i.e., immature leukocytes) continue to proliferate, they crowd out normal bone marrow production resulting in anemia, **thrombocytopenia** (i.e., low platelet count), and either low or elevated WBC counts (rarely, the WBC may be within normal range). There is also impaired development of all myeloid cells: monocytes, granulocytes (i.e., neutrophils, basophils, eosinophils), erythrocytes, and platelets.

AML is the most common form of leukemia, as well as most common cause of death from all leukemias. AML can affect any age group. However, the incidence of this disease increases with age, with the median age at time of diagnosis being about 68 years (Leukemia & Lymphoma Society, 2019a). On an annual basis, AML accounts for approximately 1% of all cancer-related deaths (NCCN, 2019a).

The exact cause of AML is unclear, but there are several known risk factors. In addition to increasing age, males have a higher incidence than females. Other risks include having been exposed to chemicals such as benzene or pesticides or exposed to ionizing radiation; and a history of prior treatment with chemotherapeutic drugs, such as alkylating agents or topoisomerase inhibitors, tobacco smoking, other blood disorders (e.g., myeloproliferative diseases), and several genetic disorders (e.g., Down syndrome, Trisomy 8, or Fanconi anemia) (Leukemia & Lymphoma Society, 2019a).

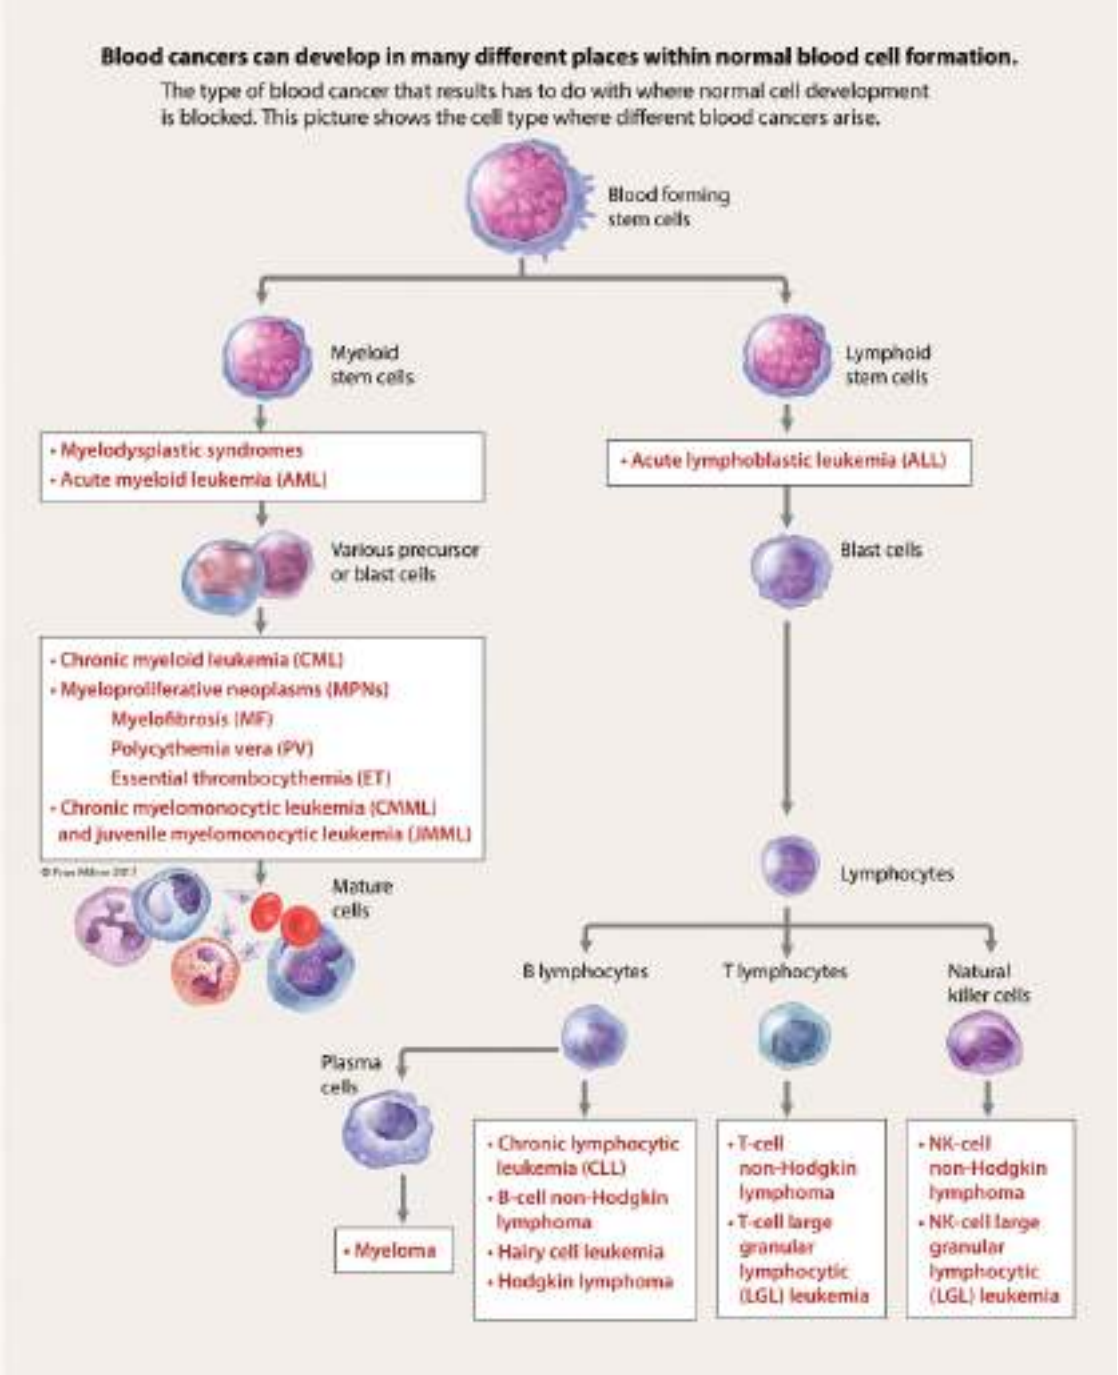

Figure 30-1 • The development of myeloid and lymphoid neoplasms. Hematologic malignancies can occur when normal cell develop is inhibited. © Fran Milner 2017.

The prognosis and survival rates are highly variable. Factors influencing a more positive outcome are younger age at diagnosis, more favorable cytogenetic alterations (which are strongly associated with younger age), and few concurrent (or mild) health problems. In contrast, patients with significant comorbidities, of older age, with cytogenetic features deemed to be adverse, or who are frail, are more likely to have a poor prognosis. AML evolving from a

preexisting clonal myeloid disease or from prior cytotoxic therapy for another malignancy or immune disease is associated with a poorer prognosis and less favorable outcomes (NCCN, 2019a).

(2009). *Wintrobe's clinical hematology* (12th ed., Fig. 72.8, p. 1680). Philadelphia, PA: Lippincott Williams & Wilkins.

Clinical Manifestations

AML often presents, initially, as nonspecific complaints that can abruptly occur or gradually worsen over time. The signs and symptoms result from inadequate production of normal blood cells, especially as the leukemic cells increasingly crowd out the bone marrow. Symptoms due to **neutropenia** (low neutrophil count) include fever and infection. Symptoms related to anemia include pallor, fatigue, weakness, dyspnea on exertion, and dizziness. Symptoms reflective of thrombocytopenia include ecchymoses (bruises), **petechiae** (pinpoint red or purple hemorrhagic spots on the skin), epistaxis (nosebleeds), and gingival bleeding. The proliferation of leukemic cells within organs leads to a variety of additional symptoms: pain from an enlarged liver or spleen, hyperplasia of the gums, and bone pain from expansion of marrow (see Fig. 30-2). Petechiae or ecchymoses are common on the skin (see Chapter 29, Fig. 29-4); occasionally, leukemic infiltrates are also seen (see Fig. 30-3). Leukemic cells can also infiltrate the gingiva or synovial spaces of joints. **Lymphadenopathy** (enlargement of lymph nodes) or **splenomegaly**

(enlargement of the spleen) is rare. Fevers may occur and are not always due to infection.

Assessment and Diagnostic Findings

To confirm the diagnosis of AML, laboratory studies need to be performed. The complete blood count (CBC) commonly shows a decrease in both erythrocytes and platelets. Although the total leukocyte count can be low, normal, or high, the percentage of normal cells is usually vastly decreased. A bone marrow analysis shows an excess (more than 20%) of blast cells (Arber, Orazi, Hasserjian, et al., 2016); this is the hallmark of the diagnosis.

AML can be further classified into seven different subgroups, based on cytogenetics, histology, and morphology of the blasts, as well as the presence of genetic mutations. The actual prognosis varies somewhat between subgroups and with the extent of cytogenetic abnormalities and genetic mutations, yet the clinical course and treatment differ substantially with only one subtype. That is, patients with the specific AML subtype acute promyelocytic leukemia (APL, or AML-M3) have higher potential for fatal coagulopathies; however, the potential to cure this form of AML is high (NCCN, 2019a).

Medical Management

The overall objective of treatment for AML is to achieve complete remission of the disease, in which there is no residual leukemic cells in the bone marrow or peripheral blood. To obtain remission, chemotherapy treatment is administered in two parts: *induction* and *consolidation*. The choice of agents for induction therapy is based on the patient's age, physical status, and history of prior antineoplastic treatment. Induction therapy typically involves high doses of cytarabine and either daunorubicin, idarubicin, or mitoxantrone; etoposide is occasionally added to the regimen. Older patients (especially those older than 70 years) or those unable to tolerate standard therapy (in poor health) may receive lower-intensity therapy (using hypomethylating agents, low doses of cytarabine, or hydroxyurea), which may extend survival without a significant increase in toxicity beyond that of the underlying disease (NCCN, 2019a).

During induction therapy, chemotherapy not only destroys leukemic cells, but also healthy cells, requiring patients to be hospitalized for several weeks (typically 4 to 6 weeks) due to severe and potentially life-threatening side effects, such as neutropenia. For some patients, an **absolute neutrophil count (ANC**; a calculation of the number of circulating neutrophils, derived from the total WBCs and the percentage of neutrophils counted in a microscope's visual field) of zero is not uncommon (see Chapter 12 for formula used to calculate the ANC). Anemia, and severe thrombocytopenia (a platelet count of less than 5000/mm^3), is also common. During this time, the patient is typically very ill, with bacterial, fungal, and occasionally viral infections; bleeding; and severe mucositis, which cause pain, diarrhea, and an inability to maintain adequate nutrition. Management consists of administering blood products (packed red blood cells [PRBCs] and platelets) and promptly treating infections. The use of granulocytic growth factors, either granulocyte colony-stimulating factor (G-CSF; filgrastim) or granulocyte-macrophage colony-stimulating factor (GM-CSF; sargramostim), may be used during the induction phase only for patients who have a life-threatening infection in order to shorten the neutropenic period (NCCN, 2019a). Patients are discharged to home once blood counts recover and the risk of infection are diminished.

When the patient has recovered from the induction therapy (i.e., the neutrophil and platelet counts have returned to normal and any infection has resolved), consolidation therapy is given to eliminate any residual leukemic cells that are not clinically detectable and to reduce the chance for recurrence of leukemia. Multiple treatment cycles of various agents are used, usually containing some form of cytarabine. Frequently, the patient receives one cycle of treatment that is almost the same as, if not identical to, the induction treatment but at lower dosages.

Allogeneic stem cell transplant is the most common form of hematopoietic stem cell transplant (HSCT) used in the treatment of AML (see Chapter 12 for discussion of HSCT). HSCT is routinely done following induction and consolidation therapy. However, in certain instances (e.g., aggressive disease), HSCT may be performed following induction. The process of HSCT requires that patients begin by receiving high-dose, aggressive chemotherapy, sometimes in tandem with radiation therapy, to destroy the hematopoietic functioning in the bone marrow and to kill any residual leukemic cells. This process is called *conditioning therapy*. Then, the patient is given human leukocyte antigen (HLA-matched) donor stems cells via intravenous (IV) infusion to reestablish bone marrow functioning and to create a new immune system (Leukemia & Lymphoma Society, 2019a). The most appropriate use and timing of HSCT remain unclear. Patients with a poorer prognosis may benefit from early HSCT; those with a good prognosis may not ever require HSCT.

While most patients with AML achieve remission after these treatments, some patients have refractory or relapsed disease, even after aggressive therapy. Approximately 10% to 40% of patients do not obtain a complete remission following induction therapy (Leukemia & Lymphoma Society, 2019a). There are several other treatment options. The induction regimen might be repeated until remission or relapse occurs. Other approaches may include treatment with enasidenib, a cytarabine-based regimen, along with other agents (e.g., cladribine, fludarabine, mitoxantrone, etoposide); palliative care; or use of a hypomethylating agent (e.g., azacitidine or decitabine).

Supportive care may be the best treatment option to consider if the patient has significant comorbidity, such as extremely poor cardiac, pulmonary, renal, or hepatic function; is older and frail; or both. In such cases, the aggressive antileukemia therapy options previously described are not indicated; occasionally, hydroxyurea or hypomethylating agents such as azacitidine may be used briefly to control the increase of blast cells. The patient's symptoms may be mitigated with antimicrobial therapy and transfusions as needed. This treatment approach provides the patient with some additional time outside the hospital; however, death frequently occurs within months, typically from infection or bleeding (refer to Chapter 13 for a discussion of palliative and end-of-life care).

Complications

Complications of AML include bleeding and infection, which are the major causes of death. The risk of bleeding correlates with the level and duration of platelet deficiency. The low platelet count can cause ecchymoses and petechiae. Major hemorrhages also may develop when the platelet count drops to less than 10,000/mm^3. The most common bleeding sources include gastrointestinal (GI), pulmonary, vaginal, and intracranial. For undetermined reasons, fever and infection also increase the likelihood of bleeding. Disseminated intravascular coagulation (DIC) is common, particularly in patients with the APL subtype (NCCN, 2019a) (see Chapter 29 for further discussion of DIC). A very high WBC count (greater than 100,000/mm^3) can cause stasis within the cerebral or pulmonary circulation.

Because of the lack of mature and normal granulocytes that help fight infection, patients with leukemia are prone to infection. The likelihood of infection increases with the degree and duration of neutropenia; neutrophil counts that persist at less than 100/mm^3 dramatically increase the risk of systemic infections. While bacterial infections commonly occur in patients with AML who are neutropenic, the risk of developing a fungal infection also increases. Fungal infections remain difficult to treat; in many cases, patients are given antifungal agents prophylactically. Granulocytic growth factors, either granulocyte colony-stimulating factor (G-CSF; filgrastim) or

granulocyte-macrophage colony-stimulating factor (GM-CSF) are used to stimulate the bone marrow to produce leukocytes, thereby shortening the period of neutropenia. These growth factors are not recommended for use in patients with APL, as differentiation syndrome (formerly known as retinoic acid syndrome), a life-threatening complication with symptoms such as unexplained fever, weight gain, hypotension, respiratory distress, and acute kidney injury can occur (NCCN, 2019a).

Massive leukemic cell destruction from chemotherapy results in the release of intracellular electrolytes and fluids into the systemic circulation. Increases in uric acid levels, potassium, and phosphate are seen; this process is referred to as tumor lysis syndrome (see Chapter 12 for further discussion of tumor lysis syndrome). The increased uric acid and phosphorus levels make the patient vulnerable to renal stone formation and renal colic, which can progress to acute kidney injury. Hyperkalemia and hypocalcemia can lead to cardiac arrhythmias; hypotension; neuromuscular effects such as muscle cramps, weakness, and spasm/tetany; and confusion; and seizures may also develop (Olsen, LeFebvre, & Brassil, 2019). Patients require a high fluid intake, and prophylaxis with allopurinol or rasburicase to prevent crystallization of uric acid and subsequent stone formation.

GI problems may result from the infiltration of abnormal leukocytes into the abdominal organs and from the toxicity of the chemotherapeutic agents. Anorexia, nausea, vomiting, diarrhea, and severe mucositis are common. Because of the profound myelosuppressive effects of chemotherapy, significant neutropenia and thrombocytopenia typically result in serious infection and increased risk of bleeding.

Nursing Management

Nursing management of the patient with acute leukemia, including AML, is presented at the end of the discussion of leukemia in this chapter.

Chronic Myeloid Leukemia

Chronic myeloid leukemia (CML) arises from a mutation in the myeloid stem cell. Normal myeloid cells continue to be produced, but there is a pathologic increase in the production of forms of blast cells. Therefore, a wide spectrum of cell types exists within the blood, from blast forms to mature neutrophils. Because there is an uncontrolled proliferation of cells, the marrow expands into the cavities of long bones, such as the femur, and cells are also formed in the liver and spleen (extramedullary hematopoiesis), resulting in enlargement of these organs that is sometimes painful.

CML results from a chromosomal translocation, where a section of deoxyribonucleic acid (DNA) is shifted from chromosome 22 to chromosome 9, forming what is known as a "fusion gene" that is abnormal. The specific fused gene found in all patients with CML is the *BCR-ABL* gene, which occurs when the *BCR* gene from chromosome 22 switches places with the *ABL* gene from chromosome 9 (Leukemia & Lymphoma Society, 2019b). Normally, the *ABL* gene signals the cells when to make tyrosine kinase; however, the abnormal *BCR-ABL* gene (known as the Philadelphia chromosome) signals cells to produce too many leukocytes and is responsible for converting normal cells into leukemic cells.

CML accounts for 15% of all new cases of leukemia (NCCN, 2019b). The average age of a patient at time of diagnosis is 67 years, but CML can occur at any age. Risk factors include increasing age, being male, having a history of smoking, and being exposed to high doses of radiation (e.g., atomic bomb survivors).

Clinical Manifestations

The clinical picture of CML varies, based upon phase of disease. There are three stages in CML that include chronic, accelerated, and blast crisis (Leukemia & Lymphoma Society, 2019b). During the chronic phase, patients have few symptoms, leukocytosis is detected by a CBC performed for some other reason, and complications from the disease itself are rare.

The accelerated phase can be insidious or rapid; it marks the process of evolution (or transformation) to the acute form of leukemia (blast crisis). In the accelerated phase of disease, blood counts begin to worsen, new chromosomal changes may be seen on analysis, and symptoms consistent with leukemia may start to appear, such as fatigue, anemia, splenomegaly, or dyspnea (NCCN, 2019b). The patient may complain of bone pain and may report fevers (without any obvious sign of infection) and weight loss.

Blast crisis or blast phase of CML is the most advanced phase. Patients in this phase exhibit signs and symptoms that are more like AML than a chronic disease. Some patients present with leukocytosis, with the WBC count exceeding 100,000/mm^3 (NCCN, 2019b). Patients with extremely high leukocyte counts may be dyspneic or slightly confused because of decreased perfusion to the lungs and brain from leukostasis (the excessive volume of leukocytes inhibits blood flow through the capillaries). The patient may have an enlarged, tender spleen, and occasionally the liver may also be enlarged and tender. Some patients have insidious symptoms, such as malaise, anorexia, and weight loss. Lymphadenopathy is uncommon, but if present, indicates late disease and a poor prognosis (NCCN, 2019b).

Medical Management

The goal of treatment for CML is to control the disease, either by obtaining remission or by keeping the patient in the chronic phase for as long as possible. CML is not considered to be curable among older adults despite advances in understanding the pathophysiology of the disease and the advent of new agents. However, the use of tyrosine kinase inhibitors (TKIs) has significantly improved treatment and long-term survival for patients with CML (Leukemia & Lymphoma Society, 2019b). Medical management is based upon the patient's age, general health, calculation of risk-score (based upon stage of disease and prognosis), and phase of disease.

TKIs work by blocking the signals within the leukemic cells that express the *BCR-ABL* protein. This inhibition prevents a series of chemical reactions that cause the cells to grow and divide, thus inducing complete remission at the cellular level. The TKI imatinib mesylate is considered to be standard of care for patients with CML. Newer, alternative TKIs approved for first-line (primary) therapy for patients in the chronic phase of CML include dasatinib or nilotinib (NCCN, 2019b). Each of these TKIs has a different toxicity profile. For example, periorbital edema is common with long-term use of imatinib; dasatinib is very myelosuppressive, and its use carries a significant risk for pleural effusion and for causing a prolonged QT interval; and nilotinib has cardiotoxic effects. Other TKIs approved for second-line therapy (when patients do not respond satisfactorily to the first-line agents) are bosutinib and ponatinib. All TKIs are metabolized by the cytochrome P450 pathway, which means that drug-to-drug interactions are common. Drugs that may decrease the effects of the TKI are corticosteroids, antiseizure medications, antacids, and St. John's wort. Drugs that may increase the effects of the TKI include grapefruit juice, certain antibiotics (e.g., clarithromycin), and azole antifungals (e.g., clotrimazole, ketoconazole).

CML is a disease that can potentially be cured with allogeneic HSCT in otherwise healthy patients who are younger than 65 years. However, with the development of TKIs, the timing of transplant has come into question. Approximately 90% of patients who receive allogeneic HSCT during the chronic phase of CML are disease free for 5 years or more (Leukemia & Lymphoma Society, 2019b).

In the acute form of CML (blast crisis), treatment may resemble induction therapy for acute leukemia, using the same medications as for AML or acute lymphocytic leukemia (ALL; see later discussion). Patients whose disease evolves into a "lymphoid" blast crisis are more likely to be able to reenter a chronic phase after induction therapy. For those whose disease evolves into AML, therapy has been largely ineffective in achieving a second chronic phase. Life-threatening infections and bleeding occur frequently in this phase.

Nursing Management

Most TKIs are oral agents; therefore, their effectiveness is dependent upon the patient's ability and motivation to adhere to the prescribed treatment regimen. These drugs may cause side effects that the patient may find difficult to manage, such as fatigue, asthenia (weakness), pruritus (itching), headache, skin rash, and oropharyngeal pain. A study conducted in Germany of patients with CML treated on an outpatient basis revealed an adherence rate of 51% to oral TKIs (Hefner, Csef, & Kunzmann, 2017), which is consistent with prior studies. In this study, forgetting to take the drug or delays of 2 or more hours from the prescribed time were the most common reported reasons for decreased adherence. Another study examining challenges to oral agent adherence conducted by Gborogen and Polek (2018) reported that over half of nurse participants reported nonadherence to oral agents among their patients. Reasons for nonadherence ranged from patient forgetfulness to perceptions of inadequate support. It is extremely important for the nurse to educate the patient about the medication regimen, how to manage side effects, drug interactions, and safe handling (Olsen et al., 2019) (see Nursing Interventions in Table 30-1). The nurse should also monitor the patient for adverse signs and symptoms of therapy, such as decreased urinary output, changes in the electrocardiogram (ECG; TKIs can cause arrhythmias and prolonged QT intervals), and myelosuppression (e.g., fevers, chills, changes in the CBC).

Acute Lymphocytic Leukemia

ALL results from an uncontrolled proliferation of immature cells (lymphoblasts) derived from the lymphoid stem cell. The cell of origin is the precursor to the B lymphocyte in approximately 75% of ALL cases; T-lymphocyte ALL occurs in approximately 25% of cases. The *BCR-ABL* translocation (see previous discussion in CML section) is found in 20% of ALL blast cells (NCCN, 2019c). ALL can occur at any age, but 75% to 80% of all cases are found in children, with the median age at diagnosis being 15 years (NCCN, 2019c). Boys are affected more often than girls; the peak incidence is 4 years of age. After 15 years of age, it is relatively uncommon, until age 45 when the incidence again rises (Leukemia & Lymphoma Society, 2018a). For those over age 45, risk factors for ALL include older age (especially over 70 years), prior exposure to chemotherapy or radiation therapy, having certain genetic conditions (e.g., especially Down syndrome; also neurofibromatosis, Klinefelter syndrome, and Fanconi anemia) (NCCN, 2019c). In the last several decades, advances in understanding the pathophysiology and molecular genetics, as well as the incorporation of targeted therapy and HSCT, have resulted in improved cure rates and overall longer survival in patients with ALL.

Clinical Manifestations

For some patients with ALL, the clinical manifestations may be nonspecific while others have no symptoms initially. The disease is commonly found incidentally with routine laboratory studies or physical exam for another condition. At the time of diagnosis, the leukocyte counts may be either higher or lower than normal, with a high proportion of immature lymphoblasts. Immature lymphocytes proliferate in the marrow and impede the development of normal myeloid cells. As a result, normal hematopoiesis is inhibited, resulting in reduced numbers of granulocytes, erythrocytes, and platelets. Manifestations of leukemic cell infiltration into other organs are more common with ALL than with other forms of leukemia and include pain from an enlarged liver or spleen as well as bone pain. The central nervous system (CNS) is frequently a site for leukemic cells; thus, patients may exhibit cranial nerve palsies or headache and vomiting because of meningeal involvement. Other extranodal sites include the testes and breasts.

TABLE 30-1 Risk Factors Associated with Lower Adherence to Oral Therapy for Chronic Myeloid Leukemia (CML)

Risk Factor Category	Risk Factor	Nursing Interventions
Patient Characteristics	Lower education level (below high school)	
	Higher self-report of functional status	
	Low self-efficacy regarding medication administration[a]	Explore with patient perceived barriers related to medication administration
	Taking medication independent of meals[a]	Develop medication administration schedule with patient; use timer/watch alarm to alert patient when to take medication
	Lack of knowledge regarding disease and treatment[a]	Provide relevant information in format understandable to patient
Social Characteristics	Living alone[a]	Evaluate need for phone follow-up, initiation of home care
	Low levels of social support	
	Low socioeconomic status	
Disease and Treatment Characteristics	Farther time from diagnosis	Monitor patient closely for side effects Monitor patient closely for complications Provide patient with information on clinical trial enrollment eligibility as advisable
	Higher rates of treatment-related side effects[a]	
	Higher number of cancer-related complications[a]	
	Not participating in a clinical trial[a]	

[a]Indicates risk factor amenable to nursing intervention.

(2019). *Chemotherapy and immunotherapy guidelines and recommendations for practice*. Pittsburgh, PA; Oncology Nursing Society.

Medical Management

The goal of treatment is to obtain remission without excess toxicity and with a rapid hematologic recovery so that additional therapy can be given if needed. Because of the heterogeneity of the disease, treatment plans are based on genetic markers of the disease as well as risk factors of the patient, primarily age. Similar to treatment for AML, treatment for ALL can be grouped into induction, consolidation, and maintenance phases. Because ALL frequently invades the CNS, preventive intrathecal chemotherapy or, less frequently, cranial irradiation, are also a key part of the treatment plan (NCCN, 2019c).

Treatment protocols for ALL tend to be complex, using a wide variety of chemotherapeutic agents and complicated administration schedules. The expected outcome of treatment is complete remission. Despite its complexity, treatment can be provided in the outpatient setting in some circumstances until severe complications develop. TKIs (e.g., imatinib) are effective in patients with Philadelphia chromosome-positive ALL; these drugs can be used alone or in combination with conventional chemotherapy (Leukemia & Lymphoma Society, 2018a).

Lymphoid blast cells are typically very sensitive to corticosteroids and to vinca alkaloids; therefore, these medications are an integral part of the initial induction therapy (NCCN, 2019c). The corticosteroid dexamethasone is preferred to prednisone, as it is more toxic to lymphoid cells and has better CNS penetration. Typically, an anthracycline is included, sometimes with asparaginase. Once a patient is in remission, special testing (immunophenotyping, immunoglobulin gene rearrangements, T-cell receptor genes, molecular testing) is done to look for residual leukemic cells; these tests can detect as few as a single ALL cell among 10,000 to 100,000 normal cells. This minimal residual disease testing is useful as a prognostic indicator. Based on these results and the rapidity in which remission is achieved, a consolidation regimen ensues, using different combinations and dosages of the drugs used in induction therapy; the goal of consolidation is to improve outcomes in those patients at high risk for relapse. For patients with relapsed or refractory B-cell precursor ALL, agents such as blinatumomab or inotuzumab ozogamicin have been found to be effective (NCCN, 2019c).

Patients with ALL can experience some unique adverse effects from treatment. The use of corticosteroids to treat ALL increases the patient's susceptibility to infection; viral infections are common. Avascular necrosis can occur in patients treated with corticosteroid-based chemotherapy, as well as with transplantation. Patients treated with asparaginase are at increased risk for thrombosis. Hepatic toxicity is also common and may necessitate cessation of supportive drugs, such as proton pump inhibitors and certain antibacterial and antifungal drugs.

Allogeneic HSCT may be considered during initial remission if disease features and testing suggest the risk of relapse is high (NCCN, 2019c; Leukemia & Lymphoma Society, 2018a). The development of chimeric

antigen receptor (CAR) T cells has significantly improved treatment outcomes and overall survival in patients with ALL (NCCN, 2019c). CAR-T therapy utilizes the patient's own immune system to fight disease; the patient's own T cells are collected, modified, and reinfused back into the patient. Treatment with CAR-T can serve as a bridge prior to transplant and has qualified patients for HSCT who were formerly ineligible. In the context of average-risk disease, HSCT may be postponed until the time of relapse, should it occur. HSCT can improve long-term disease-free survival; however, this potential benefit must be weighed with the risks associated with the procedure, including death and long-term morbid complications.

Nursing Management

Nursing management of the patient with acute leukemia, including ALL, is presented at the end of the leukemia section in this chapter.

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) is a common malignancy of older adults, and the most prevalent type of adult leukemia in the Western world (NCCN, 2019d). The average age at diagnosis is 71 years (Leukemia & Lymphoma Society, 2019c). CLL is rarely seen in Native Americans and infrequently among people of Asian descent. Unlike other forms of leukemia, a strong familial predisposition exists with CLL; the disease can occur in 10% of those with a first- or second-degree relative with the same diagnosis. Veterans of the Vietnam War who were exposed to Agent Orange may be at risk for developing this disease (see the following section), but there is no definitive link to other pesticides or exposure to chemicals. While many patients will have a normal life expectancy, others will have a very short life expectancy due to the aggressive nature of the disease.

Veterans Considerations

Agent Orange was an herbicide used as a defoliant by the U.S. military in Vietnam from 1962 until 1975, when American involvement in the Vietnam War ended. Since that time, dioxin, a chemical used in Agent Orange, has been found to be carcinogenic. In particular, there is sufficient evidence that CLL, Hodgkin lymphoma, non-Hodgkin lymphomas (NHLs), and monoclonal gammopathy of undetermined significance (MGUS) are associated with Agent Orange exposure, while there is also evidence that suggests that Agent Orange exposure may be linked to multiple myeloma (American Cancer Society [ACS], 2020a). Approximately 3 million American veterans could have been

exposed to the harmful effects of Agent Orange related to their military service in Vietnam. The U.S. Department of Veteran Affairs (VA) has administered an *Agent Orange Registry* since 1978. Qualified veterans who enroll in the registry are eligible for health care benefits and consultations. Those veterans who develop cancers secondary to exposure to Agent Orange may be eligible for VA disability benefits (see Resources for additional information for veterans exposed to Agent Orange) (ACS, 2020a).

Pathophysiology

CLL is typically derived from a malignant clone of B lymphocytes. A **clone** proliferates from a cell of origin so that descendent cells are identical to the cell of origin. In contrast to the acute forms of leukemia, most leukemic cells in CLL are fully mature. One possible mechanism that explains this oncogenesis is that these cells can escape **apoptosis** (programmed cell death), resulting in an excessive accumulation of the cells in the marrow and circulation. CLL is characterized by the progressive accumulation of leukemic cells in the bone marrow, blood, and lymphoid tissues (NCCN, 2019d).

Because the lymphocytes are small, they can easily travel through the small capillaries within the circulation, and the pulmonary and cerebral complications of leukocytosis seen with myeloid leukemias are not typically found in CLL. However, these cells often accumulate within the lymph nodes and spleen. When it takes less than 12 months for the absolute number of lymphocytes to double (lymphocyte doubling time), a more aggressive disease course may ensue.

Immunophenotyping of the circulating B cells is critical to establish the diagnosis by identifying the presence of a malignant clone of these cells; it is also used to gauge the prognosis (NCCN, 2019d). Other special cytogenetic and molecular analyses (e.g., fluorescence in situ hybridization [FISH]) are also used to guide prognosis and therapy. Beta-2 microglobulin, a protein found on the surface of lymphocytes, can be measured in the serum; an elevated level correlates with a more advanced clinical stage and poorer prognosis.

Autoimmune complications can occur at any stage, as either autoimmune hemolytic anemia or idiopathic thrombocytopenic purpura. In the autoimmune process, the reticuloendothelial system destroys the body's own erythrocytes or platelets. Patients with CLL also have a greater risk for developing other cancers. Approximately 2% to 10% of patients with CLL will experience transformation of their disease to a very aggressive lymphoma, known as Richter's transformation (NCCN, 2019d); this transformation results in markedly increased lymphadenopathy, splenomegaly, B symptoms (see **Chart 30-1**), and survival of only a few months despite treatment. Second cancers typically involve the skin, colon, lung, breast, prostate, and kidney.

Chart 30-1 RISK FACTORS

B Symptoms

These symptoms include the following:

- Fever of at least 100.4° F (38°C) that may come and go over several weeks that is not explained by an underlying infection
- Drenching night sweats
- Unintentional loss of at least 10% body weight over the past 6 months

Overview: B symptoms:

- Are constitutional symptoms, meaning that they affect multiple systems
- Can manifest with many types of hematopoietic malignancies, including chronic lymphocytic leukemia (CLL), Hodgkin lymphoma, and non-Hodgkin lymphomas (NHLs)
- Are associated with worst prognoses in patients with CLL, Hodgkin lymphoma and NHL than in patients who do not report B symptoms

Adapted from Leukemia & Lymphoma Society. (2018c). Hodgkin lymphoma. Retrieved on 7/10/2019 at: www.lls.org/sites/default/files/file_assets/PS57_Hodgkin_Lymphoma2018.pdf

Clinical Manifestations

Many patients are asymptomatic and are diagnosed incidentally during routine physical examinations or during treatment for another disease. Lymphocytosis (an increased lymphocyte count) is always present. The erythrocyte and platelet counts may be normal or, in later stages of the illness, decreased. Lymphadenopathy is common; this can be severe and sometimes painful (see Fig. 30-4). Splenomegaly may also occur.

Patients with CLL can develop B symptoms (see **Chart 30-1**) which portends a worsening prognosis. T-cell function is impaired and may be the cause of tumor progression and increased susceptibility to second malignancies and infections. Life-threatening infections are particularly common with advanced disease, and account for over half of all deaths in this patient population. Viral infections, such as herpes zoster, can become widely

disseminated. Defects in the complement system are also seen, which results in increased risk of developing infection with encapsulated organisms (e.g., *Haemophilus influenzae*). Patients should receive an annual comprehensive skin examination (as the incidence of skin cancer is higher in this group), and screening guidelines for other cancers should be followed, such as for breast, colorectal, lung, and prostate cancer (NCCN, 2019d) (see Chapter 12, Table 12-3, for cancer screening guidelines).

(2007). *Wintrobe's atlas of clinical hematology* (Fig. 5.1, p. 154). Philadelphia, PA: Lippincott Williams & Wilkins.

Medical Management

For patients with no symptoms at the time of diagnosis, the traditional "watch-and-wait" approach is often used until progression of disease is noted (which could be months to years). However, with the advent of newer treatment modalities (i.e., targeted therapies and immunotherapy), treatment may be initiated sooner in the illness trajectory (NCCN, 2019d). Additionally, clinical trials are ongoing to assess for an advantage in survival with newer agents. Various parameters are considered when treatment is selected, including the clinical stage of the disease, disease-associated symptoms, the functional status of the patient, genetic risk, and the extent and efficacy of any prior treatment. Functional status is a complex consideration; in this context, it incorporates the individual's life expectancy independent of CLL (due to other health problems), the ability to tolerate aggressive therapy (e.g., creatinine clearance is particularly important), and the ability to perform activities of daily living (Leukemia & Lymphoma Society, 2019c; NCCN, 2019d). Patients with good functional status can typically tolerate aggressive therapy and often achieve a lasting complete remission. In contrast, the objective of treatment in those with more impaired physical status focuses on controlling bothersome symptoms (e.g., drenching night sweats, painful lymphadenopathy).

Treatment for CLL is variable and can consist of a single immunotherapy agent administered in combination with chemotherapeutic agents, such as an immunotherapeutic antibody against the B-lymphocyte antigen CD20 (e.g., rituximab, ofatumumab, obinutuzumab) with chemotherapeutic agents (e.g., fludarabine, cyclophosphamide, bendamustine, chlorambucil) as initial therapy. The most commonly prescribed first-line chemotherapeutic agent is fludarabine. When the disease is accompanied by a deletion of the *TP53* gene or a mutation of this gene, TKIs such as ibrutinib or idelalisib may be used as either monotherapy or in combination with other agents (NCCN, 2019d). Depending upon the age of the patient (less than or greater than 65 years of age) and whether or not the patient has comorbidities, patients with relapsed or refractory disease may also receive newer agents such as venetoclax, duvelisib, or acalabrutinib (NCCN, 2019d).

The major side effect of fludarabine is prolonged bone marrow suppression, manifested by prolonged periods of neutropenia, lymphopenia, and thrombocytopenia, which puts patients at risk for such infections as *Pneumocystis jiroveci, Listeria,* mycobacteria, herpes viruses, and cytomegalovirus (CMV). The monoclonal antibody (MoAb) alemtuzumab is often used in combination with other chemotherapeutic agents when the disease is refractory to fludarabine, the patient has very poor prognostic markers, or it is necessary to eradicate residual disease after initial treatment. Alemtuzumab targets the CD52 antigen commonly found on CLL cells, and it is effective in clearing the marrow and circulation of these cells without

affecting the stem cells. Because CD52 is present on both B and T lymphocytes, patients receiving alemtuzumab are at significant risk for infection; prophylactic use of antiviral agents and antibiotics (e.g., trimethoprim–sulfamethoxazole) is important and needs to continue for several months after treatment ends. CMV infection is also common with alemtuzumab, idelalisib, and duvelisib, and prophylaxis is important; among commonly prescribed antiviral agents, vancyclovir is more effective than acyclovir for treating CMV (NCCN, 2019d).

Patients receiving idelalisib or duvelisib have an increased risk of hepatotoxicity, severe diarrhea, colitis, and pneumonitis. TKIs have been found to increase the risk of cardiovascular toxicities, including hypertension, prolonged QT interval, left ventricular dysfunction, and heart failure (Olsen et al., 2019). Ongoing periodic assessment of the CBC, blood chemistries, ECG, blood pressure, and bowel habits are important parameters to monitor among patients taking these various agents.

Because of the older age of most patients with CLL, allogeneic HSCT may not be an option, particularly if significant comorbidities exist. However, allogeneic HSCT might be considered for some patients with *TP53* deletions or mutations who otherwise have a poor prognosis. Morbidity and mortality rates remain high (20%); thus, this treatment modality may be reserved for those patients with high-risk disease, younger age, and high degree of match from the donor (NCCN, 2019d).

Nursing Management

Virtually all patients with CLL have reduced levels of immunoglobulins, and bacterial infections are common, independent of treatment. IV treatment with immunoglobulin (IVIG) may be given to select patients with recurrent infection. While studies have not demonstrated improved survival, the rate of developing major infections is reduced (NCCN, 2019d). Patients with CLL should receive both pneumonia and flu vaccinations as indicated. Live vaccines should be avoided. The patient with CLL is at increased risk of a host of infections; nursing interventions focused on diminishing these risks are summarized in Chapter 12, Chart 12-6.

For the procedural guidelines for managing immunoglobulin therapy, go to thepoint.lww.com/Brunner15e.

NURSING PROCESS

The Patient with Acute Leukemia

Assessment

Although the clinical picture varies with the type of leukemia as well as with the treatment implemented, the health history may reveal a range of subtle symptoms reported by the patient before the problem is detectable on physical examination. If the patient is hospitalized, assessments should be performed daily, or more frequently as warranted. Because the physical findings may be subtle initially, a thorough, systematic assessment incorporating all body systems is essential. For example, a dry cough, mild dyspnea, and diminished breath sounds may indicate a pulmonary infection. However, the infection may not be seen initially on the chest x-ray; the absence of neutrophils delays the inflammatory response against the pulmonary infection, thus delaying radiographic changes. When serial assessments are performed, current findings are compared with previous findings to evaluate improvement or worsening. Specific body system assessments are delineated in the neutropenic and bleeding precautions found in Chapter 12, Chart 12-6.

The nurse also must closely monitor the results of laboratory studies, including tracking the leukocyte count, ANC, hematocrit, platelet, creatinine and electrolyte levels, and coagulation and hepatic function tests. Culture results need to be reported immediately so that appropriate antimicrobial therapy can begin or be modified.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include:

- Risk for infection, haemorrhaging, or both
- Impaired oral mucous membrane integrity due to changes in epithelial lining of the GI tract from chemotherapy or prolonged use of antimicrobial medications
- Impaired nutritional status associated with hypermetabolic state, anorexia, mucositis, pain, and nausea
- Acute pain associated with mucositis, leukocyte infiltration of systemic tissues, fever, and infection
- Fatigue and activity intolerance associated with anemia, infection, inadequate nutrition, and deconditioning
- Fluid imbalance associated with renal dysfunction, diarrhea, bleeding, infection, increased metabolic rate, hypoproteinemia, and need for multiple intravenous medications and blood products

- Impaired ability to perform hygiene, impaired ability to dress, and impaired self toileting due to fatigue and malaise
- Anxiety and grief due to uncertainty about future, anticipatory loss, and altered role functioning
- Risk for spiritual distress
- Lack of knowledge about disease process, treatment, complication management, and self-care measures

Collaborative Problems/Potential Complications

Potential complications may include the following (see Chapter 12 for further discussion):

- Infection
- Bleeding/DIC
- Renal dysfunction
- Cardiac toxicity
- Infertility
- Tumor lysis syndrome

Planning and Goals

The major goals for the patient may include absence of complications and pain, attainment and maintenance of adequate nutrition, activity tolerance, ability to provide self-care and to cope with the diagnosis and prognosis, positive body image, and an understanding of the disease process and its treatment.

Nursing Interventions

Preventing or Managing Infection and Bleeding

The nursing interventions related to diminishing the risk of infection and bleeding are delineated in Chapter 12, Chart 12-6.

Managing Mucositis

Although emphasis is placed on the oral mucosa, the entire GI mucosa can be altered, not only by the effects of chemotherapy but also from prolonged administration of antibiotics. See Chapter 12 for assessment and management of mucositis.

Improving Nutritional Intake

The disease process can increase the patient's metabolic rate and nutritional requirements. Nutritional intake is often reduced because of pain and discomfort associated with stomatitis. Encouraging or providing mouth care before and after meals and administering analgesic agents before eating can help increase intake. If oral anesthetic agents are used, the patient must be warned to chew with extreme care to avoid inadvertently biting the tongue or buccal mucosa.

Nausea should not interfere with nutritional intake, because appropriate antiemetic therapy is highly effective. However, nausea can result from antimicrobial therapy, so some antiemetic therapy may still be required after the chemotherapy has been completed.

Small, frequent feedings of foods that are soft in texture and moderate in temperature may be better tolerated. Low-microbial diets may be prescribed (avoiding uncooked fruits or vegetables and those without a peelable skin), although there is little evidence to support this intervention (Olsen et al., 2019). Nutritional supplements are frequently used. Daily body weight (as well as intake and output measurements) is useful in monitoring fluid status. Both calorie counts and more formal nutritional assessments are often useful. Parenteral nutrition may be required to maintain adequate nutrition.

Easing Pain and Discomfort

Recurrent fevers are common in acute leukemia; at times, they are accompanied by shaking chills (rigors), which can be severe. Myalgias and arthralgias can result. Acetaminophen is typically given to decrease fever, but it also increases diaphoresis. Sponging with cool water may be useful, but cold water or ice packs should be avoided because the heat cannot dissipate from constricted blood vessels. Bedclothes need frequent changing as well. Gentle back and shoulder massage may provide comfort.

Mucositis can also cause significant discomfort. In addition to oral hygiene practices, patient-controlled analgesia can be effective in controlling the pain (see Chapter 9). With the exception of severe mucositis, less pain is associated with acute leukemia than with many other forms of cancer. However, the amount of psychological suffering that the patient endures can be immense. Patients often benefit from active listening and possible referral for professional counseling.

Decreasing Fatigue and Activity Intolerance

Fatigue is a common and oppressive symptom. Nursing interventions should focus on assisting the patient to establish a balance between activity and rest. Patients with acute leukemia need to maintain some physical activity and exercise to prevent the deconditioning that results from inactivity. The use of a high-efficiency particulate air (HEPA) filter mask can permit the patient to ambulate outside the room despite severe neutropenia. Stationary bicycles may also be set up in the room; however, many patients lack the motivation or stamina to use them. At a minimum, patients should be encouraged to sit up in a chair while awake rather than staying in bed; even this simple activity can improve the patient's tidal volume and enhance circulation. Physical therapy can also be beneficial. Patients with acute leukemia may require hospitalization for extensive nursing care (either during induction or consolidation therapy or during

resultant complications); sleep deprivation frequently results. Nurses need to implement creative strategies that permit uninterrupted sleep for at least a few hours while still administering necessary medications on schedule (see Nursing Research Profile, Chart 30-2).

Chart 30-2 **NURSING RESEARCH PROFILE**

Fatigue and Sleep Disturbances in Adults with Acute Leukemia

Bryant, A., Gosselin, T., Coffman, E., et al. (2018). Symptoms, mobility, and function, and quality of life in adults with acute leukemia during initial hospitalization. *Oncology Nursing Forum, 45*(5), 653–664.

Purpose

Patients newly diagnosed with acute leukemia require hospitalization, typically for 4 to 6 weeks, for managing aggressive induction therapy and its toxicities. These symptoms can greatly impact the patient's quality of life and ability to perform activities of daily living. The purpose of this study was to evaluate global, physical, and mental health symptoms in adults with newly diagnosed acute leukemia.

Design

This was a prospective, longitudinal study with a total of 49 adult participants, including 36 males and 13 females. Data were collected at time of hospitalization (baseline), then weekly until discharge from hospital. Evaluation tools for data included: the Patient-Reported Outcomes Measurement Information System (PROMIS) to determine several self-reported quality-of-life measures such as fatigue, anxiety, depression, pain, sleep disturbances, and global physical and mental health; the Functional Assessment of Cancer Therapy-Leukemia (FACT-Leu) to measure symptom concerns that are leukemic specific; Karnofsky Performance Status Scale (KPS) to measure function; and the Timed UP and Go Test (TUG) to measure physical mobility.

Findings

This study was the largest, to date, to evaluate the symptoms and quality of life of patients newly diagnosed with acute leukemia during hospitalization. All participants had one or more comorbidities, as well as a group mean body mass index of 30.8 (SD = 6.7), indicative of being overweight or having obesity, at time of hospitalization. No significant differences were seen in global mental health, pain, or KPS during hospitalization. There were significant decreases in fatigue ($p < 0.001$), anxiety ($p < 0.001$), depression ($p = 0.004$), and sleep disturbance ($p = 0.005$) from baseline to hospital discharge. Also significant were a decrease in leukemic symptoms ($p < 0.001$), indicating improved leukemic outcomes, which is the goal of therapy.

Nursing Implications

Nurses need to be aware of factors that can impact sleep in patients with cancer, both during and following treatment. As fatigue plays a major role in sleep disturbances, the nurse needs to assess for and develop strategies to address both concerns, especially while the patient is in the hospital. Poor sleep, fatigue, and pain can all contribute to the increased

risk for falls, so safety issues should also be addressed with the patient and the patient's family. The nurse should encourage the patient to exercise and have some physical activity as part of the daily routine, to decrease fatigue while enhancing sleep. Additionally, the nurse should have a good understanding of the symptoms common to patients with leukemia and interventions to manage them as they occur.

Maintaining Fluid and Electrolyte Balance

Febrile episodes, bleeding, and inadequate or overly aggressive fluid replacement can alter the patient's fluid status. Similarly, persistent diarrhea and vomiting that occur with certain chemotherapy and immunotherapy agents, and long-term use of certain antimicrobial agents can cause significant deficits in electrolytes. Intake and output need to be measured accurately, and daily weights should also be monitored. The patient should be assessed for signs of dehydration as well as fluid overload, with particular attention to pulmonary status and the development of dependent edema. Laboratory test results, particularly electrolytes, blood urea nitrogen, creatinine, and hematocrit, should be monitored and compared with previous results. Replacement of electrolytes, particularly potassium and magnesium, is commonly required. Patients receiving amphotericin or certain antibiotics are at increased risk for electrolyte depletion.

Improving Self-Care: Bathing, Dressing, and Toileting

Because hygiene measures are so important in this patient population, they must be performed by the nurse when the patient cannot do so. However, the patient should be encouraged to do as much as possible to preserve mobility and function as well as self-esteem. Patients may have negative feelings because they can no longer care for themselves. Empathetic listening is helpful, as is realistic reassurance that these deficits are temporary. As the patient recovers, the nurse assists them to resume more self-care. Patients are usually discharged from the hospital with a vascular access device (e.g., Hickman catheter, peripherally inserted central catheter [PICC]), and coordination with appropriate home care services is needed for catheter management.

Managing Anxiety and Grief

Being diagnosed with acute leukemia can be extremely frightening. In many instances, the need to begin treatment is emergent, and the patient has little time to process the fact that they have the illness before making decisions about therapy. Providing emotional support and discussing the uncertain future are crucial. The nurse also needs to assess how much information the patient wants to have regarding the illness, its treatment, and potential complications. This desire should be reassessed at intervals, because needs and interest in information change throughout the course of the disease and treatment. Priorities must be identified so that procedures,

assessments, and self-care expectations are adequately explained even to those who do not wish extensive information.

Many patients exhibit depressive symptoms and begin to grieve for their losses, such as normal family functioning, professional roles and responsibilities, and social roles, as well as physical functioning. The nurse can assist the patient to identify the source of the grief and encourage them to allow time to adjust to the major life changes produced by the illness. Role restructuring, in both family and professional life, may be required. It is essential to encourage the patient to identify options and to take time in making important decisions.

The patient's physical condition can deteriorate quickly and it is not often easy to discern if the patient may recover or will die from complications. Providing emotional support to both the patient and the family is critical and equally as important as is rendering expert physical care.

Discharge from the hospital can also provoke anxiety. Although most patients are eager to go home, they may lack confidence in their ability to manage potential complications and to resume their normal activity. Close communication between nurses across care settings can reassure patients that they will not be abandoned.

Encouraging Spiritual Well-Being

Because acute leukemia is a serious, potentially life-threatening illness, the nurse may offer support to enhance the patient's spiritual well-being. The patient's spiritual and religious practices should be assessed and pastoral services offered. Throughout the patient's illness, the nurse assists the patient to maintain hope. However, that hope should be realistic and will certainly change over the course of the illness. For example, the patient may initially hope to be cured, but with repeated relapses and a change to hospice or palliative care, the same patient may hope for a quiet, dignified death. (Refer to Chapter 13 for a discussion of palliative and end-of-life care.)

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Most patients cope better when they understand what is happening to them. Based on their health literacy level, and interest, educating the patient and family should begin with a focus on the disease (including some pathophysiology), its treatment, and certainly the resulting significant risk of infection and bleeding (see Chapter 29, Charts 29-7 and 29-8).

Although management of a vascular access device can be taught to most patients or family members, this care is typically performed by a home care

agency or outpatient clinic nursing staff. Patients and family members do need basic education regarding management of the vascular access device, particularly with regard to prevention of infections.

Continuing and Transitional Care. For patients who are clinically stable but require parenteral antibiotics or blood products, these procedures are most often performed in an outpatient setting. Nurses in these settings must communicate regularly. They need to inform the patient about parameters that are important to monitor, how to monitor them, and to give the patient-specific instructions about when to seek care from the physician or other health care provider.

The patient and family need to have a clear understanding of the disease, the prognosis, and how to monitor for complications or recurrence. The nurse ensures that this information is provided. Should the patient no longer respond to therapy, it is important to respect the patient's choices about treatment and end-of-life care. Advance directives or other method should be used for patients to state their end-of-life preferences (see Chapter 13, Chart 13-5). In patients with acute leukemia, death typically occurs from infection or, less frequently, from bleeding. Family members need to have information about these complications and the measures to take should either occur. Many family members cannot cope with the care required when a patient begins to bleed actively. It is important to delineate alternatives to keeping the patient at home, such as inpatient hospice units.

Evaluation

Expected patient outcomes may include:

1. Shows no evidence of infection
2. Experiences no bleeding
3. Has intact oral mucous membranes
   a. Participates in oral hygiene regimen
   b. Reports no discomfort in mouth
4. Attains optimal level of nutrition
   a. Maintains weight with increased food and fluid intake
   b. Maintains adequate protein stores (e.g., albumin, prealbumin)
5. Reports satisfaction with pain and comfort levels
6. Has less fatigue and increased activity
7. Maintains fluid and electrolyte balance
8. Participates in self-care
9. Copes with anxiety and grief
   a. Discusses concerns and fears

b. Uses stress management strategies appropriately
c. Participates in decisions regarding end-of-life care

10. Reports sense of spiritual well-being
11. Absence of complications

MYELODYSPLASTIC SYNDROMES (MDSS)

The MDSs are a group of clonal disorders of the myeloid stem cell that cause dysplasia (abnormal development) in one or more types of cell lines. These disorders commonly result in cytopenias (low blood cell counts), with the tendency to develop into acute leukemia (Sockel & Platzbecker, 2018). A common feature of MDS is anemia due to dysplasia of the erythrocytes, although leukocytes (particularly neutrophils) and platelets can also be affected. Although the bone marrow is actually hypercellular, many of the cells within it die before being released into the circulation. Therefore, the actual number of cells in the circulation is typically lower than normal. In MDS, the affected cells do not function normally. The neutrophils have diminished ability to destroy bacteria by **phagocytosis** (cellular ingestion and digestion of foreign bodies); platelets are less able to aggregate and are less adhesive than usual. The result of these defects is an increased risk of infection and bleeding, even when the actual number of circulating cells may not be excessively low.

This disease is primarily seen in older adults (median age at diagnosis is 65 to 70 years), is idiopathic in nature due to HSC damage, and occurs more often in males than females (Montalban-Bravo & Garcia-Manero, 2017; Sockel & Platzbecker, 2018). In addition, about 10% to 15% of patients will develop MDS following exposure to alkylating agents, radiotherapy, or chemicals (e.g., benzene), and/or have an inherited genetic disorder, such as Fanconi anemia or trisomy 21 (Sockel & Platzbecker, 2018). Genetic syndromes account for about 50% of cases (e.g., Down syndrome, trisomy 8 syndrome, neurofibromatosis type 1) (Leukemia & Lymphoma Society, 2019d; NCCN, 2019e).

Clinical Manifestations

The manifestations of MDS can vary widely. Some patients are asymptomatic, with the illness being discovered incidentally when a CBC is performed for other purposes. Other patients have profound symptoms and complications from the illness. Because MDS tends to occur in older adults, other concurrent chronic health conditions may exacerbate symptoms associated with the disease. Fatigue is often present, with varying levels of intensity and

frequency. Neutrophil dysfunction puts the patient at risk for recurrent pneumonias and other infections. Because platelet function can also be altered, bleeding can occur. These problems may persist in a fairly steady state for months, even years. Over time, the marrow may fail to provide enough cells despite support with transfusion or growth factors; this is called *bone marrow failure*. MDS may also progress over time; as the dysplasia evolves into a leukemic state, the complications increase in severity. However, it is important to note that the majority of patients with MDS succumb to complications from the disease itself or from other comorbidities, and not to those from acute leukemia (Leukemia & Lymphoma Society, 2019d).

Assessment and Diagnostic Findings

The CBC typically reveals a macrocytic anemia; leukocyte and platelet counts may be diminished as well. Other potential causes for cytopenia, which may include vitamin deficiencies, viral infection, GI bleeding, autoimmune disease, splenomegaly, and liver dysfunction, should be excluded. Serum erythropoietin levels may be variable and the **reticulocyte** count (immature RBCs) may be inappropriately low. The presence of blast cells on the CBC may be indicative of disease progression to acute leukemia. To help rule out other causes of anemia, other laboratory studies may include folate, serum vitamin B_{12}, ferritin, total iron-binding capacity (TIBC), iron, and thyroid-stimulating hormone (TSH).

The official diagnosis of MDS is based on the results of a bone marrow aspiration (to assess dysplasia) and biopsy (to assess characteristics of the affected cells). These tests help in determining prognosis, risk of leukemic transformation, and in some patients, the most effective therapy (Montalban-Bravo & Garcia-Manero, 2017); thus, the nurse must understand the risk stratification category of each patient. Those patients with low-risk disease have a much longer survival (as much as 10 years) compared with untreated patients with high-risk disease (where survival is usually less than 9 months) (NCCN, 2019e) (see Chapter 28 for discussion of bone marrow aspiration and biopsy).

Medical Management

Medical management strategies for MDS are based on risk stratification to determine stage of disease and prognosis. The most commonly used tool is the International Prognostic Scoring System (IPSS) that evaluates cytopenia, transfusion needs, percent of blast cells in the bone marrow, and cytogenetic characteristics (Montalban-Bravo & Garcia-Manero, 2017). Most patients with MDSs are diagnosed as having low-risk disease; for these patients, the objective of therapy is to maintain or restore quality of life, improve cytopenia,

and decrease transfusion requirements. Some patients with mild symptoms may only require periodic monitoring of laboratory studies indicative of hematologic function (e.g., CBC, reticulocyte count, folate, ferritin, iron). Approximately two thirds of patients diagnosed as low risk have cytopenic-related complications at the time of diagnosis, however, and may require blood transfusions and/or an erythropoiesis-stimulating agent.

Patients who are at low to intermediate risk and transfusion dependent are typically treated with a hypomethylating agent (e.g., azacitidine, decitabine). These agents work by inhibiting the abnormal genes regulating methylation, promoting tumor suppression genes, and permitting myeloid differentiation within the bone marrow (NCCN, 2019e). Neither drug has been shown to modify the natural trajectory of low-risk MDS; therefore, hypomethylating agents are not typically used until erythroid-stimulating agents are no longer effective in controlling transfusion dependence (NCCN, 2019e). These agents can improve cytopenia, reduce transfusion requirements, reduce the likelihood of transformation to AML, and improve overall survival.

For the patient at high risk the goals of therapy are to delay leukemic transformation and prolong life expectancy (NCCN, 2019e; Sockel & Platzbecker, 2018). Allogeneic HSCT continues to be the only potential option of cure for MDS, but is not often a viable option for most patients, as many are of advanced age with significant comorbidities. Allogeneic HSCT is recommended for patients who have hypoplastic MDS, are younger, or those who have not responded satisfactorily to other treatment options (Montalban-Bravo & Garcia-Manero, 2017; NCCN, 2019e).

Lenalidomide (a thalidomide analog) is the standard of care for patients with the chromosomal abnormality deletion 5q, are considered low risk, and are not thrombocytopenic (NCCN, 2019e). Treatment with lenalidomide may cause neutropenia and thrombocytopenia, which may necessitate treatment delays or dose reduction (NCCN, 2019e). Other immunosuppressive therapies that have shown some efficacy in the treatment of MDS are antithymocyte globulin (ATG), with or without cyclosporine, and corticosteroids. These agents are used in a subset of patients with MDS who have weakened immune responses (e.g., have neutropenia) (Montalban-Bravo & Garcia-Manero, 2017).

Patients frequently need repeated transfusions (PRBCs, platelets, or both) throughout the illness trajectory to maintain adequate hemoglobin and platelet levels (termed *transfusion dependence*). Attempts to improve anemia and decrease RBC transfusion are often successful with the use of erythroid-stimulating agents (epoetin alfa or darbopoetin alfa). Higher-than-normal doses may be required to achieve an adequate improvement in hemoglobin. Adding myeloid growth factors such as G-CSF or GM-CSF can boost responsiveness to these agents (NCCN, 2019e). The median duration of response to this therapy is 2 years; transfusion requirements typically increase by this point.

Thrombocytopenia is a challenge to manage among patients with MDS. Severe thrombocytopenia is difficult to manage because patients can quickly develop refractoriness to platelet transfusions due to alloimmunization (Leukemia & Lymphoma Society, 2019d). Moreover, bleeding can develop even when the platelet level is not excessively low, due to poor platelet function. The cause of thrombocytopenia appears to be increased apoptosis and premature marrow destruction of the platelets prior to their release into the circulation (NCCN, 2019e). The recombinant thrombopoietin receptor agonists romiplostim and eltrombopag have been developed to stimulate the proliferation and differentiation of megakaryocytes into platelets within the bone marrow. Both drugs have demonstrated the ability to significantly raise platelet counts in this population, but their duration of action may not be long. Increased rates of marrow fibrosis and AML evolution seem to be ameliorated by discontinuing the drug, but additional study is needed (NCCN, 2019e).

Iron overload is another significant problem for patients with MDS, especially in patients who routinely receive PRBC transfusions (transfusion dependent). Surplus iron is deposited in cells within the reticuloendothelial system, and later in parenchymal organs (e.g., liver). While a true cause-and-effect has not yet been established, there is significant concern that patients with transfusion-dependent MDS are at high risk for developing cardiac disorders, particularly heart failure, as well as hepatic and endocrine dysfunction (NCCN, 2019e). Excess iron, and the resultant increased oxidative stress, is also associated with pancreatic dysfunction, the development of diabetes, increased rates of infection, and decreased hematopoiesis.

To prevent or reverse the complications of iron overload, iron chelation therapy is commonly implemented. Patients with preexisting liver disease, including cirrhosis, should not receive oral iron chelators. There are studies that have found that iron overload may play a role in increased mortality and morbidity in early-stage MDS due to hepatic, cardiac, and endocrine dysfunction (NCCN, 2019e). It is recommended that all patients with MDS who have regular transfusion needs have serum ferritin levels along with the number of PRBC transfusions routinely monitored to determine iron stores and possible overload. The ferritin level should be maintained at less than 1000 mcg/L. Iron is bound to the chelating agent and then excreted in the urine. Because chelation therapy removes only a small amount of iron with each treatment, patients with chronic iron overload from RBC transfusions need to continue chelation therapy as long as the iron overload exists. Oral iron chelation with deferasirox has replaced the need for the former standard therapy, which consisted of subcutaneous infusions of deferoxamine. However, adherence remains a challenge, largely due to toxicity associated with the drug.

Infection rates are high among patients with MDS, who frequently require hospitalization. Severe neutropenia, coexisting chronic obstructive pulmonary disease (COPD) or autoimmune disease, and history of other malignancy are

associated with higher risk for developing infection, whereas the extent of thrombocytopenia, age, MDS therapy, or diabetes are not (Leukemia & Lymphoma Society, 2019d; NCCN, 2019e). Pneumonia is the most common type of infection in this patient population; bacteria (both gram negative and gram positive) are the predominant pathogens.

The administration of myeloid growth factors alone may be useful in some patients with infections and severe neutropenia, but they are not typically used to prevent infection. Prophylactic antibiotics are not routinely used so that resistant organisms do not develop, but prompt initiation of antimicrobial therapy is crucial at the onset of infection to diminish the risk of increased mortality.

Nursing Management

Caring for patients with MDS can be challenging because the illness is unpredictable. As with other hematologic disorders, some patients (especially those with no symptoms) have difficulty perceiving that they have a serious illness that can place them at risk for life-threatening complications. At the other extreme, many patients have tremendous difficulty coping with the uncertain trajectory of the illness and fear that the illness will evolve into AML. Thus, it is important for patients to understand their unique risk of the disease transforming to AML and to recognize that, for most patients, MDS is a chronic illness. It is imperative that the nurse recognizes any concurrent health problems the patient may have. This knowledge will help the nurse better plan and manage the patient's care. For example, a patient with underlying heart failure or COPD may not tolerate anemia well, nor a more rapid rate of red blood cell transfusion.

Patients with MDS need extensive education about infection risk, measures to avoid it, signs and symptoms of developing infection, and appropriate actions to take should such symptoms occur. Education should also be provided regarding the risk of bleeding. Patients need to be encouraged to serve as their own health advocate, by informing other health care providers, including dentists, that they have MDS, and their risks for infection and bleeding. Patients with MDS who are hospitalized may require neutropenic precautions.

Fatigue is often a debilitating symptom for the patient with MDS and significantly interferes with quality of life. It can impair the patient's ability to function in the work or home setting and to engage in meaningful activities, and affect the patient's overall cognitive function (Leukemia & Lymphoma Society, 2019d; NCCN, 2019e). Patients may benefit from anticipatory guidance in learning how to live with this symptom, and creative strategies may be required.

Laboratory values need to be monitored closely to anticipate the need for transfusion and to determine response to treatment with growth factors. Patients with chronic transfusion requirements often benefit from the insertion of a vascular access device for this purpose. Those patients receiving chemotherapy need extensive education regarding treatment side effects (and how to manage them) and treatment schedules. Patients receiving growth factors need education about these medications, administration schedules, and side effects.

Chelation therapy is a process that is used to remove excess iron acquired from chronic transfusions. Side effects from oral chelators commonly include diarrhea and abdominal cramping. Educating the patient to take the medication in the evening prior to dinner and gradually increasing the dosage over time may diminish these side effects. Skin rash is usually mild and rarely warrants temporarily stopping the drug. Monitoring renal function is important as a rise in serum creatinine is common. The dosage should be reduced if the serum creatinine rises by more than one third of baseline. Patients with preexisting liver disease, including cirrhosis, should not receive oral iron chelators.

MYELOPROLIFERATIVE NEOPLASMS

Myeloproliferative neoplasms originate in the HSC and are characterized by clonal proliferation of one or more myeloid cell types (Arber et al., 2016; Spivak, 2018). These Philadelphia chromosome-negative myeloproliferative disorders include polycythemia vera, essential thrombocythemia, and primary myelofibrosis.

Polycythemia Vera

Polycythemia vera (sometimes called *P vera* or primary polycythemia) is the most common of the three Philadelphia chromosome-negative myeloproliferative disorders. In polycythemia vera the bone marrow is hypercellular, and the erythrocyte, leukocyte, and platelet counts in the peripheral blood are often elevated. Erythrocyte elevation predominates; the hematocrit can exceed 60% in some cases (Tefferi & Barbui, 2019). The median age at the onset is 60 years; median survival is typically 14 to 20 years (Fowlkes, Murray, Fulford, et al., 2018a; Tefferi & Barbui, 2019).

Clinical Manifestations

Clinical manifestations are variable. Some patients at the time of initial diagnosis may be asymptomatic (Spivak, 2018). If symptoms are present, they

tend to be related to erythrocytosis, with or without leukocytosis and/or **thrombocytosis** (i.e., higher-than-normal platelet count that occurs from a disease or disorder; in this instance, the disease is polycythemia vera). This increase in blood cell mass increases blood viscosity leading to (Fowlkes et al., 2018b; Harrison, Koschmieder, Foltz, et al., 2017; Spivak, 2018):

- neurologic symptoms such as headache, dizziness, vision changes, and transient ischemic attacks (TIAs);
- abdominal symptoms such as early satiety, abdominal discomfort/pain (that can also be associated with splenomegaly);
- cardiovascular symptoms including ruddy complexion, angina, claudication, dyspnea, hypertension, and thrombophlebitis; and
- constitutional symptoms such as fatigue and night sweats.

Another common symptom is pruritus, which may be caused by histamine released from an increased number of basophils. **Erythromelalgia**, characterized by a burning, painful sensation, and erythema in the fingers or toes, may also occur. Uric acid may be elevated as well, resulting in gout and renal stones formation.

Assessment and Diagnostic Findings

Diagnosis is based upon the evaluation of clinical symptoms and laboratory findings as well as the presence of a mutation of the *JAK2* gene (Arber et al., 2016). Assessment should include palpation of the spleen, and finding if the patient has a history of thrombotic events or has ever received a blood transfusion or medications associated with causing erythrocytosis (e.g., recombinant erythropoietin), as well as assessment of cardiovascular risk factors (e.g., obesity, smoking, and poorly controlled hypertension, diabetes, or hyperlipidemia; see later discussion of thrombotic risks under Complications). Some patients with the *JAK2* mutation who do not meet the criteria for a diagnosis of polycythemia vera are identified as having "masked polycythemia vera" (McMullin, Harrison, Ali, et al., 2019; Spivak, 2018). These patients are more likely to transform to myelofibrosis (see later discussion) or AML and have a poorer overall rate of survival (McMullin et al., 2019; Spivak, 2018).

Complications

Patients with polycythemia vera are at increased risk for thromboses that may be either venous or arterial. Thrombosis can result in strokes or myocardial infarctions; thrombotic complications are the most common cause of death. Patients older than 60 years of age, those with a prior history of thrombosis, or those with an elevated platelet count (exceeding 1 million/mm^3) are at greater risk for developing thrombotic complications (Tefferi & Barbui, 2019).

Patients with enlarged spleens are also at increased risk for thrombosis. Cardiovascular risk factors thought to increase thrombotic risk include obesity, smoking, and poorly controlled hypertension, diabetes, or hyperlipidemia (Barbui, Vannucchi, Carobbio, et al., 2017).

Bleeding may also be a complication of polycythemia vera and its treatment. The bleeding can be significant and can occur in the form of nosebleeds, ulcers, frank GI bleeding, hematuria, or intracranial hemorrhage. If the patient with polycythemia vera has a bleeding complication and is taking aspirin, the aspirin should be held until the bleeding is resolved (NCCN, 2019f).

Medical Management

The objectives of management are to reduce the risk of thrombosis without increasing the risk of bleeding, reduce the risk of evolution to myelofibrosis or AML, and ameliorate symptoms associated with the disease (McMullin et al., 2019) (see Table 30-2). Specific therapy is based on an established risk stratification. Patients less than age 60 and no prior history of thrombosis are considered "low risk"; those age 60 or older, or with a history of thrombosis, or both, are considered to be "high risk" (NCCN, 2019f).

TABLE 30-2 Common Constitutional Symptoms Associated with Myeloproliferative Neoplasms

Symptoms vary between the three myeloproliferative neoplasms, both in frequency and severity. Nurses should assess these patients frequently for the presence of these symptoms and initiate appropriate measures to ameliorate them.

Symptom	P Vera (%)	ET (%)	Myelofibrosis (%)
Fatigue	85	84	94
Concentration	62	58	68
Early satiety	60	56	74
Night sweats	52	47	63
Pruritus	62	46	52
Abdominal discomfort	48	48	65
Bone pain	48	45	53
Weight loss	33	28	47
Fever	19	17	24

ET, essential thrombocythemia; P vera, polycythemia vera.

Adapted from Geyer, H. L., & Mesa, R. A. (2014). Therapy for myeloproliferative neoplasms: When, which agent, and how? *Hematology American Society of Hematology Education Program*, *2014*(1), 277–286.

Phlebotomy is considered the mainstay of therapy and is used to maintain the hematocrit level at less than 45% (Spivak, 2018) (see Fig. 30-5). It involves removing enough blood (initially 500 mL once or twice weekly) to reduce blood viscosity and to deplete iron stores, thereby rendering the patient iron deficient and consequently unable to continue to manufacture excessive RBCs. Low-dose aspirin prevents vascular thrombosis without increasing the risk of bleeding and is recommended for all patients with polycythemia vera, regardless of risk (Leukemia & Lymphoma Society, 2019e; NCCN, 2019f).

Cytoreductive therapy should be considered in patients at low risk who are symptomatic due to progressive splenomegaly, leukocytosis, thrombocytosis, or have poor tolerance to phlebotomy, or whose disease has progressed to myelofibrosis or AML (McMullin et al., 2019; NCCN, 2019f). In patients at high risk, cytoreductive therapy is considered first-line treatment and might be pursued in addition to or in place of phlebotomy. Hydroxyurea, also known as hydroxycarbamide, can be used to suppress bone marrow function, thereby controlling blood counts. It has also been associated with preventing thrombotic complications (Tefferi & Barbui, 2019). Interferon-alfa is another first-line cytoreductive agent that can be selected; it is indicated in patients younger than 60 years of age, or in patients who are pregnant or intolerant of hydroxyurea (NCCN, 2019e). Interferon-alfa can also reduce splenomegaly, prevent thrombosis, and decrease pruritus. However, it may be difficult for patients to tolerate because of its side effects (e.g., flulike symptoms, depression); it is also very costly.

Figure 30-5 • Phlebotomy can markedly reduce the plethora seen in polycythemia vera. This is evidenced here by a marked reduction in facial rubor in a patient with polycythemia vera. Reprinted with permission from Turgeon, M. L. (2012). *Clinical hematology: Theory & procedures* (5th ed., Fig. 21.10, p. 373). Philadelphia, PA: Lippincott Williams & Wilkins.

Ruxolitinib is a *JAK2* inhibitor; it is used in patients who are resistant or unable to tolerate hydroxyurea and for whom interferon-alfa is not indicated (e.g., patients older than 60 years of age). This drug has been shown to reduce splenomegaly, decrease symptoms, and improve quality of life (Fowlkes et al., 2018a; McMullin et al., 2019). Common side effects of ruxolitinib include dose-dependent anemia and thrombocytopenia.

Additional cytoreductive drugs, including busulfan, pipobroman, and anagrelide, have been shown to be effective in controlling blood counts; however, these agents have been linked to an increased risk for leukemic transformation and have significant side effects. These drugs are reserved for patients who are refractory to other cytoreductive agents or with limited life expectancy (McMullin et al., 2019).

Nursing Management

Fatigue is the most commonly reported symptom in patients with polycythemia vera. It is not always correlated to disease severity. The degree of fatigue may vary, but can become so debilitating that it impairs the patient's quality of life. There are many causes of fatigue, including a release of proinflammatory **cytokines** (proteins produced by leukocytes that are vital to

regulation of hematopoiesis, apoptosis, and immune responses), impaired hematopoiesis, depression, inactivity, and the effects of certain medications (e.g., antihypertensive medications, antihistamines) (Fowlkes et al., 2018b; NCCN, 2019e). Management of fatigue can include pharmacologic agents (e.g., erythropoiesis-stimulating agents, antidepressant drugs, stimulants such as caffeine or amphetamines) and nonpharmacologic treatments (e.g., exercise, yoga, and optimizing sleep).

Another common symptom in patients is pruritus, described as strong itching, stinging, or burning. The exact etiology is not known but is thought to be related to proinflammatory cytokines. Pruritus can be triggered by contact with water of any temperature. Other causes include consuming alcohol or caffeine, having dry skin, experiencing changes in temperature, and sweating after exercise (Fowlkes et al., 2018b; Tefferi & Barbui, 2019). Antihistamines, emollient lotion, and selective serotonin reuptake inhibitors (SSRIs) are not particularly effective in controlling pruritus. Interferon-alfa and narrow band ultraviolet B phototherapy (which uses ultraviolet light for a prescribed length of time to decrease symptoms) may be used in severe cases. As the efficacy of pharmacologic strategies may not be optimal, it is important to individualize therapy and monitor for effectiveness. The nurse may recommend bathing in tepid water, avoiding vigorous toweling off after bathing, and using cocoa butter or oatmeal-based lotions.

Potentially life-threatening complications from the disease are thrombosis or hemorrhage. Risk factors for thrombotic complications, particularly a prior history of thrombosis, smoking, obesity, and poorly controlled hypertension, diabetes, and hyperlipidemia should be assessed, and patients should be encouraged to modify their cardiovascular risk factors. Adopting or maintaining a healthy lifestyle should be encouraged. Patients should be educated about the signs and symptoms of thrombosis. To reduce the likelihood of deep vein thrombosis (DVT), sedentary behavior, crossing the legs, and wearing tight or restrictive clothing (particularly stockings) should be discouraged. Patients with a history of significant bleeding are usually advised to avoid high-dose aspirin and aspirin-containing medications, because these medications alter platelet function. Minimizing alcohol intake should also be emphasized to further diminish the risk of bleeding. Patients should be counseled about the signs of bleeding. The patient needs to be instructed to avoid iron supplements, including those in over-the-counter multivitamin supplements, because the iron can further stimulate RBC production.

Essential Thrombocythemia

Essential thrombocythemia, also called primary thrombocythemia, is a rare, chronic, Philadelphia chromosome-negative myeloproliferative disorder

characterized by an increased production of megakaryocytes. A marked increase in platelet production occurs, with the platelet count consistently greater than 450,000/mm³. The platelet count can exceed 1 to 2 million/mm³. Occasionally, the **thrombocythemia** (increase in platelets without a known cause) is accompanied by an increase in erythrocytes, leukocytes, or both; however, these cells are not increased to the extent they are in polycythemia vera or myelofibrosis (see later discussion).

The exact underlying cause of essential thrombocythemia is idiopathic (i.e., unknown). Approximately 50% to 60% of patients have the *JAK2* gene mutation, and 25% of patients have the *CALR* gene mutation (Fowlkes et al., 2018a; Tefferi & Barbui, 2019). This disease affects women twice as often as men and tends to occur later in life (median age at diagnosis is 65 to 70 years). Median survival is about 20 to 33 years (Haider, Gangat, Lasho, et al., 2016); overall survival does not differ from the general population. However, survival rates vary based upon the type of gene mutation present. For example, patients with the *CALR* mutation have fewer thrombotic events and higher survival rates compared to those with the *JAK2* mutation (Tefferi & Barbui, 2019).

Clinical Manifestations

Many patients with essential thrombocythemia are asymptomatic; the illness is frequently diagnosed as the result of an incidental finding of an elevated platelet count on a CBC. Symptoms occur most often when the platelet count exceeds 1 million/mm³; however, they do not always correlate with the extent to which the platelet count is elevated. When symptoms do occur, they primarily result from vascular occlusion. This occlusion can occur in large arterial vessels (cerebrovascular, coronary, or peripheral arteries) and deep veins, as well as in the microcirculation; inflammation that may occur in the vascular endothelium may result in erythromelalgia. More common forms of venous thromboembolism (VTE), including DVT and pulmonary embolism (PE), can also occur.

One of the most common neurologic symptoms of essential thrombocythemia is headaches. Other neurologic manifestations that may be related to compromised blood flow include dizziness; lightheadedness; paresthesias; visual changes, such as diplopia; and TIAs (Fowlkes et al., 2018b; Harrison et al., 2017). Other symptoms can include tinnitus and chest pain.

Because the platelets can be dysfunctional, minor or major hemorrhage may occur. Bleeding is commonly limited to recurrent minor manifestations (e.g., ecchymoses, hematomas, epistaxis, gum bleeding), although significant GI bleeding and intracranial hemorrhage are both possible and considered major hemorrhagic events. Bleeding typically does not occur unless the platelet count

exceeds 1.5 million/mm^3. It results from a deficiency in von Willebrand factor as the platelet count increases (NCCN, 2019f).

Assessment and Diagnostic Findings

The diagnosis of essential thrombocythemia is made by ruling out other potential disorders—either other myeloproliferative disorders or underlying illnesses that cause a reactive or secondary thrombocytosis (see later discussion). Iron deficiency should be excluded, because a reactive increase in the platelet count often accompanies this deficiency. The diagnosis is typically based upon both an evaluation of clinical manifestations and laboratory findings. The CBC will show markedly enlarged and abnormal platelets, as well as a persistently elevated platelet count (greater than 450,000/mm^3). A bone marrow examination (i.e., aspirate or biopsy) can help distinguish between true essential thrombocythemia and other myelofibrotic diseases (Tefferi & Barbui, 2019).

Complications

Complications include inappropriate formation of thrombi and hemorrhage. Patients with cardiovascular risk factors (e.g., obesity, smoking, and poorly controlled hypertension, diabetes, hyperlipidemia) are at higher risk for thrombotic complications (Tefferi & Barbui, 2019). Patients older than 60 years and those with a history of prior thrombosis are at higher risk for complications. Major bleeding tends to occur when the platelet count is very high (greater than 1.5 million/mm^3) and there is a prior history of major bleeding. Cause of death in patients is often the result of thrombosis or major bleeding (collectively called thrombohemorrhagic events) or transformation to AML or myelofibrosis (Haider et al., 2016).

Medical Management

The goals of management are to minimize the risk of thrombohemorrhagic events and to control symptoms (see Table 30-2). Treatment for essential thrombocythemia is based upon a patient's risk stratification (NCCN, 2019f). Patients at low risk are less than 60 years of age, without the *JAK2* mutation, and without a prior history of thrombosis. Typical treatment for these patients includes ongoing monitoring for new thrombosis and acquired von Willebrand factor deficiency and disease-related major bleeding; management of cardiovascular risk factors (e.g., obesity, smoking, and poorly controlled hypertension, diabetes, or hyperlipidemia); and daily low-dose aspirin as long as the patient remains asymptomatic. Patients should be monitored every 3 to 6 months for signs and symptoms of disease progression. Patients at

intermediate risk are those older than age 60, without the *JAK2* mutation, and with no prior history of thrombosis. As long as the patient has not any thrombohemorrhagic events, the treatment remains the same as for low-risk patients.

A patient is deemed high risk when there is a history of thrombosis at any age or is age 60 or older or with the *JAK2* mutation. Besides use of aspirin, treatment may also include prescribing hydroxyurea, interferon-alfa, or anagrelide (see previous discussion in polycythemia vera section), all of which are effective in decreasing platelet counts to a level below 400,000/mm^3 and reducing risk for developing arterial thrombosis and hemorrhage. However, the side effects of these agents may be intolerable. As previously noted, anagrelide has been associated with disease progression to myelofibrosis or AML (McMullin et al., 2019).

Patients who develop arterial or venous thrombosis require additional treatment. Anticoagulant therapy may be useful for patients with active thrombosis (see Chapter 26 for further discussion of anticoagulation therapy) and platelet apheresis may be used in patients with acute life-threatening thrombosis or major bleeding (see Chapter 28, Table 28-3) (NCCN, 2019f).

Nursing Management

It is important to assess patients for a history of prior thrombohemorrhagic events, because these are the primary cause of morbidity and mortality. Patients with essential thrombocythemia should be educated on signs and symptoms of hemorrhage and thrombosis, particularly the neurologic manifestations, such as visual changes, numbness, tingling, and weakness. Patients should be encouraged about medication adherence and management of side effects. In particular, patients taking aspirin should be informed about the importance of taking this medication as well as the increased risk of bleeding. Those patients taking hydroxyurea should have their CBCs monitored regularly; the dosage is adjusted based on the platelet and WBC count. Patients taking interferon-alfa may be taught to self-administer the medication and how to manage its side effects.

Cardiovascular risk factors associated with thrombotic complications should be assessed, such as obesity, smoking, and poorly controlled hypertension, diabetes, or hyperlipidemia. Measures should be identified and encouraged to reduce these risks. Additionally, patients who are at risk for bleeding should be educated about medications (e.g., aspirin, nonsteroidal anti-inflammatory agents [NSAIDs]) and other substances (e.g., alcohol, certain herbal therapies) that can alter platelet function.

Primary Myelofibrosis

Primary myelofibrosis, also known as agnogenic myeloid metaplasia or myelofibrosis with myeloid metaplasia, is the rarest of the Philadelphia chromosome-negative myeloproliferative disorders; it arises from neoplastic transformation of an early HSC. This disease is characterized by bone marrow fibrosis or scarring, extramedullary hematopoiesis (typically involving the spleen or liver), leukocytosis, thrombocytosis, elevated lactic dehydrogenase (LDH), and anemia. Some patients have **pancytopenia** (i.e., diminished leukocyte, platelet, and erythrocyte counts). Patients with primary myelofibrosis have increased **angiogenesis** (formation of new blood vessels) within the marrow. Immature forms of blood cells, including nucleated RBCs and megakaryocyte fragments, are frequently found in the circulation.

The actual etiology for primary myelofibrosis is still unknown. As with polycythemia vera and essential thrombocythemia, mutations of the *JAK2* or *CALR* gene are frequently seen; prognosis is worse in those without genetic mutations. Myelofibrosis may also be secondary in nature, evolving from polycythemia vera, or less frequently, from essential thrombocythemia. In these instances, the disease progression is then called *secondary myelofibrosis* (Harrison et al., 2017).

Primary myelofibrosis is a disease of the older adult, with a median age of diagnosis at approximately 65 to 70 years of age, and is more common in males (Leukemia & Lymphoma Society, 2019e). Another risk factor is exposure to chemicals (e.g., benzene). Average survival ranges from 2 to 14 years. Common causes of death are due to cardiovascular disease, liver failure, leukemic transformation, and consequences of marrow failure (e.g., infection or bleeding).

Approximately 90% of patients present at the time of diagnosis with splenomegaly, causing abdominal discomfort and early satiety. Many patients also experience constitutional symptoms such as fatigue, night sweats, and fever, as well as pruritus, bone pain, weight loss, cachexia, thrombosis, and bleeding (see Fig. 30-6) (Tefferi, 2018). Arterial or venous thrombosis can occur but is less frequent than that found in polycythemia vera or essential thrombocythemia. Anemia occurs due to impaired erythropoiesis.

Medical Management

The goals of therapy are based upon reducing the burden of disease (by decreasing symptoms and splenomegaly) and improving blood counts (NCCN, 2019f). Treatment is based upon a patient's risk stratification; risks are increased in patients older than 65 years of age, with WBC counts above 25,000/mm^3, with hemoglobin levels less than 10 g/dL, with blast cells present in the peripheral blood, and with presence of constitutional symptoms (e.g., pruritus, night sweats, weight loss; see Table 30-2) (NCCN, 2019f).

For patients who are at low risk and asymptomatic, observation and monitoring every 3 to 6 months is recommended. Patients at intermediate risk may be started on the *JAK2* inhibitor ruxolitinib if symptomatic (see previous discussion in Polycythemia Vera), or may be considered for allogeneic HSCT. HSCT is a useful treatment modality in younger, otherwise healthy patients; it is the only current therapy that can reverse the fibrosis within the marrow (NCCN, 2019f).

Splenectomy may be performed to control potential or actual complications of an enlarged spleen. However, a reactive thrombocytosis and leukocytosis can develop because the platelets and leukocytes are no longer sequestered by the spleen and enter the circulation. Careful considerations of the advantages and disadvantages of a splenectomy should be discussed with the patient as the procedure is not without risk.

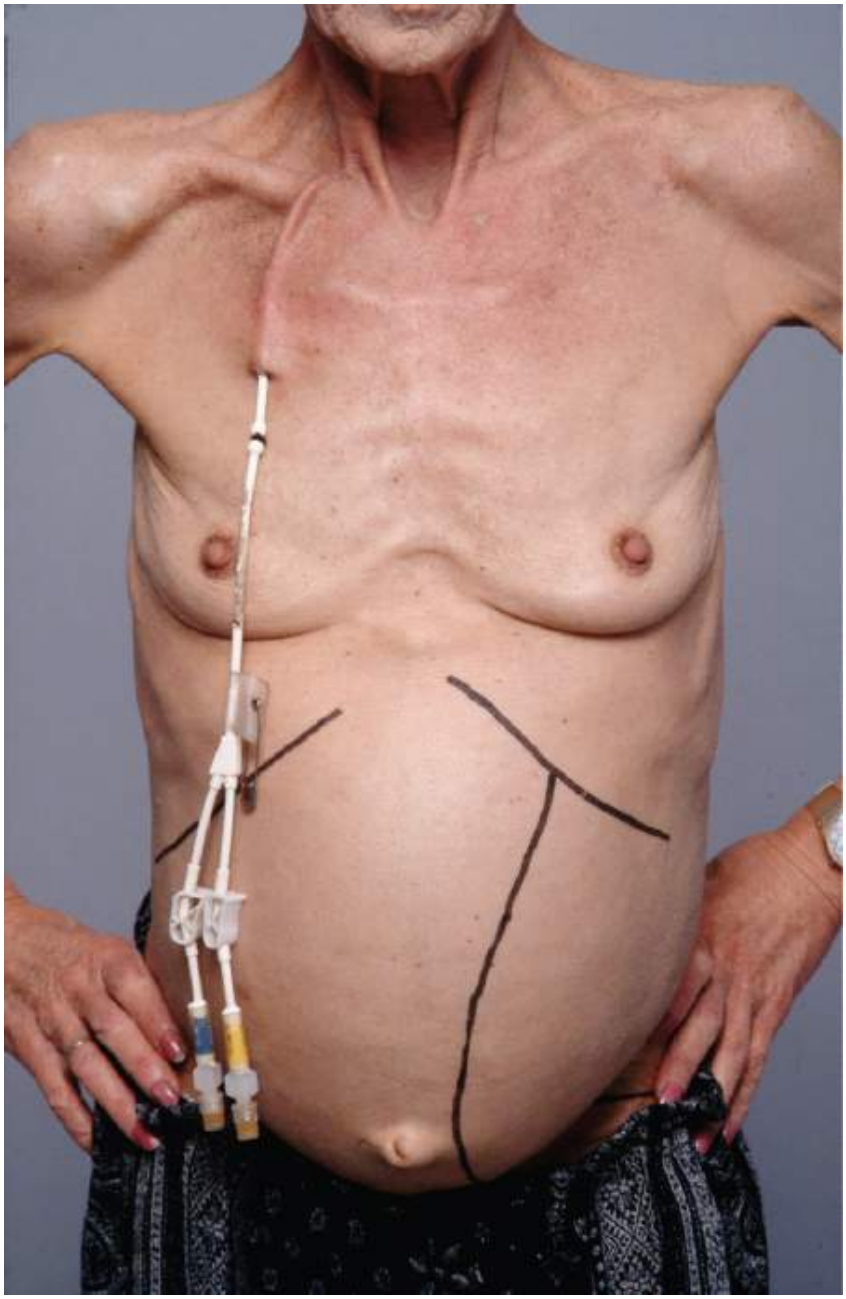

Figure 30-6 • Cachexia, severe wasting, and massively enlarged liver and spleen (hepatosplenomegaly) are seen in advanced myeloproliferative disorders, particularly myelofibrosis. (Note also the lack of adequate dressing over the patient's vascular access device.) Reprinted with permission from Tkachuk, D. C., & Hirschman, J. V. (2007). *Wintrobe's atlas of clinical hematology* (Fig. 4.1, p. 111). Philadelphia, PA: Lippincott Williams & Wilkins.

Anemia is most commonly managed with PRBC transfusions. Erythroid-stimulating agents (e.g., recombinant erythropoietin) may improve anemia to the extent that transfusion requirements are reduced. Other pharmacologic agents are used to diminish splenomegaly and improve blood counts. Hydroxyurea is often used to control high leukocyte and platelet counts and to

reduce the size of the spleen. Angiogenic inhibitors such as thalidomide or pomalidomide may be useful in improving anemia and reducing an enlarged spleen.

Nursing Management

Splenomegaly can be profound in patients with myelofibrosis, with enlargement of the spleen that may extend to the pelvic rim. This condition is extremely uncomfortable and can severely limit nutritional intake. Analgesic agents are usually ineffective. Splenomegaly, coupled with the hypermetabolic state that ensues with having an active neoplasm, results in significant weight loss, muscle wasting, and weakness. Patients benefit from small, frequent meals of foods that are high in calories and protein. Fatigue has been reported in up to 94% of patients with primary myelofibrosis (Geyer & Mesa, 2014). The nurse should educate patients about appropriate energy conservation methods. Table 30-3 identifies useful strategies at managing fatigue.

TABLE 30-3 Fatigue in Patients with Myeloproliferative Neoplasms

Self-reported strategies used to ameliorate fatigue by patients with myeloproliferative neoplasms. Data obtained from online surveys ($N = 1788$) gathered via myeloproliferative neoplasm Web sites.

Strategy	% Patients Reported Use
Setting priorities	75%
Postponing nonessential activities	74%
Exercise	73%
Naps	70%
Walking	66%
Socializing	65%
Nutrition	64%
Reading	62%
Scheduling activity during peak energy periods	62%
Pacing activities	58%
Structured daily routine	54%
Delegation	52%

Adapted from Scherber, R. M., Kosiorek, H. E., Senyak, Z., et al. (2016). Comprehensively understanding fatigue in patients with myeloproliferative neoplasms. *Cancer*, *122*(3), 477–485.

The patient needs to be educated about signs and symptoms of infection, bleeding, and thrombosis, as well as appropriate interventions if these occur. Ensuring that the patient takes steps to decrease cardiovascular risk factors

associated with developing thrombosis (e.g., obesity, smoking, and poorly controlled hypertension, diabetes, or hyperlipidemia) is also important.

LYMPHOMA

The lymphomas are neoplasms of cells of lymphoid origin. These tumors usually start in lymph nodes but can involve lymphoid tissue in the spleen, GI tract (e.g., the wall of the stomach), liver, or bone marrow (see Chapter 31, Fig. 31-1). They are often classified according to the degree of cell differentiation and the origin of the predominant malignant cell. Lymphomas are broadly classified into two categories: Hodgkin lymphoma and NHL.

Hodgkin Lymphoma

Hodgkin lymphoma is a relatively rare malignancy that has a high cure rate. It is somewhat more common in males than in females and has two peaks of incidence: one from ages 15 to 34 and the other after 60 years of age (Leukemia & Lymphoma Society, 2018c). The cause of Hodgkin lymphoma is unknown. However, several risk factors have been identified, which include age, a history of viral infections (particularly the Epstein–Barr virus, human immune deficiency virus [HIV], or human herpesvirus 8 [HHV8]), having a family history, and being exposed to cytotoxic agents. Additionally, Hodgkin lymphoma is seen more commonly in patients receiving long-term immunosuppressive therapy (e.g., organ transplant recipients) and in veterans who were exposed to the herbicide Agent Orange (see Veterans Considerations section in CLL) (Leukemia & Lymphoma Society, 2018c). The 5-year survival rate for Hodgkin lymphoma is about 92% to 94% for localized/regional disease (stage I or II) and 78% for those with distant disease (stage IV) (ACS, 2019a).

Pathophysiology

Unlike other lymphomas, Hodgkin lymphoma is unicentric in origin, meaning that it initiates in a single node. The disease spreads by contiguous extension along the lymphatic system. The malignant cell of Hodgkin lymphoma is the Reed–Sternberg cell, a gigantic tumor cell that is morphologically unique and thought to be of immature lymphoid origin. These cells arise from the B lymphocyte. They may have more than one nucleus and often have an owl-like appearance (see Fig. 30-7). The presence of Reed–Sternberg cells is the pathologic hallmark and essential diagnostic criterion.

The World Health Organization (WHO) has classified Hodgkin lymphoma into five subtypes based on pathologic analyses that reflect the natural history of the disease and suggest the prognosis (NCCN, 2019g). Four of these subtypes of Hodgkin lymphoma are recognized as being consistent with classical disease (Leukemia & Lymphoma Society, 2018c; Spinner, Varma, & Advani, 2018):

- *Nodular sclerosis*: This is the most common form of Hodgkin lymphoma, accounting for about 70% of all cases. It is seen most often in the young; among these patients, the lymph node contains elements of fibrous (sclerotic) tissue; approximately 40% of patients have B symptoms (see **Chart 30-1**). This type of Hodgkin lymphoma is highly curable.

Figure 30-7 • Reed–Sternberg cell. Reed–Sternberg cells are large, abnormal lymphocytes that may contain more than one nucleus. These cells are found in Hodgkin lymphoma. Adapted with permission from Rubin, R., Strayer, D. S., & Rubin, E. (2011). *Rubin's pathology* (6th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

- *Mixed cellularity*: This is the second most common form of Hodgkin lymphoma, accounting for 20% to 25% of all cases. This subtype is more common in older adults and in males; it is frequently seen in patients with HIV infection, and B symptoms are frequently reported.
- *Lymphocyte-depleted:* This form of Hodgkin lymphoma is rare; it is characterized by involved lymph node(s) with few normal

lymphocytes but numerous Reed–Sternberg cells. B symptoms are commonly reported.

- *Lymphocyte-rich*: This type of Hodgkin lymphoma is also an uncommon form of the disease; the lymph node(s) has numerous normal lymphocytes and Reed–Sternberg cells and B symptoms are rare.
- *Nodular lymphocytes predominant Hodgkin lymphoma* (NLPHL): This is the lone type of Hodgkin lymphoma that is not considered of the classical type. In NLPHL there are few Reed–Sternberg cells; rather, there is a predominance of lymphocyte cells called "popcorn" cells. Furthermore, there is minimal involvement of the lymph nodes as compared to the subtypes that fall under the four classical Hodgkin types. NLPHL is seen more often in males than females and the age at diagnosis is more often between 30 and 50 years. Patients tend to present with peripheral adenopathy and with early-stage disease. NLPHL is slow growing and highly curable, but some patients can relapse while others can transform to an aggressive NHL (see later discussion).

Clinical Manifestations

Hodgkin lymphoma usually begins as an enlargement of one or more lymph nodes on one side of the neck. The individual nodes are painless and firm but not hard. The most common sites for lymphadenopathy are the cervical nodes. However, other nodes that can be affected include the supraclavicular and mediastinal nodes; involvement of the iliac or inguinal nodes or spleen is much less common (Leukemia & Lymphoma Society, 2018c). A mediastinal mass may be seen on chest x-ray; occasionally, the mass is large enough to compress the trachea and cause dyspnea. B symptoms, if present, are indicative of more advanced disease (see **Chart 30-1**). These symptoms are found in about 40% of patients with Hodgkin lymphoma and are used in determining stage and prognosis (NCCN, 2019g).

All organs are vulnerable to invasion by tumor cells. Clinical manifestations result from compression of organs by the tumor, such as cough and pulmonary effusion (from pulmonary infiltrates), jaundice (from hepatic involvement or bile duct obstruction), abdominal pain (from splenomegaly or retroperitoneal adenopathy), or bone pain (from skeletal involvement). A mild anemia is the most common hematologic finding. The leukocyte count may be elevated or decreased. The platelet count is typically normal, unless the tumor has invaded the bone marrow, suppressing hematopoiesis. Laboratory tests that may be assessed to detect disease activity include the serum copper level, which may be elevated, and the **erythrocyte sedimentation rate** (ESR). The ESR

measures the rate of settling of RBCs; elevation is indicative of inflammation; it is also called the *sed rate.*

Figure 30-8 • Herpes zoster is a common complication in patients with lymphoproliferative disease, such as Hodgkin lymphoma here. Zoster infections are also common in patients on chronic steroid use for hematologic conditions and some chemotherapy regimens. Reprinted with permission from Tkachuk, D. C., & Hirschman, J. V. (2007). *Wintrobe's atlas of clinical hematology* (Fig. 5.152, p. 207). Philadelphia, PA: Lippincott Williams & Wilkins.

Other symptoms seen in patients with Hodgkin lymphoma are pruritus, which is common and can be extremely distressing, fatigue, decreased appetite, abdominal pain, splenomegaly, and although rare, occasional pain in affected lymph node after drinking alcohol (Leukemia & Lymphoma Society, 2018c). Patients may also have impaired cellular immunity, as evidenced by an absent or decreased reaction to skin sensitivity tests (i.e., Candida, mumps) and increased susceptibility to infections, particularly herpes zoster (see Fig. 30-8).

Assessment and Diagnostic Findings

Because many manifestations are similar to those occurring with infection, diagnostic studies are performed to rule out an infectious origin of the disease. The diagnosis is made by means of an excisional lymph node biopsy and the presence of Reed–Sternberg cells. Once the diagnosis is confirmed and the histologic type is established, it is necessary to assess the stage of the disease.

During the health history, the patient is assessed for any B symptoms (see **Chart 30-1**). Physical examination requires a careful, systematic evaluation of all palpable lymph node chains (see Chapter 28, Fig. 28-4), as well as the size of the spleen and liver. A chest x-ray and a computed tomography (CT) scan of the chest, abdomen, and pelvis are crucial to identify the extent of lymphadenopathy within these regions. A positron emission tomography (PET) scan is the most sensitive imaging test and is recommended for initial staging to help determine the extent of disease as well as later for evaluation of response to treatment (NCCN, 2019g). Laboratory tests include CBC with differential; serum electrolytes, blood urea nitrogen (BUN) and creatinine; ESR; liver and renal function studies; immunohistochemistry and cytogenetic evaluation; HIV testing; and hepatitis B and C testing. A multiple-gated acquisition (MUGA) scan and/or ECG should be performed prior to the start of therapy if the patient is to receive an anthracycline-based treatment regimen, as these chemotherapeutic agents are associated with adverse cardiovascular effects. Bone marrow biopsies are not routinely performed unless cytopenias are present and the PET scan is negative (NCCN, 2019g).

Medical Management

The goal in the treatment of Hodgkin lymphoma is cure, as the overall cure rate is about 90% (ACS, 2019a). Treatment is determined primarily by stage of disease, not histologic type, utilizing the Ann Arbor staging system (see Fig. 30-9).

Treatment guidelines for classical Hodgkin lymphoma (NCCN, 2019g) divide patients into groups. Patients with early disease (stage I-II) may receive one of the following combination chemotherapy regimens: ABVD (doxorubicin [trade name ***A***driamycin], ***b***leomycin, ***v***inblastine, and ***d***acarbazine) or Stanford V (doxorubicin, vinblastine, mechlorethamine, etoposide, vincristine, bleomycin, and prednisone) (see Chapter 12, Table 12-7, for further discussion of specific categories of chemotherapeutic/antineoplastic agents). Radiation therapy may or may not be included as part of the treatment regimen.

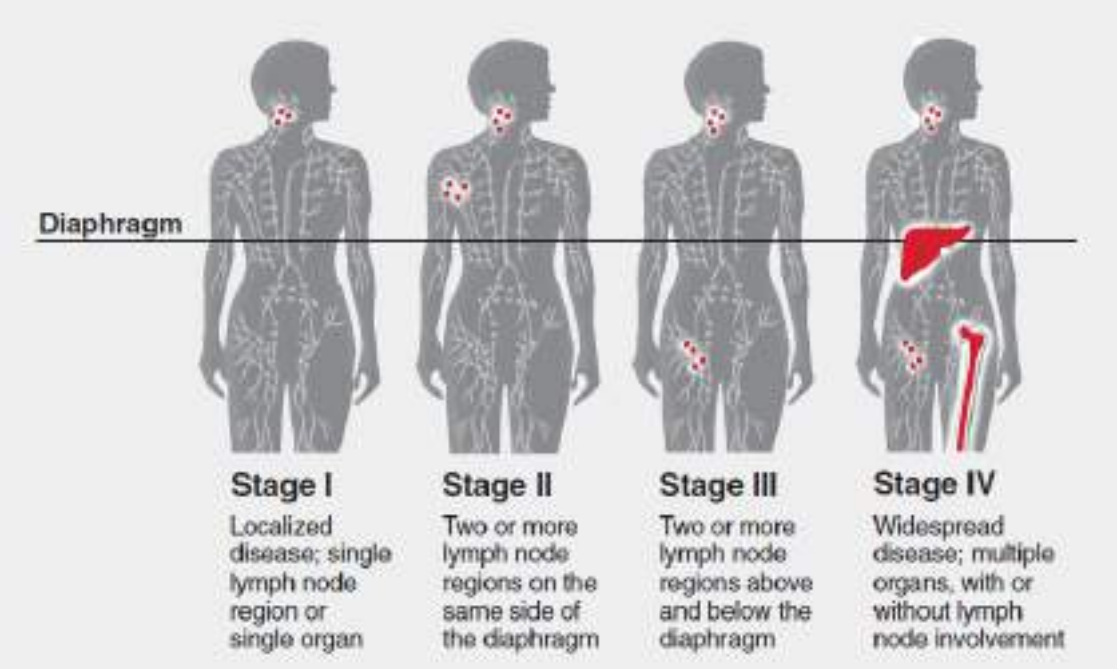

Figure 30-9 • Stages of Hodgkin lymphoma based upon the Ann Arbor staging system. Each category is subdivided and assigned to one of the following categories: Category A indicates no symptoms are present. Category B indicates the presence of B symptoms (see Chart 30-1). Category E indicates involvement of organs or tissues beyond the lymphatic system. Category S indicates involvement of the spleen. Image used with permission of The Leukemia & Lymphoma Society (Hodgkin Lymphoma, 2020).

The standard treatment for patients with advanced disease (stages III to IV) and those with B symptoms is also ABVD chemotherapy, although these patients typically receive additional cycles of chemotherapy treatment. Other combinations of chemotherapy may be used; however, these options have more toxic effects.

When a patient has a suspected relapse of disease, a biopsy and a PET scan are performed to confirm the diagnosis and stage of disease. Treatment options for patients with refractory or relapsed disease include immunotherapeutic agents, such as a monoclonal antibody (MoAb) (e.g., everolimus, brentuximab), or a checkpoint inhibitor (e.g., nivolumab, pembrolizumab) (see discussion of MoAbs and checkpoint inhibitors in Chapter 12) (Leukemia & Lymphoma Society, 2018c; NCCN, 2019g).

Treatment for patients with NLPHL in the early stage of disease may include radiation therapy only. In a few instances (patients who are stage IA), observation rather than any therapy may be an option (Spinner et al., 2018). Patients with stage IB to IIB disease may receive ABVD, CHOP (***c***yclophosphamide, doxorubicin [also less commonly called ***h***ydroxydaunorubicin], vincristine [trade name of ***O***ncovin], and ***p***rednisone),

or CVP (***c***yclophosphamide, ***v***incristine, and ***p***rednisone) regimens in combination with rituximab. Those with advanced stage disease are treated with these same regimens but with radiation therapy added.

Patients typically feel better following therapy. Late effects of treatment, which may occur months to years following treatment, include development of a secondary malignancy, or cardiovascular disease, hypothyroidism, and infertility (Leukemia & Lymphoma Society, 2018c; NCCN, 2019g). Secondary malignancies (most common are lung and breast) often develop more than 10 years following completion of therapy. This is especially true in females who received radiation therapy to the chest or axillary areas (NCCN, 2019g).

Cardiovascular disease (e.g., coronary artery disease, arrhythmias, and cardiomyopathy) is also seen 10 years posttreatment and tends to occur in patients who received mediastinal radiation or an anthracycline-based chemotherapeutic agent (e.g., daunorubicin, doxorubicin). Hypothyroidism may occur in about 50% of long-term survivors of Hodgkin lymphoma, particularly in those who received neck or upper mediastinal radiation (NCCN, 2019g). The use of some chemotherapy combinations can lead to infertility in both males and females. For instance, females of childbearing years may experience premature menopause following treatment with alkylating agents (e.g., cyclophosphamide, dacarbazine, mechlorethamine). Other organ dysfunction is also well documented, including that of the endocrine system. Persistent fatigue is common in survivors and can be exacerbated by depression and other treatment-related comorbidities (ACS, 2019a; Leukemia & Lymphoma Society, 2018c; NCCN, 2019g). Potential long-term complications associated with chemotherapy are listed in Chapter 12, Chart 12-4.

Nursing Management

The potential development of a second malignancy should be addressed with the patient when initial treatment decisions are made. However, patients need to be informed that Hodgkin lymphoma is often curable. The nurse should encourage patients to reduce factors that increase the risk of developing second cancers, such as use of tobacco and alcohol and exposure to environmental carcinogens and excessive sunlight. Screening for late effects of treatment, such as chemotherapy (see Chapter 12, Chart 12-4), is necessary. In addition, the nurse should provide education about relevant self-care strategies and disease management. See also the Nursing Management Section for Non-Hodgkin Lymphoma.

Non-Hodgkin Lymphomas

The NHLs are a heterogeneous group of cancers that originate from the neoplastic growth of lymphoid tissue. Similar to CLL, the neoplastic cells are thought to arise from a single clone of lymphocytes; however, in NHL, the cells may vary morphologically. In contrast to Hodgkin lymphoma, the lymphoid tissues involved are largely infiltrated with malignant cells. The spread of these malignant lymphoid cells occurs unpredictably; true localized disease is uncommon. Lymph nodes from multiple sites may be infiltrated, as may sites outside the lymphoid system (i.e., extranodal tissue; see Fig. 30-10).

Figure 30-10 • Any extranodal location can be a site for diffuse B-cell lymphoma, such as the thyroid, as shown here. Reprinted with permission from Tkachuk, D. C., & Hirschman, J. V. (2007). *Wintrobe's atlas of clinical hematology* (Fig. 5.87, p. 183). Philadelphia, PA: Lippincott Williams & Wilkins.

TABLE 30-4 Select Types of Lymphomas

Indolent	Aggressive
Cutaneous T cell	Anaplastic large cell
Follicular	AIDS associated
Gastric MALT	Burkitt
Lymphoplasmacytic: Waldenstrom macroglobulinemia	Diffuse large B cell
Marginal zone B cell	Mantle cell
Small-cell lymphocytic	Peripheral T cell

AIDS, acquired immune deficiency syndrome; MALT, mucosa-associated lymphoid tissue.

Adapted from Leukemia & Lymphoma Society. (2016). NHL subtypes. Retrieved on 5/14/2020 at: www.lls.org/lymphoma/non-hodgkin-lymphoma/diagnosis/nhl-subtypes

Approximately 85% of NHLs involve malignant B-cell lymphocytes, with the remaining 15% involving T-cell lymphocytes or natural killer cells (NCCN, 2019h). NHL is the seventh most common type of cancer diagnosed in the United States, accounting for about 4% to 5% of all new cancer cases each year. It occurs more commonly in males (NCCN, 2019h). The incidence increases with each decade of life; the median age at diagnosis is 66 years (Leukemia & Lymphoma Society, 2018d). The natural course of the disease is variable and dependent upon the type of lymphoma. NHLs can be categorized as **indolent** (i.e., a slow-growing cancer that often remains localized or causes few symptoms) or aggressive (i.e., a fast-growing cancer that spreads rapidly and causes significant morbidity) (see Table 30-4). For example, the 5-year survival rate for diffuse large B-cell lymphoma is 72%; for follicular lymphoma it is about 90% (96% localized disease and 85% for distant disease) (ACS, 2019b).

Although no common etiologic factor has been identified, the incidence of NHL is increased in patients who have immune deficiencies or autoimmune disorders; had prior treatment for cancer; been an organ transplant recipient; had a history of viral infections (e.g., Epstein–Barr virus, HIV, HHV8); and been exposed to herbicides, pesticides, solvents, dyes, and defoliating agents, such as Agent Orange (see Veterans Considerations section in CLL) (ACS, 2019b).

Clinical Manifestations

Symptoms of NHL are highly variable, reflecting the diverse nature of the disease. Similar to Hodgkin lymphoma, NHL may start as a painless swelling in one or more lymph nodes in the neck, axillary region, or groin. If the lymphoma is indolent in nature, symptoms may be absent or very minor.

Indolent disease accounts for about 40% of all NHL cases (Leukemia & Lymphoma Society, 2018d). However, the majority of patients are not diagnosed until the disease has progressed to a later stage, when they have become symptomatic. About one third of patients with NHL have B symptoms (see **Chart 30-1**) at the time of diagnosis (Leukemia & Lymphoma Society, 2018d).

Other symptoms depend upon enlarged lymph node site and size, which can compress organs, compromising function. For example, a mass in the mediastinum can cause cough, shortness of breath, and chest pain that may lead to cardiovascular or respiratory distress. An abdominal mass may compromise the bowel or ureters, leading to acute kidney injury or bowel obstruction. Splenomegaly can cause abdominal pain, nausea, early satiety, and weight loss.

Assessment and Diagnostic Findings

Similar to Hodgkin lymphoma, an incisional or excisional lymph node biopsy is required for immunophenotyping and cytogenetic analysis testing (NCCN, 2019h). The specific histopathologic type of the disease is used to differentiate the subtype of NHL; it also has important prognostic implications and is used to determine appropriate treatment (Leukemia & Lymphoma Society, 2018d). Flow cytometry is commonly performed to determine the specific antigen on the malignant cell. Another test that may be performed is fluorescence in situ hybridization (FISH), which analyzes the DNA and RNA of the biopsy or blood sample for chromosomal abnormalities.

Laboratory studies mirror those done for a patient with Hodgkin lymphoma (see that previous discussion). In addition, there may be testing for viruses (e.g., Epstein–Barr, HHV8, hepatitis B); polymerase chain reaction (PCR); CT scans of the chest, abdomen, and pelvis; PET scan; MUGA or ECG (if patient is to receive anthracycline-based regimen); and bone marrow biopsy and aspirate (if marrow involvement is suspected).

Although the stage of disease is important, often it is not an accurate predictor of prognosis. Two prognostic classification systems are used: the International Prognostic Index (IPI) and, for follicular lymphomas, the Follicular Lymphoma International Prognostic Index (FLIPI). Age, performance status, lactate dehydrogenase levels, stage of disease, and extranodal involvement are scored to determine risk of failure or death from disease (ACS, 2020b).

Medical Management

The goal of treatment for NHL is to obtain remission of disease by killing as many of the malignant cells as possible; in contrast, the goal is cure for

Hodgkin lymphoma. Treatment for NHL is based upon the specific subtype of lymphoma and the stage of disease. Other factors that impact treatment decisions include the patient's age, functional status, laboratory values (especially renal, hepatic, and cardiac), comorbid conditions, and presence of extranodal involvement (i.e., presence of cancer cells outside of the lymph nodes) (Leukemia & Lymphoma Society, 2016). If the disease is indolent and localized, the treatment of choice may be radiation therapy alone. "Watchful waiting" may also be a choice for patients with an indolent form of NHL, such as stage I follicular lymphoma, who have no or few symptoms at time of diagnosis.

For aggressive subtypes of NHL, combination chemotherapy is typically indicated. One of the most common combinations is CHOP. A MoAb (e.g., rituximab, obinutuzumab) may be given along with the chemotherapy (NCCN, 2019h). Radiation therapy may or may not be added to the treatment regimen. In some cases, a MoAb may be conjugated with a radioactive isotope and used for treatment (e.g., ibritumomab tiuxetan). CNS involvement is common with some aggressive forms of NHL; in this situation, cranial radiation or intrathecal chemotherapy is used in addition to systemic chemotherapy.

When NHL has relapsed or is refractory to standard treatments, other single agent or combination chemotherapy regimens may be used. For instance, the ICE regimen (i.e., ***i***fosfamide, ***c***arboplatin, and ***e***toposide) may be implemented; or agents such as bendamustine, brentuximab vedotin, romidepsin, or axicabtagene may be tried (NCCN, 2019h). Autologous HSCT (AuHSCT) is another treatment option for relapsed or refractory NHL, particularly in patients younger than 60 years (see Chapter 12 for further discussion of AuHSCT).

A rare but potentially life-threatening complication of chemotherapy is tumor lysis syndrome. Tumor lysis syndrome occurs when the intracellular content of the malignant cell breaks down and is released into the peripheral blood and typically occurs 12 to 72 hours after initiation of therapy (NCCN, 2019h). Patients with NHL at highest risk for the development of tumor lysis syndrome are those with large bulky disease and/or deemed to have high-risk or aggressive NHL (e.g., Burkitt's or diffuse large B-cell lymphoma [DLBCL]). See Chapter 12, Table 12-13, for a discussion of manifestations of and treatment for tumor lysis syndrome.

Reactivation of hepatitis B virus may be seen in patients with NHL who become immunosuppressed following chemotherapy. For example, hepatitis B reactivation can occur in patients treated with rituximab-containing regimens, even if the patient had tested negative for hepatitis B prior to start of treatment (Leukemia & Lymphoma Society, 2018d). Preemptive treatment is recommended, including antiviral therapy (i.e., lamivudine or entecavir) and close surveillance in patients at high risk.

Another rare but potentially life-threatening complication is progressive multifocal leukoencephalopathy, which may occur in patients with NHL who are severely immunocompromised and treated with chemotherapeutic agents (Leukemia & Lymphoma Society, 2018d; NCCN, 2019h). Symptoms include confusion, motor weakness or poor motor coordination, and visual and possibly speech changes. Currently, there is no effective treatment for this complication. The fatality rate is 90% and tends to occur within 2 months after the diagnosis is confirmed (NCCN, 2019h).

Nursing Management

Lymphoma is a highly complex constellation of diseases. When caring for patients with lymphoma, it is extremely important for the nurse to know the specific disease type, stage of disease, treatment history, and current treatment plan. Most of the care for patients with Hodgkin lymphoma or NHL takes place in the outpatient setting, unless complications occur (e.g., infection, respiratory compromise due to mediastinal mass). The most commonly used treatment methods are chemotherapy (often combined with a MoAb) and radiation therapy. Chemotherapy causes systemic side effects (e.g., myelosuppression, nausea, hair loss, risk of infection), whereas radiation therapy causes specific side effects that are limited to the area being irradiated. For example, patients receiving abdominal radiation therapy may experience nausea and diarrhea but not hair loss. Regardless of the type of treatment, all patients may experience fatigue (see Chapter 12, Chart 12-6, Fatigue).

The risk of infection is significant for these patients, not only from treatment-related myelosuppression but also from the defective immune response that results from the disease itself. Patients need to be educated to minimize the risks of infection, to recognize signs of possible infection, and to contact their primary provider if such signs develop (see Chapter 12, Chart 12-6, Infection).

Many lymphomas can be cured with current treatments. However, as survival rates increase, the incidence of second malignancies, particularly AML or MDS, also increases. Therefore, survivors should be screened regularly for the development of second malignancies. Survivors of both Hodgkin lymphoma and NHL may be faced with managing persistent fatigue, depression, anxiety, and cardiac and pulmonary toxicity (ACS, 2019b). Therefore, survivors should be encouraged to have regular follow-up appointments and be screened for the signs and symptoms of possible secondary malignancies. Additionally, patients should be evaluated for cardiovascular and fertility concerns with each patient visit.

The ACS (2019b) developed health behavior recommendations for cancer survivors, which include avoiding or stopping smoking, maintaining a normal body weight, practicing good nutrition habits (i.e., consuming fruits and

vegetables), and engaging in a minimum of 150 minutes of exercise per week. While many survivors do not adhere to these recommendations, those patients who do report higher health-related quality of life (ACS, 2019b).

MULTIPLE MYELOMA

Multiple myeloma is a malignant disease of the most mature form of B lymphocyte—the plasma cell. Plasma cells secrete immunoglobulins, which are proteins necessary for antibody production to fight infection. This disease accounts for approximately 1.8% of all cancers and about 17% of the hematologic malignancies in the United States (NCCN, 2019i). The etiology of multiple myeloma is not known, but risk factors are identified (see **Chart 30-3**). The incidence of multiple myeloma increases with age; the median age at diagnosis is approximately 70 years (NCCN, 2019i; Rajkumar, 2018). This disease, if left untreated, can lead to bone destruction and bone marrow failure. Due to the increased number of newer agents to fight multiple myeloma, survival of this disease has significantly improved in the last 5 years.

Pathophysiology

In multiple myeloma, the malignant plasma cells produce a specific immunoglobulin that is nonfunctional. Functional types of immunoglobulins are still produced by nonmalignant plasma cells, but in lower-than-normal quantities. The specific immunoglobulin secreted by the malignant plasma cells is referred to as the monoclonal protein, or M protein. Malignant plasma cells also secrete certain substances to stimulate angiogenesis to enhance the growth of these clusters of plasma cells. Occasionally, the malignant plasma cells infiltrate other tissue, in which case they are referred to as plasmacytomas. Plasmacytomas can occur in the sinuses, spinal cord, and soft tissues.

Chart 30-3 **RISK FACTORS**

Multiple Myeloma

- Age: rarely occurs in those less than 35 years of age; risks increase with increasing age
- African Americans have twice the risk of Whites
- Exposure to radiation, petroleum products, benzenes, and Agent Orange
- Family history, particularly among first-degree relatives (e.g., siblings, parents)
- Men have slightly higher risks than women
- Overweight or obesity
- Plasma cell disease history:
  - Monoclonal gammopathy of undetermined significance (MGUS)
  - Plasmacytoma[a]

[a]*Note*: in rare instances, may precede multiple myeloma.

Adapted from American Cancer Society (ACS). (2018). Risk factors for multiple myeloma. Retrieved on 5/15/2020 at: www.cancer.org/cancer/multiple-myeloma/causes-risks-prevention/risk-factors.html; National Comprehensive Cancer Network (NCCN). (2019i). Clinical practice guidelines in oncology: Multiple myeloma. Version 2.2019. Retrieved on 7/10/2019 at: www.nccn.org/professional/physician_gls/pdf/myeloma.pdf; Rajkumar, S. (2018). Multiple myeloma: 2018 update on diagnosis, risk-stratification, and management. *American Journal of Hematology, 93*, 1091–1110.

Multiple myeloma may evolve from a premalignant stage, known as monoclonal gammopathy of undetermined significance (MGUS) (NCCN, 2019i). Although patients with MGUS have the M protein in their blood, they generally do not have any signs and symptoms that are seen in multiple myeloma. Patients with MGUS are monitored for signs and symptoms indicative of disease progression to multiple myeloma. The rate of progression from MGUS to multiple myeloma is 0.5% to 1% per year (Rajkumar, 2018).

Clinical Manifestations

Clinical manifestations of multiple myeloma result not only from the malignant cells themselves, but also from the abnormal protein they produce. The classic clinical manifestations of multiple myeloma are referred to as the CRAB features, because they refer to the following:

- hyper***C***alcemia
- ***R***enal dysfunction
- ***A***nemia
- ***B***one destruction

Bone-related manifestations may be seen in up to 85% of patients with multiple myeloma (NCCN, 2019i). Bone pain (usually in the back or ribs) is considered to be a classic presenting symptom. Bone pain associated with multiple myeloma increases with movement and decreases with rest; patients may report that they have less pain on awakening but more during the day. In multiple myeloma, a substance secreted by the malignant plasma cells, osteoclast activating factor, and other substances, such as interleukin-6 (IL-6) stimulate osteoclasts, which break down bone matrix. In some cases, the bone breakdown or lysis can be severe enough to cause vertebral collapse and fractures, including spinal fractures, which can impinge on the spinal cord and result in spinal cord compression (see Fig. 30-11). When vertebral collapse occurs, the patient's height is reduced and kyphosis (an excessive curvature of the spine) is common.

If the bone lysis is extensive, bone lesions result and excessive ionized calcium is lost from the bone and enters the serum; hypercalcemia may therefore develop and may be manifested by excessive thirst, dehydration, constipation, altered mental status, confusion, and perhaps coma.

Quality and Safety Nursing Alert

Any older adult whose chief complaint is back pain and who has an elevated total protein level should be evaluated for possible multiple myeloma.

Renal dysfunction occurs in 33% of patients at the time of diagnosis, while 50% will experience renal dysfunction at some point during the course of the disease (Chim, Kumar, Orlowski, et al., 2018; NCCN, 2019i). The etiology of renal dysfunction is multicausal and related to: myeloma kidney as the result of Bence–Jones proteins (i.e., myeloma infiltration of the kidneys) causing obstruction in the renal tubules; hypercalcemia as the result of bone matrix lysis; amyloid deposits which may lead to renal insufficiency and/or hydronephrosis; and hyperviscosity leading to renal tubule obstruction. Other

causes of renal dysfunction in patients with multiple myeloma are infections, use of NSAIDs, and nephrotoxic agents (e.g., chemotherapy) to treat multiple myeloma (Faiman, Doss, Colson, et al., 2017).

As more malignant plasma cells are produced, the marrow has less space for erythrocyte production, and anemia may develop. If renal dysfunction is also present, anemia may also be caused by a diminished production of erythropoietin by the kidney. In the late stage of the disease, a reduced number of leukocytes and platelets may also be seen because the bone marrow is infiltrated by malignant plasma cells.

Assessment and Diagnostic Findings

All patients suspected of having multiple myeloma should have a CBC with differential, BUN, serum creatinine, creatinine clearance, serum electrolytes (especially calcium and albumin), LDH, and beta-2 microglobulin analyzed. Elevated BUN and creatinine may be indicative of renal dysfunction. The total protein level is frequently elevated because of the production of M protein. LDH and beta-2 microglobulin measure degree of tumor burden. In addition to these, a peripheral smear of the blood may reveal an abnormal stacking of RBCs (known as Rouleaux formation) due to elevated serum proteins (NCCN, 2019i). Serum protein electrophoresis or free light chain assay should be performed to detect the presence of M protein (see Fig. 30-12). This protein is elevated in patients with multiple myeloma and serves as a useful marker to monitor the extent of the disease and to gauge the patient's eventual response to therapy. Additionally, cytogenetic studies are performed to see if any of several chromosomal abnormalities typically found in patients with multiple myeloma are present. Radiographic evaluation (CT scan, MRI, and PET scan) should be performed to determine the presence of lytic bone lesions. Bone marrow aspiration and biopsy are conducted to evaluate bone marrow plasma cell abnormalities.

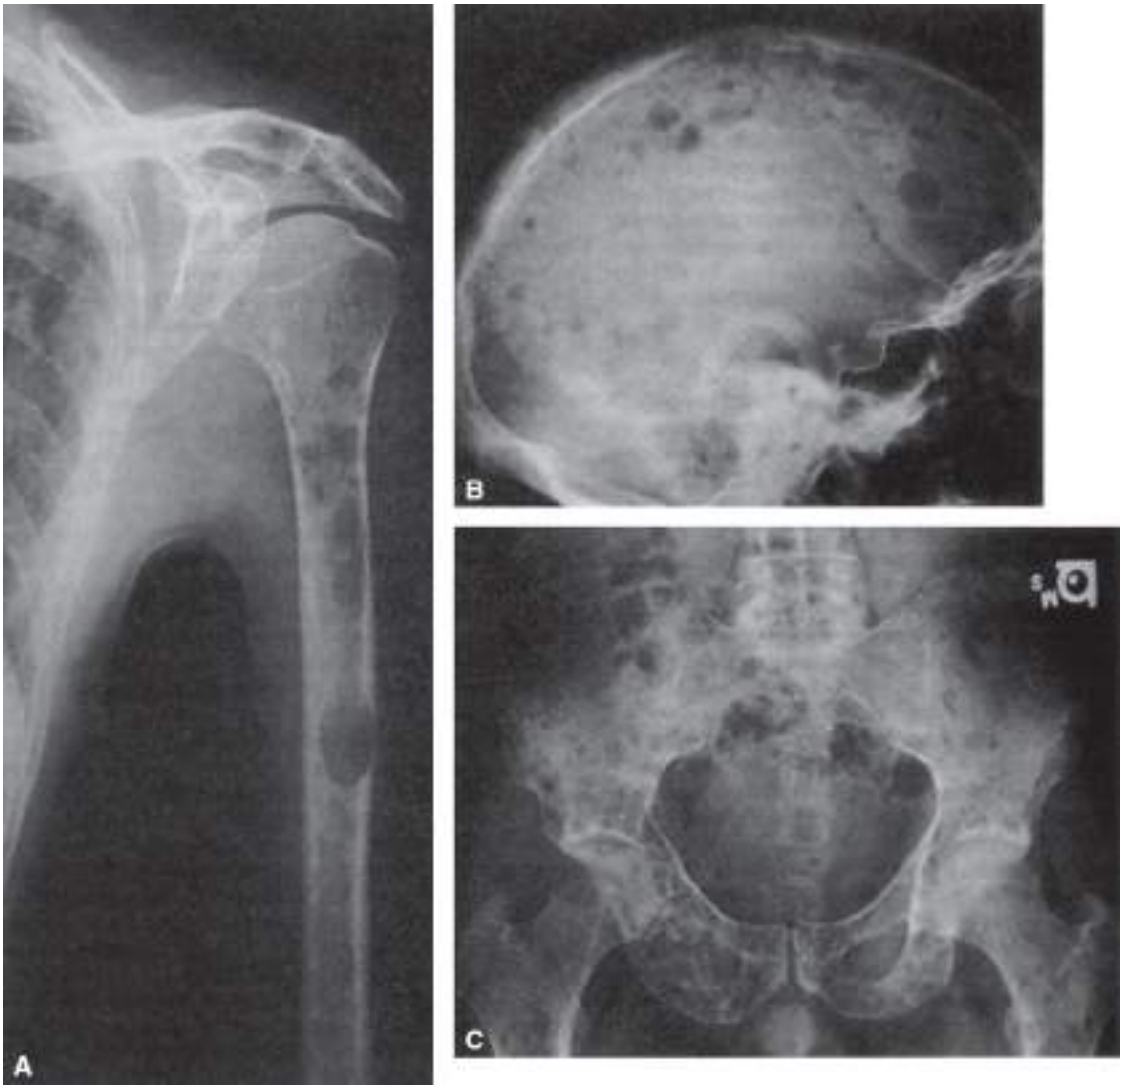

Figure 30-11 • Lytic lesions seen in the humerus and skull in patients with multiple myeloma. These lesions typically occur in the long bones, vertebrae, and skull. Long bones are susceptible to fracture when the lesion occurs near the surface of the bone; vertebrae are susceptible to collapse, resulting in loss of height and potential for spinal cord compression. Reprinted with permission from *Wintrobe's clinical hematology* (10th ed., p. 2640). Philadelphia, PA: Lippincott Williams & Wilkins.

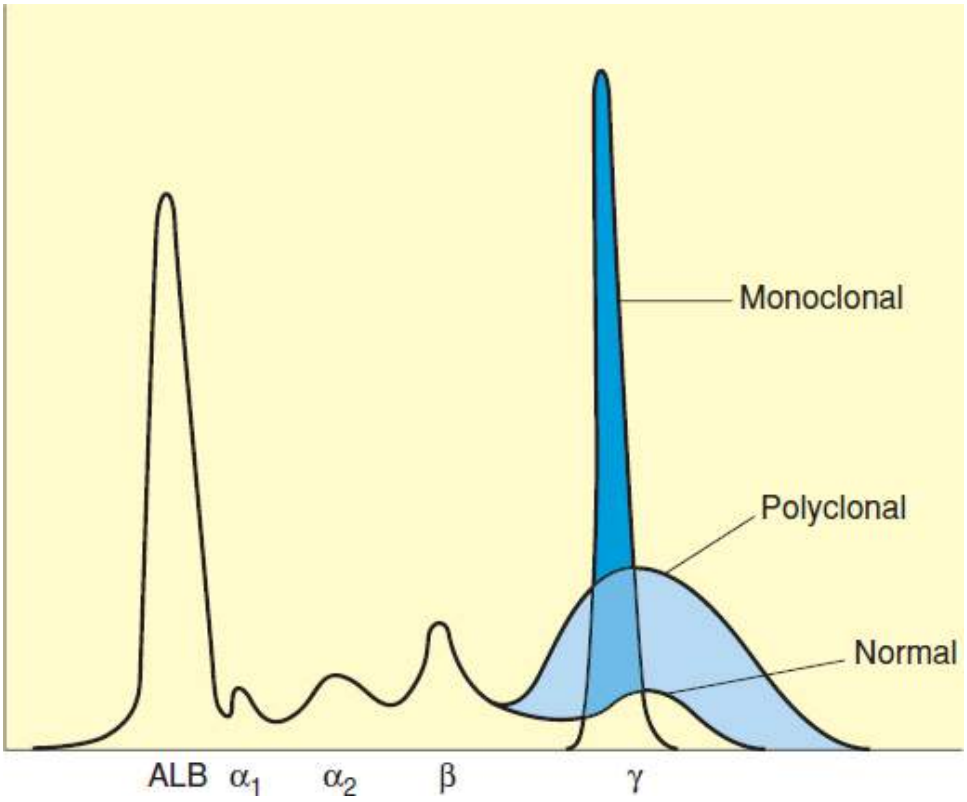

Figure 30-12 • Abnormal serum protein electrophoresis patterns contrasted with a normal pattern. Polyclonal peaks are characterized by a broad-based increase in immunoglobulin (Ig) by myriad reactive plasma cells and indicate a benign reactive process. In contrast, a narrow spike indicates homogeneity of the Ig secreted by a single clone of plasma cells. M spikes are seen in monoclonal gammopathies of undetermined significance or in plasma malignancies (myeloma, Waldenstrom macroglobulinemia). Reprinted with permission from Turgeon, M. (2012). *Clinical hematology theory & procedures* (5th ed., Fig. 20.7, p. 347). Philadelphia, PA: Lippincott Williams & Wilkins.

Diagnosis and staging of multiple myeloma was traditionally based on the CRAB criteria, and included:

- hypercalcemia (>11.5 mg/dL)
- renal insufficiency (creatinine >2 mg/dL or creatinine clearance of less than 40 mL/min)
- anemia (hemoglobin less than 10 g/dL or 2 g/dL less than normal)
- the presence of bony lesions.

The International Myeloma Working Group (IMWG) recently revised the metrics used to define the disease to include specific biomarkers (clonal plasma cells on bone marrow biopsy of 60% or greater, involved/uninvolved serum free light chain ratio of 100 or greater, and/or more than one focal lesion on MRI that is at least 5 mm or greater in size) in addition to any one or more

of the CRAB criteria (NCCN, 2019i; Rajkumar, 2018). This revision is believed to facilitate earlier diagnosis and implementation of treatment (NCCN, 2019i).

Medical Management

There is no cure for multiple myeloma; the aims of treatment are to reduce symptoms and to prolong disease progression. Therapy has changed substantively for multiple myeloma, and has resulted in impressive increases in duration of survival. Importantly, patients not only live longer, the new treatment modalities provide the opportunity for enhanced quality of life. Management of multiple myeloma depends upon whether the patient has smoldering (asymptomatic) or active (symptomatic) disease. Smoldering multiple myeloma is similar to MGUS as patients do not report any symptoms; however, there are higher levels of M protein than seen in MGUS and malignant plasma cells are present.

For most patients with smoldering multiple myeloma, observation with close surveillance for the possibility of transforming to symptomatic disease every 3 to 6 months is the standard of care (NCCN, 2019i; Rajkumar, 2018). Patients who present with symptomatic disease are evaluated for eligibility for an autologous HSCT (AuHSCT), based on age, presence of comorbidities, and risk stratification (Rajkumar, 2018).

Primary treatment for patients who are eligible for AuHSCT includes several cycles of a combination of different pharmacologic agents before stem cells are procured. These drugs all target the disease via different mechanisms than do conventional chemotherapeutic agents. Combinations of two or three drugs are commonly used with the goal of reducing the tumor burden as much as possible. These frequently include either one of the following two regimens (Rajkumar, 2018):

- Proteasome inhibitor–based bortezomib regimen, which commonly includes an immunomodulatory drug (e.g., lenalidomide, pomalidomide, or thalidomide) and the corticosteroid dexamethasone.
- MoAb-based daratumumab regimen, which commonly includes either an immunomodulatory drug (e.g., lenalidomide, pomalidomide, or thalidomide) or a proteasome inhibitor (e.g., bortezomib, carfilzomib, or ixazomib) and the corticosteroid dexamethasone.

Other agents that may be part of these regimens include doxorubicin, cyclophosphamide, cisplatin, or etoposide (see Table 30-5).

AuHSCT is considered to be the standard of care for patients with multiple myeloma following primary therapy (NCCN, 2019i), as it has demonstrated improved response rates, improved quality of life, and increased overall

survival. AuHSCT may also be indicated in patients with relapsed and refractory multiple myeloma. Single AuHSCT and tandem AuHSCT (with two AuHSCT within a 6-month period) are possible options. Another option could be an allogeneic HSCT; however, this is considered an inferior option to AuHSCT as it is associated with increased morbidity and mortality (Rajkumar, 2018).

Lenalidomide is recommended as maintenance therapy for patients following an AuHSCT and after the initial 8 to 12 cycles of primary therapy for patients who have not received an HSCT. Bortezomib may be used as an alternative maintenance treatment in patients who are intermediate to high risk.

Patients who are not candidates for AuHSCT might be prescribed the three-drug, bortezomib-based regimen, as this regimen is associated with a better response rate. For older adults or frail patients, two-drug regimens may be given (e.g., lenalidomide and dexamethasone) (Rajkumar, 2018). The regimen for patients with renal dysfunction includes bortezomib, cyclophosphamide, and dexamethasone (NCCN, 2019i).

In addition to these agents, all patients with multiple myeloma should be prescribed a bisphosphonate, such as pamidronate or zoledronic acid (NCCN, 2019i). Bisphosphonates have been shown to strengthen bone by diminishing survival of osteoclasts, thus controlling bone pain and potentially preventing bone fractures. These agents are also effective in managing and preventing hypercalcemia by preventing excessive bone resorption. Some evidence suggests that bisphosphonates may activate an antimyeloma immune response, inducing myeloma cell death, acting synergistically with antineoplastic drugs, and enhancing immune surveillance (Faiman et al., 2017) (see Chapter 36, Table 36-1, for further discussion of bisphosphonates).

Complications

Infection is a potential complication of multiple myeloma and a frequent cause of morbidity and mortality. In contrast to other hematologic malignancies, the incidence of infection does not appear to be related to the extent of neutropenia in patients with multiple myeloma. Rather, the lack of adequate levels of normal immunoglobulins, as well as other alterations of the immune system, renders the patient at increased risk for developing infection, particularly due to *Streptococcus pneumoniae* or *H. influenzae*. Therapy for the disease also predisposes the patient for acquiring infections, particularly when corticosteroids are used in treating the disease; herpes zoster and *Pneumocystis* are common causative organisms in this context (NCCN, 2019i). Infection prophylaxis with antiviral agents and antibiotics (e.g., trimethoprim–sulfamethoxazole) is important to decrease infection risk.

When plasma cells secrete excessive amounts of immunoglobulin, the serum viscosity can increase. Hyperviscosity may be manifested by bleeding

from the nose or mouth, headache, visual changes such as blurred vision or diplopia, paresthesias, or heart failure. The incidence of hyperviscosity is rare but does have the potential to be lethal. It is considered to be an oncologic emergency and as such, requires immediate intervention with aggressive hydration and plasmapheresis or therapeutic phlebotomy to reduce immunoglobulin and protein levels and to decrease symptoms (see Chapter 28, Table 28-3, for further discussion of plasmapheresis).

Neurologic complications can also occur. Spinal cord compression is the most common (see Chapter 12, Table 12-13, for discussion of manifestations and management of spinal cord compression), and other neurologic symptoms may be present, particularly peripheral neuropathy. Peripheral neuropathy may occur in as many as 75% of patients with multiple myeloma either due to infiltration of malignant plasma cells into the peripheral nerves or due to neurotoxic agents prescribed to treat the disease (e.g., bortezomib and thalidomide) (Faiman et al., 2017). Symptoms of peripheral neuropathy can range from mild discomfort to severe impairment and even paralysis and may lead to dose reduction or discontinuation of therapy.

VTE may occur in patients with myeloma; the incidence is thought to be as high as 10% (NCCN, 2019i). The risk increases substantially when high doses of corticosteroids and immumodulatory drugs (e.g., thalidomide, lenalidomide, or pomalidomide) are used to treat the disease (see Chapter 26 for further discussion of VTE management).

TABLE 30-5 Select Pharmacologic Agents for Multiple Myeloma[a]

Medication	Adverse Effects	Nursing Considerations
CHEMOTHERAPY		
Alkylating Agents Mechanism of Action: Bond with DNA, RNA, and protein molecules leading to impaired DNA replication, RNA transcription, and cell functioning; all resulting in cell death; cell cycle nonspecific		
Cisplatin Cyclophosphamide	Alopecia Bone marrow suppression (e.g., anemia, leukopenia, thrombocytopenia) Electrolyte disturbances Hemorrhagic cystitis[b] Hypersensitivity reaction Nausea and vomiting Peripheral neuropathy Renal toxicity[c] Second cancers SIADH Stomatitis	Monitor blood counts, blood chemistries and creatinine Monitor hydration status; encourage 2–3 L of fluid intake daily May premedicate patient to avoid or minimize risk for hypersensitivity reaction (e.g., dexamethasone, diphenhydramine, famotidine) and/or with antiemetics
Antitumor Antibiotic (Anthracycline-Based) Mechanism of Action: Interfere with DNA synthesis by binding DNA; prevent RNA synthesis; cell cycle nonspecific		
Doxorubicin	Alopecia Bone marrow suppression (e.g., anemia, leukopenia, thrombocytopenia) Cardiotoxicity (e.g., cardiomyopathy, arrhythmias) Diarrhea Nausea and vomiting Red urine Stomatitis	Drug is a vesicant and should be administer via central venous access. Patients should have ECG, MUGA scan to evaluate cardiac function prior to initiation of treatment. Educate patient to understand that urine will be red in color as drug is excreted.
Topoisomerase II Inhibitor Mechanism of Action: Induce breaks in the DNA strand by binding to enzyme topoisomerase, preventing cells from dividing; specific to the S phase of the cell cycle		
Etoposide	Alopecia Anorexia Bone marrow suppression (e.g., anemia, leukopenia, thrombocytopenia) Diarrhea Hypotension Hypersensitivity reaction Nausea and vomiting Stomatitis	Monitor blood counts. Monitor vital signs (especially blood pressure) prior to, during, and following administration. May premedicate patient to avoid or minimize risk for hypersensitivity reaction (e.g., dexamethasone, diphenhydramine, famotidine) and/or with antiemetics
CORTICOSTEROID		

Mechanism of Action: Induce apoptosis in myeloma cells and markedly decrease bone pain		
Dexamethasone	Cataract formation Dental caries Fluid retention Immunosuppression Increased appetite, weight gain Insomnia Osteoporosis Peptic ulcers Pseudodiabetes Psychosis Venous thromboembolism	Monitor blood counts Monitor blood glucose levels Monitor intake and output, assess for peripheral edema Assess daily weights Assess stools for occult blood Educate patient on methods to decrease risk for infection (e.g., flu vaccine, antibiotic prophylaxis as indicated) Educate patient to follow-up with dental and eye examinations Risk for venous thromboembolism is increased in patients concomitantly taking immunomodulators
IMMUNOMODULATORS Mechanism of Action: Display broad antimyeloma effects by inhibiting angiogenesis and by mitigating the effects of the cytokines interleukin-6 and tumor necrosis factor (both support myeloma cell growth)		
Lenalidomide Pomalidomide Thalidomide	Arthralgia[d] Bone marrow suppression (e.g., anemia, leukopenia, thrombocytopenia)[d,e] Constipation[f] Fatigue, dizziness, sedation[f] Fetal birth defects Peripheral neuropathy[f] Rash, dry skin Venous thromboembolism	Pregnancy test prior to initial therapy; repeat every 4 wk in women of childbearing age Male patients should be educated to use strict methods of contraception Patients must be educated about the teratogenic effects of therapy Excreted by the kidneys; therefore, monitor renal function, including urine output and serum creatinine and urea nitrogen Patient may be prescribed antithrombotic prophylaxis (e.g., aspirin, DOAC, LMWH, warfarin) (see Chapter 26 for further discussion of these drugs and nursing interventions) Risk for venous thromboembolism is increased in patients concomitantly taking corticosteroids Monitor blood counts in patients taking lenalidomide and pomalidomide Assess for peripheral neuropathy in patients taking thalidomide (see Table 30-6)
MONOCLONAL ANTIBODIES		

Mechanism of Action: Antibodies made from clonal immune cells that target specific antigens found on the surface of multiple myeloma cells; various agents target different antigenic receptors and therefore, adverse effects may differ		
Daratumumab	Back pain, arthralgia Bone marrow suppression (e.g., anemia, leukopenia, thrombocytopenia) Constipation or diarrhea Fatigue Herpes zoster reactivation Hypersensitivity reaction: most common with first infusions; manifestations include dyspnea, bronchospasm, cough, rhinitis Injection site reaction Insomnia Nausea and vomiting	May premedicate patient to avoid or minimize risk for hypersensitivity reaction (e.g., acetaminophen, diphenhydramine, methylprednisolone) and/or with antiemetics Monitor blood counts. Prophylactic antiviral agents may be considered in patients with history of herpes zoster. Female patients should avoid becoming pregnant or breastfeeding while on drug, as risks to fetus are unknown
Elotuzumab	Anorexia Bone marrow suppression (e.g., anemia, leukopenia, thrombocytopenia) Bradycardia or tachycardia Constipation or diarrhea Fatigue Hypersensitivity reaction: include dyspnea, bronchospasm, cough, rhinitis Peripheral neuropathy	May premedicate patient to avoid or minimize risk for hypersensitivity reaction (e.g., acetaminophen, diphenhydramine, dexamethasone, famotidine) Monitor blood counts Assess for peripheral neuropathy (see Table 30-6)
PROTEASOME INHIBITORS Mechanism of Action: Proteasomes process and clear the excess mis/unfolded protein that accumulates within malignant plasma cells; inhibiting this process causes an excess accumulation of these proteins that results in apoptosis of malignant cells		
Bortezomib Carfilzomib Ixazomib	Bone marrow suppression (e.g., anemia, leukopenia, thrombocytopenia) Cardiovascular events, such as heart failure, ischemia, arrhythmias (*more common with carfilzomib*) Constipation or diarrhea Fatigue Fetal birth defects Herpes zoster reactivation Metabolized via the cytochrome P450 system[g]	Monitor blood counts Patients should have ECG, MUGA scan to evaluate cardiac function prior to initiation of treatment, particularly with carfilzomib. Female patients should avoid becoming pregnant or breastfeeding. Prophylactic antiviral agents may be considered in patients with history of herpes zoster For patients prescribed bortezomib, advocate for SQ rather than IV administration, to diminish

	Nausea and vomiting Peripheral neuropathy (*more common with bortezomib)* Renal dysfunction Reversible posterior leukoencephalopathy syndrome (RPLS), evidenced by seizures, visual disturbances, delirium, and hypertension Transient thrombocytopenia[h]	likelihood of peripheral neuropathy (see Table 30-6 for further discussion) Monitor urine output and blood creatinine and urea nitrogen If RPLS suspected, discontinue treatment and call primary provider Monitor platelet counts in patients taking bortezomib; assess for signs of occult bleeding (e.g., black tarry stools, petechiae formation) Monitor for drug-to-drug interactions in patients taking ixazomib Ixazomib may be taken orally; administer at least 1 h prior to or 2 h post meal

[a]Refer to Chapter 12 for additional nursing interventions to mitigate adverse effects of antineoplastic therapy.

[b]Specific to cyclophosphamide.

[c]Specific to cisplatin.

Gerontologic Considerations

Historically, aggressive multiple myeloma therapy, particularly HSCT, was limited to patients younger than age 65, but this approach has changed. Patients older than age 65 who have excellent organ function (i.e., renal, hepatic, cardiopulmonary) and who have fewer comorbidities may tolerate more intense treatment, including AuHSCT (Faiman et al., 2017; NCCN, 2019i). Determining an older adult patient's ability to tolerate therapy *a priori* is important. In addition to chronologic age, organ function, and comorbidity, the ability to independently perform activities of daily living is another

important factor. A comprehensive assessment of all these factors is useful to better determine the level of "fitness" in a given patient. Patients categorized as frail may develop more severe toxicity associated with therapy and consequently are more likely to discontinue that treatment.

The older adult patient may have different goals of care from that of younger patients. Effective symptom control, preserving cognitive function, and maintaining independence are often viewed as higher priority than survival in the older adult. Discussing these goals of care as well as the patient's physical and social needs can provide a more personalized approach to treating the older adult with multiple myeloma. Using lower doses of agents and focusing on side effect management are important treatment strategies. Side effects should be managed without additional medications to reduce the burden of polypharmacy. Incorporating the expertise of a palliative care clinician may be extremely beneficial, not only in devising an appropriate treatment plan, but also in managing symptoms and side effects more effectively.

Nursing Management

Pain management is very important in patients with multiple myeloma. NSAIDs can be very useful for mild pain or can be given in combination with opioid analgesics. Because NSAIDs can cause gastritis and renal dysfunction, renal function must be carefully monitored and patients assessed for GI complications; many patients are unable to use NSAIDs due to concurrent or newly developed renal insufficiency. Long-acting opioids are often prescribed to afford adequate pain relief.

Nursing care should focus on assessing for signs and symptoms of hypercalcemia. Common presenting symptoms include polyuria and GI problems (nausea, constipation, anorexia). Patients progressively become more dehydrated, with possible confusion and stupor as well as decreased renal function as the hypercalcemia worsens. Treatment for hypercalcemia includes aggressive hydration, bisphosphonates, and/or corticosteroids. See Chapter 12, Table 12-13, for a discussion of manifestations of and treatment for hypercalcemia.

Patient education should include methods to prevent and minimize the risk of infection, reportable signs and symptoms, medication side effects, and pain management. Any new complaint or worsening of pain requires immediate intervention. Another key nursing responsibility is to assess for and provide emotional/psychological support. Educating patients about effective coping skills to aid in dealing with multiple myeloma and its treatment is a key intervention.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The patient needs to be educated about activity restrictions (e.g., lifting no more than 10 lb, the use of proper body mechanics) to reduce the risk of pathologic fracture. Braces are occasionally needed to support the spinal column, but may be uncomfortable and hamper adherence. Bisphosphonate therapy has markedly reduced the severity and extent of bone pain. However, patients need to understand the importance of comprehensive oral hygiene and good dental care to diminish the likelihood of developing osteonecrosis of the jaw that may arise from bisphosphonate therapy.

Renal function must be monitored closely. Kidney injury can become severe, and dialysis may be needed. Maintaining high urine output (3 L/day) can be very useful in preventing or limiting this complication, as is treating the underlying disease. The patient also needs to be educated about the signs and symptoms of hypercalcemia. While hypercalcemia usually occurs at the onset of the disease, it can also develop at the time of disease progression or when multiple myeloma becomes refractory to therapy. Maintaining mobility and hydration are important to diminish exacerbations of this complication.

Because antibody production is impaired, infections, particularly bacterial infections, are common and can be life-threatening. The patient needs education regarding appropriate infection prevention measures and should be advised to contact the primary provider immediately if fever or other signs and symptoms of infection develop. The patient should receive pneumococcal and influenza vaccines. Prophylactic antibiotics, such as trimethoprim–sulfamethoxazole, are often used, particularly when patients are treated with corticosteroid-containing regimens to prevent *Pneumocystis jirovecii* pneumonia (NCCN, 2019i). The antiviral agent acyclovir may be prescribed when patients are treated with bortezomib-based regimens to diminish the potential development of viral infection, such as herpes zoster. The patient must be educated about the indications for these prophylactic measures.

Continuing and Transitional Care

Many medications prescribed to treat multiple myeloma, particularly the immunomodulatory drugs (e.g., lenalidomide, thalidomide), are associated with higher risks of VTE formation, particularly when used concurrently with high doses of corticosteroids or erythropoietin. Other VTE risk factors include decreased mobility, obesity, prior thromboembolic events, diabetes, cardiac or renal disease, and the presence of a vascular access device (e.g., PICC). It is important to maintain mobility and to use strategies that enhance venous return (e.g., anti-embolism stockings, avoid crossing the legs). For patients without additional risk factors, VTE can be prevented by taking low-dose aspirin.

Those patients with additional risk factors for developing VTE should receive anticoagulation therapy (see Chapter 26 for further discussion).

Peripheral neuropathy is a frequent issue for patients with multiple myeloma, affecting over 50% at the time of diagnosis (Faiman et al., 2017). It is particularly commonplace in patients who are prescribed thalidomide or bortezomib. Painful neuropathy can be quite disabling and may interfere with the patient's ability to perform normal activities of daily living (Olsen et al., 2019) (see Table 30-6). The nurse needs to carefully assess for symptoms related to peripheral neuropathy and make assessments of the home for safety. Sensation (touch, temperature, pain, vibration, proprioception), ankle reflexes, distal muscle strength, and blood pressure should be evaluated. Other risk factors for peripheral neuropathy (e.g., diabetes, vitamin deficiencies, viral infection, or excessive alcohol consumption) should be aggressively managed. Patients should be educated to report any symptoms of peripheral neuropathy and to not minimize such symptoms, because prompt cessation of therapy or reducing the dose can prevent the neuropathy from progressing. Resuming treatment with a lower dosage and at a longer interval between dosing may diminish the worsening of peripheral nerve damage. Recovery can occur over time, although it may be incomplete. Gabapentinoids (e.g., gabapentin, pregabalin), tricyclic antidepressants (e.g., amitriptyline, nortriptyline), and selective SSRIs (e.g., duloxetine) can be prescribed to diminish pain; opioids are fairly ineffective in this context.

TABLE 30-6 Peripheral Neuropathy Associated with Multiple Myeloma

Type of Neuropathy	Manifestations	Nursing Interventions/Patient Education
Sensory	Hypoesthesia	Warn patient to avoid extreme temperatures (e.g., bathwater) Inspect feet for trauma, potential infection Use loose-fitting stockings
	Paresthesia (tingling)	Gentle massage Gentle ROM exercises
	Hyperalgesia (pain) Toes and fingers Soles of feet/palms	Gentle massage (cocoa butter or menthol-based cream/lotion) Apply lidocaine 5% patch to affected area every 12 h Consider gabapentin, tricyclic antidepressants (e.g., amitriptyline)
Motor	Muscle cramps	Maximize hydration, ambulation (Quinine is not recommended)
	Tremor	
	↓ Strength in distal muscles	
	Gait disturbance ↓ Fine motor function (e.g., handwriting, buttoning clothes)	Encourage the use of appropriate footwear Consider ambulatory aides (e.g., walker) Remove scatter rugs; perform a home safety evaluation PT referral OT referral (if severe limitations)
Autonomic Nervous System	Orthostatic hypotension	Warn patient to avoid abrupt position change Maximize hydration Consult with primary provider about adjusting antihypertensive medications, diuretics
	Bradycardia	Assess/warn patient for impact (fatigue, impairment in function) Consult with primary provider about adjusting drugs that cause bradycardia (e.g., calcium channel blockers, beta-blockers, alpha-/beta-adrenergic blockers, digoxin). Explore the use of activity to increase heart rate
	Sexual dysfunction	Explore alternative means of sexual activity beyond penile-vaginal intercourse Consult with primary provider about the use of erectile dysfunction medication
	Constipation	Maximize fluid intake, fiber Use stool softeners, laxatives

Note: Peripheral neuropathy can be classified into three main categories. Within each category, specific manifestations are delineated as well as relevant nursing interventions. If the neuropathy is related to multiple myeloma therapy, it is crucial to promptly stop the potentially offending medication. It is also important to reduce the impact from other

predisposing factors. For example, diabetes should be well controlled and alcohol consumption reduced.

↓, decreased; OT, occupational therapy; PT, physical therapy; ROM, range of motion.

Adapted from Autissier, E. (2019). Chemotherapy-induced peripheral neuropathy. *Clinical Journal of Oncology Nursing*, *23*(4), 405–410; Olsen, M., LeFebvre, K., & Brassil, K. (2019). *Chemotherapy and immunotherapy guidelines and recommendations for practice*. Pittsburgh, PA: Oncology Nursing Society.

As many drugs used in treating multiple myeloma are given orally, the nurse must ensure that the patient fully understands how to take the medication, manage side effects, and know what steps can be taken to diminish or mitigate adverse effects (see Table 30-6).

CRITICAL THINKING EXERCISES

1 ipc You work on an inpatient oncology unit and are assigned to care for a 47-year-old woman with AML who is a week and a half post induction therapy. The multidisciplinary team is now rounding on your patient and asks you for a brief report. What complications would you anticipate the patient could experience at this time? What key information do you think you should provide the multidisciplinary team? What aspects of multidisciplinary care do you identify?

2 pq You work in an outpatient infusion center and are assigned to provide a first treatment for a 74-year-old African American man who was recently diagnosed with multiple myeloma. What key assessment and laboratory studies would you focus on and why? Are there any comorbidities that could impact this patient's treatment?

3 ebp You are caring for a 57-year-old patient with diffuse large B-cell lymphoma who is not a candidate for autologous HSCT. The patient had only a partial response to consolidation therapy and is in the hospital to manage an infection. What do you anticipate are the best treatment options available for this patient? What are the possible adverse effects that you need to monitor? What evidence-based nursing interventions would you employ to manage this patient's care?

UNIT 7 Immunologic Function

Case Study

UTILIZING A TEAM APPROACH TO CARE FOR THE PATIENT WITH HIV

You are working in a community health center with an interdisciplinary team to provide care for patients with human immune deficiency virus (HIV). The team consists of a physician,

nurse, pharmacist, social worker, mental health counselor, and a registered dietician. The team is discussing the interdisciplinary management plan for a 21-year-old Hispanic male who recently became positive for HIV infection. The goal is to develop strategies for him to treat his HIV infection and prevent progression to acquired immune deficiency syndrome (AIDS). How can you, as the sole nurse on the team, foster open communication, mutual respect, and shared decision-making within the team to achieve quality patient care?

QSEN Competency Focus: **Teamwork and Collaboration**

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Teamwork and Collaboration Definition: Function effectively within nursing and interprofessional teams, fostering open communication, mutual respect, and shared decision-making to achieve quality patient care.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Describe scopes of practice and roles of health care team members Describe strategies for identifying and managing overlaps in team member roles and accountabilities Recognize contributions of other individuals and groups in helping patient/family achieve health goals	Describe the various roles of the team in managing a patient with HIV. How does your role complement the other members of the team? Why does this patient require a variety of team members to facilitate his disease management?
Skills	
Demonstrate awareness of own strengths and limitations as a team member Initiate plan for self-development as a team member	Discuss how the team approaches the management of the laboratory findings for this patient who is newly diagnosed with HIV. Describe how each member can provide education to him regarding the antiretroviral medications and how they can be used to manage the abnormal laboratory results related to this disease process. Describe how the role of the team changes during the various phases of the disease process.
Attitudes	
Value teamwork and the relationships	After the members of the team meet with the patient, what are ways each member can advocate for this patient's needs? How can you ensure all team

upon which it is based	members are communicating and collaborating together as a team?
Value different styles of communication used by patients, families, and health care providers

31 Assessment of Immune Function

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the body's general immune responses and the stages of the immune response.
2. Differentiate between cellular and humoral immune responses.
3. Specify the effects of select variables on function of the immune system.
4. Use assessment parameters for determining the status of patients' immune function.

NURSING CONCEPTS

Assessment
Cellular Regulation
Immunity
Infection
Nutrition

GLOSSARY

agglutination: clumping effect occurring when an antibody acts as a cross-link between two antigens

antibody: a protein substance developed by the body in response to and interacting with a specific antigen

antigen: substance that induces the production of antibodies

antigenic determinant: the specific area of an antigen that binds with an antibody-combining site and determines the specificity of the antigen–antibody reaction

apoptosis: programmed cell death that results from the digestion of deoxyribonucleic acid by end nucleases

B cells: cells that are important for producing a humoral immune response

cellular immune response: the immune system's third line of defense, involving the attack of pathogens by T cells

complement: series of enzymatic proteins in the serum that, when activated, destroy bacteria and other cells

cytokines: generic term for nonantibody proteins that act as intercellular mediators, as in the generation of immune response

cytotoxic T cells: lymphocytes that lyse cells infected with virus; also play a role in graft rejection

epitope: any component of an antigen molecule that functions as an antigenetic determinant by permitting the attachment of certain antibodies

genetic engineering: emerging technology designed to enable replacement of missing or defective genes

helper T cells: lymphocytes that attack foreign invaders (antigens) directly

humoral immune response: the immune system's second line of defense (*synonym:* antibody response)

immune response: the coordinated response of the components of the immune system to a foreign agent or organism

immune system: the collection of organs, cells, tissues, and molecules that mediate the immune response

immunity: the body's specific protective response to a foreign agent or organism; resistance to disease, specifically infectious diseases

immunopathology: study of diseases resulting in dysfunctions within the immune system

immunoregulation: complex system of checks and balances that regulates or controls immune responses

immunosenescence: the gradual deterioration of the immune system brought on by the aging process

interferons: proteins formed when cells are exposed to viral or foreign agents; capable of activating other components of the immune system

lymphokines: substances released by sensitized lymphocytes when they come in contact with specific antigens

memory cells: cells that are responsible for recognizing antigens from previous exposure and mounting an immune response

natural killer (NK) cells: lymphocytes that defend against microorganisms and malignant cells

null lymphocytes: lymphocytes that destroy antigens already coated with the antibody

opsonization: the coating of antigen–antibody molecules with a sticky substance to facilitate phagocytosis

phagocytic cells: cells that engulf, ingest, and destroy foreign bodies or toxins

phagocytic immune response: the immune system's first line of defense, involving white blood cells that have the ability to ingest foreign particles

stem cells: precursors of all blood cells; reside primarily in the bone marrow

suppressor T cells: lymphocytes that decrease B-cell activity to a level at which the immune system is compatible with life

T cells: cells that are important for producing a cellular immune response

Immunity is the body's specific protective response to a foreign agent or organism. The **immune system** functions as the body's defense mechanism against invasion and allows a rapid response to foreign substances in a specific manner. Genetic and cellular responses result. Any qualitative or quantitative change in the components of the immune system can produce profound effects on the integrity of the human organism. Immune function is affected by a variety of factors, such as central nervous system integrity, general physical and emotional status, medications, dietary patterns, and the stress of illness, trauma, or surgery. Immune memory is a property of the immune system that provides protection against harmful microbial agents despite the timing of re-exposure to the agent. Tolerance is the mechanism by which the immune system is programmed to eliminate foreign substances such as microbes, toxins, and cellular mutations but maintains the ability to accept self-antigens. Some credence is given to the concept of surveillance, in which the immune system is in a perpetual state of vigilance, screening and rejecting any invader that is recognized as foreign to the host. The term **immunopathology** refers to the study of diseases that result from dysfunctions within the immune system. Immune system dysfunctions can occur across the lifespan; many are

genetically based, others are acquired. Disorders of the immune system may stem from excesses or deficiencies of immunocompetent cells, alterations in the function of these cells, immunologic attack on self-antigens, or inappropriate or exaggerated responses to specific antigens (Table 31-1).

Primary immunodeficiencies and acquired immune disorders affect large numbers of the population. Thus, nurses in many practice settings need to understand how the immune system functions as well as immunopathologic processes. In addition, knowledge about assessment and care of people with immunologic disorders enables nurses to make appropriate management decisions.

TABLE 31-1 Immune System Disorders

Disorder	Description
Autoimmunity	Normal protective immune response paradoxically turns against or attacks the body, leading to tissue damage
Hypersensitivity	Body produces inappropriate or exaggerated responses to specific antigens
Gammopathies	Overproduction of immunoglobulins
Immune deficiencies	
Primary	Deficiency results from improper development of immune cells or tissues; usually congenital or inherited
Secondary	Deficiency results from some interference with an already developed immune system; usually acquired later in life

Anatomic and Physiologic Overview

Accurate assessment of immune function necessitates the nurse having a good working knowledge of the anatomy and physiology of the immune system.

Anatomy of the Immune System

The immune system is composed of an integrated collection of various cell types, each with a designated function in defending against infection and invasion by other organisms. Supporting this system are molecules that are responsible for the interactions, modulations, and regulation of the system. These molecules and cells participate in specific interactions with immunogenic **epitopes** (antigenic determinants) present on foreign materials, initiating a series of actions in a host, including the inflammatory response, the lysis of microbial agents, and the disposal of foreign toxins. The major components of the immune system include central and peripheral organs, tissues, and cells (Fig. 31-1).

Bone Marrow

The white blood cells (WBCs) involved in immunity are produced in the bone marrow (Fig. 31-2). Like other blood cells, lymphocytes are generated from **stem cells** (undifferentiated cells). There are two types of lymphocytes—**B cells**, also called B lymphocytes, and **T cells**, also called T lymphocytes (Fig. 31-3).

Lymphoid Tissues

The spleen, composed of red and white pulp, acts somewhat like a filter. The red pulp is the site where old and injured red blood cells (RBCs) are destroyed. The white pulp contains concentrations of lymphocytes. The lymph nodes, which are connected by lymph channels and capillaries, are distributed throughout the body. They remove foreign material from the lymph system before it enters the bloodstream. The lymph nodes also serve as centers for immune cell proliferation. The remaining lymphoid tissues contain immune cells that defend the body's mucosal surfaces against microorganisms (Klimov, 2019).

Function of the Immune System

The basic function of the immune system is to remove foreign antigens such as viruses and bacteria to maintain homeostasis. There are two general types of immunity: natural (innate) and acquired (adaptive). Natural immunity or nonspecific immunity is present at birth. Acquired or specific immunity develops after birth. Each type of immunity has a distinct role in defending the body against harmful invaders, but the various components are usually interdependent (Klimov, 2019).

Natural Immunity

Natural immunity, which is nonspecific, provides a broad spectrum of defense against and resistance to infection. It is considered the first line of host defense following antigen exposure, because it protects the host without remembering prior contact with an infectious agent (Norris, 2019). Responses to a foreign invader are very similar from one encounter to the next, regardless of the

number of times the invader is encountered. Natural (innate) immunity coordinates the initial response to pathogens through the production of cytokines and other effector molecules, which either activate cells for control of the pathogen (by elimination) or promote the development of the acquired **immune response**. The cells involved in this response are monocytes, macrophages, dendritic cells, **natural killer (NK) cells**, basophils, eosinophils, and granulocytes. The early events in this process are critical in determining the nature of the adaptive immune response. Natural immune mechanisms can be divided into two stages: immediate (generally occurring within minutes) and delayed (occurring within several days after exposure) (Norris, 2019).

White Blood Cell Action

The cellular response is the key to the effective initiation of the immune response. WBCs, or leukocytes, participate in both the natural and the acquired immune responses. Granular leukocytes, or granulocytes (so called because of granules in their cytoplasm), fight invasion by foreign bodies or toxins by releasing cell mediators, such as histamine, bradykinin, and prostaglandins, and by engulfing the foreign bodies or toxins. Granulocytes include neutrophils, eosinophils, and basophils.

Neutrophils (polymorphonuclear leukocytes) are the first cells to arrive at the site where inflammation occurs. Eosinophils and basophils, other types of granulocytes, increase in number during allergic reactions and stress responses. Nongranular leukocytes include monocytes or macrophages (referred to as histiocytes when they enter tissue spaces) and lymphocytes. Monocytes are the first to arrive on the scene and function as **phagocytic cells**, engulfing, ingesting, and destroying greater numbers and quantities of foreign bodies or toxins than granulocytes do. Lymphocytes, consisting of B cells and T cells, play major roles in humoral and cell-mediated immune responses. About 70% to 80% of lymphocytes in the blood are T cells, and about 10% to 15% are B cells (Haynes, Soderberg, & Fauci, 2018).

Inflammatory Response

The inflammatory response is a major function of the natural immune system that is elicited in response to tissue injury or invading organisms. Chemical mediators assist this response by minimizing blood loss, walling off the invading organism, activating phagocytes, and promoting formation of fibrous scar tissue and regeneration of injured tissue. The inflammatory response (discussed further in Chapter 5) is facilitated by physical and chemical barriers that are part of the human organism.

Physical and Chemical Barriers

Activation of the natural immunity response is enhanced by processes inherent in physical and chemical barriers. Physical surface barriers include intact skin,

mucous membranes, and cilia of the respiratory tract, which prevent pathogens from gaining access to the body. The cilia of the respiratory tract, along with coughing and sneezing responses, filter and clear pathogens from the upper respiratory tract before they can invade the body further. Chemical barriers, such as mucus, acidic gastric secretions, enzymes in tears and saliva, and substances in sebaceous and sweat secretions, act in a nonspecific way to destroy invading bacteria and fungi. Viruses are countered by other means, such as interferon (see discussion later in chapter).

Immune Regulation

Regulation of the immune response involves balance and counterbalance. Dysfunction of the natural immune system can occur when the immune components are inactivated or when they remain active long after their effects are beneficial. A successful immune response eliminates the responsible antigen. If an immune response fails to develop and clear an antigen sufficiently, the host is considered immunocompromised or immunodeficient. If the response is overly robust or misdirected, allergies, asthma, or autoimmune disease results. The immune system's recognition of one's own cells or tissues as "foreign" rather than as self is the basis of many autoimmune disorders (Norris, 2019). While the immune response is critical to the prevention of disease, it must be well controlled to curtail immunopathology. Most microbial infections induce an inflammatory response mediated by T cells and cytokines, which, in excess, can cause tissue damage (Haynes et al., 2018). Therefore, regulatory mechanisms must be in place to suppress or halt the immune response. This is mainly achieved by the production of cytokines and transformation of growth factor that inhibit macrophage activation. In some cases, T-cell activation is so acute that these mechanisms fail, and pathology develops. Ongoing research on **immunoregulation** holds the promise of preventing graft rejection and aiding the body in eliminating cancerous or infected cells (Chae & Bothwell, 2018; Romano, Fanelli, Albany, et al., 2019).

Although natural immunity can often effectively combat infections, many pathogenic microbes have evolved that resist natural immunity. Acquired immunity is necessary to defend against these resistant agents.

Acquired Immunity

Acquired (adaptive) immunity usually develops due to prior exposure to an antigen through immunization (vaccination) or by contracting a disease, both of which generate a protective immune response. Weeks or months after exposure to a disease or vaccine, the body produces an immune response that is sufficient to defend against the disease on re-exposure. In contrast to the rapid but nonspecific natural immune response, this form of immunity relies on the recognition of specific foreign antigens. The acquired immune response

is broadly divided into two mechanisms: (1) the cell-mediated response, involving T-cell activation, and (2) effector mechanisms, involving B-cell maturation and production of antibodies (Haynes et al., 2018).

The two types of acquired immunity are known as active and passive and are interrelated. Active acquired immunity refers to immunologic defenses developed by the person's own body. This immunity typically lasts many years or even a lifetime. Passive acquired immunity is temporary immunity transmitted from a source outside the body that has developed immunity through previous disease or immunization. Examples include immunity resulting from the transfer of antibodies from the mother to an infant in utero or through breast-feeding or receiving injections of immune globulin. Active and passive acquired immunity involve humoral and cellular (cell-mediated) immunologic responses (described later).

Response to Invasion

When the body is invaded or attacked by bacteria, viruses, or other pathogens, it has three means of defense:

- The phagocytic immune response
- The humoral or antibody immune response
- The cellular immune response

The first line of defense, the **phagocytic immune response**, primarily involves the WBCs (granulocytes and macrophages), which ingest foreign particles and destroy the invading agent; eosinophils are only weakly phagocytic. Phagocytes also remove the body's own dying or dead cells. Cells in necrotic tissue that are dying release substances that trigger an inflammatory response. **Apoptosis**, or programmed cell death, is the body's way of destroying worn-out cells such as blood or skin cells or cells that need to be renewed (Norris, 2019).

A second protective response, the **humoral immune response** (*synonym:* antibody response), begins with the B lymphocytes, which can transform themselves into plasma cells that manufacture antibodies. An **antibody** is a protein substance developed by the body, transported in the bloodstream, and attempts to disable invaders. The third mechanism of defense, the **cellular immune response**, involves the T lymphocytes, which can turn into special cytotoxic (or killer) T cells that can attack the pathogens.

The structural part of the invading or attacking organism that is responsible for stimulating antibody production is called an **antigen** (or an immunogen). For example, an antigen can be a small patch of proteins on the outer surface of a microorganism. Not all antigens are naturally immunogenic; some must be coupled to other molecules to stimulate the immune response. A single bacterium or large molecule, such as a diphtheria or tetanus toxin, may have several antigens, or markers, on its surface, thus inducing the body to produce many different antibodies. Once produced, an antibody is released into the

bloodstream and carried to the attacking organism. There, it combines with the antigen, binding with it like an interlocking piece of a jigsaw puzzle (Fig. 31-4). There are four well-defined stages in an immune response: recognition, proliferation, response, and effector (Fig. 31-5).

Recognition Stage

Recognition of antigens as foreign, or non-self, by the immune system is the initiating event in any immune response. Recognition involves the use of lymph nodes and lymphocytes for surveillance. Lymph nodes are widely distributed internally throughout the body and in the circulating blood, as well as externally near the body's surfaces. They continuously discharge small lymphocytes into the bloodstream. These lymphocytes patrol the tissues and vessels that drain the areas served by that node. Lymphocytes recirculate from the blood to lymph nodes and from the lymph nodes back into the bloodstream in a continuous circuit. Lymphocytes and other cells have "microbial sensors" that identify molecules on microbes and other microorganisms. The interaction of these sensors with the offending agent sets off a cascade aimed at destroying the microbe. Invading organisms have pathogen-associated molecular patterns (PAMPs) contained in their cell membranes that are recognized by the immune system cells. Once the receptors on the immune cells reach the PAMPs, the immune response is triggered. Macrophages play an important role in helping the circulating lymphocytes process the antigens. Both macrophages and neutrophils have receptors for antibodies and complement; as a result, they coat microorganisms with antibodies, complement, or both, thereby enhancing phagocytosis (Norris, 2019).

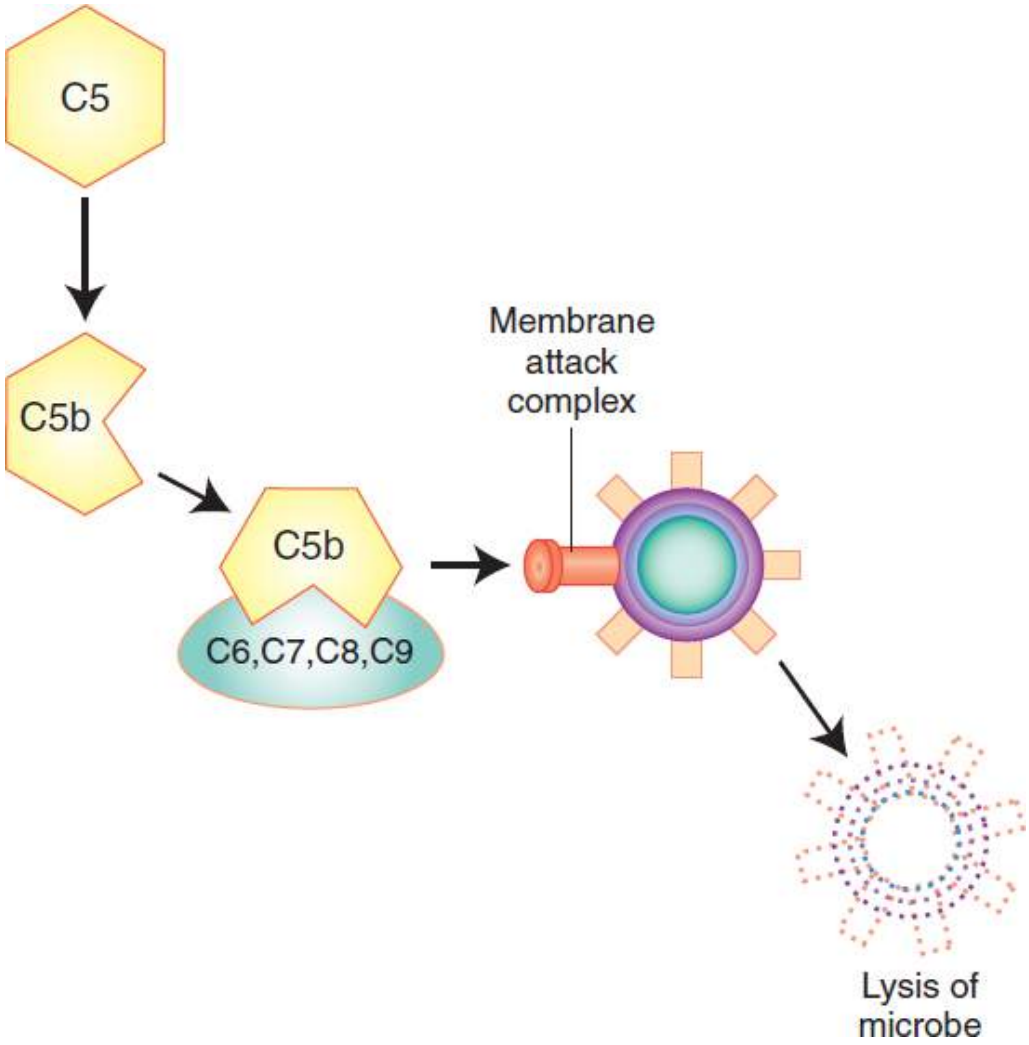

Figure 31-4 • Complement-mediated immune responses. Reprinted with permission from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed., second figure in Understanding box, p. 286). Philadelphia, PA: Wolters Kluwer.

In a streptococcal throat infection, for example, the streptococcal organism gains access to the mucous membranes of the throat. A circulating lymphocyte moving through the tissues of the throat comes in contact with the organism. The lymphocyte recognizes the antigens on the microbe as different (non-self) and the streptococcal organism as antigenic (foreign). This triggers the second stage of the immune response—proliferation.

Proliferation Stage

The circulating lymphocytes containing the antigenic message return to the nearest lymph node. Once in the node, these sensitized lymphocytes stimulate some of the resident T and B lymphocytes to enlarge, divide, and proliferate. T lymphocytes differentiate into cytotoxic (or killer) T cells, whereas B

lymphocytes produce and release antibodies. Enlargement of the lymph nodes in the neck in conjunction with a sore throat is one example of the immune response.

Response Stage

In the response stage, the differentiated lymphocytes function in either a humoral or a cellular capacity. This stage begins with the production of antibodies by the B lymphocytes in response to a specific antigen. The cellular response stimulates the resident lymphocytes to become cells that attack microbes directly rather than through the action of antibodies. These transformed lymphocytes are known as cytotoxic (killer) T cells.

Viral antigens induce a cellular response. This response is manifested by the increasing number of T lymphocytes (lymphocytosis) seen in the blood tests of people with viral illnesses such as infectious mononucleosis. (Cellular immunity is discussed later in this chapter.) Most immune responses to antigens involve both humoral and cellular responses, although one usually predominates. For example, during transplant rejection, the cellular response involving T cells predominates, whereas in the bacterial pneumonias and sepsis, the humoral response involving B cells plays the dominant protective role (Chart 31-1).

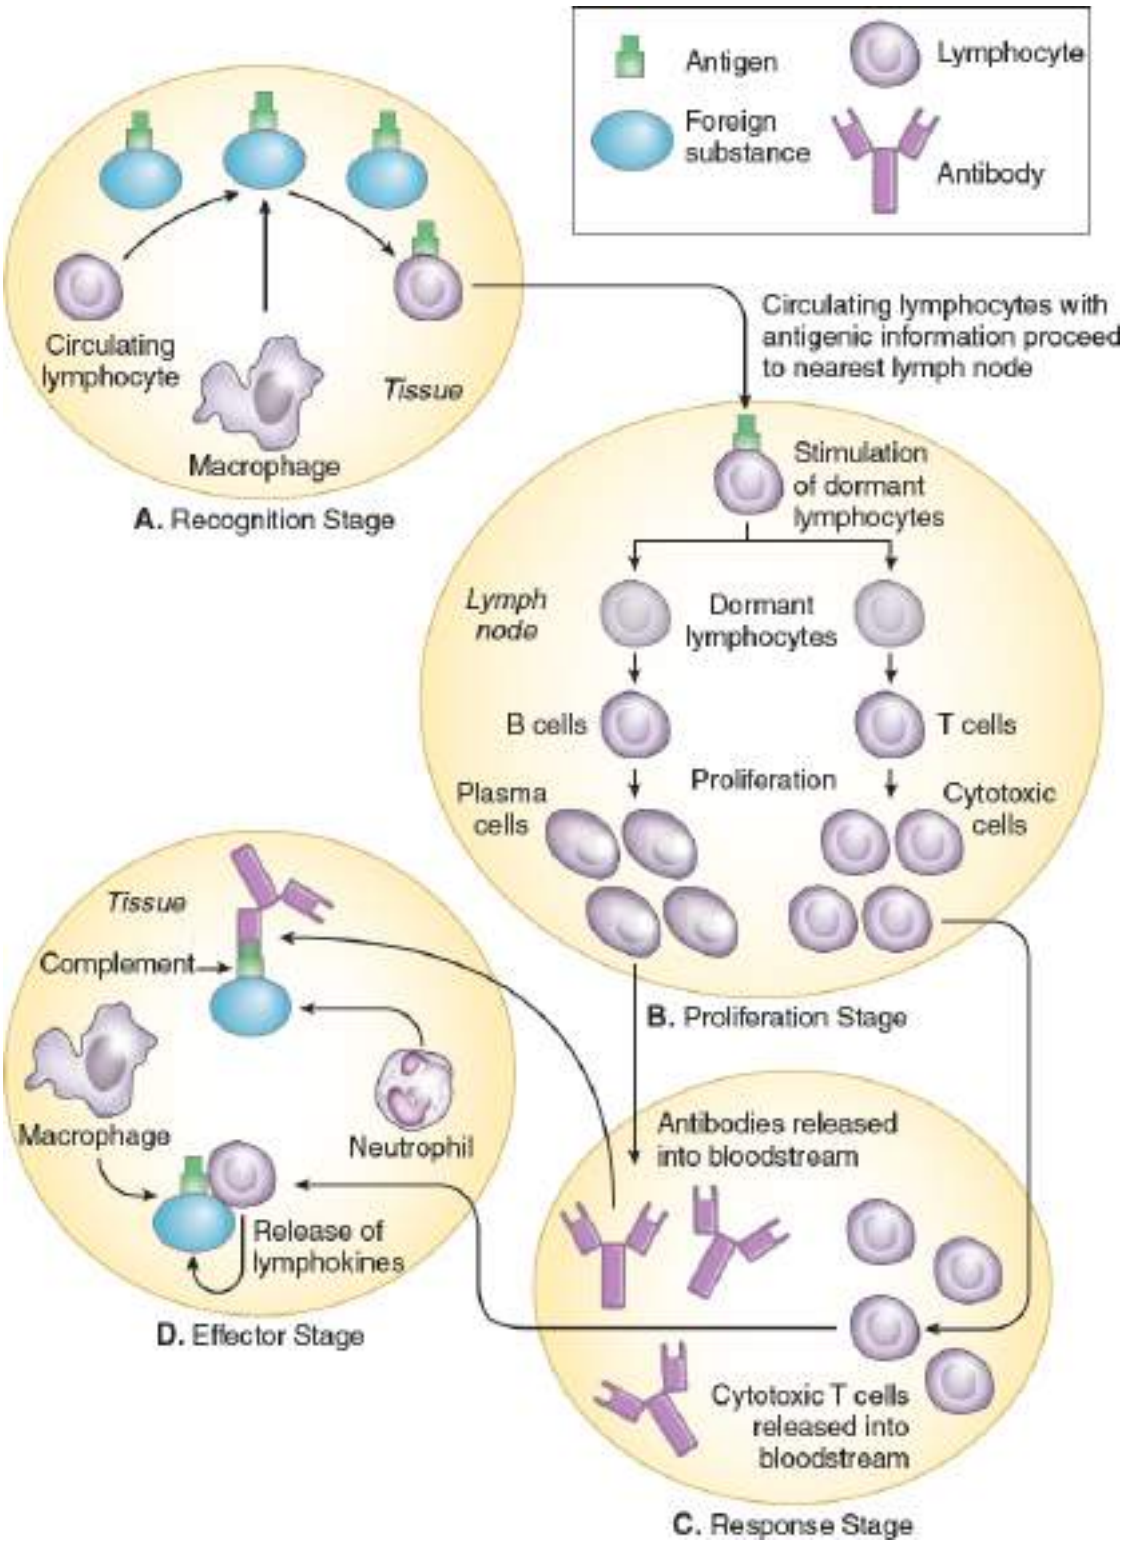

Figure 31-5 • Stages of the immune response. **A.** In the *recognition stage,* antigens are recognized by circulating lymphocytes and macrophages. **B.** In the *proliferation stage,* the dormant lymphocytes proliferate and differentiate into cytotoxic (killer) T cells or B cells responsible for formation and release of antibodies. **C.** In the *response stage,* the cytotoxic T cells and the B cells perform cellular and humoral functions, respectively. **D.** In the

effector stage, antigens are destroyed or neutralized through the action of antibodies, complement, macrophages, and cytotoxic T cells.

Chart 31-1

Comparison of Humoral and Cellular Immune Responses

Humoral Responses (B Cells)

- Bacterial phagocytosis and lysis
- Anaphylaxis
- Allergic hay fever and asthma
- Immune complex disease
- Bacterial and some viral infections

Cellular Responses (T Cells)

- Transplant rejection
- Delayed hypersensitivity (tuberculin reaction)
- Graft-versus-host disease
- Tumor surveillance or destruction
- Intracellular infections
- Viral, fungal, and parasitic infections

Effector Stage

In the effector stage, either the antibody of the humoral response or the cytotoxic (killer) T cell of the cellular response reaches and connects with the antigen on the surface of the foreign invader. This action initiates activities involving an interplay of antibodies (humoral immunity), complement, and action by the cytotoxic T cells (cellular immunity).

Humoral Immune Response

The humoral response is characterized by the production of antibodies by B lymphocytes in response to a specific antigen. Following antibody production, the macrophages of natural immunity and the special T lymphocytes of cellular immunity are involved in antigen recognition.

Antigen Recognition

Several theories explain the mechanisms by which B lymphocytes recognize the invading antigen and respond by producing antibodies. It is known that B lymphocytes recognize and respond to invading antigens in more than one way.

The B lymphocytes respond to some antigens by directly triggering antibody formation; however, in response to other antigens, they need the assistance of T cells to trigger antibody formation. With the help of macrophages, the T lymphocytes are believed to recognize the antigen of a foreign invader. The T lymphocyte picks up the antigenic message, or "blueprint," of the antigen and returns to the nearest lymph node with that message. B lymphocytes stored in the lymph nodes are subdivided into thousands of clones, which are stimulated to enlarge, divide, proliferate, and differentiate into plasma cells capable of producing specific antibodies to the antigen. Other B lymphocytes differentiate into B-lymphocyte clones with a memory for the antigen. These memory cells are responsible for the more exaggerated and rapid immune response in a person who is repeatedly exposed to the same antigen.

Role of Antibodies

Antibodies are large proteins, called *immunoglobulins,* that consist of two subunits, each containing a light and a heavy peptide chain held together by a chemical link composed of disulfide bonds. Each subunit has one portion that serves as a binding site for a specific antigen and another portion that allows the antibody molecule to take part in the complement system.

Antibodies defend against foreign invaders in several ways, and the type of defense used depends on the structure and composition of both the antigen and the immunoglobulin. The antibody molecule has at least two combining sites, or Fab fragments (Fig. 31-6). One antibody can act as a cross-link between two antigens, causing them to bind or clump together. This clumping effect, referred to as **agglutination**, helps clear the body of the invading organism by facilitating phagocytosis. Some antibodies assist in the removal of offending organisms through **opsonization**. In this process, the antigen–antibody molecule is coated with a sticky substance that also facilitates phagocytosis.

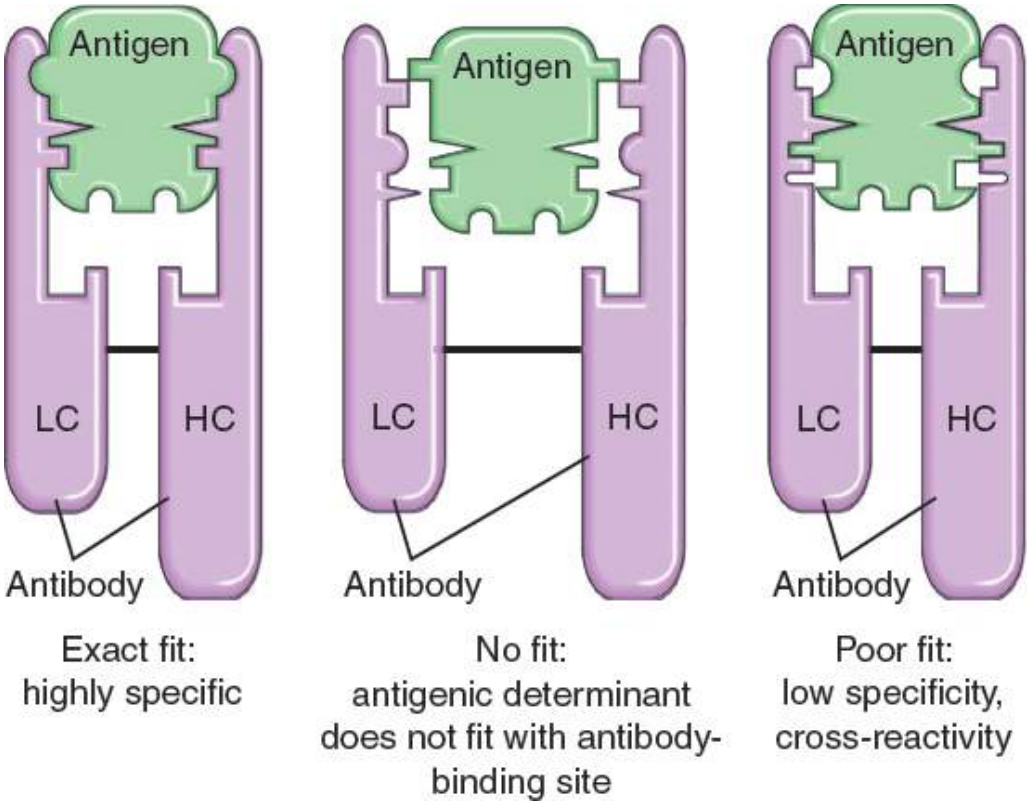

Figure 31-6 • Antigen–antibody binding. (**Left**) A highly specific antigen–antibody complex. (**Center**) No match and, therefore, no immune response. (**Right**) Poor fit or match with low specificity; antibody reacts to antigen with similar characteristics, producing cross-reactivity. HC, heavy chain; LC, light chain.

Chart 31-2

Major Characteristics of the Immunoglobulins

IgG (75% of Total Immunoglobulin)

- Appears in serum and tissues (interstitial fluid)
- Assumes a major role in bloodborne and tissue infections
- Activates the complement system
- Enhances phagocytosis
- Crosses the placenta

IgA (15% of Total Immunoglobulin)

- Appears in body fluids (blood, saliva, tears, and breast milk, as well as pulmonary, gastrointestinal, prostatic, and vaginal secretions)
- Protects against respiratory, gastrointestinal, and genitourinary infections
- Prevents absorption of antigens from food
- Passes to neonate in breast milk for protection

IgM (10% of Total Immunoglobulin)

- Appears mostly in intravascular serum
- Appears as the first immunoglobulin produced in response to bacterial and viral infections
- Activates the complement system

IgD (0.2% of Total Immunoglobulin)

- Appears in small amounts in serum
- Possibly influences B-lymphocyte differentiation, but role is unclear

IgE (0.004% of Total Immunoglobulin)

- Appears in serum
- Takes part in allergic and some hypersensitivity reactions
- Combats parasitic infections

Ig, immunoglobulin.

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Antibodies also promote the release of vasoactive substances, such as histamine and slow-reacting substances, two of the chemical mediators of the inflammatory response. Antibodies do not function in isolation; rather, they mobilize other components of the immune system to defend against the invader.

The body can produce five different types of immunoglobulin (Ig). Each of the five types, or classes, is identified by a specific letter of the alphabet, IgA,

IgD, IgE, IgG, and IgM. Classification is based on the chemical structure and biologic role of the individual immunoglobulin. Major characteristics of the immunoglobulins are summarized in Chart 31-2. The normal laboratory values for the three major Igs (IgA, IgG, and IgM) can be found in Appendix A on thePoint at thepoint.lww.com.

Antigen–Antibody Binding

The portion of the antigen involved in binding with the antibody is referred to as the **antigenic determinant**. The most efficient immunologic responses occur when the antibody and antigen fit like a lock and key. Poor fit can occur with an antibody that was produced in response to a different antigen. This phenomenon is known as cross-reactivity. For example, in acute rheumatic fever, the antibody produced against *Streptococcus pyogenes* in the upper respiratory tract may cross-react with the patient's heart tissue, leading to heart valve damage.

Cellular Immune Response

The T lymphocytes are primarily responsible for cellular immunity. Stem cells continuously migrate from the bone marrow to the thymus gland, where they develop into T cells. Despite the partial degeneration of the gland at puberty, T cells continue to develop in the thymus gland. Several types of T cells exist, each with designated roles in the defense against bacteria, viruses, fungi, parasites, and malignant cells. T cells attack foreign invaders directly rather than by producing antibodies.

Cellular reactions are initiated, with or without the assistance of macrophages, by the binding of an antigen to an antigen receptor located on the surface of a T cell. The T cells then carry the antigenic message, or blueprint, to the lymph nodes, where the production of other T cells is stimulated. Some T cells remain in the lymph nodes and retain a memory for the antigen. Other T cells migrate from the lymph nodes into the general circulatory system and ultimately to the tissues, where they remain until they bind with their respective antigens or die (Norris, 2019).

Types of T Lymphocytes

T cells include effector T cells, suppressor T cells, and memory T cells. The two major categories of effector T cells—helper T cells (also referred to as $CD4^+$ cells) and cytotoxic T cells (also referred to as $CD8^+$ cells)—participate in the destruction of foreign organisms. T cells interact closely with B cells, indicating that humoral and cellular immune responses are not separate, unrelated processes but rather are branches of the immune response that interact.

Helper T cells are activated on recognition of antigens and stimulate the rest of the immune system. When activated, helper T cells secrete **cytokines**, which attract and activate B cells, cytotoxic T cells, NK cells, macrophages, and other cells of the immune system. Cytokines are proteins produced by the cells of the immune system that determine the actions of the immune system cells. Separate subpopulations of helper T cells produce different types of cytokines and determine whether the immune response will be the production of antibodies or a cell-mediated immune response. Helper T cells also produce **lymphokines**, one category of cytokines (Table 31-2).

Cytotoxic T cells (killer T cells) attack the antigen directly by altering the cell membrane, causing cell lysis (disintegration), and releasing cytolytic enzymes and cytokines. Lymphokines can recruit, activate, and regulate other lymphocytes and WBCs. These cells then assist in destroying the invading organism. Delayed-type hypersensitivity is an example of an immune reaction that protects the body from antigens through the production and release of lymphokines (see later discussion).

Suppressor T cells have the ability to decrease B-cell production, thereby keeping the immune response at a level that is compatible with health (e.g., sufficient to fight infection adequately without attacking the body's healthy tissues). **Memory cells** are responsible for recognizing antigens from previous exposure and mounting an immune response (Table 31-3).

Null Lymphocytes and Natural Killer Cells

Null lymphocytes and NK cells are other lymphocytes that assist in combating organisms. These cells are distinct from B cells and T cells and lack the usual characteristics of those cells. **Null lymphocytes**, a subpopulation of lymphocytes, destroy antigens already coated with antibody. These cells have special receptor sites on their surface that allow them to connect with the end of antibodies; this is known as antibody-dependent, cell-mediated cytotoxicity.

NK cells are a class of lymphocytes that recognize infected and stressed cells and respond by killing these cells and by secreting macrophage-activating cytokine. The helper T cells contribute to the differentiation of null and NK cells.

Complement System

Circulating plasma proteins, known as **complement**, are made in the liver and activated when an antibody connects with its antigen. Complement plays an important role in the defense against microbes. Destruction of an invading or attacking organism or toxin is not achieved merely by the binding of the antibody and antigens; it also requires activation of complement, the arrival of killer T cells, or the attraction of macrophages. Complement has three major physiologic functions: defending the body against bacterial infection, bridging

natural and acquired immunity, and disposing of immune complexes and the by-products associated with inflammation (Klimov, 2019).

The proteins that comprise complement interact sequentially with one another in a cascading effect. The complement cascade is important to modifying the effector arm of the immune system. Activation of complement allows important events, such as removal of infectious agents and initiation of the inflammatory response, to take place. These events involve active parts of the pathway that enhance chemotaxis of macrophages and granulocytes, alter blood vessel permeability, change blood vessel diameters, cause cells to lyse, alter blood clotting, and cause other points of modification. These macrophages and granulocytes continue the body's defense by devouring the antibody-coated microbes and by releasing bacterial products.

The complement cascade may be activated by any of three pathways: classic, lectin, and alternative. The classic pathway is triggered after antibodies bind to microbes or other antigens and is part of the humoral type of adaptive immunity. The lectin pathway is activated when a plasma protein (mannose-binding lectin) binds to terminal mannose residue on the surface glycoproteins of microbes. The alternative pathway is triggered when complement proteins are activated on microbial surfaces. This pathway is part of natural immunity.

Complement components, prostaglandins, leukotrienes, and other inflammatory mediators all contribute to the recruitment of inflammatory cells, as do chemokines, a group of cytokines. The activated neutrophils pass through the vessel walls to accumulate at the site of infection, where they phagocytize complement-coated microbes. This response is usually therapeutic and can be lifesaving if the cell attacked by the complement system is a true foreign invader. However, if that cell is part of the human organism, the result can be devastating disease and even death. Many autoimmune diseases and disorders characterized by chronic infection are thought to be caused in part by continued or chronic activation of complement, which in turn results in chronic inflammation. The RBCs and platelets have complement receptors and, as a result, play an important role in the clearance of immune complexes that consist of antigen, antibody, and components of the complement system (Norris, 2019).

TABLE 31-2 Cytokines of Innate and Adaptive Immunity

Cytokines	Source	Biologic Activity
Interleukin-1 (IL-1)	Macrophages, endothelial cells, some epithelial cells	Wide variety of biologic effects; activates endothelium in inflammation; induces fever and acute-phase response; stimulates neutrophil production
Interleukin-2 (IL-2)	$CD4^+$, $CD8^+$ T cells	Growth factor for activated T cells; induces synthesis of other cytokines; activates cytotoxic T lymphocytes and NK cells
Interleukin-3 (IL-3)	$CD4^+$ T cells	Growth factor for progenitor hematopoietic cells
Interleukin-4 (IL-4)	$CD4^+$ T_H2 cells, mast cells	Promotes growth and survival of T, B, and mast cells; causes T_H2 cell differentiation; activates B cells and eosinophils and induces IgE-type responses
Interleukin-5 (IL-5)	$CD4^+$ T_H2 cells	Induces eosinophil growth and development
Interleukin-6 (IL-6)	Macrophages, endothelial cells, T lymphocytes	Stimulates the liver to produce mediators of acute-phase inflammatory response; also induces proliferation of antibody-producing cells by the adaptive immune system
Interleukin-7 (IL-7)	Bone marrow stromal cells	Primary function in adaptive immunity; stimulates pre-B cells and thymocyte development and proliferation
Interleukin-8 (IL-8)	Macrophages, endothelial cells	Primary function in adaptive immunity; chemoattracts neutrophils and T lymphocytes; regulates lymphocyte homing and neutrophil infiltration
Interleukin-10 (IL-10)	Macrophages, some T-helper cells	Inhibitor of activated macrophages and dendritic cells; decreases inflammation by inhibiting T_H1 cells and release of interleukin-12 from macrophages
Interleukin-12 (IL-12)	Macrophages, dendritic cells	Enhances NK cell cytotoxicity in innate immunity; induces T_H1 cell differentiation in adaptive immunity
Type I interferons (IFN-α, IFN-β)	Macrophages, fibroblasts	Inhibit viral replication, activate NK cells, and increase expression of MHC-I molecules on virus-infected cells
Interferon-γ (IFN-γ)	NK cells, $CD4^+$ and $CD8^+$ T lymphocytes	Activates macrophages in both innate immune responses and adaptive cell–mediated immune responses; increases expression of MHC I and II and antigen processing and presentation
Tumor necrosis factor α (TNF-α)	Macrophages, T cells	Induces inflammation, fever, and acute-phase response; activates neutrophils and endothelial cells; kills cells through apoptosis
Chemokines	Macrophages,	Large family of structurally similar cytokines that

	endothelial cells, T lymphocytes	stimulate leukocyte movement and regulate the migration of leukocytes from the blood to the tissues
Granulocyte–monocyte CSF (GM-CSF)	T cells, macrophages, endothelial cells, fibroblasts	Promotes neutrophil, eosinophil, and monocyte maturation and growth; activates mature granulocytes
Granulocyte CSF (G-CSF)	Macrophages, fibroblasts, endothelial cells	Promotes growth and maturation of neutrophils consumed in inflammatory reactions
Monocyte CSF (M-CSF)	Macrophages, activated T cells, endothelial cells	Promotes growth and maturation of mononuclear phagocytes

CSF, colony-stimulating factor; IgE, immunoglobulin E; MHC, major histocompatibility complex; NK, natural killer; T_H1, T-helper type 1; T_H2, T-helper type 2.

Immunomodulators

Antimicrobial agents and vaccines have yielded considerable therapeutic success and the immune system usually works effectively; however, many infectious diseases remain difficult clinical challenges. Treatment success may be compromised by defects of the immune system; in this case, enhancement of the host immune response may be therapeutically beneficial. An immunomodulator (also known as a biologic response modifier) affects the host via direct or indirect effects on one or more components of the immunoregulatory network. Interferons, colony-stimulating factors, and monoclonal antibodies (MoAbs) are examples of agents used to help enhance the immune system (Davis & Ballas, 2017).

TABLE 31-3 Lymphocytes Involved in Immune Responses

Type of Immune Response	Cell Type	Function
Humoral	B lymphocyte	Produces antibodies or immunoglobulins (IgA, IgD, IgE, IgG, IgM)
Cellular	T lymphocyte	
	Helper T	Attacks foreign invaders (antigens) directly
		Initiates and augments inflammatory response
	Helper T_1	Increases activated cytotoxic T cells
	Helper T_2	Increases B-cell (BG8) antibody production
	Suppressor T	Suppresses the immune response
	Memory T	Remembers contact with an antigen and on subsequent exposures mounts an immune response
	Cytotoxic T (killer T)	Lyses cells infected with virus; plays a role in graft rejection
Nonspecific	Non-T or non–B-lymphocyte null cell	Destroys antigens already coated with antibody
	Natural killer cell (granular lymphocyte)	Defends against microorganisms and some types of malignant cells; produces cytokines

Interferons

Interferon, one type of biologic response modifier, is a nonspecific viricidal protein that is naturally produced by the body and capable of activating other components of the immune system. Interferons continue to be investigated to determine their roles in the immune system and their potential therapeutic effects in disorders characterized by disturbed immune responses. These substances have antiviral and antitumor properties. In addition to responding to viral infection, interferons are produced by T lymphocytes, B lymphocytes, and macrophages in response to antigens. They are thought to modify the immune response by suppressing antibody production and cellular immunity. They also facilitate the cytolytic role of macrophages and NK cells. Interferons are used to treat immune-related disorders (e.g., multiple sclerosis) and chronic inflammatory conditions (e.g., chronic hepatitis). Research continues to evaluate the effectiveness of interferons in treating cancers (Makowska, Braunschweig, Denecke, et al., 2019) and acquired immunodeficiency syndrome.

Colony-Stimulating Factors

Colony-stimulating factors are a group of naturally occurring glycoprotein cytokines that regulate production, differentiation, survival, and activation of hematopoietic cells. Erythropoietin stimulates RBC production. Thrombopoietin plays a key regulatory role in the growth and differentiation of bone marrow cells. Interleukin-5 (IL-5) stimulates the growth and survival of eosinophils and basophils. Stem cell factor and IL-3 serve as stimuli for multiple hematopoietic cell lines. Granulocyte colony-stimulating factor, granulocyte–macrophage colony-stimulating factor, and macrophage colony-stimulating factor all serve as growth factors for specific cell lines. These cytokines have attracted considerable interest for their potential role in immunomodulation (Leleu, Gay, Flament, et al., 2017).

Monoclonal Antibodies

MoAbs have become available through technologic advances, enabling investigators to grow and produce targeted antibodies for specific pathologic organisms. This type of specificity allows MoAbs to destroy pathologic organisms and spare normal cells. The specificity of MoAbs depends on identifying key antigen proteins that are present on the surface of tumors, but not on normal tissues. When the MoAb attaches to the cell surface antigen, it blocks an important signal transduction pathway for communication between the malignant cells and the extracellular environment. The results may include an inability to initiate apoptosis, reproduce, or invade surrounding tissues (Pento, 2017; Singh, Tank, Dwiwedi, et al., 2018).

Advances in Immunology

Important developments in immunology revolve around advances in genetic engineering, use of stem cells, and immunotherapy treatments.

Genetic Engineering

One of the more remarkable evolving technologies is **genetic engineering**, which uses recombinant deoxyribonucleic acid (DNA) technology. Two facets of this technology exist. The first permits scientists to combine genes from one type of organism with genes of a second organism. This type of technology allows cells and microorganisms to manufacture proteins, monokines, and lymphokines, which can alter and enhance immune system function. The second facet of recombinant DNA technology involves gene therapy. If a specific gene is abnormal or missing, experimental recombinant DNA technology may be capable of restoring normal gene function. For example, a recombinant gene is inserted into a virus particle. When the virus particle splices its genes, the virus automatically inserts the missing gene and

theoretically corrects the genetic anomaly. Extensive research into recombinant DNA technology and gene therapy is ongoing (Gonçalves & Paiva, 2017).

Stem Cells

Stem cells are capable of self-renewal and differentiation; they continually replenish the body's entire supply of both RBCs and WBCs. Some stem cells, described as totipotent cells, have tremendous capacity to self-renew and differentiate. Embryonic stem cells, described as pluripotent, give rise to numerous cell types that are able to form tissues. Research has shown that stem cells can restore an immune system that has been destroyed (Haynes et al., 2018). Stem cell transplantation has been carried out in humans with certain types of immune dysfunction, such as severe combined immunodeficiency; clinical trials using stem cells are under way in patients with a variety of disorders having an autoimmune component, including systemic lupus erythematosus, rheumatoid arthritis, scleroderma, and multiple sclerosis. Research with embryonic stem cells has enabled investigators to make substantial gains in developmental biology, gene therapy, therapeutic tissue engineering, and the treatment of a variety of diseases (Haynes et al., 2018).

Cancer and Immunotherapy

It has long been understood that the immune system plays a role in fighting off malignancies. Recent advances in cancer treatment have sought to augment the body's natural antitumor activity and to shut down the pathways that allow malignancies to elude the immune system, which has led to the development of such treatments as MoAbs, cancer vaccines, immune adjuvants, immune checkpoint inhibitors, chimeric antigen receptor (CAR) T-cell therapy and cytokines. These immunotherapeutic treatments are designed to stimulate the patient's immune system to mount its own defense against the cancer and have revolutionized the treatment of many different cancer types. See Chapter 12 for a discussion on the use of immunotherapy in cancer (Gonçalves & Paiva, 2017; Ribas & Wolchok, 2018).

Assessment of the Immune System

An assessment of immune function begins during the health history and physical examination. Areas to be assessed include nutritional status; infections and immunizations; allergies; disorders and disease states, such as autoimmune disorders, cancer, and chronic illnesses; surgeries; medications; and blood transfusions. In addition to inspection of general characteristics,

palpation of the lymph nodes and examinations of the skin, mucous membranes, and respiratory, gastrointestinal, musculoskeletal, genitourinary, cardiovascular, and neurosensory systems are performed (Chart 31-3).

Health History

The history should note the patient's age along with information about past and present conditions and events that may provide clues to the status of the patient's immune system.

Gender

There are differences in the immune system functions of men and women. For example, many autoimmune diseases have a higher incidence in females than in males, a phenomenon believed to be correlated with sex hormones. In the past two decades, research has revealed that sex hormones are integral signaling modulators of the immune system. Sex hormones play definitive roles in lymphocyte maturation, activation, and synthesis of antibodies and cytokines. In autoimmune disease, expression of sex hormones is altered, and this change contributes to immune dysregulation (Rainville, Tsyglakova, & Hodes, 2018).

Gerontologic Considerations

Immunosenescence is the term for age-related changes in the immune system. These changes have been linked to the increased rates of illness and mortality in older adults (Tariq, Hazeldine, & Lord, 2017). Some of the changes that occur in immunosenescence include, but are not limited to, bone marrow defects, dysfunction of the thymus gland, and impaired lymphocytes. Cellular changes occur as the result of aging and include impaired neutrophil function, decreased circulating macrophages, impaired dendritic cell function, and reduced T-cell activation. As the immune system undergoes age-associated alterations, its response to infections progressively deteriorates. The capacity for self-renewal of hematopoietic stem cells diminishes. There is a notable decline in the total number of phagocytes, coupled with an intrinsic reduction in their activity. The cytotoxicity of NK cells decreases, contributing to a decline in humoral immunity (Tariq et al., 2017). Inflammatory cytokines also tend to increase with age. Acquired immunity may be negatively affected as the efficacy of vaccines is frequently decreased in older adults (Smetana, Chlibek, Shaw, et al., 2018).

Chart 31-3 ASSESSMENT

Assessing for Immune Dysfunction

Be alert for the following signs and symptoms:

Respiratory System

- Changes in respiratory rate
- Cough (dry or productive)
- Abnormal lung sounds (wheezing, crackles, rhonchi)
- Rhinitis
- Hyperventilation
- Bronchospasm

Cardiovascular System

- Hypotension
- Tachycardia
- Arrhythmia
- Vasculitis
- Anemia

Gastrointestinal System

- Hepatosplenomegaly
- Colitis
- Vomiting
- Diarrhea

Genitourinary System

- Frequency and burning on urination
- Hematuria
- Discharge

Musculoskeletal System

- Joint mobility, edema, and pain

Skin

- Rashes
- Lesions
- Dermatitis
- Hematomas or purpura
- Edema or urticaria
- Inflammation
- Discharge

Neurosensory System

- Cognitive dysfunction
- Hearing loss
- Visual changes
- Headaches and migraines
- Ataxia
- Tetany

Older adults have an increased incidence of infections, autoimmune diseases, metabolic diseases, osteoporosis, and neurologic disorders (Eliopoulos, 2018; Tariq et al., 2017). The increased incidence of autoimmune diseases may be from a decreased ability of antibodies to differentiate between self and non-self. Failure of the surveillance system to recognize mutant or abnormal cells may also be responsible, in part, for the high incidence of cancer associated with increasing age.

Age-related changes in many body systems also contribute to impaired immunity (Table 31-4). For example, postmenopausal females are at a greater risk for urinary tract infections due to residual urine, urinary incontinence, and estrogen deficiency (Jung & Brubaker, 2019). Secondary changes, including malnutrition and poor circulation, as well as the breakdown of natural mechanical barriers such as the skin, place the aging immune system at even greater disadvantage against infection (Tariq et al., 2017).

The effects of the aging process and psychological stress interact, with the potential to negatively influence immune integrity (Gidron, 2019). Consequently, continual assessment of the physical and emotional status of older adults is imperative, because early recognition and management of factors influencing immune response may prevent or mitigate the high morbidity and mortality seen with illness in the older adult population.

Nutrition

Nutritional status is a key determinant of health. Traditionally, the relationship between infection and nutrition focused on the effect of nutrients on host defenses and the effect of infection on nutritional needs (Yaqoob, 2017). This has expanded in scope to encompass the role of specific nutrients in acquired immune function—the modulation of inflammatory processes and the virulence of the infectious agent itself (Lang & Aspinall, 2017). Iron and the immune system are linked in homeostasis and pathology, thus making it essential for maximum function (Martins, Almeida, Lima, et al., 2017). The list of nutrients affecting infection, immunity, inflammation, and cell injury has expanded from traditional proteins to several vitamins, multiple minerals, and, more recently, specific lipid components of the diet. The role of micronutrients and fatty acids on the response of cells and tissues to hypoxic and toxic

damage has been recognized, suggesting that there is another dimension to the relationship. Deficiencies in micronutrients have been connected to impairment in various body functions, including immunity (Carr & Maggini, 2017; Mikkelsen & Apostolopoulos, 2018). Zinc deficiency in particular has been linked to the development of a number of diseases. Zinc plays an important role in homeostasis, immune function, and apoptosis, among other functions (Wessels, Maywald, & Rink, 2017).

TABLE 31-4 Age-Related Changes in Immunologic Function

Body System	Changes	Consequences
Immune	Impaired function of B and T lymphocytes Failure of lymphocytes to recognize mutant or abnormal cells Decreased antibody production Failure of immune system to differentiate "self" from "non-self" Suppressed phagocytic immune response	Suppressed responses to pathogenic organisms with increased risk for infection Increased incidence of cancers Anergy (lack of response to antigens applied to the skin [allergens]) Increased incidence of autoimmune diseases Absence of typical signs and symptoms of infection and inflammation Dissemination of organisms usually destroyed or suppressed by phagocytes (e.g., reactivation or spread of tuberculosis)
Gastrointestinal	Decreased gastric secretions and motility Decreased phagocytosis by the liver's Kupffer cells Altered nutritional intake with inadequate protein intake	Proliferation of intestinal organisms resulting in gastroenteritis and diarrhea Increased incidence and severity of hepatitis B; increased incidence of liver abscesses Suppressed immune response
Urinary	Decreased kidney function and changes in lower urinary tract function (enlargement of prostate gland, neurogenic bladder); altered genitourinary tract flora	Urinary stasis and increased incidence of urinary tract infections
Pulmonary	Impaired ciliary action due to exposure to smoke and environmental toxins	Impaired clearance of pulmonary secretions; increased incidence of respiratory infections
Integumentary	Thinning of skin with less elasticity; loss of adipose tissue	Increased risk of skin injury, breakdown, and infection
Circulatory	Impaired microcirculation	Stasis and pressure injuries
Neurologic function	Decreased sensation and slowing of reflexes	Increased risk of injury, skin ulcers, abrasions, and burns

Adapted from Eliopoulos, C. (2018). *Gerontological nursing* (9th ed.). Philadelphia, PA: Wolters Kluwer.

The effects exerted by polyunsaturated fatty acids on immune system functions are under investigation. Studies suggest that these elements play a role in diminishing the incidence and severity of inflammatory disorders. Research suggests that diets high in olive oil are not as immunosuppressive as diets rich in fish oil. The contribution of immune modulation by lipids to the high risk of infectious complications associated with the use of parenteral nutrition is unclear (Raman, Almutairdi, Mulesa, et al., 2017).

Depletion of protein reserves results in atrophy of lymphoid tissues, depression of antibody response, reduction in the number of circulating T cells, and impaired phagocytic function. As a result, susceptibility to infection is greatly increased. During periods of infection or serious illness, nutritional requirements may be further altered, potentially contributing to depletion of protein, fatty acid, vitamin, and trace elements and causing even greater risk of impaired immune response and sepsis (Wischmeyer, 2018). Nutritional intake that supports a competent immune response plays an important role in reducing the incidence of infections (Shlisky, Bloom, Beaudreault, et al., 2017); patients whose nutritional status is compromised have a delayed postoperative recovery and often experience more severe infections and delayed wound healing. There is evidence that nutrition plays a role in the development of cancer and that diet and lifestyle can alter the risk of cancer development as well as other chronic diseases (Theodoratou, Timofeeva, Li, et al., 2017). The nurse must assume a proactive role in ensuring the best possible nutritional intake for all patients as a vital step in preventing disease and poor outcomes. The nurse must assess the patient's nutritional status, caloric intake, and quality of foods ingested (see Chapter 4 for further discussion of nutritional assessment).

Immunization

The patient is asked about childhood and adult immunizations, including vaccinations to provide protection against influenza, pneumococcal diseases, herpes zoster, pertussis, and the usual childhood diseases (e.g., measles, mumps). Education about the importance of adhering to the recommended schedule for adult vaccines should be initiated. See Chapter 3, Table 3-3: Select Health Promotion Screening for Adults for more information about adult immunizations.

Infection

A history of past and present infections and the dates and types of treatments, along with a history of any multiple persistent infections, fevers of unknown origin, lesions or sores, or any type of drainage, as well as the response to treatment, are obtained.

Known past or present exposure to tuberculosis is assessed, and the dates and results of any tuberculin tests (purified protein derivative [PPD] test) and chest x-rays are documented. Recent exposure to any infections, recent travel, and dates are elicited. The nurse must assess whether the patient has been exposed to any sexually transmitted infections (STIs) or bloodborne pathogens such as hepatitis B, C, and D viruses and human immune deficiency virus (HIV). A history of STIs such as gonorrhea, syphilis, human papillomavirus infection, and chlamydia can alert the nurse that the patient may have been exposed to HIV or hepatitis. Herpes simplex virus infections have a significant impact on health, causing a wide range of diseases (e.g., oral and genital herpes).

Allergy

The patient is asked about any allergies, including types of allergens (e.g., pollens, dust, plants, cosmetics, food, medications, vaccines, latex), the symptoms experienced, and seasonal variations in occurrence or severity in the symptoms. A history of testing and treatments, including prescribed and over-the-counter medications that the patient has taken or is currently taking for these allergies and the effectiveness of the treatments, is obtained. All medication and food allergies are listed on paper records with an allergy alert sticker or within the patient's electronic health record (EHR) to make others aware of these allergies. Continued assessment for potential allergic reactions in the patient is vital. See Chapter 33 for more information on allergies.

Disorders and Diseases

Part of the focused immunologic assessment includes determining whether the patient has a history of autoimmune disorders, neoplasms, chronic illnesses, surgeries, or any recent major stressors that may place the patient at increased risk.

Autoimmune Disorders

Autoimmune disorders affect people of both genders of all ages, ethnicities, and social classes. Autoimmune disorders are a group of disorders that can affect almost any cell or tissue in the body (Norris, 2019). As mentioned previously, they tend to be more common in women because estrogen tends to enhance immunity. Androgen, on the other hand, tends to be immunosuppressive. Autoimmune diseases are a leading cause of death by disease in females of reproductive age.

The patient is asked about any autoimmune disorders, such as lupus erythematosus, rheumatoid arthritis, multiple sclerosis, or psoriasis. The onset, severity, remissions and exacerbations, functional limitations, treatments that the patient has received or is currently receiving, and effectiveness of the

treatments are described. Certain autoimmune diseases appear to be genetically linked, so a family history of these is important (Generali, Ceribelli, Stazi, et al., 2017) (Chart 31-4).

Neoplastic Disease

If there is a history of cancer in the family, more information is obtained, including the type of cancer, age at onset, and relationship (maternal or paternal) of the patient to the affected family members. Dates and results of any cancer screening tests for the patient are documented.

A history of cancer in the patient is also obtained, along with the type of cancer, date of diagnosis, and treatment modalities used. Immunosuppression contributes to the development of cancers; however, cancer itself is immunosuppressive, as are many treatments for cancer. Large tumors can release antigens into the blood, and these antigens combine with circulating antibodies and prevent them from attacking the tumor cells. Furthermore, tumor cells may possess special blocking factors that coat tumor cells and prevent their destruction by killer T lymphocytes. During the early development of tumors, the body may fail to recognize the tumor antigens as foreign and subsequently fail to initiate destruction of the malignant cells. Hematologic cancers, such as leukemia and lymphoma, are associated with altered production and function of WBCs and lymphocytes.

Chart 31-4 **GENETICS IN NURSING PRACTICE**

Immunologic Disorders

An immunologic disorder is a disorder of a person's immune system, which is a network of cells, tissues, and organs that work together to defend the body against attacks by foreign invaders such as bacteria, parasites, and fungi that can cause infection. A number of immunologic disorders have a known inheritance pattern, while others are noted to have a genetic abnormality that is influenced by environmental exposures. Therefore, the pattern of inheritance is unclear in some immunologic disorders. Examples of immunologic disorders caused by a genetic abnormality include:

- Adenosine deaminase deficiency (autosomal recessive)
- Alopecia areata
- Alopecia totalis
- Asthma
- Ataxia telangiectasia (autosomal recessive)
- Autoimmune polyglandular syndrome
- Bruton agammaglobulinemia (X-linked)
- Burkitt lymphoma
- Crohn's disease
- Diabetes, type 1
- DiGeorge syndrome (Autosomal dominant)
- Familial Mediterranean fever
- Job syndrome (autosomal dominant and recessive)
- Purine nucleoside phosphorylase deficiency (autosomal dominant)
- Severe combined immunodeficiency (primarily X-linked)
- Wiskott–Aldrich syndrome (X-linked)

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Immunologic Disorders

- Collect a family history for both maternal and paternal relatives for three generations.
- Assess family history for other family members with histories of immunologic disorders.
- Obtain information about family members with a history of recurrent infections or illness.
- Recognize ethnic risk (non-Ashkenazi Jewish, Armenian, Arab, and Turkish are at greater risk for familial Mediterranean fever; Caucasians have a higher incidence of Crohn's disease)

Patient Assessment

- Assess for symptoms such as changes in respiratory status associated with asthma (e.g., wheezing, or airway hyperresponsiveness; mucosal edema; and mucus production).
- Gather information regarding immunizations and whether an altered response to any immunization has occurred.
- Assess for symptoms of immunodeficiency disorders, such as unexplained weight gain or loss, skin rashes, changes in hair texture or distribution, joint or muscle pain, intolerance to cold, irregular menstrual periods, abdominal discomfort, or the presence of diarrhea.
- Identify pattern of sickness with regard to frequency of colds, respiratory infections, or history of illness that tends to linger.
- Obtain history of childhood illnesses and details of the illness experience.
- Assess for medical history of frequent or recurrent infections.
- Learn about susceptibility to infections, assess for patterns (frequency, length of illness, severity of symptoms), and recognize infections that would be atypical for age.
- Inquire about environmental exposures (e.g., smoke, chloroform, metal or dust particles, paint).
- Ask about exposure to other viruses such as Epstein–Barr or Influenza.

See Chapter 6, Chart 6-7 for components of genetic counseling.

All treatments that the patient has received or is currently receiving, such as radiation, chemotherapy, and immunotherapy, are recorded in the health history. In addition, the nurse should elicit information related to complementary or alternative modalities that have been used and the response to these efforts. Radiation destroys lymphocytes and decreases the ability to mount an effective immune response. The size and extent of the irradiated area determine the extent of immunosuppression. Whole-body irradiation may leave the patient completely immunosuppressed. Chemotherapy and other cancer treatments also affect bone marrow function, destroying cells that contribute to an effective immune response and resulting in immunosuppression. Immunotherapy can cause inflammatory overreactions of the immune system that mimic autoimmune disorders (Kroschinsky, Stolzel, von Bonin, et al., 2017; Munro, 2019).

Chronic Illness and Surgery

The health assessment includes a history of chronic illness, particularly diabetes, renal disease, or chronic obstructive pulmonary disease (COPD). The

onset and severity of illnesses, as well as treatment that the patient is receiving for the illness, are obtained. Chronic illness may contribute to immune system impairments in various ways. Kidney injury is associated with a deficiency in circulating lymphocytes. In addition, immune defenses may be altered by acidosis and uremic toxins. In diabetes, an increased incidence of infection has been associated with vascular insufficiency, neuropathy, and poor control of serum glucose levels. Recurrent respiratory tract infections are associated with COPD due to altered inspiratory and expiratory function and ineffective airway clearance. In addition, a history of organ transplantation or surgical removal of the spleen, lymph nodes, or thymus should be noted, because these conditions may place the patient at risk for impaired immune function (Bagatini, Cardoso, dos Santos, et al., 2017; Dionne, Dehority, Brett, et al., 2017).

Special Problems

Conditions such as burns and other forms of injury and infection may contribute to altered immune system function. Major burns cause impaired skin integrity and compromise the body's first line of defense. Loss of large amounts of serum occurs with burn injuries and depletes the body of essential proteins, including immunoglobulins.

The physiologic and psychological stressors associated with surgery or injury stimulate cortisol release from the adrenal cortex; increased serum cortisol also contributes to suppression of normal immune responses. The immune system's inflammatory response to surgery is followed by an anti-inflammatory compensatory response, and it is thought that these responses may contribute to postoperative complications (Cerra, 2018).

Patients who have had an ischemic stroke or transient ischemic attack (TIA) are at risk for infection following the event. Evidence suggests that an acute stroke leads to immunosuppression and a subsequently high infection risk; infection is the leading cause of death following a stroke (Hoffmann, Harms, Ulm, et al., 2017). Stroke-induced immunosuppression is linked to the development of stroke-associated pneumonia, which is the most common infection seen in patients who have had a stroke (Liu, Chu, Chen, et al., 2018).

Medications and Blood Transfusions

A list of past and present medications is obtained. In large doses, antibiotics, corticosteroids, cytotoxic agents, salicylates, nonsteroidal anti-inflammatory drugs, and anesthetic agents can cause immune suppression (Table 31-5).

A history of blood transfusions is obtained; previous exposure to foreign antigens through transfusion may be associated with abnormal immune function. In addition, although the risk of HIV transmission through blood transfusion is extremely low in patients who received a transfusion after 1985

(when testing of blood for HIV was initiated in the United States), a small risk remains.

The patient is also asked about the use of herbal agents and over-the-counter medications. Because many herbal agents have not been subjected to rigorous testing, their effects have not been fully identified. It is important, therefore, to ask patients about their use of these substances, to document their use, and to educate patients about untoward effects that may alter immune responsiveness.

Lifestyle Factors

Personal lifestyle choices have an impact on the immune system. Poor nutritional intake, smoking (Qiu, Liang, Liu, et al., 2017), excessive consumption of alcohol (Rehm, Gmel, Gmel, et al., 2017), illicit drug use, and occupational or residential exposure to environmental radiation and pollutants have been associated with impaired immune function and are assessed in a detailed patient history. Although factors that are not consistent with a healthy lifestyle are predominately responsible for ineffective immune function, positive lifestyle factors can also negatively affect immune function and require assessment. For example, rigorous exercise or competitive exercise—usually considered a positive lifestyle factor—can be a physiologic stressor and cause negative effects on immune response (Aoi & Naito, 2019; Shaw, Merien, Braakhuis, et al., 2018).

TABLE 31-5 Select Medications and Effects on the Immune System

Drug Classification (and Examples)	Effects on the Immune System
Antibiotics (in Large Doses)	**Bone Marrow Suppression**
ceftriaxone	Eosinophilia, hemolytic anemia, hypoprothrombinemia, neutropenia, thrombocytopenia
cefuroxime sodium	Eosinophilia, hemolytic anemia, hypoprothrombinemia, neutropenia, thrombocytopenia
chloramphenicol	Leukopenia, aplastic anemia
dactinomycin	Agranulocytosis, neutropenia
fluoroquinolones (ciprofloxacin, levofloxacin)	Hemolytic anemia, methemoglobinemia, eosinophilia, leukopenia, pancytopenia
gentamicin sulfate	Agranulocytosis, granulocytosis
macrolides (erythromycin, azithromycin, clarithromycin)	Neutropenia, leukopenia
penicillins	Agranulocytosis
streptomycin	Leukopenia, neutropenia, pancytopenia
vancomycin	Transient leucopenia
Antithyroid Drugs	
propylthiouracil	Agranulocytosis, leukopenia
Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) (in Large Doses)	**Inhibit Prostaglandin Synthesis or Release**
aspirin	Agranulocytosis
COX-2 inhibitors (celecoxib)	Anemia, allergy, no other major adverse effects
ibuprofen	Leukopenia, neutropenia
indomethacin	Agranulocytosis, leukopenia
phenylbutazone	Pancytopenia, agranulocytosis, aplastic anemia
Adrenal Corticosteroids	**Immunosuppression**
prednisone	
Antineoplastic Agents (cytotoxic agents)	**Immunosuppression**
cyclophosphamide	Leukopenia, neutropenia
cisplatin	Leukopenia
cyclosporine	Leukopenia, inhibits T-lymphocyte function
Antimetabolites	**Immunosuppression**
pyrimidine antagonist	Leukopenia, eosinophilia
folic acid antagonist	Leukopenia, aplastic bone marrow
purine antagonist	Leukopenia, pancytopenia

COX, cyclo-oxygenase.

Psychoneuroimmunologic Factors

The bidirectional pathway between the brain and immune system (the mind–body system) is referred to as psychoneuroimmunology. Patient assessment must also address psychoneuroimmunologic factors, such as stress and psychological illness, that may be influencing the patient's health. The immune response is regulated and modulated in part by neuroendocrine influences. Lymphocytes and macrophages have receptors that can respond to neurotransmitters and endocrine hormones. Lymphocytes can produce and secrete adrenocorticotropic hormone and endorphinlike compounds. Cells in the brain, especially in the hypothalamus, can recognize prostaglandins, interferons, and interleukins, as well as histamine and serotonin, all of which are released during the inflammatory process. Like all other biologic systems functioning to maintain homeostasis, the immune system is integrated with other psychophysiologic processes and is regulated and modulated by the brain. These relationships may have immunologic consequences (Lasselin, Schedlowski, Lekander, et al., 2019).

Growing evidence indicates that a measurable immune system response can be positively influenced by biobehavioral strategies such as relaxation, imagery techniques, biofeedback, humor, hypnosis, mindfulness-based strategies, and yoga (Park & Han, 2017; Pascoe, Thompson, & Ski, 2017; Reich, Lengacher, Klein, et al., 2017). Therefore, the assessment should address the patient's general psychological status and the patient's use of and response to these strategies. See the Nursing Research Profile in Chart 31-5.

Physical Assessment

During the physical examination (see Chart 31-3), the skin and mucous membranes are assessed for lesions, dermatitis, purpura (subcutaneous bleeding), urticaria, inflammation, or any discharge. Any signs of infection are noted. The patient's temperature is recorded, and the patient is observed for chills and sweating. The anterior and posterior cervical, supraclavicular, axillary, and inguinal lymph nodes are palpated for enlargement; if palpable nodes are detected, their location, size, consistency, and reports of tenderness on palpation are noted. Joints are assessed for tenderness, swelling, increased warmth, and limited range of motion. The patient's respiratory, cardiovascular, genitourinary, gastrointestinal, and neurosensory systems are evaluated for signs and symptoms indicative of immune dysfunction. Any functional limitations or disabilities the patient may have are also assessed.

Diagnostic Evaluation

A series of blood tests and skin tests, as well as bone marrow biopsy, may be performed to evaluate the patient's immune competence. Specific laboratory and diagnostic tests are discussed in greater detail along with individual disease processes in subsequent chapters in this unit. Select laboratory and diagnostic tests used to evaluate immune competence are summarized in Chart 31-6.

Nursing Management

The nurse needs to be aware that patients undergoing evaluation for possible immune system disorders experience not only physical pain and discomfort with certain types of diagnostic procedures but also many psychological reactions. It is the nurse's role to counsel, educate, and support patients throughout the diagnostic process. Many patients may be extremely anxious about the results of diagnostic tests and the possible implications of those results for their future health, employment, and personal relationships. This is an ideal time for the nurse to provide counseling and education, should these interventions be warranted.

Chart 31-5 NURSING RESEARCH PROFILE

Stress Reduction and Effect on Inflammatory Cytokines

Reich, R. R., Lengacher, C. A., Klein, T. W., et al. (2017). A randomized controlled trial of the effects of mindfulness-based stress reduction (MBSR[BC]) on levels of inflammatory biomarkers among recovering breast cancer survivors. *Biological Research for Nursing*, *19*(4), 456–464.

Purpose

The purpose of this study was to evaluate the efficacy of the Mindfulness-Based Stress Reduction (Breast Cancer) (MBSR[BC]) program versus usual care in normalizing blood levels of proinflammatory cytokines among breast cancer survivors.

Design

This was a substudy of a large randomized controlled trial. A total of 322 participants were randomized to a 6-wk MBSR(BC) program or usual care. Blood samples, demographic data (age, race, and ethnicity), and clinical data (disease stage and treatments) were collected at baseline, 6 wks, and 12 wks. Plasma cytokines (IL-1β, IL-6, IL-10), tumor necrosis factor α (TNF-α), transforming growth factor β1, and soluble tumor necrosis factor receptor 1 (sTNFR1) were assayed. Linear mixed models were used to assess the cytokine levels across the three time points by group.

Findings

Three of the cytokines were not detectable and thus not analyzed further. For the remaining cytokines (TNF-α, IL-6, sTNFR1), TNFα and IL-6 increased during the follow-up period between 6 and 12 wks, but not during the MBSR(BC) training period (baseline to 6 wks). The sTNFR1 levels did not change across the 12-wk study period significantly. The s cytokines TNF-α and IL-6 may be markers for recovery.

Nursing Implications

Patients recovering from cancer treatment are at increased risk for infections and increased levels of psychological distress. Stress reducing activities and programs such as the 2 h per wk mindfulness program can be implemented in clinical practice as part of an interdisciplinary approach to cancer care. Nurses should advise patients that the programs may not take effect immediately; in fact, some of the increases in cytokine levels were not seen until 6 wks after the program ended.

Chart 31-6

Select Tests for Evaluating Immunologic Status

Various laboratory tests may be performed to assess immune system activity or dysfunction. The studies assess leukocytes and lymphocytes, humoral immunity, cellular immunity, phagocytic cell function, complement activity, hypersensitivity reactions, specific antigen–antibodies, or human immune deficiency virus infection.

Humoral (Antibody-Mediated) Immunity Tests

- B-cell quantification with monoclonal antibody
- In vivo immunoglobulin synthesis with T-cell subsets
- Specific antibody response
- Total serum globulins and individual immunoglobulins (electrophoresis, immunoelectrophoresis, single radial immunodiffusion, nephelometry, and isohemagglutinin techniques)

Cellular (Cell-Mediated) Immunity Tests

- Total lymphocyte count
- T-cell and T-cell subset quantification with monoclonal antibody
- Delayed hypersensitivity skin test
- Cytokine production
- Lymphocyte response to mitogens, antigens, and allogeneic cells
- Helper and suppressor T-cell functions

CRITICAL THINKING EXERCISES

1 pq You are caring for an 80-year-old woman who is admitted to a long-term care facility after having a stroke. What potential immunity-related complications do you need to be aware of for this patient? What are your priority nursing observations and assessments? Identify priorities for this patient's care given her recent stroke.

2 ebp A 40-year-old woman with melanoma is being treated with immunotherapy and is admitted to your hospital for treatment-related pneumonitis. She is prescribed high-dose corticosteroids for treatment of the pneumonitis. The patient has asked you to explain what is happening to her and why this has occurred. How will you educate her and her family about her current condition? Develop an evidence-based education plan for the patient and her family. Discuss the criteria used to assess the strength of the evidence for your education plan.

3 ipc A 35-year-old pregnant woman with systemic lupus erythematosus (SLE) presents with an acute flare-up of her symptoms. How might psychosocial and emotional factors impact her health? What interdisciplinary referrals would you anticipate for this patient's care?

32 Management of Patients with Immune Deficiency Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Identify the pathophysiology, clinical manifestations, and nursing management of patients with primary immune deficiency disorders.
2. Describe the modes of transmission of human immune deficiency virus infection and prevention strategies.
3. Explain the pathophysiology associated with the clinical manifestations of human immune deficiency virus and acquired immune deficiency syndrome and the purpose of antiretroviral therapy.
4. Use the nursing process as a framework for care of the patient with human immune deficiency virus/acquired immune deficiency syndrome.
5. Identify available resources for patients and support systems to promote self-management of immune deficiency disorders.

NURSING CONCEPTS

Family
Immunity
Infection
Nutrition

GLOSSARY

candidiasis: fungal infection, usually of skin or mucous membranes, caused by Candida species

enzyme immunoassay (EIA): a blood test that can determine the presence of antibodies to HIV in the blood or saliva; a variant of this test is called enzyme-linked immunosorbent assay (ELISA)

HIV-1: retrovirus isolated and recognized as the etiologic agent of HIV disease

HIV encephalopathy: clinical syndrome characterized by a progressive decline in cognitive, behavioral, and motor functions

immune reconstitution inflammatory syndrome (IRIS): a syndrome that results from rapid restoration of pathogen-specific immune responses to opportunistic infections

Kaposi sarcoma: malignancy that involves the epithelial layer of blood and lymphatic vessels

latent reservoir: the integrated HIV provirus within the $CD4^+$ T cell during the resting memory state; does not express viral proteins and is invisible to the immune system and antiviral medications

***Mycobacterium avium* complex (MAC):** opportunistic infection caused by mycobacterial organisms that commonly causes a respiratory illness but can also infect other body systems

opportunistic infection: illness caused by various organisms, some of which typically do not cause disease in people with normal immune systems

peripheral neuropathy: disorder characterized by sensory loss, pain, muscle weakness, and wasting of muscles in the hands or legs and feet

***Pneumocystis* pneumonia (PCP):** common opportunistic lung infection; pathogen implicated is *Pneumocystis jirovecii*

polymerase chain reaction (PCR): a sensitive laboratory technique that can detect and quantify HIV in a person's blood or lymph nodes

post-exposure prophylaxis (PEP): taking antiretroviral medicines as soon as possible, but no more than 72 hours (3 days) after possible HIV exposure; two to three drugs are usually prescribed which must be taken for 28 days

pre-exposure prophylaxis (PrEP): prevention method for HIV-negative people who are at high risk of HIV infection; involves taking a specific combination of HIV medicines daily; use with condoms and other prevention tools

primary immune deficiency diseases (PIDDs): rare, genetic disorders that impair the immune system

progressive multifocal leukoencephalopathy: opportunistic infection that infects brain tissue and causes damage to the brain and spinal

cord

retrovirus: a virus that carries genetic material in ribonucleic acid (RNA) instead of DNA and contains reverse transcriptase

viral load test: measures the quantity of HIV RNA or DNA in the blood

viral set point: amount of virus present in the blood after the initial burst of viremia and the immune response that follows

wasting syndrome: involuntary weight loss consisting of both lean and fat body mass

The human immune system is complex and multidimensional. It works to protect against invasion by foreign substances, protect against the proliferation of neoplastic cells, and plays a key role in inflammation and healing. Patients with primary or secondary immune system disorders (Norris, 2019) require care from nurses who are knowledgeable about the pathophysiology, diagnostic procedures, and interventions that are used in the management of these disorders.

PRIMARY IMMUNE DEFICIENCIES DISEASES

The majority of **primary immune deficiency diseases** (**PIDDs**), rare inherited disorders that impair the immune system, are commonly diagnosed in infancy, with a male-to-female ratio of 5 to 1. However, some PIDDs are not diagnosed until adolescence or early adulthood, when the gender distribution equalizes. Diagnosis at this stage frequently is confounded by frequent use of antibiotics that mask symptoms. Adults may present with clinical episodes of infectious diseases beyond the scope of normal immunocompetence, such as infections that are unusually persistent, recurrent, or resistant to treatment and that involve unexpected dissemination of disease or atypical pathogens. These rare inherited disorders not only lead to frequent infections, but also to increased risk of autoimmune disorders and malignancy (Hajjar, Guffey, Minard, et al., 2017).

Pathophysiology

There are more than 200 forms of PIDDs affecting about 500,000 people in the United States, and more than 270 different genes are associated with PIDDs. These rare genetic diseases prevent the body from developing normal immune responses resulting in a complex group of disorders with a wide array of clinical presentations. Many present during the first year of life and may be chronic, debilitating, and costly (National Institute of Allergy and Infectious Diseases [NIAID], 2019a).

Clinical Manifestations

Major signs and symptoms include multiple infections despite aggressive treatment, infections with unusual or opportunistic organisms, failure to thrive or poor growth, and a significant family history. Fatigue was reported in 18% of patients with PIDDs (Hajjar et al., 2017). See Table 32-1 for select PIDDs along with some of their clinical manifestations.

Assessment and Diagnostic Findings

There is often a considerable delay between the onset of symptoms and time of diagnosis of PIDDs. Because of the genetic origins of PIDDs, family history should be carefully assessed but epidemiologic data about specific infectious agents should be considered as well.

Laboratory tests are used to identify antibody deficiencies, cellular (T-cell) defects, neutrophil disorders, and complement deficiencies. A complete blood cell count with manual differential should always be analyzed first. Lymphopenia may indicate an immunologic abnormality; serum Ig levels (IgG, IgM, and IgA) and antibody responses to vaccines should be assessed to detect a humoral immune defect. Age-matched normal ranges need to be used since antibody levels change as the person ages (Fischbach & Fischbach, 2018).

Prevention

Live vaccines are contraindicated in patients with antibody deficiency disorders. The patient is incapable of generating antibodies and the live substance in the vaccine can cause disease. Family planning should be addressed in terms of future pregnancies; in some situations, prenatal in utero testing of a fetus can determine whether the infant will be affected.

Medical Management

A pattern of unusually frequent, opportunistic, or severe infections generates the possibility of a PIDD and initial testing or referral to an immunologist. Patients with neutropenia are at increased risk for developing severe infections despite substantial advances in supportive care. Epidemiologic shifts occur periodically and must be detected early because they influence prophylactic, empiric, and specific strategies for medical management. Attention to infection control practices is important, especially with the emergence of multidrug-resistant organisms.

Hematopoietic stem cell transplantation (HSCT) is a curative modality. The stem cells may be from embryos or adults. Toxicity and reduced efficacy are

frequent limitations of HSCT. See Chapter 12 for further discussion of HSCT.

Another therapy involves the use of cells as vehicles for the delivery of genes or gene products. Gene therapy has had many adverse effects; the first studies in human participants revealed numerous toxicities with this therapy. Rapidly emerging new technologies allowing precise DNA targeting may prove to be a useful approach (McDermott & Murphy, 2019).

Pharmacologic Therapy

Pharmacologic treatment depends upon the type and severity of presenting infection and the particular PIDD diagnosis. Prophylactic drug treatment prevents some bacterial and fungal infections but it must be used with caution because it has been implicated in the emergence of resistant organisms. The choices for empiric therapy include combination regimens and monotherapy. Specific choices depend on local factors (epidemiology, susceptibility/resistance patterns, availability, cost). Patients with antibody deficiencies receive regular Ig replacement therapy including both IV immunoglobulin (IVIG) and subcutaneous immunoglobulin (SCIG) to provide functional antibodies (Stonebraker, Hajjar, & Orange, 2018; Vitiello, Emmi, Silvestri, et al., 2019).

TABLE 32-1 Select Primary Immune Deficiency Disorders (PIDDs)

Disorder	Characteristics
Autoimmune lymphoproliferative syndrome (ALPS)	Unusually high numbers of lymphocytes accumulate in the lymph nodes, liver, and spleen leading to enlargement of those organs. Causes numerous autoimmune problems including low levels of red blood cells, platelets, and neutrophils that can increase the risk of infection and hemorrhage.
Autoimmune polyglandular syndrome type 1 (APS-1) (also called autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy [APECED])	Causes a diverse range of symptoms, including autoimmunity against different types of organs and increased susceptibility to candidiasis, a fungal infection caused by *Candida* yeast.
CARD9 Deficiency and other syndromes of susceptibility to candidiasis	Results in susceptibility to fungal infections such as candidiasis; particularly susceptible to Candida infections of the central nervous system.
Chronic granulomatous disease (CGD)	May be caused by mutations in one of five different genes. Phagocytes are unable to kill certain bacteria and fungi resulting in increased susceptibility to infections.
Common variable immunodeficiency (CVID)	Caused by a variety of genetic abnormalities resulting in defective ability of immune cells to produce normal amounts of antibodies, resulting in frequent bacterial or viral infections of the upper airway, sinuses, and lungs.
Congenital neutropenia syndromes	Characterized by low levels of neutrophils from birth.
CTLA4 Deficiency	Autoimmunity, low levels of antibodies, and excessive numbers of lymphocytes which infiltrate the gut, lungs, bone marrow, central nervous system, kidneys resulting in recurrent infections.
DOCK8 Deficiency	Lower-than-normal numbers of immune cells, which have a diminished capacity to move through dense tissues like the skin leading to recurrent viral infections of the skin and respiratory system.
GATA2 Deficiency	Characterized by immune deficiency, lung disease, problems of the vascular and lymphatic systems, and myelodysplastic syndrome (a condition characterized by ineffective blood cell production).
Glycosylation disorders with immune deficiency	Defects in glycosylation, which refers to the attachment of sugars to proteins; can disrupt the immune system resulting in immune deficiency.
Hyper-immunoglobulin E syndrome (HIES)	A rare primary immune deficiency disease characterized by eczema, recurrent staphylococcal skin abscesses, recurrent lung infections, eosinophilia (a high number of eosinophils in the blood) and high serum levels of IgE.

Hyper-immunoglobulin M (hyper-IgM) syndromes	Immune system fails to produce normal IgA, IgG, and IgE antibodies but can produce normal or elevated IgM.
Interferon gamma, interleukin 12, interleukin 23 deficiencies	Interferon gamma, interleukin 12, and interleukin 23 are key signals that raise alert against bacteria and other infectious microbes; deficiencies result in susceptibility to infections caused by bacteria and viruses.
Leukocyte adhesion deficiency (LAD)	Phagocytes are unable to move to the site of an infection resulting in an inability to fight pathogens resulting in recurrent, life-threatening infections and poor wound healing.
PI3 Kinase disease	Genetic mutations overactivate an important immune signaling pathway causing a change reaction that disrupts the infection-fighting B and T cells resulting in a weakened immune system and frequent bacterial and viral infections.
PLCG2-associated antibody deficiency and immune dysregulation (PLAID)	Rare disorder with allergic response to cold (cold urticaria) as the most distinct symptom.
Severe combined immune deficiency (SCID)	Group of rare, life-threatening disorders caused by mutations in different genes involved in development and function of T and B cells; infants appear healthy at birth but are highly susceptible to severe infections.
Warts, hypogammaglobulinemia, infections, and myelokathexis syndrome (WHIMS)	Low levels of white blood cells, especially neutrophils, which predispose to frequent infections and persistent warts.
Wiskott–Aldrich syndrome (WAS)	Problems with B and T cells and platelets resulting in prolonged episodes of bleeding, recurrent bacterial and fungal infections and increased risk of cancers and autoimmune diseases.

Nursing Management

Many patients with PIDDs have comorbid autoimmune disorders, such as thyroid disease, rheumatoid arthritis, cytopenias, and inflammatory bowel disease. Many patients require immunosuppression to ensure engraftment of depleted bone marrow during transplantation procedures. For this reason, nursing care must be meticulous. Appropriate hand hygiene and infection prevention precautions are essential. See Chapter 66, Chart 66-1 for hand hygiene methods and Chart 66-2 for a summary of infection prevention precautions. Institutional policies and procedures related to infection prevention care must be followed scrupulously until definitive evidence demonstrates that precautions are unnecessary. Continual monitoring of the patient's condition is critical, so early signs of impending infection may be detected and treated before they seriously compromise the patient's status.

Patients and caregivers in the home are taught how to administer medications, including regular Ig replacement therapy, if prescribed. Instruction is provided to the patient and family about how to administer the therapy at home (see Chart 32-1). Nurses provide ongoing education and support for the patient and family.

ACQUIRED IMMUNE DEFICIENCY

Immune deficiency can be acquired due to medical treatment such as chemotherapy (see Chapter 12) or infection from pathogens such as human immune deficiency virus (HIV). Advances have been made in treating HIV infection and acquired immune deficiency syndrome (AIDS); however, AIDS remains a critical public health issue in communities across the United States and around the world. Prevention, early detection, and ongoing treatment remain important aspects of care for people living with HIV infection or AIDS, who are sometimes referred to as persons living with HIV/AIDS (PLWHA). The American Nurses Association (ANA) has issued a position statement in support of efforts to end HIV (ANA, 2019).

HIV Infection and AIDS

Since the disease now known as AIDS was first identified in 1981, remarkable progress has been made in improving the length and quality of life for PLWHA. During the first decade, progress was associated with the recognition and treatment, including prophylactic medications, of **opportunistic infections** (illnesses caused by various organisms, some of which usually do not cause disease in people with normal immune systems). The second decade witnessed progress in the development of highly active antiretroviral drug therapies (HAART) as well as continuing progress in the treatment of opportunistic infections. The third decade has focused on issues of preventing

new infections, adherence to antiretroviral therapy (ART), development of second-generation combination medications that affect different stages of the viral life cycle, and continued need for an effective vaccine. The HIV antibody test, an **enzyme immunoassay** (**EIA**; or a variant of this test called *enzyme-linked immunosorbent assay* [ELISA]), became available in 1984, allowing early diagnosis of the infection before the onset of symptoms. Since then, HIV infection has been best managed as a chronic disease, most appropriately in an outpatient care setting, whereas AIDS may involve acute conditions that require hospitalization.

Chart 32-1 HOME CARE CHECKLIST

Home Administration of Ig Replacement Therapy

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of immune deficiency on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State what types of changes are needed (if any) to maintain a clean home environment and prevent infection.
- State how to contact the primary provider, the team of home care professionals overseeing care, and intravenous supply vendor.
- State how to obtain medical supplies and carry out dressing changes, IV access site care, and other prescribed regimens.
- Identify the benefits and expected outcome of regular Ig replacement therapy.
- State rationale for prophylactic use of acetaminophen and diphenhydramine before treatment begins.
- State the rationale for prehydration on the day before infusion.
- Demonstrate how to prepare regular Ig replacement therapy.
- Demonstrate how to administer regular Ig replacement therapy.
- Demonstrate how to clean and maintain IV equipment, as applicable.
- Identify side effects and adverse effects of regular Ig replacement therapy.
- Demonstrate how to monitor for adverse effects of regular Ig replacement therapy.
- Describe to whom, how, and when to report adverse effects of regular Ig replacement therapy.
- Describe appropriate actions to take for adverse effects.
- Verbalize understanding of emergency measures for anaphylactic shock.
- Describe time periods associated with possible development of adverse reactions

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Epidemiology

Since the first cases of AIDS were reported in the United States in 1981, surveillance case definitions for HIV infection and AIDS have undergone several revisions (in 1985, 1987, 1993, 2008, and 2014) in response to diagnostic advances. Criteria for a confirmed case of HIV infection can be met by either laboratory evidence or clinical evidence but laboratory evidence, usually obtained through blood tests, is preferred over clinical evidence (e.g.,

patient signs and symptoms). A case of HIV infection can be classified in one of five HIV infection stages (0, 1, 2, 3, or unknown). Stage 0 indicates early HIV infection, inferred from laboratory testing; stages 1, 2, and 3 are based on the $CD4^+$ T-lymphocyte count; while cases with no information on $CD4^+$ T-lymphocyte count or percentage are classified as stage unknown (Centers for Disease Control and Prevention [CDC], 2014). See Table 32-2 for further explanation of stages.

In July 2015, the Obama White House released the *National HIV/AIDS Strategy for the United States: Updated to 2020*. This document has four Strategic Goals, which include reducing new infections; increasing access to care and improving health outcomes for people living with HIV; reducing HIV-related health disparities and health inequities; and achieving a more coordinated national response to the HIV epidemic. The strategy is being updated by the Office of HIV/AIDS and Infectious Disease Policy (OHAIDP, 2019).

According to the CDC, 1,006,691 persons aged 13 years and older are living with HIV infection, and an additional 534,515 are living with AIDS in the United States (CDC, 2019a). From 2012 through 2016, the rate of diagnoses of HIV infection decreased, although the annual number of diagnoses remained stable as survival rates have increased. The incidence was 11.8 per 100,000 persons for 2017, with men accounting for 81% of all HIV infection diagnoses (CDC, 2019a). The incidence per 100,000 persons was 41.1 for Blacks/African Americans, followed by 16.1 for Hispanics/Latinos, and 12.6 for persons of multiple races. The highest rate (32.9%) was for persons aged 25 to 29 years, followed by 28.7% for persons aged 20 to 24 years. Male-to-male sexual contact (MSM) (70%, including 3% male-to-male sexual contact and injection drug use) and those attributed to heterosexual contact (24%) accounted for approximately 94% of diagnosed HIV infections. Rates within the United States were 16.1% in the South, 10.6% in the Northeast, 9.4% in the West, and 7.4% in the Midwest (CDC, 2019a). Data about infections in transgender persons were not collected.

TABLE 32-2 HIV Infection Stages 1, 2, and 3 Based on Age-Specific Laboratory Data

	Age on Date of CD4+ T-Lymphocyte Test					
	<1 yr		1–6 yrs		≥6 yrs	
Stage	Cells/μL	%	Cells/μL	%	Cells/μL	%
1	≥1500	≥34	≥1000	≥30	≥500	≥26
2	750–1499	26–33	500–999	22–29	200–499	14–25
3	<750	<26	<500	<22	<200	<14

If a stage-3-defining opportunistic illness has been diagnosed, then the stage is 3 regardless of CD4+ T-lymphocyte test.

Stage-3-Defining Opportunistic Illnesses in HIV Infection
Bacterial infections, multiple or recurrent (only among children aged less than 6 yrs)
Candidiasis of bronchi, trachea, or lungs
Candidiasis of esophagus
Cervical cancer, invasive (only in persons aged 6 yrs or older)
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 mo duration)
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 mo
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy attributed to HIV
Herpes simplex: chronic ulcers (>1 mo duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 mo)
Histoplasmosis, disseminated or extrapulmonary Isosporiasis, chronic intestinal (>1 mo duration)
Kaposi sarcoma
Lymphoma, Burkitt (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
Mycobacterium avium complex or Mycobacterium kansasii, disseminated or extrapulmonary
Mycobacterium tuberculosis of any site, pulmonary (only in persons aged 6 yrs or older) disseminated, or extrapulmonary
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis jirovecii (previously known as "Pneumocystis carinii") pneumonia (PCP)
Pneumonia, recurrent (only in persons aged 6 yrs or older)
Progressive multifocal leukoencephalopathy
Salmonella septicemia (recurrent)
Toxoplasmosis of brain, onset at age >1 mo
Wasting syndrome attributed to HIV

Adapted from Centers for Disease Control and Prevention (CDC). (2014). Revised surveillance case definition for HIV infection—United States, 2014. *MMWR. Recommendations and Reports: Morbidity and Mortality Weekly Report. Recommendations and Reports, 63*(RR-03), 1–10.

According to the World Health Organization ([WHO], 2019), HIV through its morbid consequence of AIDS has claimed more than 32 million lives globally; in 2018, 770,000 people died from HIV-related causes. Globally, there were approximately 37.9 million people living with HIV at the end of 2018, with 1.7 million people becoming newly infected in 2018. The WHO African Region is the most affected region, with 25.7 million people living with HIV in 2018. The African region also accounts for almost two thirds of the global total of new HIV infections. Between 2000 and 2018, new HIV infections fell by 37%, and HIV-related deaths fell by 45% with 13.6 million lives saved due to patients receiving effective medication during that same period. The decrease in infection rates and deaths was the result of many efforts by national HIV programs supported by a range of funding partners (WHO, 2019).

HIV Transmission

Inflammation and breaks in the skin or mucosa result in the increased probability that an HIV exposure will lead to infection. Human immune deficiency virus type 1 (**HIV-1**) is transmitted in body fluids (blood, seminal fluid, vaginal secretions, amniotic fluid, and breast milk) that contain infected

cells. Higher amounts of HIV and infected cells in the body fluid are associated with the probability that the exposure will result in infection. Mother-to-child transmission of HIV-1 may occur in utero, at the time of delivery, or through breast-feeding, but most perinatal infections are thought to occur during labor and delivery. HIV is not transmitted through casual contact (see Chart 32-2).

Blood and blood products can transmit HIV to recipients. However, the risk associated with transfusions has been virtually eliminated as a result of voluntary self-deferral, completion of a detailed health history, extensive testing, heat treatment of clotting factor concentrates, and more effective virus inactivation methods. Donated blood is tested for antibodies to HIV-1, human immune deficiency virus-2 (retrovirus identified in 1986 in patients with AIDS in Western Africa), and the p24 antigen; since 1999, additional testing has been performed.

Chart 32-2 RISK FACTORS

Risks Associated with HIV Infection

- Sharing infected injection drug use equipment
- Having sexual relations with infected persons (both genders)
- Infants born to mothers with HIV infection or who are breast-fed by HIV-infected mothers
- People who received organ transplants, HIV-infected blood, or blood products (especially between 1978 and 1985)

Adapted from Centers for Disease Control and Prevention (CDC). (2019a). HIV Surveillance Report, 2017. Retrieved on 10/21/2019 at: www.cdc.gov/hiv/library/reports/hiv-surveillance.html

Gerontologic Considerations

According to the CDC, 91,127 persons between the ages of 60 and 64 years are living with HIV infection, and an additional 58,526 persons are living with AIDS. For persons aged 65 years and older, 82,046 persons are living with HIV infection and an additional 52,995 persons are living with AIDS (CDC, 2019a). Many were diagnosed with HIV in their younger years and are benefitting from effective treatment. However, thousands of older adults unknowingly become infected with HIV every year. Older adults are less likely than younger people to get tested. Thirty-five percent of persons aged 50 and older were diagnosed with late-stage infection or AIDS, indicating a failure to screen for HIV in this population. Although this rate is an improvement from 2011, when it was 42%, it is still high. Late diagnosis has an adverse impact on

treatment effectiveness (CDC, 2019b). Medicare will pay for annual screenings up until age 65 but there needs to be a special indication (such as unprotected sex with an infected partner) for a person to be screened after that age in order for Medicare to cover the cost of testing (CDC, 2019a).

Persons are often embarrassed to share that they have engaged in activities associated with HIV infection and so might not disclose this to the health care provider. The provider needs to use other cues, such as the presence of other sexually transmitted diseases, and recommend HIV testing. Providers may bring societal age and gender biases to their perceptions of patient sexuality, which influence their communication about sexual health with older adult patients. For some providers, assumptions that discussions about sexual health will offend their patients, as well as their own discomfort with talking to older adults about sex, inhibit them from assessing risk factors that may indicate a need for HIV and STI testing.

Comorbidities in older persons with HIV/AIDS include type 2 diabetes; non-AIDS cancerous diseases; cardiovascular disease; osteoporosis; and depression (Guaraldi, Malagoli, Calcagno, et al., 2018). Due to the high number of chronic illnesses, polypharmacy along with drug interactions becomes a major clinical challenge. Loneliness has been defined as the distress that exists between actual and desired relationships and is different from the concept of aloneness or living alone. Loneliness was studied in older persons living with HIV/AIDS by Greene and colleagues, who found that 58% of the participants reported at least some loneliness. Compared to participants who did not report feeling lonely, those who did report loneliness were more likely to smoke, misuse alcohol, or use illicit drugs. They also reported less physical social supports in place, depressive symptoms, poor or fair health-related quality of life, and functional impairment in one or more Instrumental Activities of Daily Living (IADLs) (Greene, Hessol, Perissinotto, et al., 2018). Loneliness has been associated with increased mortality in the general population.

Prevention of HIV Infection

Nurses need to participate in efforts to prevent HIV infection by educating patients how to eliminate or reduce risks associated with HIV infection and AIDS, particularly in younger adults, in order to promote a healthy lifestyle and longevity (Eliopoulos, 2018). HIV is transmitted through the exchange of some infected body fluids (see Chart 32-2). While behavioral interventions such as encouraging the use of condoms are highly effective in reducing the transmission of HIV, the HIV-negative person must be motivated and have the freedom to choose to use the method. In some situations, however, that freedom is absent. For example, a lack of freedom exists in a discordant couple (those in which only one partner has HIV) if the husband refuses to use

condoms and the wife's cultural and religious beliefs require sexual activity with her husband. In this context, **pre-exposure prophylaxis (PrEP)** might be appropriate. PrEP involves taking one pill containing two HIV medications (tenofovir disoproxil fumarate 300 mg and emtricitabine 200 mg) daily in order to avoid the risk of sexual HIV acquisition in adults and adolescents age 12 and older. HIV status should be checked every 3 months to be sure that the person has not become infected. The ultimate goal of PrEP is to reduce the acquisition of HIV infection with its resulting morbidity, mortality, and cost to individuals and society (CDC, 2019c). For persons taking ART as prescribed and achieving and maintaining viral suppression, there is no risk of transmitting HIV through sex. Since PrEP does not prevent other sexually transmitted infections, which are increasing (CDC, 2019d), it is important for couples to also use a condom.

Preventive Education

Prevention of HIV infection is achieved through: (a) behavioral interventions have been effective in reducing the risk of acquiring or transmitting HIV by ensuring that people have the information, motivation, and skills necessary to reduce their risk; (b) HIV testing, because most people change behaviors to protect their partners if they know they are infected with HIV; and (c) linkage to treatment and care, which enables individuals with HIV to live longer, healthier lives and reduce their risk of transmitting HIV (CDC, 2019e). The CDC (2019f), through the HIV/AIDS Prevention Research Synthesis Project, provides information about evidence-based behavioral interventions that can be used in a number of settings with targeted populations. Strategies to protect against infection are outlined in Chart 32-3. Other than abstinence, consistent and correct use of condoms (see Chart 32-4) is the only effective method to decrease the risk of sexual transmission of HIV infection. When latex male condoms are used consistently and correctly during vaginal or anal intercourse, they are highly effective in preventing the sexual transmission of HIV. Nonlatex condoms made of natural materials such as lambskin are available for people with latex allergy but will not protect against HIV infection. A male condom should be used for oral contact with the penis, and a dental dam (a flat piece of latex used by dentists to isolate a tooth for treatment) or an altered condom can be used for oral contact with the vagina or rectum. Voluntary medical male circumcision (VMMC) is 50% to 60% effective at preventing the acquisition of HIV infection. This is a key intervention in generalized epidemic settings with high HIV prevalence and low male circumcision rates (Ensor, Davies, Rai, et al., 2019).

Chart 32-3 HEALTH PROMOTION

Protecting Against HIV Infection
All patients should be advised to:

- Abstain from exchanging sexual fluids (semen and vaginal fluid).
- Reduce the number of sexual partners to one.
- Always use latex condoms. If the patient is allergic to latex, nonlatex condoms should be used; however, they will not protect against HIV infection.
- Not reuse condoms.
- Avoid using cervical caps or diaphragms without using a condom as well.
- Always use dental dams for oral–genital or anal stimulation.
- Avoid anal intercourse, because this practice may injure tissues; if not possible, use lubricant—there are water and silicone-based products designed for anal sex.
- Avoid manual–anal intercourse ("fisting").
- Avoid sharing needles, razors, toothbrushes, sex toys, or blood-contaminated articles.
- Consider PrEP if regularly engage in high-risk behaviors.
- Use needle-exchange programs (as appropriate) and do not share drug-using equipment.

Patients who are HIV seropositive should also be advised to:

- Take ART regularly to achieve viral suppression.
- Inform previous, present, and prospective sexual and drug-using partners of their HIV-positive status. If the patient is concerned for their safety, advise the patient that many states have established mechanisms through the public health department in which professionals are available to notify exposed contacts.
- Avoid having unprotected sex with another HIV-seropositive person. Cross-infection with that person's HIV can increase the severity of infection.
- Not donate blood, plasma, body organs, or sperm.

ART, antiretroviral therapy; PrEP, pre-exposure prophylaxis.

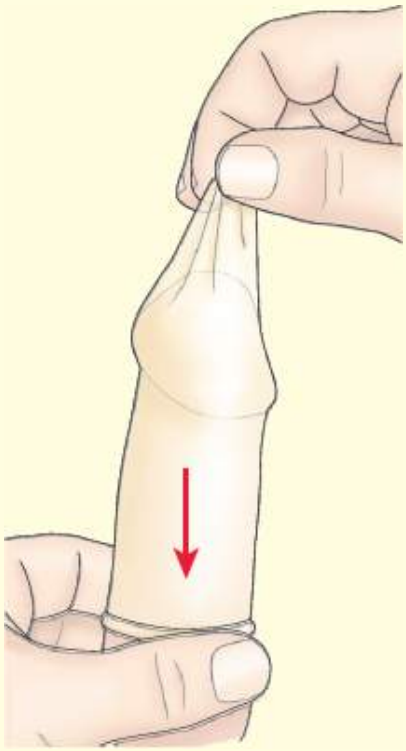
Chart 32-4 PATIENT EDUCATION

The Correct Way to Use a Male Condom

The nurse instructs the patient to:

- Put on a new condom before any kind of sex.
- Hold the condom by the tip to squeeze out the air.

- Unroll the condom all the way over the erect penis.



- Have sex.
- Hold the condom so it cannot come off the penis.
- Pull out.

- Use a new condom if you want to have sex again or if you want to have sex in a different place (e.g., in the anus and then in the vagina).

Note: Keep condoms cool and dry. Never use skin lotions, baby oil, petroleum jelly, or cold cream as lubricants; the oil in these products will cause the latex condom to break. Products made with water (such as K-Y jelly or glycerin) are safer to use.

The polyurethane female condom, which is an effective contraceptive, provides a physical barrier that prevents exposure to genital secretions containing HIV, such as semen and vaginal fluid, and is inserted by the woman (see Chapter 50). Other safe and effective woman-controlled methods such as microbicides remain elusive although clinical trials continue globally. Microbicides are gels, films, or suppositories that can kill or neutralize viruses and bacteria; vaginal and rectal microbicides are being researched to see if they can prevent sexual transmission of HIV.

Total abstinence from addictive drugs might not be a realistic short-term goal. The harm reduction framework uses practical strategies and ideas aimed at reducing negative consequences associated with drug use. It is also a movement for social justice built on a belief in, and respect for, the rights of people who use drugs. Using a harm reduction framework, the nurse works with people who inject drugs to assist them to increase their healthy behaviors. Sharing of drug-use equipment is a high-risk behavior for a number of bloodborne infections and should be avoided. Syringe services programs are also referred to as syringe exchange programs and needle exchange programs. Although the services they provide may vary, they are community-based programs that provide access to sterile needles and syringes, facilitate safe disposal of used syringes, and provide and link to other important services and programs (CDC, 2019g). Therefore, under the harm reduction framework, participation in needle exchange programs is encouraged since they do not promote increased drug use; on the contrary, they have been found to decrease the incidence of bloodborne infections in people who inject drugs. Nurses should refer patients to accessible needle exchange programs whenever available.

Related Reproductive Education

Because HIV infection in women often occurs during the childbearing years, family planning issues need to be addressed. Attempts to achieve pregnancy by couples in which only one partner has HIV (known as discordant couples) expose the unaffected partner to the virus. Efforts at artificial insemination using processed semen from an HIV-infected partner continue. Studies are needed, because HIV has been found in the spermatozoa of patients with HIV infection, and it is possible that HIV can replicate in the male germ cell. Women considering pregnancy need to have accurate information about the

risks of transmitting HIV infection to themselves, their partner, and their future children, and about the benefits of taking ART to reduce perinatal HIV transmission. Results from the Evidence for Contraceptive Options and HIV Outcomes (ECHO) Trial Consortium found that, among African women seeking effective contraception and living in areas of high HIV incidence, there was no substantial difference in HIV risk among the methods evaluated (DMPA-IM, a copper IUD, and a levonorgestrel implant) and all methods were safe and highly effective (ECHO Trial Consortium, 2019). HIV-infected women in resource-rich settings should be instructed not to breast-feed their infants, because HIV is transmitted through breast milk.

Prevention in Lesbian, Gay, Bisexual, Transgender, and Queer Persons

Many health care providers are insufficiently prepared to meet the unique health needs of those who identify as lesbian, gay, bisexual, transgender, and queer (LGBTQ). Young gay men, in particular, are at higher risk for contracting HIV (CDC, 2019a). At the same time, these sexual and gender minorities experience significant challenges due to family rejection, lack of social support, stigma, isolation, minority stress, as well as abuse and harassment. Nurses need to be culturally competent in order to be effective in educating these unique populations about prevention methods (see Chapter 54).

Reducing the Risk of Transmission to Health Care Providers

Prevention of HIV and AIDS among health care providers involves the use of standard precautions to prevent exposure, using post-exposure prophylaxis when exposure does occur and hopefully, in the near future, the use of a vaccine.

Standard Precautions

Implementation of appropriate hand hygiene measures (see Chapter 66, Chart 66-1 for further information on hand hygiene methods) remains the most effective measure to prevent transmission of organisms. To reduce the risk of exposure of health care workers to HIV, the CDC developed standard precautions (see Chart 32-5; also see Chapter 66, Chart 66-2) which are designed to reduce the risk of transmission of pathogens. Standard precautions are used when working with all patients in all health care settings, regardless of their diagnosis or presumed infectious status.

Post-Exposure Prophylaxis for Health Care Providers

Post-exposure prophylaxis (PEP) includes taking antiretroviral medicines as soon as possible, but no more than 72 hours (3 days) after possible HIV exposure; three drugs are prescribed. Health care workers who are exposed to a needle stick involving HIV-infected blood in a health care setting have a 0.3% risk of becoming HIV infected; the risk of infection due to occupational exposure is very low (CDC, 2018a).

Occupational exposure is an urgent medical concern and should be managed immediately after possible exposure—the sooner the better; every hour counts (CDC, 2018a). The CDC suggests that these post-exposure guidelines be followed after occupational and other exposures such as sexual assault. Chart 32-6 provides the strategies and emphasizes the need for quick action. See the Resources section for the phone number for the Health Resources and Service Administration (HRSA) Post-exposure Prophylaxis Hotline which is answered by a health care provider.

Chart 32-5

Recommendations for Standard Precautions

- **Hand hygiene:** Use after touching blood, body fluids, secretions, excretions, or contaminated items; immediately after removing gloves; and between patient contacts.
- **Personal protective equipment:**
  - *Gloves:* Use for touching blood, body fluids, secretions, excretions, and contaminated items, and for touching mucous membranes and nonintact skin.
  - *Gown:* Use during procedures and patient care activities when contact of clothing/exposed skin with blood or body fluids, secretions, and excretions is anticipated.
  - *Mask, eye protection (goggles), face shield*[1]: Use during procedures and patient care activities likely to generate splashes or sprays of blood, body fluids, and secretions, especially suctioning or endotracheal intubation.
- **Soiled patient care equipment:** Handle in a manner that prevents transfer of microorganisms to others and to the environment; wear gloves if visibly contaminated; and perform hand hygiene.
- **Environmental control:** Develop procedures for routine care, cleaning, and disinfection of environmental surfaces, especially frequently touched surfaces in patient care areas.
- **Textiles and laundry:** Handle in a manner that prevents transfer of microorganisms to others and to the environment.
- **Needles and other sharps:** Do not recap, bend, break, or hand manipulate used needles; if recapping is required, use a one-handed scoop technique only; use safety features when available; and place used sharps in a puncture-resistant container.
- **Patient resuscitation:** Use mouthpiece, resuscitation bag, and other ventilation devices to prevent contact with mouth and oral secretions.
- **Patient placement:** Prioritize for single-patient room if patient is at increased risk for transmission, is likely to contaminate the environment, does not maintain appropriate hygiene, or is at increased risk for acquiring infection or developing adverse outcome following infection.
- **Respiratory hygiene/cough etiquette** (source containment of infectious respiratory secretions in symptomatic patients, beginning at initial point of encounter, such as triage and reception areas in emergency departments and provider offices): Instruct symptomatic people to cover mouth and nose when sneezing or coughing, use tissues and dispose in no-touch receptacle, observe hand hygiene after soiling of hands with respiratory secretions, and wear surgical mask if tolerated.

[1]During aerosol-generating procedures on patients with suspected or proven infections transmitted by respiratory aerosols (e.g., severe acute

respiratory syndrome), wear a fit-tested N95 or higher respirator in addition to gloves, gown, and face/eye protection.

Adapted from Centers for Disease Control and Prevention (CDC). (2018a). Updated U.S. Public Health Service guidelines for the management of occupational exposures to HIV and recommendations for postexposure prophylaxis. Retrieved on 10/27/2019 at: stacks.cdc.gov/view/cdc/20711

Vaccination

In the face of a global pandemic, the search for an effective vaccine against the HIV remains an urgent priority. The first U.S. government-sponsored phase I trial of an HIV vaccine was launched in 1987 and intensive efforts worldwide using a variety of strategies continue (NIAID, 2019b).

Chart 32-6

Post-HIV Exposure Prophylaxis for Health Care Providers

If you sustain an occupational exposure to HIV, take the following actions immediately:

- Alert your supervisor and initiate the occupational exposure reporting system used in the setting.
- Determine the HIV status of the exposure source (i.e., patient) when possible to guide appropriate use of HIV post-exposure prophylaxis (PEP). Use rapid-testing if the HIV status of the patient is unknown. Check laws in your state as you proceed to determine HIV status of the source patient.

Get counseling at the time of exposure and at follow-up appointments:

- Exposed health care providers (HCP) are advised to use precautions (e.g., use of barrier contraception and avoidance of blood or tissue donations, pregnancy, and, if possible, breast-feeding) to prevent secondary transmission, especially during the first 6 to 12 weeks after exposure.
- For exposures for which PEP is prescribed, HCPs are informed regarding the following:
  - Possible drug toxicities (e.g., rash and hypersensitivity reactions that could imitate acute HIV seroconversion and the need for monitoring)
  - Possible drug interactions
  - The need for adherence to PEP regimens

Undergo early reevaluation after exposure:

- Regardless of whether an HCP is taking PEP, reevaluation of exposed HCP within 72 hours after exposure is strongly recommended, as additional information about the exposure or the source patient may be available.

Follow up with HIV testing and appointments. At a minimum, this follow-up should include:

- HIV testing at baseline and at 6 weeks, 12 weeks, and 6 months after exposure; alternatively, if the HCP is certain that a fourth-generation combination HIV p24 antigen–HIV antibody test is being utilized, then HIV testing could be performed at baseline, 6 weeks after exposure, and 4 months after exposure
- Complete blood counts and renal and hepatic function tests (at baseline and 2 weeks after exposure; further testing may be indicated if abnormalities are detected)

Note: All HIV testing results should preferably be given to the exposed HCP during face-to-face appointments.

Adapted from Centers for Disease Control and Prevention (CDC). (2018a). Updated U.S. Public Health Service guidelines for the management of

occupational exposures to HIV and recommendations for postexposure prophylaxis. Retrieved on 10/27/2019 at: stacks.cdc.gov/view/cdc/20711

Pathophysiology

Because HIV is an infectious disease, it is important to understand how HIV-1 integrates itself into a person's immune system and how the immune response plays a pivotal role in the course of HIV disease. This knowledge is also essential for understanding medication therapy and vaccine development. Viruses are intracellular parasites. HIV is in the subfamily of lentiviruses and is a **retrovirus** because it carries its genetic material in the form of ribonucleic acid (RNA) rather than deoxyribonucleic acid (DNA) (Norris, 2019).

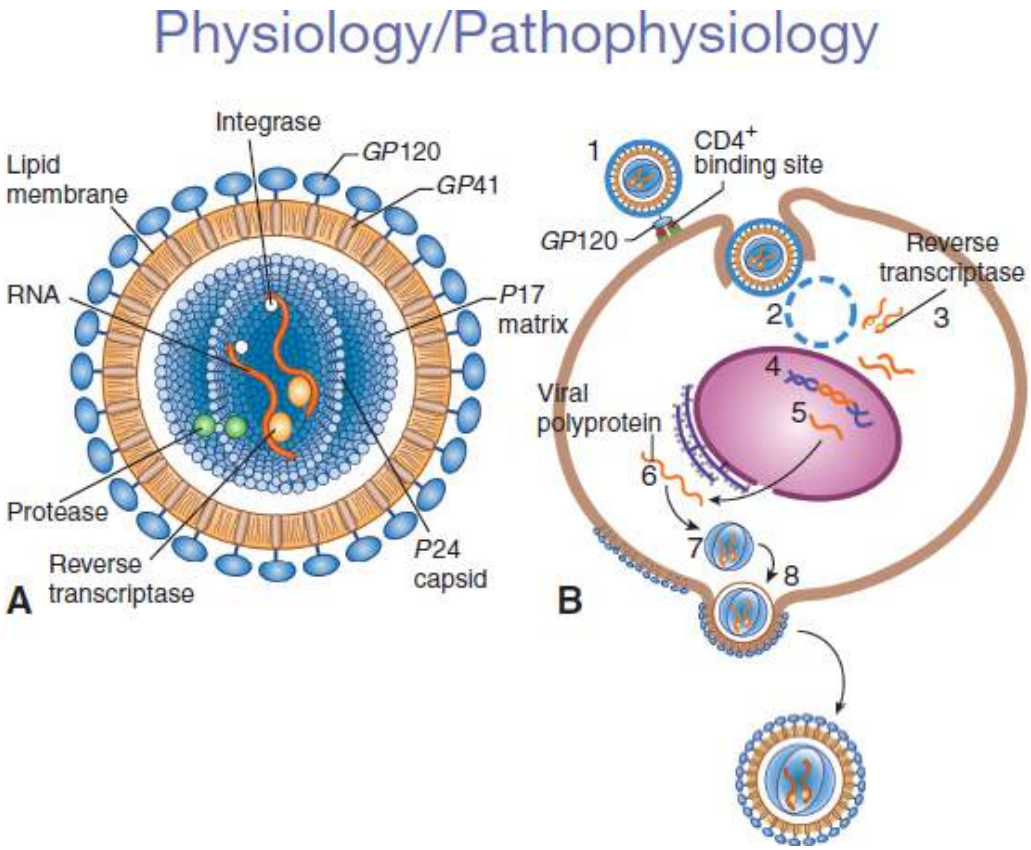


Figure 32-1 • Structure of HIV-1 virus. The virus surrounded by a lipid envelope. Reprinted with permission from Norris, T. L., & Lalchandani, R. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed., Fig. 12.7 (left side)). Philadelphia, PA: Wolters Kluwer.

Two genetically different but closely related forms of HIV (HIV-1 and HIV-2) have been identified. Globally, it has been estimated that one to two million individuals have HIV-2, including people with HIV-1/HIV-2 dual infection.

The course of illness is slower when infection is caused by HIV-2, which seems to be more common in Western Africa compared to HIV-1, which is more common in other regions of the globe (Panel, 2019). Blood tests may be used to screen for both forms of HIV. As shown in Figure 32-1, HIV consists of a viral core, containing viral RNA, which is surrounded by an envelope consisting of protruding glycoproteins.

All viruses target specific cells. HIV targets cells with $CD4^+$ receptors, which are expressed on the surface of T lymphocytes, monocytes, dendritic cells, and brain microglia. Mature T cells (T lymphocytes) are composed of two major subpopulations that are defined by cell surface receptors of $CD4^+$ or $CD8^+$. Approximately two thirds of peripheral blood T cells are $CD4^+$, and approximately one third is $CD8^+$. Most people have about 700 to 1000 $CD4^+$ cells/mm^3, but a level as low as 500 cells/mm^3 can be considered within normal limits.

The HIV life cycle is complex. Figure 32-2 illustrates the seven stages of the life cycle and the various classes of antiretroviral medications that target each specific stage (HIV Information, 2020; Norris, 2019).

In resting (nondividing) $CD4^+$ cells, HIV survives in a latent state as an integrated **provirus** that produces few or no viral particles. These resting $CD4^+$ T cells can be stimulated to produce new particles if something activates them, such as another infection. When a resting T cell that harbors this integrated DNA (also known as provirus) becomes activated against HIV or other microbes, the cell begins to produce new copies of both RNA and viral proteins. Consequently, whenever the infected $CD4^+$ cell is activated, HIV replication and budding occur, which can destroy the host cell. Newly formed HIV released into the blood can infect other $CD4^+$ cells.

HIV-1 mutates quickly, at a relatively constant rate, with about 1% of the virus's genetic material changing annually. HIV-1 exhibits substantial genetic diversity, and several different genotypes of HIV-1 exist throughout the world. There is a major group (group M), which consists of subtypes A through L, and a more diverse collection of outliers, which has been referred to as groups N and O. Subtype B HIV-1 viruses predominate in the Western world; this genetic variation is one of the major reasons why effective vaccine development has been such a challenge.

Stages of HIV Infection

There are five stages of HIV infection based on clinical history, physical examination, laboratory evidence (CDC, 2014), signs and symptoms, and associated infections and malignancies. See Table 32-2.

The period from infection with HIV to the development of HIV-specific antibodies is known as **primary infection or acute HIV infection** (previously known as the window period) and is part of stage 0 (CDC, 2014). Acute HIV

infection is the interval between the appearance of detectable HIV RNA and the first detection of antibodies. Initially, persons test negative on the HIV antibody blood test, although they are not only infected, but also highly contagious because their viral loads are very high. About 40% to 80% of patients develop clinical symptoms of a nonspecific viral illness (e.g., fever, fatigue, or rash) lasting 1 to 2 weeks. After 2 to 3 weeks, antibodies to the glycoproteins of the HIV envelope can be detected in the sera of people infected with HIV, but most of these antibodies lack the ability to totally control the virus. By the time neutralizing antibodies can be detected, HIV-1 is firmly established in the host.

Primary or acute infection is characterized by high levels of viral replication, widespread dissemination of HIV throughout the body, and destruction of $CD4^+$ T cells, which leads to dramatic drops in $CD4^+$ T-cell counts (normally 500 to 1500 cells/mm^3 of blood). The host responds to the HIV infection through a $CD4^+$ T-cell response that causes other immune cells, such as $CD8^+$ lymphocytes, to increase their killing of infected, virus-producing cells. The body produces antibody molecules in an effort to contain the free HIV particles (outside cells) and assist in their removal. During this stage, the virus is widely disseminated in lymphoid tissue, and a **latent reservoir** within resting memory $CD4^+$ T cells is created.

During stage 1, the amount of virus in the body after the initial immune response subsides results in a **viral set point** which reflects an equilibrium between HIV levels and the immune response. Untreated, this set point can last for years and is inversely correlated with disease prognosis. The higher the viral set point, the poorer the prognosis. After the viral set point is reached, a chronic stage persists in which the immune system cannot eliminate the virus despite its best efforts. This set point varies greatly from patient to patient and dictates the subsequent rate of disease progression; on average, 8 to 10 years can pass before a major HIV-related complication develops. In this prolonged, chronic stage (stage 1), patients feel well and have few, if any, symptoms, which is why this stage had been referred to as asymptomatic. Apparent good health continues because $CD4^+$ T-cell levels remain high enough to preserve immune defensive responses, but, over time, the number of $CD4^+$ T cells decrease.

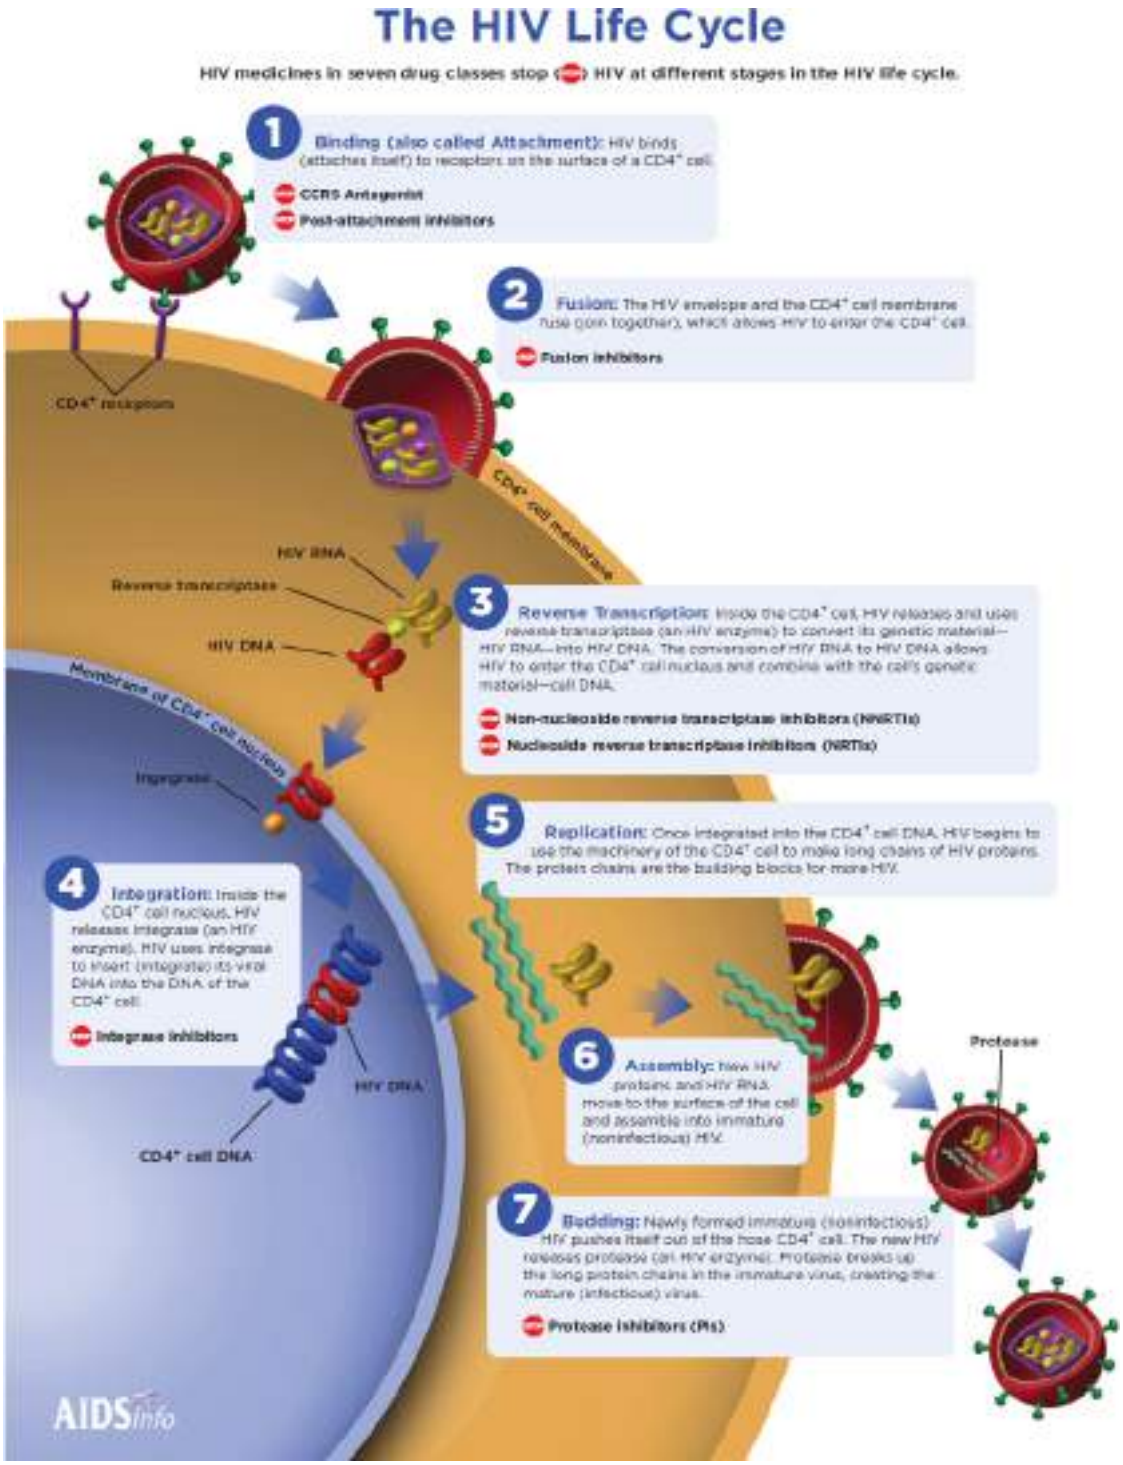

Figure 32-2 • The HIV life cycle. Adapted from HIV Information, 2020.

Stage 2 occurs when CD4+ T-lymphocyte cells decrease to between 200 and 499 cells/mm^3 and had previously been referred to as the symptomatic stage. Stage 3 is diagnosed when the count drops below 200 cells/mm^3 and the person has AIDS. HIV disease progression is classified from less to more severe; once a case is classified into a surveillance severity stage, it cannot be

reclassified into a less severe stage even if the $CD4^+$ T lymphocytes increase, which often occurs when a person receives ART. A stage 3, AIDS, diagnosis has implications for services (e.g., disability benefits, housing, and food stamps), because these programs are often linked to living with severe immune dysfunction.

Assessment and Diagnostic Findings in HIV Infection

During the first stage of HIV infection, the patient may have no symptoms or generalized signs and symptoms such as fatigue or skin rash. Patients who are in later stages of HIV infection may have a variety of symptoms related to their immunosuppressed state. The staging system requires laboratory evidence of HIV infection in order to diagnose HIV or AIDS (see Table 32-2).

HIV Tests

Several tests are used to diagnose HIV infection, and others are used to determine the stage and severity of the infection. A serologic testing algorithm for recent HIV seroconversion (STARHS) analyzes HIV-positive blood samples to determine whether an HIV infection is recent or has been ongoing. There are three types of HIV diagnostic tests: antibody tests, antigen/antibody tests, and nucleic acid (RNA) tests. Antibody tests detect antibodies, not HIV itself, while antigen and RNA tests directly detect HIV. The CDC recommends tests for HIV antigens and HIV nucleic acid because studies from high-risk populations found that antibody testing alone might miss a considerable percentage of HIV infections detectable by virologic tests, especially during stage 0.

Blood tests can detect HIV infection sooner after exposure compared to oral fluid tests because the level of antibody in blood is higher than it is in oral fluid. Likewise, antigen/antibody and RNA tests detect infection in blood before antibody tests. Some newer antigen/antibody laboratory tests can sometimes find HIV as soon as 3 weeks after exposure to the virus.

Follow-up testing is performed if the initial test result is positive to ensure a correct diagnosis. These tests include:

- antibody *differentiation tests,* which distinguishes HIV-1 from antibodies
- *HIV-1 nucleic acid tests,* which looks for the virus RNA directly

Table 32-3 identifies common blood tests used for screening.

Since negative perceptions and judgments associated with being HIV infected continue to persist, stigma remains one of the biggest social challenges (Glynn, Llabre, Lee, et al., 2019). When the result of the HIV antibody test is received, it is carefully explained to the patient in private (see Chart 32-7). All test results are confidential. Education and counseling about

the test result and about preventing transmission are essential. The patient's psychological response to a positive test result may include feelings of panic, depression, and hopelessness. The social and interpersonal consequences of a positive test result can be devastating. The patient may lose their sexual partner, housing, and their job because of disclosure. They may be subjected to physical abuse and, although illegal, experience discrimination in employment as well as social ostracism. For these reasons and others, patients who test positive may need ongoing counseling as well as referrals for social, financial, medical, and psychological support services. The HIV Care Continuum (CDC, 2019h) starts when patients receive their positive HIV blood test results. They must be connected to health care services to evaluate their stage of HIV infection and start treatment.

TABLE 32-3 HIV Screening Blood Tests

Laboratory Test	Indications
HIV-1/HIV-2 immunoassay	Tests for both HIV-1 and HIV-2 antibodies
HIV/1-HIV-2 antigen/antibody combination immunoassay	Tests for both virus (antigen) and antibody for both HIV-1 and HIV-2
HIV-1 differentiation assay	Differentiates HIV-1 from HIV-2
HIV-1 nucleic acid amplification test	Tests directly for virus
HIV-1 p24 antigen	Tests directly for virus

HIV, human immune deficiency virus.

Chart 32-7

HIV Test Results: Implications for Patients

Interpretation of Positive Antibody Test Results

- Antibodies to HIV are present in the blood (the patient has been infected with the virus, and the body has produced antibodies).
- HIV is active in the body, and the patient can transmit the virus to others.
- Despite HIV infection, the patient does not necessarily have AIDS.
- The patient is not immune to HIV (the antibodies do not indicate immunity).

Interpretation of Negative Test Results

- Antibodies to HIV are not present in the blood at this time, which can mean that the patient has not been infected with HIV or, if infected, the body has not yet produced antibodies (stage 0).
- The patient should continue taking precautions. The test result does not mean that the patient is immune to the virus, nor does it mean the patient is not infected; it just means that the body may not have produced antibodies yet. If viral test used, a negative result is more consistent with the conclusion that the patient is uninfected.

AIDS, acquired immune deficiency syndrome; HIV, human immune deficiency virus.

Adapted from Centers for Disease Control and Prevention (CDC). (2018b). Quick reference guide: Recommended laboratory HIV testing algorithm for serum or plasma specimens. Retrieved on 10/28/2019: stacks.cdc.gov/view/cdc/50872

Patients whose test results are seronegative may develop a false sense of security, possibly resulting in continued high-risk behaviors or feelings that they are immune to the virus. These patients may need ongoing counseling to help modify high-risk behaviors and to encourage returns for repeated testing. Other patients may experience anxiety regarding the uncertainty of their status. In addition to screening for HIV, patients should be screened for other bloodborne coinfections such as hepatitis; other STIs such as syphilis; and other infections associated with T-cell immunity such as tuberculosis (TB). The rates of coinfection of hepatitis C and HIV are approximately 25% (Starbird, Hong, Sulkowski, et al., 2020).

Staging

Two surrogate markers are used routinely to assess immune function and level of HIV viremia: $CD4^+$ T-cell count ($CD4^+$ count) and plasma HIV RNA (viral load). $CD4^+$ count should be measured in all patients at entry into care. **Viral**

load tests use target amplification methods to quantify HIV RNA or DNA levels in the plasma. Target amplification methods include reverse transcriptase–**polymerase chain reaction** (RT-PCR) and nucleic acid sequence–based amplification (NAT). A widely used viral load test measures plasma HIV RNA levels. Currently, these tests are used to track viral load and response to treatment of HIV infection. RT-PCR is also used to detect HIV in high-risk seronegative people before antibodies are measurable, to confirm a positive EIA result, and to screen neonates. HIV culture or quantitative plasma culture and plasma viremia are additional tests that measure viral burden, but they are used infrequently. Viral load is a better predictor of the risk of HIV disease progression than the $CD4^+$ count. The lower the viral load, the longer the time to AIDS diagnosis and the longer the survival time.

Treatment of HIV Infection

The U.S. Department of Health and Human Services Panel on Antiretroviral Guidelines for Adults and Adolescents (Panel) (2019) is composed of HIV specialists from across the country who regularly meet to review the latest scientific evidence. The $CD4^+$ count serves as the major laboratory indicator of immune function and prophylaxis for opportunistic infections, and is the strongest predictor of subsequent disease progression and survival (Panel, 2019). New drugs offer strategies based on the interaction between the life cycle of HIV and the host response, improvements in potency and activity even against multidrug-resistant viruses, dosing convenience, and tolerability. Goals of ART treatment include: (1) reduce HIV-associated morbidity and prolong the duration and quality of survival, (2) restore and preserve immunologic function, (3) maximally and durably suppress plasma HIV viral load, and (4) prevent HIV transmission (Panel, 2019). HIV suppression with ART may also decrease inflammation and immune activation thought to contribute to higher rates of cardiovascular and other end-organ damage. ART is recommended for all HIV-infected patients regardless of their viral load or $CD4^+$ count (Panel, 2019). Optimal viral suppression is defined generally as a viral load persistently below the level of detection (HIV RNA less than 20 to 75 copies/mL, depending on the assay used). Providers, in partnership with patients, make treatment decisions based on a number of factors, including whether the patient has already taken ART or is ART-naive and the willingness of the patient to adhere to the lifelong treatment regimen.

Achieving viral suppression requires the use of combination ART regimens that generally include three active drugs from two or more drug classes (Panel, 2019). Viral load suppression to below limits of assay detection usually occurs within the first 12 to 24 weeks of taking ART. Predictors of virologic reduction include: (1) low baseline viremia; (2) high potency of the ART regimen; (3)

tolerability of the regimen; (4) convenience of the regimen; and (5) excellent adherence to the regimen.

More than 30 antiretroviral (ARV) drugs in seven classes are Food and Drug Administration (FDA)–approved for treatment of HIV infection. These seven classes target different stages of the HIV/host interaction. Examples include the nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) (stage 3), non-nucleoside reverse transcriptase inhibitors (NNRTIs) (stage 3), protease inhibitors (PIs) (stage 7), integrase strand transfer inhibitors (INSTIs) (stage 4), a fusion inhibitor (stage 2), a CCR5 antagonist (stage 1), and a $CD4^+$ post-attachment inhibitor (stage 1) (see Fig. 32-2). In addition, some drugs are used as pharmacokinetic enhancers (or boosters) to improve the effectiveness of other ARV drugs (Panel, 2019). The Panel (2019) provides clear directions regarding which medications should be prescribed for both ART-naive and experienced patients.

The CDC estimates that HIV has not yet been diagnosed in about 13% of the people living with HIV in the United States. After receiving an HIV diagnosis, about 75% of individuals are linked to care within 30 days, but only 57% of persons who receive an HIV diagnosis are retained in HIV care. It is estimated that only 55% of persons with diagnosed HIV are virally suppressed because of poor linkage to care and retention in care (Panel, 2019). Viral loads are often not suppressed because the patient is not adhering to the treatment plan. Psychosocial barriers such as depression and other mental illnesses, neurocognitive impairment, low health literacy, low levels of social support, stressful life events, high levels of alcohol consumption and active substance use, homelessness, poverty, nondisclosure of HIV serostatus, denial, stigma, and inconsistent access to medications affect adherence to ART. Failure to adopt practices that facilitate adherence, such as linking medication taking to daily activities or using a medication reminder system or a pill organizer, is also associated with treatment failure (Panel, 2019). Simplifying treatment regimens and decreasing the number of medications that must be taken each day also helps to increase patients' adherence to therapy. Although antiretroviral regimens have become less complex, side effects create barriers to adherence and inadequate dosing can lead to viral resistance. It is difficult to predict patients' adherence to medication regimens, but a positive relationship between the patient and health care provider is associated with better adherence (Hill, Golin, Pack, et al., 2020).

Chart 32-8 summarizes strategies that health care providers can encourage to promote treatment regimen adherence. Many real-time monitoring systems, such as electronic pill boxes, are under investigation as well as pharmacologic monitoring of blood and hair (Hill et al., 2020). Real-time monitoring has the potential to enhance ART intervention programs by providing objective information about medication taking behaviors. Every health care encounter

should be used as an opportunity to briefly review the treatment regimen, identify any new issues, and reinforce successful behaviors.

Laboratory tests evaluate whether ART is effective for a specific patient. An adequate $CD4^+$ response for most patients on ART is an increase in $CD4^+$ count in the range of 50 to 150 mm^3 per year, generally with an accelerated response in the first 3 months (Panel, 2019). Viral load should be measured at baseline and on a regular basis thereafter because viral load is the most important indicator of response to ART.

Adverse effects associated with all HIV treatment regimens include hepatotoxicity, nephrotoxicity, and osteopenia, along with increased risk of cardiovascular disease and myocardial infarction (see Table 32-4). Many of the antiretroviral agents may cause fat redistribution syndrome and metabolic alterations such as dyslipidemia and insulin resistance, which put the patient at risk for early-onset heart disease and diabetes. The fat redistribution syndrome (lipodystrophy) consists of lipoatrophy (localized subcutaneous fat loss in the face, arms, legs, and buttocks) and lipohypertrophy (central visceral fat [lipomata] accumulation in the abdomen, although possibly in the breasts, dorsocervical region [buffalo hump], and within the muscle and liver). Facial wasting, characterized as a sinking of the cheeks, eyes, and temples caused by the loss of fat tissue under the skin, may be treated by injectable fillers such as poly-l-lactic acid (see Fig. 32-3). These changes can disturb the body image of people living with HIV/AIDS and may be a reason that they decline or stop ART.

Chart 32-8

Promoting Adherence to ART

Strategies	Examples
Use a multidisciplinary team approach. Provide an accessible, trustworthy health care team.	• Nonjudgmental providers, nurses, social workers, pharmacists, and medication managers.
Strengthen early linkage to care and retention in care.	• Encourage health care team participation in linkage to and retention in care.
Assess patient readiness to start ART.	• Address specific concerns such as drug interactions between ART and hormones for transgender patients.
Evaluate patient's knowledge about HIV disease, prevention and treatment and, on the basis of the assessment, provide HIV-related information.	• Consider the patient's current knowledge base, provide information about HIV, including the natural history of the disease, HIV viral load and $CD4^+$ count and expected clinical outcomes according to these parameters, and therapeutic and prevention consequences of nonadherence.
Identify facilitators, potential barriers to adherence, and necessary medication management skills before starting ART medication.	• Assess patient's cognitive competence and any impairment. • Assess behavioral and psychosocial challenges including depression, mental illnesses, levels of social support, high levels of alcohol consumption and active substance use, nondisclosure of HIV serostatus and stigma. • Identify and address language and literacy barriers. • Assess beliefs, perceptions, and expectations about taking ART (e.g., impact on health, side effects, disclosure issues, consequences of nonadherence). • Ask about medication taking skills and foreseeable challenges with adherence (e.g., past difficulty keeping appointments, adverse effects from previous medications, issues managing other chronic medications, need for medication reminders and organizers). • Assess structural issues including unstable housing, lack of income, unpredictable daily schedule, lack of prescription drug coverage, lack of continuous access to medications.
Provide needed resources.	• Provide or refer for mental health and/or substance abuse treatment.

	• Provide resources to obtain prescription drug coverage, stable housing, social support, and income and food security. • Encourage use of valid Internet sites for health-related information.
Involve the patient in ARV regimen selection.	• Review regimen potency, potential side effects, dosing frequency, pill burden, storage requirements, food requirements, and consequences of nonadherence. • Assess daily activities and tailor regimen to predictable and routine daily events. • Use single tablet fixed-dose combination formulation. • Assess if cost/co-payment for drugs can affect access to medications and adherence.
Assess adherence at every clinic visit.	• Monitor viral load as a strong biologic measure of adherence. • Use a simple behavioral rating scale. • Employ a structured format that normalizes or assumes less-than-perfect adherence and minimizes socially desirable or “white coat adherence” responses. • Ensure that other members of the health care team also assess adherence.
Use positive reinforcement to foster adherence success.	• Inform patients of low or nondetectable levels of HIV viral load and increases in $CD4^+$ cell counts. • When needed, consider providing incentives and rewards for achieving high levels of adherence and treatment success.
Identify the type of and reasons for nonadherence.	• Failure to fill the prescription(s). • Failure to understand dosing instructions. • Complexity of regimen (e.g., pill burden, size, dosing schedule, food requirements). • Pill aversion. • Pill fatigue. • Adverse effects. • Inadequate understanding of drug resistance and its relationship to adherence. • Cost-related issues. • Depression, drug and alcohol use, homelessness, poverty.

	• Stigma. • Nondisclosure. • Other potential barriers.
Select from among available effective treatment adherence interventions.	• Use evidence-based interventions to promote adherence. • Use adherence-related tools to complement education and counseling interventions (e.g., pill boxes, dose planners, reminder devices). • Use community resources to support adherence (e.g., visiting nurses, community workers, family, peer advocates). • Use patient prescription assistance programs. • Use motivational interviews.
Systematically monitor retention in care.	• Record and follow up on missed visits.
On the basis of any problems identified through systematic monitoring, consider options to enhance retention in care given resources available.	• Provide outreach for those patients who drop out of care. • Use peer or paraprofessional treatment navigators. • Employ incentives to encourage clinic attendance or recognize positive clinical outcomes resulting from good adherence. • Arrange for directly observed therapy (if feasible).

Adapted from Panel on Antiretroviral Guidelines for Adults and Adolescents (Panel). (2019). Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents. Department of Health and Human Services. Strategies to Improve Linkage to Care, Retention in Care, Adherence to Appointments, and Adherence to Antiretroviral Therapy (pp. 236–237).

TABLE 32-4 Select Antiretroviral Agents

Generic Name (Abbreviation) and Single-Tablet Combination Names (Italic)	Food Interactions	Adverse Effects
Nucleoside Reverse Transcriptase Inhibitors (NRTIs)		
Abacavir (ABC) *Trizivir* (ABC/ZDV/3TC) *Epzicom* (ABC/3TC) (ABC/3TC/DTG)	Take without regard to meals	Hypersensitivity reaction, which can be fatal; symptoms may include fever, rash, nausea, vomiting, diarrhea, abdominal pain, malaise or fatigue, loss of appetite, and respiratory symptoms such as sore throat, cough, shortness of breath.
Didanosine (ddl)	Take half hour before or 2 h after meals	Pancreatitis, peripheral neuropathy, retinal changes, nausea, diarrhea, lactic acidosis with fatty degeneration of the liver, insulin resistance/diabetes.
Emtricitabine (FTC) *Atripla* (FTC/EFV/TDF) *Biktarvy* (BIC/TAF/FTC) *Complera* (RPV/TDF/FTC) *Descovy* (TAF/FTC) *Genvoya* (EVG/c/TAF/FTC) *Odefsey* (RPV/TAF/FTC) *Symtuza* (DRV/c/TAF) *Stribild* (FTC/EVG/c/TDF) *Truvada* (FTC/TDF)	Take without regard to meals	Minimal toxicity; hyperpigmentation/skin discoloration. Severe acute exacerbation of hepatitis may occur in patients with HBV/HIV coinfection who discontinue FTC.
Lamivudine (3TC) *Cimduo* (TDF/3TC) *Combivir* (ZDV/3TC) *Epzicom* (ABC/3TC) *Temixys* (TDF/3TC) *Trizivir* (ABC/ZDV/3TC) *Delstrigo* (DOR/TDF/3TC)	Take without regard to meals	Minimal toxicity. Severe acute exacerbation of hepatitis may occur in patients with HBV/HIV coinfection who discontinue 3TC.

Dovato (DTG/3TC) *Symfi/Symfi LO* (EFV/TDF/3TC) *Triumeq* (DTG/ABC/3TC)		
Stavudine (d4T)	Take without regard to meals	Peripheral neuropathy; lipoatrophy; pancreatitis; lactic acidosis/severe hepatomegaly with hepatic steatosis (this is a rare, but potentially life-threatening, toxicity); hyperlipidemia; insulin resistance/diabetes mellitus; rapidly progressive ascending neuromuscular weakness (rare)
Tenofovir alafenamide (TAF) *Biktarvy* (BIC/TAF/FTC) *Descovy* (TAF/FTC) *Genvoya* (EVG/c/TAF/FTC) *Odefsey* (RPV/TAF/FTC) *Symtuza* (DRV/c/TAF/FTC)	Take without regard to meals	Renal insufficiency, Fanconi syndrome, and proximal renal tubulopathy are less likely to occur with TAF than with TDF. Osteomalacia and decrease in bone mineral density are less likely to occur with TAF than with TDF. Severe acute exacerbation of hepatitis may occur in patients with HBV/HIV coinfection who discontinue TAF. Diarrhea, nausea, headache
Tenofovir disoproxil fumarate (TDF) *Atripla* (EFV/TDF/FTC) *Cimduo* (TDF/3TC) *Complera* (RPV/TDF/FTC) *Delstrigo* (DOR/TDF/3TC) *Stribild* (EVG/c/TDF/FTC) *Symfi/Symfi Lo* (EFV/TDF/3TC) *Temixys* (TDF/3TC) *Truvada* (TDF/FTC)	Take without regard to meals	Renal insufficiency, Fanconi syndrome, proximal renal tubulopathy, osteomalacia, decrease in bone mineral density. Severe acute exacerbation of hepatitis may occur in patients with HBV/HIV coinfection who discontinue TDF. Asthenia, headache, diarrhea, nausea, vomiting, flatulence
Zidovudine (AZT or ZDV) *Combivir* (3TC/AZT) *Trizivir* (ABC/3TC/AZT)	Take without regard to meals	Bone marrow suppression; macrocytic anemia or neutropenia; nausea, vomiting, headache, insomnia, asthenia, nail pigmentation; lactic acidosis/severe hepatomegaly with hepatic steatosis (this is a rare, but potentially life-threatening, toxicity). Hyperlipidemia; insulin resistance/diabetes mellitus; lipoatrophy; myopathy
Non-Nucleoside Reverse Transcriptase Inhibitors		
Doravirine (DOR)	Take without	Nausea, dizziness, abnormal dreams

Delstrigo (DOR/TDF/3TC)	regard to meals	
Efavirenz (EFV) *Atripla* (EFV/TDF/FTC) *Symfi/Symfi Lo* (EFV/TDF/3TC)	Take on empty stomach at bedtime	Rash; neuropsychiatric symptoms; serum transaminase elevations; hyperlipidemia; QT interval prolongation Use of EFV may lead to false-positive results with some cannabinoid and benzodiazepine screening assays.
Etravirine (ETR)	Take following a meal	Rash, including Stevens–Johnson syndrome; HSRs, characterized by rash, constitutional findings, and sometimes organ dysfunction (including hepatic failure), have been reported; nausea.
Nevirapine (NVP)	Take without regard to meals	Rash (reported in approximately 50% of cases), including Stevens–Johnson syndrome; symptomatic hepatitis, including fatal hepatic necrosis; symptomatic hepatitis occurs at a significantly higher frequency in ARV-naive female patients with pre-NVP $CD4^+$ counts >250 cells/mm^3 and in ARV-naive male patients with pre-NVP $CD4^+$ counts >400 cells/mm^3. NVP should not be initiated in these patients unless the benefit clearly outweighs the risk.
Rilpivirine (RPV) *Complera* (RPV/TDF/FTC) *Juluca* (DTG/RPV) *Odefsey* (RPV/TAF/FTC)	Take with a meal	Rash, depression, insomnia, headache, hepatotoxicity, QT interval prolongation
Protease Inhibitors		
Atazanavir (ATV) *Evotaz (ATV/c)*	Take with food	Indirect hyperbilirubinemia; prolonged PR interval (some patients experience asymptomatic first-degree AV block); EKG changes; hyperglycemia; fat maldistribution; possible increased bleeding episodes in patients with hemophilia; Cholelithiasis; nephrolithiasis; renal insufficiency; serum transaminase elevations; hyperlipidemia (especially with RTV boosting); rash; hyperglycemia; fat maldistribution
Darunavir (DRV) *Prezcobix (DRV/c)*	Take with food	Rash: DRV has a higher allergy risk, Stevens–Johnson syndrome, toxic epidermal necrolysis, acute generalized exanthematous pustulosis, and erythema multiforme have been reported. Hepatotoxicity; diarrhea; nausea; headache; hyperlipidemia; serum

		transaminase elevation; hyperglycemia; fat maldistribution. An increase in serum creatinine may occur when DRV is administered with COBI.
Fosamprenavir (FPV)	Tablets may be taken with or without food	Rash has been reported in 12–19% of patients on FPV. FPV has an increased allergy risk. Diarrhea, nausea, vomiting, headache, hyperlipidemia, serum transaminase elevation, hyperglycemia, fat maldistribution, possible increase in the frequency of bleeding episodes in patients with hemophilia, nephrolithiasis.
Indinavir (IDV)	For upboosted IDV: Should be taken 1 h before or 2 h after meals; may take with skim milk or low-fat meal For RTV-boosted IDV: Can be taken with or without food Drink at least 48 oz of water daily	Nephrolithiasis, GI intolerance, nausea, hepatitis, indirect hyperbilirubinemia, hyperlipidemia, headache, asthenia, blurred vision, dizziness, rash, metallic taste, thrombocytopenia, alopecia, hemolytic anemia, hyperglycemia, fat maldistribution, possible increased bleeding episodes in patients with hemophilia.
Lopinavir + ritonavir (LPV/r)	Tablet: take without regard to meals Oral solution: take with food; contains 42% alcohol	GI intolerance, nausea, vomiting, diarrhea, asthenia, pancreatitis, hyperlipidemia (especially hypertriglyceridemia), elevated serum transaminase, hyperglycemia, insulin resistance/diabetes mellitus, fat maldistribution, possible increased bleeding episodes in patients with hemophilia, EKG changes.
Nelfinavir (NFV)	Dissolve tablets in a small amount of water, mix admixture well, and consume immediately. Take with food	Diarrhea, hyperlipidemia, hyperglycemia, fat maldistribution, possible increased bleeding episodes in patients with hemophilia, serum transaminase elevation.
Ritonavir (RTV)	Take with food	GI intolerance, nausea, vomiting, diarrhea, paresthesias (circumoral and extremities), hyperlipidemia (especially

		hypertriglyceridemia), hepatitis, asthenia, taste perversion, hyperglycemia, fat maldistribution, possible increased bleeding in patients with hemophilia.
Saquinavir (SQV)	Take with meals or within 2 h after meal	GI intolerance, nausea, diarrhea, abdominal pain and dyspepsia, headache, hyperlipidemia, elevated transaminase enzymes, hyperglycemia, fat maldistribution, possible increased bleeding episodes in patients with hemophilia, EKG changes.
Tipranavir (TPV)	Take with food	Hepatotoxicity; clinical hepatitis (including hepatic decompensation and hepatitis-associated fatalities) has been reported. Skin rash. Rare cases of fatal and nonfatal intracranial hemorrhages have been reported. Hyperlipidemia, hyperglycemia, fat maldistribution. Possible increase in the frequency of bleeding episodes in patients with hemophilia.
Integrase Strand Transfer Inhibitors		
Dolutegravir (DTG) *Dovato* (DTG/3TC) *Juluca* (DTG/RPV) *Triumeq* (DTG/ABC/3TC)	Take without regard to meals	Insomnia, headache, depression and suicidal ideation (rare; usually occurs in patients with preexisting psychiatric conditions). Weight gain, hepatotoxicity. Preliminary data suggest an increased rate of neural tube defects in infants born to mothers who were taking DTG at the time of conception. Hypersensitivity reaction, including rash, constitutional symptoms, and organ dysfunction (including liver injury), have been reported.
Elvitegravir (EVG) *Stribild (EVG/c/FTC/TDF)*	Take with food	Nausea, diarrhea, depression and suicidal ideation (rare; usually occurs in patients with preexisting psychiatric conditions).
Raltegravir (RAL)	Take without regard to meals	Rash including Stevens–Johnson, hypersensitivity reaction and toxic epidermal necrolysis. Nausea, headache, diarrhea, pyrexia, CPK elevation, muscle weakness, rhabdomyolysis, insomnia. Depression and suicidal ideation (rare; usually occurs in patients with preexisting psychiatric conditions).
Fusion Inhibitor		
Enfuvirtide (T-20)	Injected	Local injection site reactions (e.g., pain, erythema, induration, nodules and cysts, pruritus, ecchymosis) in almost 100% of patients. Increased incidence of bacterial

		pneumonia. Hypersensitivity reaction can occur and rechallenge is not recommended.
CCR5 Antagonist		
Maraviroc (MVC)	Take without regard to meals; requires CCR5 tropism blood test before starting	Abdominal pain, cough, fever, dizziness, headache, orthostatic hypotension, nausea, bladder irritation; possible liver problems and cardiac events; an increased risk for some infections; a slight increase in cholesterol levels; orthostatic hypotension, especially in patients with severe renal insufficiency.
CD4 Post-Attachment Inhibitor		
Ibalizumab (IBA)	IV administration	Diarrhea, dizziness, nausea, rash

Department of Health and Human Services. Retrieved on 10/28/18 at: aidsinfo.nih.gov/contentfiles/lvguidelines/adultandadolescentgl.pdf

ART Drug Resistance

Drug resistance is the ability of pathogens to withstand the effects of medications that should be toxic to them. There are two major components of ART resistance: (1) transmission of drug-resistant HIV at the time of initial infection and (2) selective drug resistance in patients who are receiving nonsuppressive regimens. Genotypic and phenotypic resistance assays are used to assess viral strains and inform selection of treatment strategies. Genotypic assays detect drug-resistant mutations present in relevant viral genes while phenotypic assays measure the ability of a virus to grow in different concentrations of ART drugs. Resistance testing in persons who are chronically infected is recommended at the time of entry into HIV care. Although no definitive prospective data exist to support the choice of one type of resistance testing over another, genotypic testing is generally preferred because of lower cost, more rapid turnaround time, the assay's ability to detect mixtures of wild-type and resistant virus, and the relative ease of interpreting test results. If therapy is deferred, repeat testing soon before initiation of ART should be considered because the patient may have acquired drug-resistant virus (i.e., superinfection) (Panel, 2019).

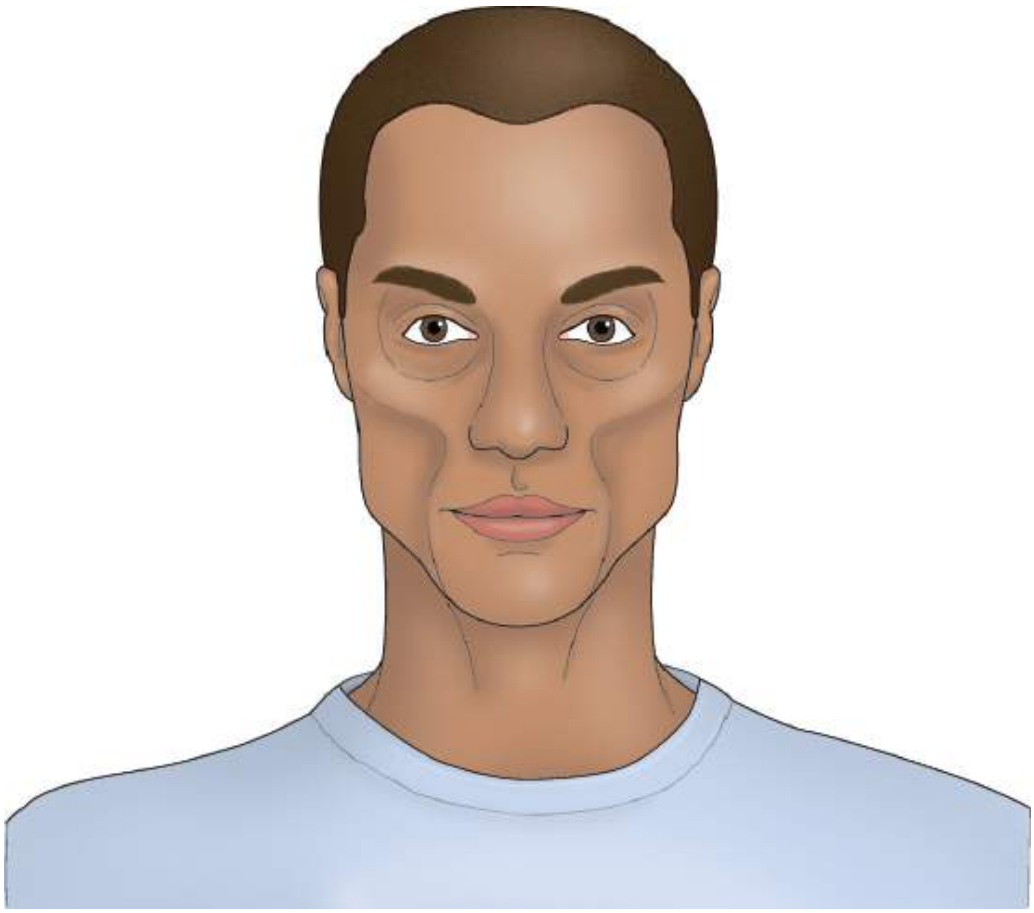

Figure 32-3 • Facial lipoatrophy.

Immune Reconstitution Inflammatory Syndrome

Immune reconstitution inflammatory syndrome (IRIS) results from rapid restoration of organism-specific immune responses to infections that cause either the deterioration of a treated infection or new presentation of a subclinical infection. This syndrome typically occurs during the initial months after beginning ART and is associated with a wide spectrum of organisms, most commonly mycobacteria, herpes viruses, and deep fungal infections. IRIS is characterized by fever, respiratory and/or abdominal symptoms, and worsening of the clinical manifestations of an opportunistic infection or the appearance of new manifestations. IRIS is treated with anti-inflammatory medications such as cortisone. The nurse should be alert to the possibility of IRIS, especially in the 3-month period after treatment with ART is initiated, because this syndrome is associated with significant morbidity and patients often require hospital admission.

Paradoxical tuberculosis-associated immune reconstitution inflammatory syndrome (TB-IRIS) is a serious complication that arises during successful ART in patients with HIV-TB co-infection who are receiving TB treatment. In the majority of patients, TB-IRIS occurs within the first few weeks of ART but can occur much later. Patients with HIV-TB co-infection with low $CD4^+$

counts who start ART are at high risk of developing TB-IRIS. Although the immunopathogenesis of TB-IRIS is still not completely understood, the explosive restoration of T-cell function is believed to play a distinct role (Narendran, Oliveira-de-Souza, Vinhaes, et al., 2019).

Clinical Manifestations

Patients with HIV/AIDS experience a number of symptoms related to the disease, side effects of treatment, and other comorbidities, including pancreatitis, hepatitis, and cardiometabolic abnormalities. The clinical manifestations of HIV/AIDS are widespread and may involve virtually any organ system. Patients in stage 3 or AIDS (see Table 32-2) are severely immune depressed and can develop opportunistic infections. Nurses need to understand the causes, signs and symptoms, and interventions, including self-management strategies that can enhance the quality of life for patients throughout the different stages of the illness. Symptom assessment tools can be used to assess patients' symptom intensity and severity. PLWHA use a variety of self-management strategies to minimize common symptoms.

Respiratory Manifestations

Shortness of breath, dyspnea (labored breathing), cough, chest pain, and fever are associated with various opportunistic infections, such as those caused by *Pneumocystis jirovecii, Mycobacterium avium-intracellulare,* cytomegalovirus (CMV), and *Legionella* species.

Pneumocystis Pneumonia

***Pneumocystis* pneumonia (PCP)** is caused by *P. jirovecii* (formerly *P. carinii*) (Panel on Opportunistic Infections in Adults and Adolescents with HIV [OI-Panel], 2019) and is associated with $CD4^+$ T-lymphocyte ($CD4^+$) cell counts less than 200 cells/mm^3. The most common manifestations of PCP are subacute onset of progressive dyspnea, fever, nonproductive cough, and chest discomfort that worsens within days to weeks. In mild cases, pulmonary examination usually is normal at rest. With exertion, tachypnea, tachycardia, and diffuse dry (cellophane) rales may be auscultated. Fever is apparent in most cases and may be the predominant symptom. Hypoxemia is the most characteristic laboratory abnormality, along with elevated lactate dehydrogenase levels. Because clinical presentation, blood tests, and chest X-rays are not pathognomonic for PCP, and because the organism cannot be cultivated routinely, histopathologic or cytopathologic demonstration of organisms in tissue, bronchoalveolar lavage fluid, or induced sputum samples is required for a definitive diagnosis (OI-Panel, 2019).

Mycobacterium Avium Complex

***Mycobacterium avium* complex (MAC)** disease is a common opportunistic infection that typically occurs in patients with $CD4^+$ T-lymphocyte ($CD4^+$) cell counts less than 50 cells/mm^3. MAC is caused by infection with different types of mycobacterium: *Mycobacterium avium, Mycobacterium intracellulare,* or *Mycobacterium kansasii.* Early symptoms may be minimal and can precede detectable mycobacteremia by several weeks and include fever, night sweats, weight loss, fatigue, diarrhea, and abdominal pain. A confirmed diagnosis of disseminated MAC disease is based on compatible clinical signs and symptoms coupled with the isolation of MAC from cultures of blood, lymph node, bone marrow, or other normally sterile tissue or body fluids (OI-Panel, 2019).

Tuberculosis

The estimated annual risk of reactivation with TB among those with untreated HIV infection and latent TB infection is 3% to 16% and approximates the lifetime risk for individuals without HIV infection who have latent TB infection. TB disease can occur at any $CD4^+$ T-lymphocyte ($CD4^+$ cell) count, although the risk increases with progressive immune deficiency. Testing for latent TB at the time of HIV diagnosis should be routine, regardless of an individual's risk of TB exposure. Individuals with negative diagnostic tests for latent TB who have stage 3 HIV infection should be retested once their $CD4^+$ count increases due to ART. Screening for symptoms (asking for cough of *any* duration) coupled with chest radiography is recommended to exclude TB disease in a patient with a positive skin test or interferon-gamma release assays. Latent TB in a person with HIV infection is treated with isoniazid, supplemented with pyridoxine to prevent peripheral neuropathy, for 9 months since it has proven efficacy, good tolerability, and infrequent severe toxicity (OI-Panel, 2019).

TB disease can develop in the lungs as well as in extrapulmonary sites such as the central nervous system (CNS), bone, pericardium, stomach, peritoneum, and scrotum and initial diagnostic testing is directed at the anatomic site of symptoms or signs, such as the lungs, lymph nodes, and cerebrospinal fluid. TB in individuals with advanced immune deficiency can be rapidly progressive and fatal if treatment is delayed and such patients often have smear-negative sputum specimens. Therefore, after collection of available specimens for culture and molecular diagnostic tests, empiric treatment for TB is warranted in patients with clinical and radiographic presentation suggestive of HIV-related TB. Treatment of suspected TB in individuals with HIV infection is the same as for those who are HIV uninfected and should include an initial four-drug combination of isoniazid, rifampin, pyrazinamide, and ethambutol (OI-Panel, 2019).

Gastrointestinal Manifestations

The gastrointestinal manifestations of HIV infection and AIDS include loss of appetite, nausea, vomiting, oral and esophageal candidiasis, and chronic diarrhea. Gastrointestinal symptoms may be related to the direct inflammatory effect of HIV on the cells lining the intestines. Some of the enteric pathogens that occur most frequently, identified by stool cultures or intestinal biopsy, are *Cryptosporidium muris, Salmonella* species, *Isospora belli, Giardia lamblia,* cytomegalovirus (CMV), *Clostridium difficile,* and *M. avium-intracellulare.* In patients with AIDS, the effects of diarrhea can be devastating in terms of profound weight loss (more than 10% of body weight), fluid and electrolyte imbalances, perianal skin excoriation, weakness, and inability to perform the usual activities of daily living.

Candidiasis

Oropharyngeal and esophageal **candidiasis** (fungal infections) are common in patients with HIV infection. Oropharyngeal candidiasis is characterized by painless, creamy white, plaquelike lesions that can occur on the buccal surface, hard or soft palate, oropharyngeal mucosa, or tongue surface. Lesions can be easily scraped off with a tongue depressor or other instrument which is in contrast to lesions associated with oral hairy leukoplakia. In women with early-stage HIV infection, *Candida* vulvovaginitis usually presents the same as in women without HIV infection, with white adherent vaginal discharge associated with mucosal burning and itching of mild-to-moderate severity and sporadic recurrences (OI-Panel, 2019).

HIV Wasting Syndrome

Wasting syndrome is the involuntary loss of more than 10% of one's body weight while having experienced diarrhea or weakness and fever for more than 30 days. Wasting refers to the loss of muscle mass, although part of the weight loss may also be due to loss of fat.

Oncologic Manifestations

Those with HIV/AIDS are at greater risk of developing certain cancers. These include **Kaposi sarcoma** (KS), lymphoma, and invasive cervical cancer. KS and lymphomas are discussed next. Cervical carcinoma is described later in the Gynecologic Manifestations section.

Kaposi Sarcoma

KS is caused by human herpesvirus-8 (HHV-8); affects eight times more men than women; and may spread through sexual contact. It involves the epithelial layer of blood and lymphatic vessels. AIDS-related KS exhibits a variable and aggressive course, ranging from localized cutaneous lesions to disseminated disease involving multiple organ systems. Cutaneous signs may be the first

manifestation of HIV; they can appear anywhere on the body and are usually brownish pink to deep purple. They may be flat or raised and surrounded by ecchymosis (hemorrhagic patches) and edema (see Fig. 32-4). Rapid development of lesions involving large areas of skin is associated with extensive disfigurement and significant body image issues. The location and size of some lesions can lead to venous stasis, lymphedema, and pain. Ulcerative lesions disrupt skin integrity and increase discomfort and susceptibility to infection. The most common sites of visceral involvement are the lymph nodes, gastrointestinal tract, and lungs. Involvement of internal organs may eventually lead to organ failure, hemorrhage, infection, and death.

Figure 32-4 • Lesions of the AIDS-related Kaposi sarcoma. Whereas some patients may have lesions that remain flat, others experience extensively disseminated, raised lesions with edema. Reprinted with permission from DeVita, V. T., Jr., Hellman, S., & Rosenberg, S. (Eds.). (1993). *AIDS: Etiology, diagnosis, treatment, and prevention* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Diagnosis of KS is confirmed by biopsy of suspected lesions. Prognosis depends on the extent of the tumor, the presence of other symptoms of HIV infection, and the $CD4^+$ count. Death may result from tumor progression, but more often it results from other complications of HIV infection.

AIDS-Related Lymphomas

AIDS-related lymphomas include both Hodgkin lymphoma and non-Hodgkin lymphoma. Non-Hodgkin lymphoma is more common. AIDS-related

lymphoma is usually aggressive; there are three main types: diffuse large B-cell; B-cell immunoblastic; and small noncleaved cell lymphoma. Symptoms include weight loss, night sweats, and fever. The complete blood count might be abnormal and a biopsy will confirm the diagnosis.

Neurologic Manifestations

HIV-related brain changes have profound effects on cognition, including motor function, executive function, attention, visual memory, and visuospatial function. Neurologic dysfunction results from direct effects of HIV on nervous system tissue, opportunistic infections, primary or metastatic neoplasm, cerebrovascular changes, metabolic encephalopathies, or complications secondary to therapy. Immune system response to HIV infection in the CNS includes inflammation, atrophy, demyelination, degeneration, and necrosis.

Subcortical Neurodegenerative Disease

Approximately 20% of those living with HIV infection are at risk for developing a subcortical neurodegenerative disease known as HIV-associated neurocognitive disorder (HAND) (Cummins, Waters, Aggar, et al., 2019). The signs of HAND can be subtle and include changes in language, memory, problem solving and slowing of psychomotor skills (Cummins et al., 2019). Early identification is important as HAND can be treated by changing ART medications.

Peripheral Neuropathy

Peripheral neuropathy is a common neurologic symptom at any stage of HIV infection. It may be a side effect of some ART drugs, and may occur in a variety of patterns, with distal sensory polyneuropathy or distal symmetric polyneuropathy the most frequently occurring type. It can lead to significant pain of feet and hands and functional impairment. Patients use a variety of physical and psychological self-management strategies to minimize this symptom.

HIV Encephalopathy

HIV encephalopathy was formerly referred to as AIDS dementia complex (see Chart 32-9). It is a clinical syndrome that is characterized by a progressive decline in cognitive, behavioral, and motor functions as a direct result of HIV infection. HIV has been found in the brain and cerebrospinal fluid (CSF) of patients with HIV encephalopathy. The brain cells infected by HIV are predominantly the $CD4^+$ cells of monocyte–macrophage lineage. HIV infection is thought to trigger the release of toxins or lymphokines that result in cellular dysfunction, inflammation, or interference with neurotransmitter function rather than cellular damage.

Chart 32-9

Care of the Patient with HIV Encephalopathy

Chronic Confusion

- Assess mental status and neurologic functioning.
- Monitor for medication interactions, infections, electrolyte imbalance, and depression.
- Frequently orient the patient to time, place, person, reality, and the environment.
- Use simple explanations.
- Instruct the patient to perform tasks in incremental steps.
- Provide memory aids (clocks and calendars).
- Provide memory aids for medication administration.
- Post activity schedule.
- Give positive feedback for appropriate behavior.
- Educate caretakers about orienting patient to time, place, person, reality, and the environment.
- Encourage the patient to designate a responsible person to assume power of attorney.

Disturbed Sensation

- Assess sensory impairment.
- Decrease number of stimuli in the patient's environment.
- Correct inaccurate perceptions.
- Provide reassurance and safety if the patient displays fear.
- Provide a secure and stable environment.
- Educate caregivers about recognizing inaccurate sensory perceptions.
- Provide caregivers techniques to correct inaccurate perceptions.
- Instruct the patient and caregivers to report any changes in the patient's vision to the patient's health care provider.

Risk for Injury

- Assess the patient's level of anxiety, confusion, or disorientation.
- Assess the patient for delusions or hallucinations.
- Remove potentially dangerous objects from the patient's environment.
- Structure the environment for safety (ensure adequate lighting, avoid clutter, provide bed rails if needed).
- Supervise smoking.
- Do not let the patient drive a car if confusion is present.
- Instruct the patient and caregiver in home safety.
- Provide assistance as needed for ambulation and in getting in and out of bed.
- Pad headboard and side rails if the patient has seizures.

Self-Care Deficits

- Encourage activities of daily living within the patient's level of ability.
- Encourage independence, but assist if the patient cannot perform an activity.
- Demonstrate any activity that the patient is having difficulty accomplishing.
- Monitor food and fluid intake.
- Weigh patient weekly.
- Encourage the patient to eat, and offer nutritious meals, snacks, and adequate fluids.
- If patient is incontinent, establish a routine toileting schedule.
- Educate caregivers about meeting the patient's self-care needs.

Signs and symptoms may be subtle and difficult to distinguish from fatigue, depression, or the adverse effects of treatment for infections and malignancies. Early manifestations include memory deficits, headache, difficulty concentrating, progressive confusion, psychomotor slowing, apathy, and ataxia. Later stages include global cognitive impairments, delay in verbal responses, a vacant stare, spastic paraparesis, hyperreflexia, psychosis, hallucinations, tremor, incontinence, seizures, mutism, and death.

Confirming the diagnosis of HIV encephalopathy can be difficult. Extensive neurologic evaluation includes a computed tomography scan, which may indicate diffuse cerebral atrophy and ventricular enlargement. Other tests that may detect abnormalities include magnetic resonance imaging, analysis of CSF through lumbar puncture, and brain biopsy.

Cryptococcus Neoformans

A fungal infection *Cryptococcus neoformans* is another common opportunistic infection among patients with AIDS, and it causes neurologic disease. Cryptococcal meningitis is characterized by symptoms such as fever, headache, malaise, stiff neck, nausea, vomiting, mental status changes, and seizures. Diagnosis is confirmed by CSF analysis.

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a demyelinating CNS disorder that affects the oligodendroglia. Clinical manifestations often begin with mental confusion and rapidly progress to include blindness, aphasia, muscle weakness, paresis (partial or complete paralysis), and death. ART has greatly reduced the mortality associated with this disorder.

Other Neurologic Disorders

Other infections involving the nervous system include *Toxoplasma gondii,* CMV, and *Mycobacterium tuberculosis* infections.

Depressive Manifestations

Depression and apathy are neuropsychiatric complications of HIV infection. Estimates suggest that the prevalence of current depression is between 12% and 60% in persons with HIV/AIDS (Lu, Hsiao, Sheng, et al., 2018). Similarly, apathy, which refers to reduced, self-initiated, cognitive, emotional, and behavioral activity, is also commonly reported among those living with a diagnosis of HIV. Alcohol and cocaine use—both current and former—have been associated with depression and apathy in this population, and depression has been associated with less adherence with ART medications (Lu et al., 2018).

Integumentary Manifestations

Cutaneous manifestations are associated with HIV infection and the accompanying opportunistic infections and malignancies. KS (described earlier) and opportunistic infections such as herpes zoster and herpes simplex are associated with painful vesicles that disrupt skin integrity. Molluscum contagiosum is a viral infection characterized by deforming plaque formation. Seborrheic dermatitis is associated with an indurated, diffuse, scaly rash involving the scalp and face. Patients with AIDS may also exhibit a generalized folliculitis associated with dry, flaking skin or atopic dermatitis, such as eczema or psoriasis. Many patients treated with the antibacterial agent trimethoprim–sulfamethoxazole develop a drug-related rash that is pruritic with pinkish-red macules and papules (Panel, 2019). Patients with any of these rashes experience discomfort, have body image changes, and are at increased risk for infection from disrupted skin integrity.

Gynecologic Manifestations

Persistent, recurrent vaginal candidiasis may be the first sign of HIV infection in women. Past or present genital ulcers are a risk factor for the transmission of HIV infection. Women with HIV infection are more susceptible to genital ulcers and venereal warts and have increased rates of incidence and recurrence of these conditions. Ulcerative STIs such as chancroid, syphilis, and herpes are more severe in women with HIV infection. Human papillomavirus (HPV) causes venereal warts and is a risk factor for cervical intraepithelial neoplasia, a cellular change that is frequently a precursor to cervical cancer. Women who are HIV seropositive and have cervical carcinoma present at a more advanced stage of disease and have more persistent and recurrent disease and a shorter interval to recurrence and death than women without HIV infection.

Women with HIV are at increased risk for pelvic inflammatory disease, a reportable infection, and the associated inflammation may increase HIV transmission to the uninfected sexual partner. Moreover, women with HIV infection appear to have a higher incidence of menstrual abnormalities,

including amenorrhea or bleeding between periods, than do women without HIV infection.

Medical Management

Treatment of Opportunistic Infections and Coinfection with Hepatitis C

Guidelines for the treatment of opportunistic infections should be consulted for the most current recommendations (OI-Panel, 2019). Although ART is highly effective in keeping the $CD4^+$ cell count high, opportunistic infections continue to cause considerable morbidity and mortality for three main reasons: (1) many patients are unaware of their HIV infection and present with an opportunistic infection as the initial indicator of their disease, (2) some patients are aware of their HIV infection but do not take antiretroviral agents because of psychosocial or economic factors, and (3) others receive prescriptions for antiretroviral medications but fail to attain adequate virologic and immunologic response as a result of issues related to adherence, pharmacokinetics, or unexplained biologic factors.

Coinfection with hepatitis C requires careful medical management for the PLWHA. Hepatitis C is curable with an 8- to 12-week drug therapy in most patients. However, the medications for the treatment of hepatitis C interact with many ART medications and therefore need to be carefully managed to avoid interactions and maximize adherence (OI-Panel, 2019; Starbird et al., 2020).

Pneumocystis Pneumonia

Persons in stage 3 HIV infection should receive chemoprophylaxis to prevent PCP with trimethoprim–sulfamethoxazole if they have $CD4^+$ counts less than 200 cells/mm^3 or a history of oropharyngeal candidiasis (OI-Panel, 2019). Once the $CD4^+$ count improves, prophylaxis can be discontinued. When a person is diagnosed with PCP, trimethoprim–sulfamethoxazole is the treatment of choice, lowering the dose if there is abnormal renal function. Adjunctive corticosteroids are indicated as early as possible, preferentially within 72 hours after starting specific PCP therapy. Treatment duration is usually 21 days; rates of adverse reaction to trimethoprim–sulfamethoxazole are high including rash (30% to 55%) (including Stevens–Johnson syndrome), fever (30% to 40%), leukopenia (30% to 40%), hepatitis (20%), thrombocytopenia (15%), azotemia (1% to 5%), and hyperkalemia. Because long-term survival is possible for patients in whom ART is effective, individuals with AIDS and severe PCP should be given the option to choose mechanical ventilation and critical care management if their functional status is such that it would be appropriate, just

as with patients without HIV infection. Paradoxical IRIS has been reported following PCP and starting ART (OI-Panel, 2019).

Mycobacterium Avium Complex

Initial treatment of MAC disease should consist of two or more antimycobacterial drugs to prevent or delay the emergence of resistance. Clarithromycin is the preferred first agent; however, azithromycin can be substituted for clarithromycin when drug interactions or intolerance to clarithromycin preclude its use. Ethambutol is the recommended second drug (OI-Panel, 2019).

Cryptococcal Meningitis

Cryptococcosis among patients with HIV infection most commonly occurs as a subacute meningitis or meningoencephalitis with fever, malaise, and headache. Treating cryptococcosis consists of three phases: induction, consolidation, and maintenance therapy. The preferred induction treatment for cryptococcal meningitis and other forms of extrapulmonary cryptococcosis is the IV lipid formulation of amphotericin B in combination with fluconazole. Serious potential adverse effects of amphotericin B include anaphylaxis, kidney and hepatic impairment, electrolyte imbalances, anemia, fever, and severe chills. After at least 2 weeks of successful induction therapy—defined as substantial clinical improvement and a negative CSF culture after repeat lumbar puncture—amphotericin B and flucytosine can be discontinued. Follow-up or consolidation therapy is then initiated with oral fluconazole daily which should continue for at least 8 weeks (OI-Panel, 2019).

Cytomegalovirus Retinitis

Retinitis caused by CMV is a leading cause of blindness in patients with AIDS. Oral valganciclovir, IV ganciclovir, IV ganciclovir followed by oral valganciclovir, IV foscarnet, IV cidofovir, and a ganciclovir intraocular implant coupled with valganciclovir are all effective treatments for CMV retinitis (OI-Panel, 2019). All of these drugs have significant toxicities (bone marrow suppression, neutropenia, hepatitis, renal toxicity, seizures, etc.) and are used with caution.

Antidiarrheal Therapy

Although many forms of diarrhea respond to treatment, it is not unusual for this condition to recur and become a chronic problem for the patient with HIV infection. Therapy with octreotide acetate, a synthetic analogue of somatostatin, has been shown to effectively manage chronic severe diarrhea. High concentrations of somatostatin receptors have been found in the gastrointestinal tract and in other tissues. Somatostatin inhibits many

physiologic functions, including gastrointestinal motility and intestinal secretion of water and electrolytes.

Chemotherapy

Kaposi Sarcoma

KS can be treated with local therapy, radiation therapy, chemotherapy, and biologic therapy depending upon the location of the lesions.

Lymphoma

There is no standard treatment for AIDS-related peripheral or systemic lymphoma. The treatment plan is adjusted for each patient and usually includes one or more of combination chemotherapy, high-dose chemotherapy and stem cell transplant.

Antidepressant Therapy

Treatment for depression in people with HIV infection involves cognitive behavioral therapy integrated with pharmacotherapy (Lu et al., 2018). If depressive symptoms are severe and of sufficient duration, treatment with antidepressants may be initiated. Antidepressants such as imipramine, desipramine, and fluoxetine may be used, because these medications also alleviate the fatigue and lethargy that are associated with depression. A psychostimulant such as methylphenidate may be used in low doses in patients with neuropsychiatric impairment. Electroconvulsive therapy may be an option for patients with severe depression who do not respond to pharmacologic interventions.

Nutrition Therapy

Alterations in lipid metabolism are associated with HIV infection and ART. Malnutrition increases the risk of infection and the incidence of opportunistic infections. Nutrition therapy should be part of the overall management plan and should be tailored to meet the nutritional needs of the patient, whether by oral diet, enteral tube feedings, or parenteral nutritional support, if needed. As with all patients, a healthy diet is essential for the patient with HIV infection. For all patients with AIDS who experience unexplained weight loss, calorie counts and weight monitoring should be obtained to evaluate nutritional status and initiate appropriate therapy. The goal is to maintain the ideal weight and, when necessary, to increase weight.

Appetite stimulants have been successfully used in patients with AIDS-related anorexia. Megestrol acetate, a synthetic oral progesterone preparation, promotes significant weight gain and inhibits cytokine IL-1 synthesis. In patients with HIV infection, it increases body weight primarily by increasing

body fat stores. Dronabinol, which is a synthetic tetrahydrocannabinol, the active ingredient in marijuana, has been used to relieve nausea and vomiting associated with cancer chemotherapy. After beginning dronabinol therapy, almost all patients with HIV infection experience a modest weight gain. The effects on body composition are unknown.

Oral supplements may be used when the diet is deficient in calories and protein. Ideally, oral supplements should be lactose free (people with HIV infection may be intolerant to lactose), high in calories and easily digestible protein, low in fat with the fat easily digestible, palatable, inexpensive, and tolerated without causing diarrhea. Nutritional supplements have been developed specifically for people with HIV infection and AIDS. Parenteral nutrition is the final option because of its prohibitive cost and associated risks, including possible infection.

Complementary, Alternative, and Integrative Health Therapies

People with HIV infection, along with many Americans, report the use of complementary, alternative, and integrative therapies. Combined with traditional therapies, these may improve the patient's overall well-being. However, there can be adverse drug–drug interactions between certain therapies (e.g., St. John's wort) and some ART.

Although there is insufficient research on the effects of complementary, alternative, and integrative therapies, a growing body of literature reports benefits for modalities involving nutrition, exercise, psychosocial treatment, and Chinese medicine. See Chapter 4 for further information on complementary, alternative, and integrative therapies.

Many patients who use these therapies do not report their use to their health care providers. To obtain a complete health history, the nurse should ask about the patient's use of complementary, alternative, and integrative therapies. Patients may need to be encouraged to report their use of these therapies to their primary provider. Problems may arise, for example, when patients are using complementary, alternative, and integrative therapies while participating in clinical drug trials; alternative therapies can have significant adverse side effects, making it difficult to assess the effects of the medications in the clinical trial. The nurse needs to become familiar with the potential adverse side effects of these therapies; if it is suspected that the therapy is causing side effects, the nurse needs to discuss this with the patient, the alternative therapy provider, and the primary provider. The nurse needs to view complementary, alternative, and integrative therapies with an open mind and try to understand the importance of this treatment to the patient. This approach will improve communication with the patient and reduce conflict.

Supportive Care

Patients who are weak and debilitated as a result of chronic illness associated with HIV infection and AIDS typically require many kinds of supportive care. Nutritional support may be as simple as providing assistance in obtaining or preparing meals. For patients with more advanced nutritional impairment resulting from decreased intake, wasting syndrome, or gastrointestinal malabsorption associated with diarrhea, parenteral feedings may be required. Imbalances that result from nausea, vomiting, and profuse diarrhea often necessitate IV fluid and electrolyte replacement.

Management of skin breakdown associated with KS, perianal skin excoriation, or immobility entails thorough and meticulous skin care that involves regular turning, cleansing, and applications of medicated ointments and dressings. To combat pain associated with skin breakdown, abdominal cramping, peripheral neuropathy, or KS, the nurse administers analgesic agents at regular intervals around the clock. Patients with a history of drug abuse will need to have tailored approaches for pain management. Relaxation and guided imagery may help reduce pain and anxiety.

Pulmonary symptoms, such as dyspnea and shortness of breath, may be related to opportunistic infections, KS, or fatigue. For patients with these symptoms, oxygen therapy, relaxation training, and energy conservation techniques may be effective. Patients with severe respiratory dysfunction may require mechanical ventilation. Before mechanical ventilation is instituted, the procedure is explained to the patient and the caregiver.

As noted previously, with the advent of ART, there are generally more positive outcomes than could be achieved years ago, and a patient mechanically ventilated has a reasonable likelihood of survival. However, if the patient decides to forego mechanical ventilation, those wishes must be followed. Ideally, the patient has prepared an advance directive identifying preferences for treatments and end-of-life care, including hospice care. If the patient has not identified preferences in advance, treatment options are described so that the patient can make informed decisions and have those wishes respected.

Nurses should anticipate that patients as well as family and friends will need support and time to share concerns. In some family systems, more than one person might be living with HIV/AIDS.

NURSING PROCESS

The Patient with HIV Infection

The nursing care of patients with HIV infection is complicated by many emotional, social, and ethical issues. The plan of care for the patient with AIDS (see Chart 32-10) is individualized to meet the needs of the patient. Care includes many of the interventions and concerns cited in the Supportive Care section.

Assessment

Nursing assessment includes identification of potential risk factors, including a history of risky sexual practices or IV/injection drug use. The patient's physical status and psychological status are assessed.

Nutritional status is assessed by obtaining a dietary history and identifying factors that may interfere with oral intake, such as anorexia, nausea, vomiting, oral pain, or difficulty swallowing. In addition, the patient's ability to purchase, prepare, and store food safely is assessed. Weight history (i.e., changes over time), anthropometric measurements, and blood urea nitrogen (BUN), serum protein, albumin, and transferrin levels provide objective measurements of nutritional status.

Chart 32-10 PLAN OF NURSING CARE

Care of the Patient with AIDS

NURSING DIAGNOSIS: Diarrhoae associated with enteric pathogens or HIV infection

GOAL: Resumption of usual bowel habits

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's normal bowel habits. 2. Assess for diarrhea: frequent, loose stools; abdominal pain or cramping, volume of liquid stools, and exacerbating and alleviating factors. 3. Obtain stool cultures, and administer antimicrobial therapy as prescribed. 4. Initiate measures to reduce hyperactivity of bowel. a. Maintain food and fluid restrictions as prescribed. Suggest BRAT diet (*b*ananas, *r*ice, *a*pplesauce, *t*ea, and *t*oast). b. Discourage smoking and use of electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars. c. Avoid bowel irritants such as fatty or fried foods, raw vegetables, and nuts. Offer small, frequent meals.	1. Provides baseline for evaluation. 2. Detects changes in status, quantifies loss of fluid, and provides basis for nursing measures. 3. Identifies pathogenic organism; therapy targets specific organism. 4. Promotes bowel rest, which may decrease acute episodes. a. Reduces stimulation of bowel. b. Eliminates nicotine, which acts as bowel stimulant. c. Prevents stimulation of bowel and abdominal	• Exhibits return to normal bowel patterns • Reports decreasing episodes of diarrhea and abdominal cramping • Identifies and avoids foods that irritate the gastrointestinal tract • Takes appropriate therapy as prescribed • Exhibits normal stool cultures • Maintains adequate fluid intake • Maintains body weight and reports no additional weight loss • States rationale for avoiding smoking • Enrolls in program to stop smoking and using ENDS • Uses medication as prescribed

5. Administer anticholinergic antispasmodics and opioids or other medications as prescribed. 6. Maintain fluid intake of at least 3 L/day unless contraindicated.	distention and promotes adequate nutrition. 5. Decreases intestinal spasms and motility. 6. Prevents hypovolemia.	• Maintains adequate fluid status • Exhibits normal skin turgor, moist mucous membranes, adequate urine output, and absence of excessive thirst

NURSING DIAGNOSIS: Risk for infection associated with immune deficiency
GOAL: Absence of infection

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor for infection: fever, chills, and diaphoresis; cough; shortness of breath; oral pain or painful swallowing; creamy-white patches in oral cavity; urinary frequency, urgency, or dysuria; redness, swelling, or drainage from wounds; vesicular lesions on face, lips, or perianal area. 2. Educate patient or caregiver about need to report possible infection. 3. Monitor white blood cell (WBC) count and differential. 4. Obtain cultures of wound drainage, skin lesions, urine, stool, sputum, mouth, and blood as prescribed. Administer	1. Allows for early detection of infection, essential for prompt initiation of treatment. Repeated and prolonged infections contribute to patient's debilitation. 2. Allows early detection of infection. 3. Elevated WBC count possibly associated with infection. 4. Assists in determining offending organism to	• Identifies reportable signs and symptoms of infection • Reports signs and symptoms of infection if present • Exhibits and reports absence of fever, chills, and diaphoresis • Exhibits normal (clear) breath sounds without adventitious breath sounds • Maintains weight • Reports adequate energy level without excessive fatigue

antimicrobial therapy as prescribed. 5. Instruct patient in ways to prevent infection. a. Clean kitchen and bathroom surfaces with disinfectants. b. Clean hands thoroughly after exposure to body fluids. c. Avoid exposure to others' body fluids or sharing eating utensils. d. Turn, cough, and deep breathe, especially when activity is decreased. e. Maintain cleanliness of perianal area. f. Avoid handling pet excreta or cleaning litter boxes, birdcages, or aquariums. g. Cook meat and eggs thoroughly. 6. Maintain aseptic technique when performing invasive procedures such as venipunctures, bladder catheterizations, and injections.	initiate appropriate treatment. 5. Minimizes exposure to infection and transmission of HIV infection to others. 6. Prevents hospital-acquired infections.	• Reports absence of shortness of breath and cough • Exhibits pink, moist oral mucous membranes without fissures or lesions • Takes appropriate therapy as prescribed • Experiences no infection • States rationale for strategies to avoid infection • Modifies activities to reduce exposure to infection or infectious persons • Practices "safer sex" • Avoids sharing eating utensils and toothbrush • Exhibits normal body temperature • Uses recommended techniques to maintain cleanliness of skin, skin lesions, and perianal area • Has others handle pet

		excreta and cleanup • Uses recommended cooking techniques

NURSING DIAGNOSIS: Impaired airway clearance associated with *Pneumocystis* pneumonia, increased bronchial secretions, and decreased ability to cough associated with weakness and fatigue

GOAL: Improved airway clearance

Nursing Interventions	Rationale	Expected Outcomes
1. Assess and report signs and symptoms of altered respiratory status, tachypnea, the use of accessory muscles, cough, color and amount of sputum, abnormal breath sounds, dusky or cyanotic skin color, restlessness, confusion, or somnolence. 2. Obtain sputum sample for culture as prescribed. Administer antimicrobial therapy as prescribed. 3. Provide pulmonary care (cough, deep breathing, postural drainage, and vibration) every 2 to 4 hours. 4. Assist patient in attaining semi- or high Fowler position. 5. Encourage adequate rest periods.	1. Indicates abnormal respiratory function. 2. Aids in identification of pathogenic organisms. 3. Prevents stasis of secretions and promotes airway clearance. 4. Facilitates breathing and airway clearance. 5. Maximizes energy expenditure and prevents excessive fatigue. 6. Facilitates expectoration of secretions; prevents stasis of secretions.	• Maintains normal airway clearance: • Respiratory rate <20 breaths/min • Unlabored breathing without the use of accessory muscles and flaring nares (nostrils) • Skin color pink (without cyanosis) • Alert and aware of surroundings • Arterial blood gas values normal • Normal breath sounds without adventitious

6. Initiate measures to decrease viscosity of secretions. a. Maintain fluid intake of at least 3 L/day unless contraindicated. b. Humidify inspired air as prescribed. c. Consult with primary provider concerning the use of mucolytic agents delivered through nebulizer or intermittent positive pressure breathing treatment. 7. Perform tracheal suctioning as needed. 8. Administer oxygen therapy as prescribed. 9. Assist with endotracheal intubation; maintain ventilator settings as prescribed.	7. Removes secretions if patient is unable to do so. 8. Increases availability of oxygen. 9. Maintains ventilation.	breath sounds • Begins appropriate therapy • Takes medication as prescribed • Reports improved breathing • Maintains clear airway • Coughs and takes deep breaths every 2 to 4 hours as recommended • Demonstrates appropriate positions and practices postural drainage every 2 to 4 hours • Reports reduced breathing difficulty when in semi- or high Fowler position • Practices energy-conserving strategies and alternates rest with activity • Demonstrates reduction in thickness (viscosity) of pulmonary secretions

- Reports increased ease in coughing up sputum
- Uses humidified air or oxygen as prescribed and indicated
- Indicates need for assistance with removal of pulmonary secretions
- Understands need for and cooperates with endotracheal intubation and the use of a mechanical ventilator
- Verbalizes concerns about respiratory difficulty, intubation, and mechanical ventilation

NURSING DIAGNOSIS: Impaired nutritional intake associated with decreased oral intake
GOAL: Intake of nutrients sufficient to meet metabolic needs

Nursing Interventions	Rationale	Expected Outcomes
1. Assess nutritional status with height, weight, age; blood urea nitrogen, serum protein, albumin, transferrin, hemoglobin, and hematocrit levels; and cutaneous anergy. 2. Obtain dietary history, including likes and dislikes and food intolerances. 3. Assess factors that interfere with oral intake. 4. Consult with dietitian to determine patient's nutritional needs.	1. Provides objective measurement of nutritional status. 2. Defines need for nutritional education; helps individualize interventions. 3. Provides basis and directions for interventions. 4. Facilitates meal planning.	• Identifies factors limiting oral intake, and uses resources to promote adequate dietary intake • Reports increased appetite • States understanding of nutritional needs • Identifies ways to reduce factors that limit oral intake • Rests before meals • Eats in pleasant, odor-free environment • Arranges meals to coincide with visitors' visits
5. Reduce factors limiting oral intake. a. Encourage patient to rest before meals b. Plan meals so that they do	5. Addresses factors limiting intake. a. Minimizes fatigue, which can decrease appetite. b. Decreases noxious stimuli.	• Reports increased dietary intake • Uses oral hygiene before meals • Takes analgesic agents before

not occur immediately after painful or unpleasant procedures. c. Encourage patient to eat meals with visitors or others when possible. d. Encourage patient to prepare simple meals or to obtain assistance with meal preparation if possible. e. Serve small, frequent meals: 6/day. f. Limit fluids 1 hour before meals and with meals. 6. Instruct patient in ways to supplement nutrition: consume protein-rich foods (meat, poultry, fish) and carbohydrates (pasta, fruit, breads). 7. Consult with primary provider and dietitian about alternative feeding (enteral or parenteral nutrition). 8. Consult with social worker or	c. Limits social isolation. d. Limits energy expenditure. e. Prevents overwhelming patient. f. Reduces satiety. 6. Provides additional proteins and calories. 7. Provides nutritional support if patient is unable to take sufficient amounts by mouth. 8. Increases availability of resources and nutrition.	meals as prescribed • Identifies ways to increase protein and caloric intake • Identifies foods high in protein and calories • Consumes foods high in protein and calories • Reports decreased rate of weight loss • Maintains adequate caloric intake • States rationale for enteral or parenteral nutrition if needed • Demonstrates skill in preparing alternate sources of nutrition

community liaison about financial assistance if patient cannot afford food.		

NURSING DIAGNOSIS: Lack of knowledge associated with means of preventing HIV transmission
GOAL: Increased knowledge concerning means of preventing disease transmission

Nursing Interventions	Rationale	Expected Outcomes
1. Instruct patient, family, and friends about routes of transmission of HIV. 2. Instruct patient, family, and friends about means of preventing transmission of HIV. a. Avoid sexual contact with multiple partners, and use precautions if sexual partner's HIV status is not certain. b. Use condoms during sexual intercourse (vaginal, anal, oral–genital); avoid mouth contact with the penis, vagina, or rectum; avoid	1. Knowledge about disease transmission can help prevent spread of disease; may also alleviate fears. 2. Reduces transmission risk. a. The risk of infection increases with the number of sexual partners, male or female, and sexual contact with those who engage in high-risk behaviors. b. Risk of HIV transmission is reduced. c. Many sex workers are infected with HIV through sexual contact with multiple partners or	• Patient, family, and friends state means of transmission • Reports and demonstrates practices to reduce exposure of others to HIV • Demonstrates knowledge of safer sexual practices • Identifies means of preventing disease transmission • States that sexual partners are informed about patient's positive HIV status in blood • Avoids IV/injection drug use and sharing of drug

sexual practices that can cause cuts or tears in the lining of the rectum, vagina, or penis. c. Avoid sex with sex workers and others at high risk. d. Do not use IV/injection drugs; if addicted and unable or unwilling to change behavior, use clean needles and syringes. e. Women who may have been exposed to HIV through sexual or drug practices should consult with a primary provider before becoming pregnant; consider the use of antiretroviral agents if pregnant. f. Consider using PrEP	IV/injection drug use. d. Clean needles and syringes are the only way to prevent HIV transmission for those who continue to use drugs. Taking precautions is important for those who are antibody positive to prevent transmitting HIV. e. HIV can be transmitted from mother to child in utero; the use of antiretroviral agents during pregnancy significantly reduces perinatal transmission of HIV. f. Taking ART before engaging in high-risk activity seems to protect against infection.	equipment with others • Understands risks and benefits associated with PrEP

NURSING DIAGNOSIS: Social isolation associated with stigma of the disease, withdrawal of support systems, isolation procedures, and fear of infecting others

GOAL: Decreased sense of social isolation

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's usual patterns of social interaction. 2. Observe for behaviors indicative of social isolation, such as decreased interaction with others, hostility, noncompliance, sad affect, and stated feelings of rejection or loneliness. 3. Provide instruction concerning modes of transmission of HIV. 4. Assist patient to identify and explore resources for support and positive mechanisms for coping (e.g., contact with family, friends, AIDS task force). 5. Allow time to be with patient other than for medications and procedures. 6. Encourage participation in diversional activities such as reading,	1. Establishes basis for individualized interventions. 2. Promotes early detection of social isolation, which may be manifested in several ways. 3. Provides accurate information, corrects misconceptions, and alleviates anxiety. 4. Enables mobilization of resources and supports. 5. Promotes feelings of self-worth and provides social interaction. 6. Provides distraction.	• Shares with others the need for valued social interaction • Demonstrates interest in events, activities, and communication • Verbalizes feelings and reactions to diagnosis, prognosis, and life changes • Identifies modes of transmission of HIV • States ways of preventing transmission of HIV to others while maintaining contact with valued friends and relatives • Reveals HIV/AIDS diagnosis to others when appropriate • Identifies resources (i.e., family, friends, and support groups) • Uses resources

television, or handcrafts.		when appropriate • Accepts offers of assistance and support • Reports decreased sense of isolation • Maintains contacts with those of importance to them • Develops or continues hobbies that effectively serve as diversion or distraction

Collaborative Problems: Opportunistic infections; impaired breathing; wasting syndrome and fluid and electrolyte imbalances; adverse reaction to medications

Goal: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
Opportunistic Infections		
1. Monitor vital signs including temperature. 2. Obtain laboratory specimens, and monitor test results. 3. Instruct the patient and caregiver about signs and symptoms of infection and the need to report them early.	1. Changes in vital signs such as increases in pulse rate, respirations, blood pressure, and temperature may indicate infection. 2. Smears and cultures can identify causative agents such as bacteria, fungi, and protozoa, and sensitivity studies can identify antibiotics or other medications effective against the causative agent. 3. Early recognition of symptoms facilitates prompt treatment and avoids extra complications.	• Exhibits stable vital signs • Experiences control of infection • Identifies signs and symptoms correctly and experiences no complications • Identifies signs and symptoms that are reportable to the primary provider • Takes medications as prescribed
Impaired Breathing		
1. Monitor respiratory rate and pattern. 2. Auscultate the chest for breath sounds and	1. Rapid shallow breathing, diminished breath sounds, and shortness of breath may indicate respiratory failure resulting in hypoxia. 2. Crackles and wheezes may indicate fluid in the	• Maintains stable respiratory rate and pattern within the normal limits

abnormal lung sounds. 3. Monitor pulse rate, blood pressure, and oxygen saturation levels.	lungs, which disrupts respiratory function and alters the blood's oxygen-carrying capacity. 3. Changes in pulse rate, blood pressure, and oxygen levels may indicate the development of respiratory or cardiac failure.	• Exhibits no adventitious lung sounds; normal breath sounds • Has stable pulse rate and blood pressure within normal limits, and exhibits no evidence of hypoxia • Oxygen saturation levels within acceptable range
Wasting Syndrome and Fluid and Electrolyte Disturbances		
1. Monitor weight and laboratory values for nutritional status. 2. Monitor intake and output and laboratory values for fluid and electrolyte imbalance (potassium, sodium, calcium, phosphorus, magnesium, and zinc). 3. Monitor for and report	1. Weight loss, malnutrition, and anemia are common in HIV infection and increase risk of superinfection. 2. Chronic diarrhea, inadequate oral intake, vomiting, and profuse sweating deplete electrolytes. Small intestine inflammation may impair the absorption of fluids and electrolytes. 3. Fluid loss results in decreased circulating volume leading to tachycardia, dry skin and mucous membranes, poor skin turgor, elevated urine specific gravity, and	• Maintains stable weight • Eats a nutritious diet • Attains and maintains hemoglobin, hematocrit, and ferritin levels within normal limits • Sustains fluid and electrolyte balance within normal limits • Exhibits no signs and symptoms of dehydration

signs and symptoms of dehydration.	thirst. Early detection allows early treatment.	
Reactions to Medications		
1. Monitor for medication interactions. 2. Monitor for and promptly report side effects from antiretroviral agents. 3. Instruct the patient and caregiver in the medication regimen.	1. People with HIV infection receive many medications for HIV and for disease complications. Early detection of medication interactions is necessary to prevent complications. 2. Side effects from antiretroviral agents can be life-threatening. Serious side effects include anemia, pancreatitis, peripheral neuropathy, mental confusion, and persistent nausea and vomiting. Corrective measures need to be instituted. 3. Knowledge of the medication purpose, correct administration, side effects, and strategies to manage or prevent side effects promotes safety and greater compliance with treatment.	• Experiences no serious side effects or complications from medications • Correctly describes medication regimen and complies with therapy, including adaptations in eating routines and type of food used with prescribed medications

The patient's level of knowledge about HIV infection, modes of disease transmission, and adherence to ART are evaluated. In addition, the level of knowledge of family (biologic and family of choice) and friends is assessed. The patient's psychological reaction to the diagnosis of HIV infection is important to explore. Reactions vary among patients and may include denial, anger, fear, shame, withdrawal from social interactions, and depressive symptoms (Lu et al., 2018). It is often helpful to gain an

understanding of how the patient has dealt with illness and major life stresses in the past. The patient's resources for support are also identified.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired nutritional intake associated with decreased oral intake
- Social isolation associated with stigma of HIV infection, withdrawal of support systems, isolation procedures, and fear of infecting others
- Grief associated with changes in lifestyle and roles
- Lack of knowledge associated with HIV infection, means of preventing HIV transmission, ART, and self-management strategies

Collaborative Problems/Potential Complications

Possible complications may include the following:

- Adverse effects of medications
- Development of HAND
- Body image changes

Planning and Goals

Goals for the patient may include improved nutritional status, increased socialization, expression of grief, increased knowledge regarding disease prevention and self-care, and absence of complications.

Nursing Interventions

Improving Nutritional Status

Nutritional status is assessed by monitoring weight; dietary intake; and serum albumin, BUN, protein, and transferrin levels. The patient is also assessed for factors that interfere with oral intake, such as anorexia and lactose intolerance. Based on the results of assessment, the nurse can implement specific measures to facilitate oral intake. The dietitian is consulted to determine the patient's nutritional requirements.

The patient is encouraged to eat foods that are easy to swallow and to avoid spicy or sticky food items and foods that are excessively hot or cold. Oral hygiene before and after meals is encouraged. The patient who is underweight is instructed about ways to enhance the nutritional value of meals. Adding eggs, butter, or fortified milk (milk to which powdered skim milk has been added to increase the caloric content) to gravies, soups, or milkshakes can provide additional calories and protein. High-calorie,

nutritional foods such as puddings, powders, milkshakes, and nutritional supplements may also be useful.

Decreasing the Sense of Isolation

People with HIV are at risk for double stigmatization. They have what society refers to as a "dreaded disease," and they may have a lifestyle that differs from what is considered acceptable by many people. The diagnosis might prompt disclosure about hidden lifestyles or behaviors to family, friends, coworkers, and health care providers. As a result, people with HIV infection may be overwhelmed with emotions such as anxiety, guilt, shame, and fear. They also may be faced with multiple losses, such as loss of financial security, normal roles and functions, self-esteem, privacy, ability to control bodily functions, ability to interact meaningfully with the environment, and sexual functioning as well as rejection by sexual partners, family, and friends. Some patients may harbor feelings of guilt because of their lifestyle or because they may have infected others in current or previous relationships. Other patients may feel anger toward sexual partners who transmitted the virus to them. Infection control measures used in the hospital or at home may further contribute to the patient's emotional isolation. Any or all of these stressors may cause the patient to withdraw both physically and emotionally from social contact.

Nurses are in a key position to provide an atmosphere of acceptance and understanding for people with HIV infection and their social networks. The patient's usual level of social interaction is assessed as early as possible to provide a baseline for monitoring changes in behaviors that suggest social isolation (e.g., decreased interaction with staff or family, hostility, nonadherence). Patients are encouraged to express feelings of isolation and loneliness, with the assurance that these feelings are not unique or abnormal.

Providing information about how to protect themselves and others may help patients avoid social isolation. Patients, family, and friends must be reassured that HIV is not spread through casual contact. Education of ancillary personnel, nurses, and physicians helps reduce factors that might contribute to patients' feelings of isolation.

Coping with Grief

The nurse can help the patient verbalize feelings and explore and identify resources for support and mechanisms for coping, especially when the patient is grieving anticipated losses. The patient is encouraged to maintain contact with family, friends, and coworkers and to use local or national support groups and hotlines. If possible, losses are identified and addressed. The patient is encouraged to continue usual activities whenever possible. Consultations with mental health counselors are useful for many patients and their families.

Improving Knowledge of HIV

The patient and family are educated about HIV infection, means of preventing HIV transmission, ART, and appropriate self-care measures. Information about the purpose of the medications, their correct administration, side effects, and strategies to manage or prevent side effects is provided.

Monitoring and Managing Potential Complications

Side Effects of Medications. Adverse effects are of concern in patients who receive numerous medications for HIV infection. Many medications can cause severe toxic effects. Patients and their caregivers need to know which signs and symptoms of side/toxic effects should be reported immediately to their primary care provider (see Table 32-4).

In addition to medications used to treat HIV infection, other medications that may be required include opioids, tricyclic antidepressants, and NSAIDs for pain relief; medications for treatment of opportunistic and coinfections; antihistamines (diphenhydramine for relief of pruritus; acetaminophen or aspirin for management of fever; and antiemetic agents for control of nausea and vomiting). Concurrent use of these medications can cause many drug interactions, resulting in hepatic and hematologic abnormalities. Therefore, careful monitoring of laboratory test results is essential.

During each contact with the patient, the nurse not only asks about side effects, but also about how well the patient is adhering to the medication regimen. To promote adherence, the nurse should assist the patient to organize and plan the medication schedule. Individualized adherence plans should consider housing and social support issues, in addition to health indicators including possible drug–drug interactions. Self-reported adherence measures can distinguish clinically meaningful patterns of medication-taking behaviors; therefore, nurses should assess if patients can describe how they are taking their ART.

Research suggests that the development of effective self-management strategies leads to increased ART adherence (Schreiner, Perazzo, Currie, et al., 2019), PLWHA at risk for high treatment burden and subsequent nonadherence are those with multiple comorbidities and low social support (Schreiner et al., 2019). See the Nursing Research Profile in Chart 32-11.

Monitoring for HAND. Each contact with the patient is also an opportunity to assess for the presence of HAND. A baseline assessment and then an annual assessment for signs and symptoms are recommended (Cummins et al., 2019). Nurses also need to educate caregivers about signs and symptoms of this subtle disorder.

Body Image Changes. Body image changes often occur in patients with HIV and are an important collaborative problem. The nurse helps the patient verbalize feelings and explore and identify resources for support and mechanisms for coping with body image changes. Consultations with

mental health counselors may be indicated for patients adjusting to body image changes.

Chart 32-11 **NURSING RESEARCH PROFILE**

Treatment Burden in People Living with HIV

Schreiner, N., Perazzo, J., Currie, J., et al. (2019). A descriptive, cross-sectional study examining treatment burden in people living with HIV. *Applied Nursing Research*, *46*, 31–36.

Purpose

Successful HIV treatment associated with advances in ART has resulted in HIV being classified as a chronic condition. The purposes of this study were to: (1) describe persons living with HIV/AIDS (PLWHA) experiencing high levels of treatment burden who are at high risk for self-management nonadherence, and (2) test the relationship between known antecedent correlates (the number of chronic conditions, social capital, and age) of self-management and treatment burden in community dwelling sample of PLWHA while controlling for socio-demographics. As an indicator of social support, the relationship between social capital and treatment burden was tested.

Design

This was a descriptive, correlational, cross-sectional secondary analysis of a larger, multi-site study that examined physical activity patterns of PLWHA. Participants were ≥18 years of age and had confirmed HIV (HIV+ ELISA with confirmatory PCR or Western blot). An additional inclusion criterion was diagnosis of two or more chronic conditions identified in the patient's medical record. The Treatment Burden Questionnaire-13 (TBQ-13) was used to measure participant treatment burden. The TBQ-13 is a psychometrically tested instrument containing 13 items inquiring about burden associated with self-management tasks such as medication administration, self-monitoring of chronic conditions, or changes in diet. The TQB-13 asks the respondent to rank the level of burden for each question with responses ranging from 0-No Burden, to 10-Very High Burden, with summed scores ranging from 0 to 130 (higher scores indicating greater treatment burden). The Social Capital Measurement Tool was used to measure social resources.

Findings

Participants were on average 50 years of age; most were African American, male, Medicaid insured, and had a high school diploma. There was a mean of 3.63 (SD = 1.76) chronic conditions and the mean treatment burden score was 22.84 (SD = 24.57). Based on established cut-off points for low, medium, and high treatment burden, the sample experienced low levels of treatment burden, though there was wide variation in treatment burden scores. Approximately 60 PLWHA (58%) reported low treatment burden, 27 (26%) moderate treatment burden, and 16 (16%) high treatment burden. The number of comorbidities was

positively associated with treatment burden, and social resources were negatively correlated with treatment burden.

Nursing Implications

Nurses need to be aware that there are potential benefits of treatment burden screening that may help to improve self-management adherence. These results can help inform nurses how to improve the self-management adherence in PLWHA who are affected by treatment burden in the clinical setting.

PROMOTING, HOME, COMMUNITY-BASED, AND TRANSITIONAL CARE

Educating Patients About Self-Care. Patients, families, and friends are educated about the routes of transmission of HIV. The nurse discusses precautions the patient can use to avoid transmitting HIV sexually (see Charts 32-2 and 32-3) or through sharing of body fluids, especially blood. Patients and their families or caregivers must receive instructions about how to prevent disease transmission, including hand hygiene techniques and methods for safely handling and disposing of items soiled with body fluids. Clear guidelines about avoiding and controlling infection, keeping regular health care appointments, symptom management, nutrition, rest, and exercise are necessary (see Chart 32-12). The importance of personal and environmental hygiene is emphasized. Caregivers are taught hand hygiene and appropriate infection prevention precautions (see Chapter 66, Charts 66-1 and 66-2). Kitchen and bathroom surfaces should be cleaned regularly with disinfectants to prevent growth of fungi and bacteria. Patients with pets are encouraged to have another person clean areas soiled by animals, such as birdcages and litter boxes. If this is not possible, patients should use gloves to clean the area and then wash their hands afterward. Patients are advised to avoid exposure to others who are sick or who have been recently vaccinated, especially with live vaccine. The importance of avoiding smoking, excessive alcohol, and over-the-counter and street drugs is emphasized. Patients who are HIV positive or who inject drugs are instructed not to donate blood. IV/injection drug users who are unwilling to stop using drugs are advised to avoid sharing drug equipment with others.

Caregivers in the home are taught how to administer medications. The medication regimens used for patients with HIV infection can be complex and expensive. Patients receiving combination therapies for the treatment of HIV infection require careful education about the importance of taking medications as prescribed and explanations and assistance in fitting the medication regimen into their lives (see Chart 32-8). If the patient requires enteral or parenteral nutrition, instruction is provided to the patient and family about how to administer nutritional therapies at home. Nurses provide ongoing education and support for the patient and family.

Continuing and Transitional Care. Many people with HIV remain in their community and continue their usual daily activities, whereas others can no longer work or maintain their independence. Families or caregivers may need assistance in providing supportive care. Many community-based organizations provide a variety of services for people living with HIV infection; nurses can help identify these services.

Home, community-based, transitional, and hospice nurses are in an excellent position to provide the support and guidance that is so often needed in the home setting. Home health nurses are key to the safe and effective administration of parenteral antibiotics, chemotherapy, and nutrition in the home.

During home visits, the nurse assesses the patient's physical and emotional status and home environment. The patient's adherence to the therapeutic regimen is assessed, and strategies are suggested to assist with adherence. The patient is assessed for progression of disease and for adverse side effects of medications. Previous education is reinforced, and the importance of keeping follow-up appointments is stressed.

Chart 32-12 **HOME CARE CHECKLIST**

Infection Prevention for the Patient with Immune Deficiency

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of immune deficiency on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in lifestyle (e.g., hygiene, activity) necessary to decrease risk for infection.
  - Maintain good hand hygiene technique before eating, after using the bathroom, and before and after performing health care procedures.
  - Maintain total body hygiene and foot care to prevent bacterial and fungal diseases.
  - Maintain skin integrity, using cream and emollients to prevent or manage dry, chafed, or cracked skin.
  - Maintain good oral hygiene and dental checkups.
  - Avoid people with infections, recent vaccinations, and crowds.
  - Perform deep breathing; use incentive spirometer every 4 hours while awake if mobility is restricted.
  - Provide adequate lubrication with gentle vaginal manipulation during sexual intercourse; avoid anal intercourse.
- State changes in home environment necessary to decrease risk for infection.
  - Avoid cleaning birdcages and litter boxes; consider avoiding garden work (soil) and fresh flowers in stagnant water.
  - Identify the rationale for frequent cleaning of kitchen and bathroom surfaces with disinfectant.
- Verbalize understanding of ways to maintain a nutritious diet and adequate calories and necessary changes to decrease risk of infection.
- State the reason for avoiding the eating of raw fruits and vegetables, cooking all foods thoroughly, and immediately refrigerating all leftover food.
- Identify rationale and benefits of avoiding alcohol, tobacco, and unprescribed medications.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Verbalize ways to cope with stress successfully, plans for regular exercise, and rationale for obtaining adequate rest.
- Identify signs and symptoms of infection to report to the primary provider, such as fever; chills; wet or dry cough; breathing problems; white patches in the mouth; swollen glands; nausea; vomiting; persistent abdominal pain; persistent diarrhea; problems

with urination or changes in the character of the urine; red, swollen, or draining wounds; sores or lesions on the body; persistent vaginal discharge with or without itching; and severe fatigue.
- Demonstrate how to monitor for signs of infection.
- Describe to whom, how, and when to report signs of infection.
- Describe appropriate actions to take should infection occur.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Complex wound care or respiratory care may be required in the home. Patients and families are often unable to meet these skilled care needs without assistance. Nurses may refer patients to community programs that offer a range of services for patients, friends, and families, including help with housekeeping, hygiene, and meals; transportation and shopping; individual and group therapy; support for caregivers; telephone networks for the homebound; and legal and financial assistance. These services are typically provided by both professionals and nonprofessional volunteers. A social worker may be consulted to identify sources of financial support, if needed.

Home health and hospice nurses are increasingly called on to provide physical and emotional support to patients and families as patients with AIDS enter the terminal stages of disease. This support takes on special meaning when people with AIDS lose friends and when family members fear the disease or feel anger concerning the patient's lifestyle. The nurse encourages the patient and family to discuss end-of-life decisions and to ensure that care is consistent with those decisions, all comfort measures are employed, and the patient is treated with dignity at all times.

Evaluation

Expected patient outcomes may include:

1. Maintains adequate nutritional status
2. Experiences decreased sense of social isolation
3. Progresses through grieving process
4. Reports increased understanding of HIV infection, prevention of HIV transmission, and ART, and participates in self-management strategies as possible
5. Remains free of complications

Emotional and Ethical Concerns

Nurses in all settings are called on to provide care for patients with HIV infection. In doing so, they encounter not only the physical challenges of this epidemic but also emotional and ethical concerns. The concerns raised by health care professionals involve issues such as fear of infection, responsibility for giving care, values clarification, confidentiality, developmental stages of patients and caregivers, and poor prognostic outcomes.

Many patients with HIV infection have engaged in "stigmatized" behaviors. Because these behaviors challenge some traditional religious and moral values, nurses may feel reluctant to care for these patients. In addition, health care providers may still have fear and anxiety about disease transmission despite education concerning infection control and the low incidence of transmission to health care providers. Nurses are encouraged to examine their personal beliefs and to use the process of values clarification to approach controversial issues (see Chapter 1, Chart 1-10). The ANA's Code of Ethics for Nurses (ANA, 2015) provides guidance including the first provision which states, "The nurse practices with compassion and respect for the inherent dignity, worth, and unique attributes of every person" (p. 1).

Nurses are responsible for protecting the patient's right to privacy by safeguarding confidential information. Inadvertent disclosure of confidential patient information may result in personal, financial, and emotional hardships for the patient. The controversy surrounding confidentiality concerns the circumstances in which information may be disclosed to others (see Chart 32-13). Health care team members need accurate patient information to conduct assessment, planning, implementation, and evaluation of patient care. Failure to disclose HIV status could compromise the quality of patient care. Sexual partners of patients infected with HIV should know about the potential for infection and the need to engage in safer sex practices, as well as the possible need for testing and health care. Nurses are advised to discuss concerns about confidentiality with nurse administrators and to consult professional nursing organizations such as the Association of Nurses in AIDS Care and legal experts in their state to identify the most appropriate course of action.

Chart 32-13 ETHICAL DILEMMA

What if Maintaining Confidentiality Results in Harm?

Case Scenario

You are a nurse employed on a *per diem* basis for a home health agency. A nursing professor whom you know has received funding to conduct a mixed methods research study on men in your community who are experiencing homelessness and living with being human immune deficiency virus (HIV) positive. She has funds to pay nurses with community health experience to gather data for her study, and you were solicited and received education to serve as one of her nurse data collectors. You are assigned to conduct interviews at a homeless shelter for veterans. Eligible participants must sign an informed consent prior to being interviewed; this informed consent was approved by an institutional review board (IRB) at the nursing professor's university and was also approved by the governance board of the homeless shelter for veterans. One day while you are conducting an interview with T.M., a 28-year-old man with a history of male prostitution and substance use disorder (SUD), he suddenly begins to cry softly and says to you "I am sorry…. I just feel life is no longer worth living. I need to end things and stop going on like this." After further validating the meaning of his words, you learn that T.M. has made a plan to commit suicide. The informed consent that T.M. has signed contains assurances that his name and any information that he shares will not be divulged to anyone outside of the research team. You are conflicted about whether or not you may share his suicidal intentions with anyone.

Discussion

It is standard practice that participants who enroll in research studies are guaranteed confidentiality of their identities. However, T.M. is a particularly vulnerable research participant because he is homeless and HIV positive. Interviewing a participant in a research study who is vulnerable can cause emotional distress that might cause harm. Ideally, this contingency should have been identified by the nursing professor and the IRB, and there should have been additional information in the informed consent that identified a behavioral health professional who could be contacted should participants experience distress. Furthermore, the clause in the informed consent that assured T.M. of the confidential nature of the interview should have specified that this confidentiality would need to be breached if it was determined that participant safety was compromised.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Can the principle of nonmaleficence be considered the preeminent principle that guides your decision regarding next steps?

- Assume that the informed consent does not make any of the specifications previously noted to protect vulnerable participants. Would you feel obligated to relay these findings to the nursing professor who serves as the principal investigator of the research team? Would you feel obligated to relay these findings to the social worker at the homeless shelter? Now assume that the provisions to protect T.M. were indeed specified in the informed consent. Would that change whether or not you would notify either the nursing professor or the social worker?
- What resources might be mobilized to be of assistance to you as you navigate your role as a research assistant? What are your legal and ethical obligations? Do you have the right or the responsibility to contact the nursing professor's IRB?

Resources

See Chapter 1, Chart 1-10, for Steps of an Ethical Analysis and Ethics Resources.

Education and provision of up-to-date information help to alleviate apprehension and prepare nurses to deliver safe, high-quality patient care. Interdisciplinary meetings allow participants to support one another and provide comprehensive patient care. Staff support groups give nurses an opportunity to solve problems and explore values and feelings about caring for patients with AIDS and their families; they also provide a forum for grieving. Other sources of support include nursing administrators, peers, and spiritual advisors.

CRITICAL THINKING EXERCISES

1 ebp Your patient is a 33-year-old transgender woman who has been diagnosed as HIV infected, stage 2. The patient tells you that they do not want to take ART because it is interfering with their self-managed hormone therapy. What is the evidence about the drug/drug interaction between ART and transitional hormone therapy? What strategies could you identify to promote adherence to ART regimen? What are the consequences of discontinuing ART?

2 pq A 55-year-old male who uses injection drugs and is HIV infected comes to the clinic where you work. He tells you that he has been experiencing night sweats, late afternoon fevers, cough, and weight loss. Identify this patient's health priorities and state the next steps you will use to meet his identified needs and other health promotion needs.

3 ipc Your patient, a heterosexual woman who is HIV infected, tells you that she wants to have unprotected sexual relations with her male partner who is HIV negative. What preventive measures should you educate this patient about? What additional members of the health care team should be included in the care of this patient?

33 Assessment and Management of Patients with Allergic Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the physiologic events involved with allergic reactions and types of hypersensitivity.
2. Use appropriate parameters for assessment of the status of patients with allergic disorders.
3. Identify the pathophysiology, clinical manifestations, and management of patients with allergic disorders.
4. Specify measures to prevent and manage anaphylaxis.
5. Use the nursing process as a framework for care of the patient with allergic rhinitis.

NURSING CONCEPTS

Cellular Regulation
Immunity
Infection

GLOSSARY

allergen: substance that causes manifestations of allergy

allergy: inappropriate and often harmful immune system response to substances that are normally harmless

anaphylaxis: rapid clinical response to an immediate immunologic reaction between a specific antigen and antibody

angioedema: condition characterized by urticaria and diffuse swelling of the deeper layers of the skin (*synonym*: angioneurotic edema)

antibody: protein substance developed by B cells in response to and interacting with a specific antigen

antigen: substance that the body identifies as a foreign invader; antigens induce the production of antibodies

antihistamine: medication that opposes the action of histamine

atopic dermatitis: type I hypersensitivity involving inflammation of the skin evidenced by itching, redness, and a variety of skin lesions

atopic march: a progression of allergic disease beginning with atopic dermatitis continuing to IgE-mediated food allergy, asthma, and allergic rhinitis

atopy: term often used to describe immunoglobulin E–mediated diseases (i.e., atopic dermatitis, asthma, and allergic rhinitis) with a genetic component

B cells: lymphocyte cells that are stimulated to produce antibodies

bradykinin: a substance that stimulates nerve fibers and causes pain

eosinophil: granular leukocyte

erythema: diffuse redness of the skin

hapten: incomplete antigen

histamine: substance in the body that causes increased gastric secretion, dilation of capillaries, and constriction of the bronchial smooth muscle

hypersensitivity: abnormal heightened reaction to a stimulus of any kind

immunoglobulins: a family of closely related proteins capable of acting as antibodies

leukotrienes: a group of chemical mediators that initiate the inflammatory response

mast cells: connective tissue cells that contain heparin and histamine in their granules

plasma cells: upon stimulation by antigen, B lymphocytes differentiate into plasma cells that secrete antibodies

prostaglandins: unsaturated fatty acids that have a wide assortment of biologic activity

serotonin: chemical mediator that acts as a potent vasoconstrictor and bronchoconstrictor

T cells: lymphocyte cells that participate in cellular immunity and assist in humoral (B-cell) immunity

urticaria: a round, reddened skin elevation or hives

Allergic disorders are common and are encountered by nurses in every setting, from the community to the intensive care unit. Expert management of patients with allergic disorders is integral to nursing regardless of the practice setting. This chapter covers general allergic assessment and management of various allergic disorders including anaphylaxis.

The human body is bombarded by a host of potential invaders—allergens as well as microbial organisms—that constantly threaten its defenses. These invaders are termed **antigens**. After penetrating the body's defenses, these antigens, if allowed to continue unimpeded, disrupt the body's enzyme systems and destroy its vital tissues. To protect against these antigens, the body is equipped with an elaborate defense system.

The epithelial cells that coat the skin and make up the lining of the respiratory, gastrointestinal, and genitourinary tracts provide the first line of defense against microbial invaders. The structure and continuity of these surfaces and their resistance to penetration are initial deterrents to antigens (Marshall, Warrington, Watson, et al., 2018).

One of the most effective defense mechanisms is the body's capacity to equip itself rapidly with antibodies specifically designed to combat each new invader—namely, specific protein antigens. Antibodies react with antigens in a variety of ways: (1) by coating the antigens' surfaces, (2) by neutralizing the antigens, and (3) by precipitating the antigens out of solution if they are dissolved. The antibodies prepare the antigens so that the phagocytic cells of the blood and the tissues can eliminate them. However, although this system is normally protective, in some cases the body produces inappropriate or exaggerated responses to specific antigens, and the result is an allergic or hypersensitivity disorder.

Physiologic Overview

An allergic reaction is a manifestation of tissue injury resulting from interaction between an antigen and an **antibody** (a protein substance developed by B cells in response to and interacting with a specific antigen) (Marshall et al., 2018). **Allergy** is an inappropriate and often harmful response of the immune system to normally harmless substances, called **allergens** (e.g., dust, weeds, pollen, dander). Chemical mediators released in allergic reactions may produce symptoms that range from mild to life-threatening.

In allergic reactions, the body encounters allergens that are types of antigens, usually proteins that the body's defenses recognize as foreign, and a series of events occurs in an attempt to render the invaders harmless, destroy them, and remove them from the body. There is a generalized white blood cell response to the entrance of antigens into the body. Specific types of white blood cells, called B lymphocytes (also called B cells), are specifically triggered by the presence of antigen. B lymphocytes differentiate into **plasma cells**, which then secrete antibodies that attack the antigen.

Specific antibodies develop in response to specific antigens. Antibodies combine with antigens in a special way, which has been likened to a lock and key. Antigens (the keys) fit only certain antibodies (the locks). Hence, the term *specificity* refers to the specific reaction of an antibody to an antigen. There are many variations and complexities in these patterns. In addition, antibodies have memory for the specific antigen, so that upon future exposure, the lock and key reaction occurs again (Actor, 2019).

Function of Immunoglobulins

Antibodies that are formed by plasma cells in response to an immunogenic stimulus constitute a group of serum proteins called **immunoglobulins**. Grouped into five classes (IgG, IgA, IgM, IgD, and IgE), immunoglobulins can be found in the lymph nodes, tonsils, appendix, and Peyer patches of the intestinal tract or circulating in the blood and lymph. These antibodies are capable of binding with a wide variety of antigens. Immunoglobulins of the IgE class are involved in allergic disorders and some parasitic infections. IgE-producing cells are located in the respiratory and intestinal mucosa. Two or more IgE molecules bind together to an allergen and trigger **mast cells** or basophils to release chemical mediators, such as histamine, serotonin, kinins, slow-reacting substances of anaphylaxis, and the neutrophil factor, which produces allergic skin reactions, asthma, and hay fever. **Atopy** refers to IgE-mediated diseases, such as allergic rhinitis, that have a genetic component (Actor, 2019). See Chapter 31 for more information on immunoglobulins.

Role of B Cells

B cells, or B lymphocytes, are programmed to produce one specific antibody. On encountering a specific antigen, B cells generate plasma cells, at the site of antibody production. The plasma cells secrete antibodies for the purpose of destroying and removing the antigens. B cells participate in humoral immunity (also called antibody-mediated immunity), which is one kind of adaptive immunity (Marshall et al., 2018).

Role of T Cells

There are different types of **T cells**, or T lymphocytes, that participate in cellular immunity (also called cell-mediated immunity), a type of adaptive immunity. T helper cells are specific types of T lymphocytes that assist B cells in the immune response. T cells secrete substances that direct the flow of cell activity and stimulate macrophages. Macrophages present the antigens to the T cells and initiate the immune response. They also digest antigens and assist in removing cells and other debris (Marshall et al., 2018).

Function of Antigens

Antigens are divided into two groups: complete protein antigens and low-molecular-weight substances. Complete protein antigens, such as animal dander, pollen, and horse serum, stimulate a complete humoral response. A humoral response is another name for a B lymphocyte–mediated response. See Chapter 31 for a discussion of humoral immunity. Low-molecular-weight substances, such as medications, function as **haptens** (incomplete antigens), binding to tissue or serum proteins to produce a carrier complex that initiates an antibody response. In an allergic reaction, the production of antibodies requires active communication between cells. When the allergen is absorbed through the respiratory tract, gastrointestinal tract, or skin, allergen sensitization occurs. In the humoral response, B cells mature into allergen-specific secreting plasma cells that synthesize and secrete antigen-specific antibodies (Marshall et al., 2018).

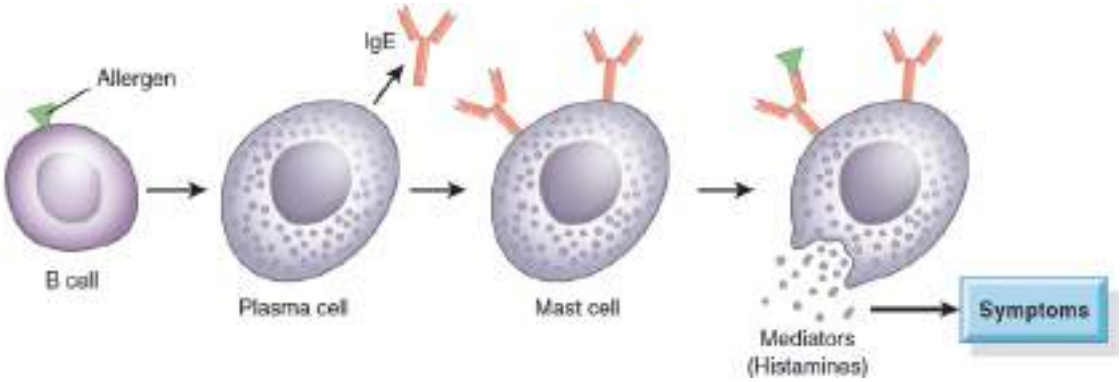

Figure 33-1 • Antigen stimulates activation of a B cell (B lymphocyte), which then transforms into a plasma cell that secretes immunoglobulins. Immunoglobulins stimulate mast cells to release histamine and other inflammatory mediators.

Function of Chemical Mediators

Mast cells, which are located in the skin, respiratory tract, and gastrointestinal tract, play a major role in IgE-mediated immediate hypersensitivity. When mast cells are stimulated by antigens, powerful chemical mediators, such as

histamine, are released, causing a sequence of physiologic events that result in symptoms of immediate hypersensitivity (see Fig. 33-1). There are two types of chemical mediators: primary and secondary. Primary mediators are preformed and are found in mast cells or basophils. Secondary mediators are inactive precursors that are formed or released in response to primary mediators. Table 33-1 summarizes the actions of primary and secondary chemical mediators (Castells, 2017).

Primary Mediators

Histamine, eosinophil chemotactic factor of anaphylaxis, platelet-activating factor, and prostaglandins are primary chemical mediators in allergic responses.

Histamine

Histamine, which is released by mast cells, plays an important role in the immune response. It is the first chemical mediator to be released in immune and inflammatory responses. It is synthesized and stored in high concentrations in body tissues exposed to environmental substances. Histamine's effects peak 5 to 10 minutes after antigen contact and include the following: erythema; localized edema in the form of wheals; pruritus; contraction of bronchial smooth muscle, resulting in wheezing and bronchospasm; dilation of small venules and constriction of larger vessels; and increased secretion of gastric and mucosal cells, resulting in diarrhea. Histamine action results from stimulation of histamine-1 (H_1) and histamine-2 (H_2) receptors. H_1 receptors are found predominantly on bronchiolar and vascular smooth muscle cells; H_2 receptors are found on gastric parietal cells (Castells, 2017).

Certain medications are categorized by their action at these receptors. Diphenhydramine is an example of an **antihistamine**, a medication that displays an affinity for H_1 receptors. Cimetidine targets H_2 receptors to inhibit gastric secretions in peptic ulcer disease.

TABLE 33-1 Chemical Mediators of Hypersensitivity

Mediators	Action
Primary Mediators	
Preformed and Found in Mast Cells or Basophils	
Histamine (preformed in mast cells)	Vasodilation Smooth muscle contraction, increased vascular permeability, increased mucus secretions
Eosinophil chemotactic factor of anaphylaxis (preformed in mast cells)	Attracts eosinophils
Platelet-activating factor (requires synthesis by mast cells, neutrophils, and macrophages)	Smooth muscle contraction Incites platelets to aggregate and release serotonin and histamine
Prostaglandins (chemically derived from arachidonic acid; require synthesis by cells)	D and F series → bronchoconstriction E series → bronchodilation D, E, and F series → vasodilation
Basophil kallikrein (preformed in mast cells)	Frees bradykinin, which causes bronchoconstriction, vasodilation, and nerve stimulation
Secondary Mediators	
Inactive Precursors Formed or Released in Response to Primary Mediators	
Bradykinin (derived from precursor kininogen)	Smooth muscle contraction, increased vascular permeability, stimulates pain receptors, increased mucus production
Serotonin (preformed in platelets)	Smooth muscle contraction, increased vascular permeability
Heparin (preformed in mast cells)	Anticoagulant
Leukotrienes (derived from arachidonic acid and activated by mast cell degranulation) C, D, and E or slow-reacting substance of anaphylaxis	Smooth muscle contraction, increased vascular permeability

Adapted from Norris, T. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Eosinophil Chemotactic Factor of Anaphylaxis

Eosinophil chemotactic factor of anaphylaxis affects the movement of **eosinophils** (granular leukocytes) to the site of allergens. It is preformed in the mast cells and is released from disrupted mast cells.

Platelet-Activating Factor

Platelet-activating factor is responsible for initiating platelet aggregation and leukocyte infiltration at sites of immediate hypersensitivity reactions. It also causes vasodilation, bronchoconstriction, and increased vascular permeability (Castells, 2017).

Prostaglandins

Prostaglandins produce smooth muscle contraction as well as vasodilation and increased capillary permeability. They sensitize pain receptors and increase the pain associated with inflammation. In addition, prostaglandins induce inflammation and enhance the effects of mediators of inflammatory response. Local manifestations include erythema, heat, and edema (Castells, 2017).

Secondary Mediators

Leukotrines, bradykinin, and serotonin are all secondary chemical mediators.

Leukotrienes

Leukotrienes are chemical mediators that initiate the inflammatory response. Many manifestations of inflammation can be attributed in part to leukotrienes. In addition, leukotrienes cause smooth muscle contraction, bronchial constriction, mucus secretion in the airways, and the typical wheal-and-flare reactions of the skin. Compared with histamine, leukotrienes are 100 to 1000 times more potent in causing bronchospasm (Castells, 2017).

Bradykinin

Bradykinin is a substance that has the ability to cause increased vascular permeability, vasodilation, hypotension, and contraction of many types of smooth muscle, such as the bronchi. Increased permeability of the capillaries results in edema. Bradykinin stimulates nerve cell fibers and produces pain.

Serotonin

Serotonin is a chemical mediator that acts as a potent vasoconstrictor and causes contraction of bronchial smooth muscle.

Hypersensitivity

Although the immune system defends the host against infections and foreign antigens, immune responses can themselves cause tissue injury and disease. **Hypersensitivity** is an excessive or aberrant immune response to any type of stimulus (Actor, 2019). It usually does not occur with the first exposure to an allergen. Rather, the reaction follows a re-exposure after sensitization, or buildup of antibodies, in a predisposed person. Injurious or pathologic immune

reactions are classed as hypersensitivity reactions. To promote understanding of the immunopathogenesis of disease, hypersensitivity reactions have been classified into four specific types of reactions (see Fig. 33-2).

Anaphylactic (Type I) Hypersensitivity

The most severe hypersensitivity reaction is **anaphylaxis**. An unanticipated severe allergic reaction that is rapid in onset, anaphylaxis is characterized by edema in many tissues, including the larynx, and is often accompanied by hypotension, bronchospasm, and cardiovascular collapse in severe cases. Anaphylaxis is a severe type I hypersensitivity reaction, which is an immediate reaction beginning within minutes of exposure to an antigen. Primary chemical mediators are responsible for the symptoms of type I hypersensitivity because of their effects on the skin, lungs, and gastrointestinal tract. If chemical mediators continue to be released, a delayed reaction may occur and may last for up to 24 hours (Marshall et al., 2018).

Clinical symptoms are determined by the amount of the allergen, the amount of mediator released, the sensitivity of the target organ, and the route of allergen entry. Type I hypersensitivity reactions may include both local and systemic anaphylaxis (Actor, 2019).

Cytotoxic (Type II) Hypersensitivity

Type II, or cytotoxic hypersensitivity occurs when antibodies are directed against antigens on cells or basement membranes of tissues. This reaction can lead to cell lysis and tissue damage. Type II hypersensitivity reactions are associated with several disorders. The best example is a hemolytic transfusion reaction. For example, if a person with type A blood is mistakenly given type B blood, anti-B antibodies are triggered in the recipient that attack the infused type B blood cells and cause hemolysis (Actor, 2019).

Immune Complex (Type III) Hypersensitivity

Type III, or immune complex hypersensitivity, is a damaging inflammatory reaction caused by the insoluble immune complexes formed by antigens that bind to antibodies. These complexes are too large to be cleared from the circulation by phagocytic action. The immune complexes are deposited in tissues or vascular endothelium and trigger inflammation at different sites throughout the body. An example of this kind of hypersensitivity reaction occurs in rheumatoid arthritis. An unknown antigen triggers antibody formation, which then forms immune complexes that are deposited in the joints. Many autoimmune disorders are type III hypersensitivity reactions. In autoimmune reactions, such as systemic lupus erythematosus, patients form autoantibodies that form immune complexes that deposit in the lungs, skin, and kidney (Actor, 2019).

Delayed (Type IV) Hypersensitivity

Type IV, or delayed hypersensitivity, is a T cell–mediated immune reaction after exposure to an antigen. This immune reaction typically occurs 24 to 48 hours after exposure to an antigen. The prototypical type IV hypersensitivity reaction occurs in response to the subcutaneous injection of purified protein derivative (PPD) antigen from *Mycobacterium tuberculosis*. Patients who have had previous exposure or have tuberculosis (TB) infection will demonstrate a reaction of erythema and induration due to sensitized T cells (Actor, 2019).

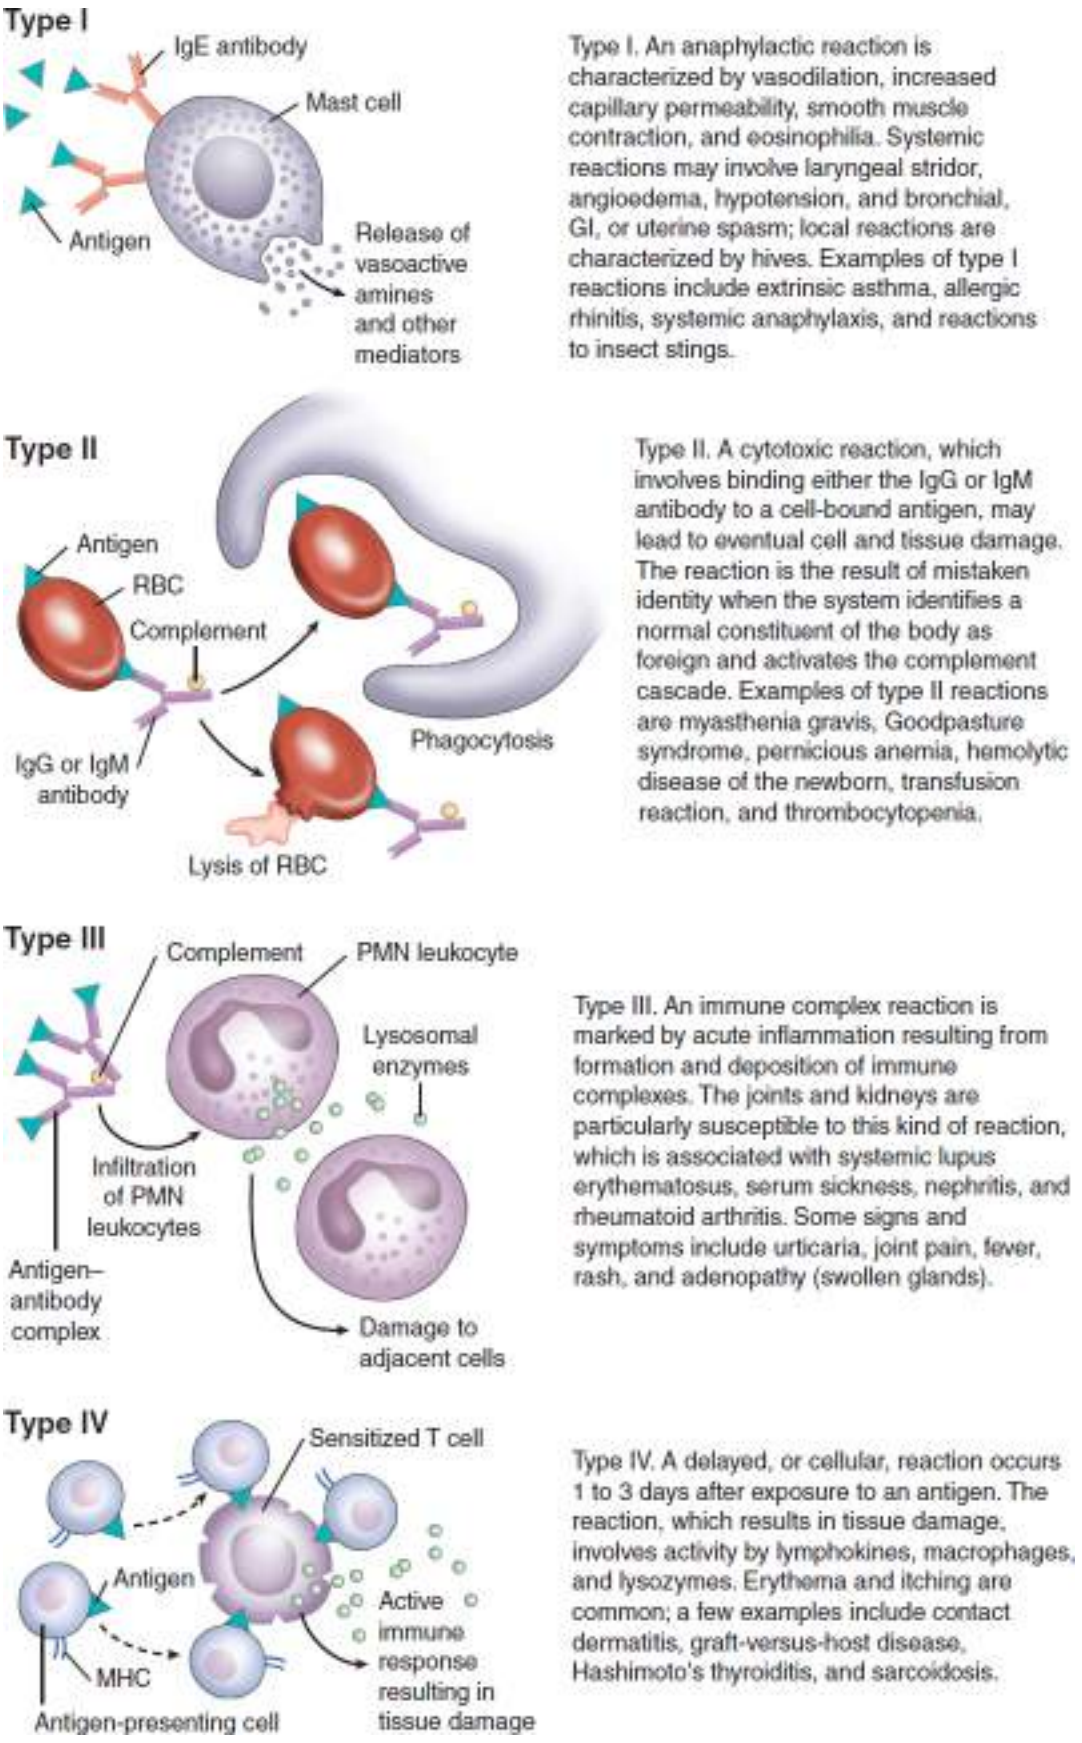

Figure 33-2 • Four types of hypersensitivity reactions. GI, gastrointestinal; Ig, immunoglobulin; PMN, polymorphonuclear;

RBC, red blood cell.

Assessment

A comprehensive allergy history and a thorough physical examination provide useful data for the diagnosis and management of allergic disorders. An allergy assessment form is useful for obtaining and organizing pertinent information (see Chart 33-1).

The degree of difficulty and discomfort experienced by the patient because of allergic symptoms and the degree of improvement in those symptoms with and without treatment are assessed and documented. The relationship of symptoms to exposure to possible allergens is noted.

Chart 33-1 ASSESSMENT

Allergy Assessment Form

Name _____ Age _____ Sex _____ Date _____

I. Chief complaint: _____

II. Present illness: _____

III. Collateral allergic symptoms: _____

Diagnostic Evaluation

Diagnostic evaluation of the patient with allergic disorders commonly includes blood tests, smears of body secretions, skin tests, and the serum-specific IgE test (formerly known as radioallergosorbent test [RAST]). Results of laboratory blood studies provide supportive data for various diagnostic possibilities; however, they are not the major criteria for the diagnosis of allergic disease (Kowal & DuBuske, 2017).

Complete Blood Count with Differential

The white blood cell (WBC) count is usually within normal limits except when infection and inflammation are present along with an allergic disorder. Eosinophils, which are granular leukocytes, normally make up 2% to 5% of the total number of WBCs. They can be found in blood, sputum, and nasal secretions. A level greater than 5% to 10% is considered abnormal and may be found in patients with allergic disorders (Kowal & DuBuske, 2017).

Eosinophil Count

An actual count of eosinophils can be obtained from blood samples or smears of secretions. During symptomatic episodes, smears obtained from nasal secretions and sputum of patients with allergies usually reveal an increase in eosinophils, indicating an active allergic response (Kowal & DuBuske, 2017).

Total Serum Immunoglobulin E Levels

High total serum IgE levels support the diagnosis of allergic disease. In the majority of cases, the antibody typically responsible for an allergic reaction

belongs to the IgE isotype. Patients with this disorder are said to have an IgE-mediated allergic disease (Kowal & DuBuske, 2017).

Skin Tests

Skin testing entails the intradermal injection or superficial application (epicutaneous) of solutions at several sites. Depending on the suspected cause of allergic signs and symptoms, many different solutions may be applied at separate sites. These solutions contain individual antigens representing an assortment of allergens most likely to be implicated in the patient's disease. Positive (wheal-and-flare) reactions are clinically significant when correlated with the history, physical findings, and results of other laboratory tests. Skin testing is considered the most accurate confirmation of allergy (Kowal & DuBuske, 2016).

The results of skin tests complement the data obtained from the history. They indicate which of several antigens are most likely to provoke symptoms and indicate the intensity of the patient's sensitization. The dosage of the antigen (allergen) injected is also important. Most patients are hypersensitive to more than one allergen. Under testing conditions, they may not react (although they usually do) to the specific allergens that induce their attacks.

When there is doubt about the validity of the skin tests, a serum-specific IgE test or a provocative challenge test may be performed. If a skin test is indicated, there is a reasonable suspicion that a specific allergen is producing symptoms in a patient with allergies. However, several precautionary steps must be observed before skin testing with allergens is performed:

- Testing is not performed during periods of bronchospasm.
- Epicutaneous tests (scratch or prick tests) are performed before other testing methods, in an effort to minimize the risk of systemic reaction.
- Emergency equipment must be readily available to treat anaphylaxis.

Types of Skin Tests

The methods of skin testing include prick skin tests, scratch tests, and intradermal skin testing. After negative prick or scratch tests, intradermal skin testing is performed with allergens that are suggested by the patient's history to be problematic. The back is the most suitable area of the body for skin testing because it permits the performance of many tests. A multitest applicator with multiple test heads is commercially available for simultaneous administration of antigens by multiple punctures at different sites. Research suggests that use of a multi-prong applicator for allergy testing decreases patient discomfort and application time (Pestotnik & Krueger, 2018). A negative response on a skin test cannot be interpreted as an absence of sensitivity to an allergen. Such a

response may occur with insufficient sensitivity of the test or with the use of an inappropriate allergen in testing. Therefore, it is essential to observe the patient undergoing skin testing for an allergic reaction even if the previous response was negative (Kowal & DuBuske, 2016).

Interpretation of Skin Test Results

Familiarity with and consistent use of a grading system are essential. The grading system used should be identified on a skin test record for later interpretation. A positive reaction, evidenced by the appearance of an urticarial wheal (round, reddened skin elevation) (see Fig. 33-3), localized **erythema** (diffuse redness) in the area of inoculation or contact, or pseudopodia (irregular projection at the end of a wheal) with associated erythema is considered indicative of sensitivity to the corresponding antigen. False-positive results may occur because of improper preparation or administration of allergen solutions (Kowal & DuBuske, 2016).

Quality and Safety Nursing Alert

Corticosteroids and antihistamines, including over-the-counter allergy medications, suppress skin test reactivity and should be stopped 48 to 96 hours before testing, depending on the duration of their activity. False-positive results may occur because of improper preparation or administration of allergen solutions.

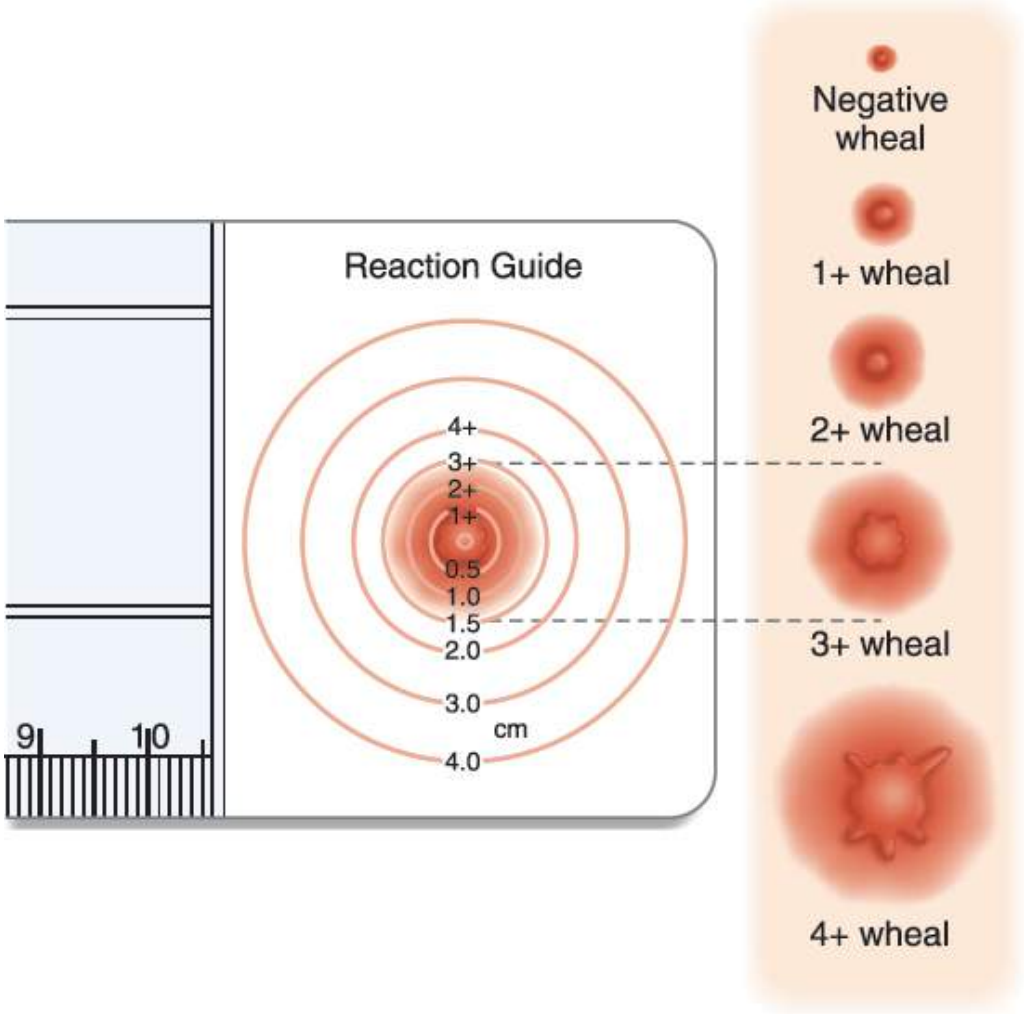

Figure 33-3 • Interpretation of reactions: Negative = wheal soft with minimal erythema; 1+ = wheal present (5 to 8 mm) with associated erythema; 2+ = wheal (7 to 10 mm) with associated erythema; 3+ = wheal (9 to 15 mm), slight pseudopodia possible with associated erythema; 4+ = wheal (12 mm+) with pseudopodia and diffuse erythema.

Positive or negative skin tests are interpreted in the context of a patient's history, clinical signs, and exposure to allergens. The following guidelines are used for the interpretation of skin test results:

- Skin tests are used most frequently with the diagnosis of allergic rhinitis.
- Negative test results are helpful in ruling out food allergy.
- Positive skin tests correlate highly with food allergy.

The use of skin tests to diagnose immediate hypersensitivity to medications is limited, because metabolites of medications, not the medications themselves, are usually responsible for causing hypersensitivity.

Provocative Testing

Provocative testing involves the direct administration of the suspected allergen to the sensitive tissue, such as the conjunctiva, nasal or bronchial mucosa, or gastrointestinal tract (by ingestion of the allergen), with observation of target organ response. This type of testing is helpful in identifying clinically significant allergens in patients who have a large number of positive tests. Major disadvantages of this type of testing are the limitation of one antigen per session and the risk of producing severe symptoms, particularly bronchospasm, in patients with asthma (Kowal & DuBuske, 2016).

Serum-Specific IgE Test

The serum-specific IgE test, formerly known as RAST, is an automated test performed on blood samples by a pathology laboratory. As the name suggests, it detects free antigen-specific IgE in serum as opposed to antigen-specific IgE bound to mast cells in the skin. The advantages of this test over other tests include decreased risk of systemic reaction, stability of antigens, and lack of dependence on skin reactivity modified by medications. The major disadvantages include limited allergen selection and reduced sensitivity compared with intradermal skin tests, lack of immediate results, and higher cost (Kowal & DuBuske, 2017).

ALLERGIC DISORDERS

There are two types of IgE-mediated allergic reactions: atopic and nonatopic disorders. Although the underlying immunologic reactions of the two types of disorders are the same, the predisposing factors and manifestations are different. Atopy is defined as the genetic predisposition to mount an IgE response to inhaled or ingested innocuous proteins. Atopic diseases consist of asthma, allergic rhinitis, and atopic dermatitis. All share a common pathogenesis, mediated by IgE, and are frequently present together in the same individual and in families. The nonatopic disorders lack the genetic component and organ specificity of the atopic disorders. Latex allergy (see later discussion) can present as an IgE-mediated anaphylaxis, type I reaction, or a type IV hypersensitivity referred to as contact dermatitis (Stokes & Casale, 2019).

Unfolding Patient Stories: Jennifer Hoffman • Part 2

Recall from Chapter 20 Jennifer Hoffman, who came to the clinic with continued symptoms of asthma. The nurse confirmed that she was following the asthma action plan; however, Jennifer now returns to the clinic with worsening symptoms. What assessment findings would indicate to the nurse that Jennifer is having a hypersensitivity reaction to an allergen(s)? What questions can assist the nurse in identifying the causative agent(s)? What interventions should be implemented when allergen(s) are identified?

Care for Jennifer and other patients in a realistic virtual environment: ***vSim*** *for Nursing* (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Anaphylaxis

Anaphylaxis is a clinical response to an immediate (type I hypersensitivity) immunologic reaction between a specific antigen and an antibody. The reaction results from a rapid release of IgE-mediated chemicals, which can induce a severe, life-threatening reaction (Actor, 2019).

Pathophysiology

Anaphylaxis is a type I IgE allergic reaction to an antigen, a foreign substance that has entered the body. It is caused by the cross-links of an allergen with allergen-specific IgE antibodies found on the surface membrane of mast cells and basophils, leading to cellular degranulation. The subsequent release of histamine and other bioactive mediators causes activation of platelets, eosinophils, and neutrophils. Histamine, prostaglandins, and inflammatory leukotrienes are potent vasoactive mediators that are implicated in the vascular permeability changes, flushing, **urticaria** (hives), angioedema, hypotension, and bronchoconstriction that characterize anaphylaxis. Smooth muscle spasm, bronchospasm, mucosal edema and inflammation, and increased capillary permeability result. Symptoms of anaphylaxis are sudden in onset and progress in severity over minutes to hours (Kemp, 2018).

Closely resembling anaphylaxis is an anaphylactoid reaction, which is caused by the release of mast cell and basophil mediators triggered by non–immunoglobulin E (IgE)-mediated events. This nonallergenic anaphylaxis reaction may occur with medications, food, exercise, or cytotoxic antibody transfusions. The reaction may be local or systemic. Local reactions usually

involve urticaria and angioedema at the site of the antigen exposure. Although possibly severe, nonallergenic anaphylaxis reactions are rarely fatal. Systemic reactions occur within about 30 minutes after exposure and involve cardiovascular, respiratory, gastrointestinal, and integumentary organ systems. For the most part, the treatment of nonallergenic anaphylaxis reaction is identical to that of anaphylaxis (Campbell & Kelso, 2018).

Common causes of anaphylaxis are listed in Chart 33-2. Antibiotics and radiocontrast agents cause the most serious anaphylactic reactions. Penicillin is the most common medication to cause anaphylaxis. Approximately 10% of the population report having an allergy to penicillin. However, less than 5% have clinically significant IgE or T cell–mediated penicillin allergy (Shenoy, Macy, Rowe, et al., 2019).

Chart 33-2

Common Causes of Anaphylaxis

Foods

Peanuts, tree nuts (e.g., walnuts, pecans, cashews, almonds), shellfish (e.g., shrimp, lobster, crab), fish, milk, eggs, soy, wheat

Medications

Antibiotics, especially penicillin and sulfa antibiotics, allopurinol, radiocontrast agents, anesthetic agents (lidocaine, procaine), vaccines, hormones (insulin, vasopressin, adrenocorticotropic hormone), aspirin, nonsteroidal anti-inflammatory drugs

Other Pharmaceutical/Biologic Agents

Animal serums (tetanus antitoxin, snake venom antitoxin, rabies antitoxin), antigens used in skin testing

Insect Stings

Bees, wasps, hornets, yellow jackets, ants (including fire ants)

Latex

Medical and nonmedical products containing latex

Clinical Manifestations

Anaphylactic reactions produce a clinical syndrome that affects multiple organ systems. Reactions may be categorized as mild, moderate, or severe. The time from the exposure to the antigen to the onset of symptoms is a good indicator of the severity of the reaction—the faster the onset, the more severe the

reaction. The severity of previous reactions does not determine the severity of subsequent reactions, which could be the same or more or less severe. The severity depends on the degree of allergy and the dose of allergen exposure (Actor, 2019).

Mild systemic reactions consist of peripheral tingling and a sensation of warmth, possibly accompanied by a sensation of fullness in the mouth and throat. Nasal congestion, periorbital swelling, pruritus, sneezing, and tearing of the eyes can also be expected. The onset of symptoms begins within the first 2 hours after the exposure.

Moderate systemic reactions may include flushing, warmth, anxiety, and itching in addition to any of the milder symptoms. More serious reactions include bronchospasm and edema of the airways or larynx with dyspnea, cough, and wheezing. The onset of symptoms is the same as for a mild reaction (Kemp, 2018).

Severe systemic reactions have an abrupt onset with the same signs and symptoms described previously. These symptoms progress rapidly to bronchospasm, laryngeal edema, severe dyspnea, cyanosis, and hypotension. Dysphagia (difficulty swallowing), abdominal cramping, vomiting, diarrhea, and seizures can also occur. Cardiac arrest and coma may follow. Severe reactions are also referred to as anaphylactic shock (Marshall et al., 2018) (see Chapter 11).

Prevention

Strict avoidance of potential allergens is an important preventive measure for the patient at risk for anaphylaxis. Those at risk for anaphylaxis from insect stings should avoid areas populated by insects and should use appropriate clothing, insect repellent, and caution to avoid further stings.

If avoidance of exposure to allergens is impossible, an autoinjector system for epinephrine will be prescribed. The patient should be instructed to carry and administer epinephrine to prevent an anaphylactic reaction in the event of exposure to the allergen. People who are sensitive to insect bites and stings, those who have experienced food or medication reactions, and those who have experienced idiopathic or exercise-induced anaphylactic reactions should always carry an emergency kit that contains epinephrine. Autoinjection devices are commercially available for first aid and deliver premeasured doses of epinephrine (Comerford & Durkin, 2020). The autoinjector system requires no preparation, and the self-administration technique is not complicated. The patient must be given an opportunity to demonstrate the correct technique for use; a training device can be used for educating about the correct technique. Verbal and written information about the emergency kit, as well as strategies to avoid exposure to threatening allergens, must also be provided (Campbell & Kelso, 2018).

Screening for allergies before a medication is prescribed or first administered is an important preventive measure. A careful history of any sensitivity to suspected antigens must be obtained before administering any medication, particularly in parenteral form, because this route is associated with the most severe anaphylaxis. Nurses caring for patients in any setting (hospital, home, outpatient diagnostic testing sites, long-term care facilities) must assess patients' risks for anaphylactic reactions. Patients are asked about previous exposure to contrast agents used for diagnostic tests and any allergic reactions, as well as reactions to any medications, foods, insect stings, and latex. People who are predisposed to anaphylaxis should wear medical identification such as a bracelet or necklace, which identifies allergies to medications, food, and other substances.

People who are allergic to insect venom may require venom immunotherapy, which is used as a control measure and not a cure. The most common serious allergic reactions to insect stings are from the Hymenoptera family, which includes bees, ants, wasps, and yellow jackets (Warrell, 2019). Venom immunotherapy is an effective treatment for people with systemic reactions to an insect sting. It reduces the systemic reaction, reduces the risk of future large local reactions, and improves quality of life (Larsen, Broge, & Jacobi, 2016).

Patients with diabetes who are allergic to insulin and those who are allergic to penicillin may require desensitization. Desensitization is based on controlled anaphylaxis, with a gradual release of mediators. Patients who undergo desensitization are cautioned to avoid lapses in therapy, because this may lead to the reappearance of the allergic reaction when the use of the medication is resumed (Castells & Solensky, 2017).

Medical Management

Management depends on the severity of the reaction. Initially, respiratory and cardiovascular functions are evaluated. If the patient is in cardiac arrest, cardiopulmonary resuscitation (CPR) is instituted (Campbell & Kelso, 2018). Supplemental oxygen is provided during CPR or if the patient is cyanotic, dyspneic, or wheezing. Epinephrine, in a 1:1000 dilution, is given subcutaneously in the upper extremity or thigh and may be followed by a continuous intravenous infusion. Most adverse events associated with administration of epinephrine (i.e., adrenaline) occur when the dose is excessive or is given intravenously. Patients at risk for adverse effects include older patients and those with hypertension, arteriopathies, or known ischemic heart disease.

Antihistamines and corticosteroids should not be given in place of epinephrine. However, they may also be given as adjunct therapy (Campbell & Kelso, 2018).

Intravenous fluids (e.g., normal saline solution), volume expanders, and vasopressor agents are given to maintain blood pressure and normal hemodynamic status. In patients with episodes of bronchospasm or a history of bronchial asthma or chronic obstructive pulmonary disease, aminophylline and corticosteroids may also be given to improve airway patency and function. See Chapter 11 for management of anaphylactic shock.

Patients who have experienced anaphylactic reactions and received epinephrine should be transported to the local emergency department (ED) for observation and monitoring because of the risk for a "rebound" or delayed reaction 4 to 8 hours after the initial allergic reaction. However, the observation time should be individualized based on the severity of the anaphylaxis. Longer periods of observation should be considered for patients who ingested the allergen, required more than one dose of epinephrine, had hypotension or pharyngeal edema, or have a history of asthma (Lieberman, 2018).

Nursing Management

If a patient is experiencing an allergic response, the nurse assesses the patient for signs and symptoms of anaphylaxis. Airway, breathing pattern, and vital signs are assessed. The patient is observed for signs of increasing edema and respiratory distress. Prompt notification of the rapid response team, the provider, or both is required. Rapid initiation of emergency measures (e.g., intubation, administration of emergency medications, insertion of intravenous lines, fluid administration, and oxygen administration) is important to reduce the severity of the reaction and to restore cardiovascular function. The nurse documents the interventions used and the patient's vital signs and response to treatment (Campbell & Kelso, 2018).

The patient who has recovered from anaphylaxis needs to be educated about what occurred, how to avoid future exposure to antigens, and how to administer emergency medications to treat anaphylaxis. The nurse assesses the health literacy level of the patient and determines the best method of providing discharge instructions (Wilkin, 2020). See the Nursing Research Profile in Chart 33-3.

Patients who have experienced an anaphylactic reaction should receive a prescription for an autoinjectable epinephrine device. The nurse educates the patient and family in their use and has the patient and family return demonstrate correct administration (Moore, Kemp, & Kemp, 2015) (see Chart 33-4).

Chart 33-3 NURSING RESEARCH PROFILE

Using Video Discharge Instructions

Wilkin, Z. L. (2020). Effects of video discharge instructions on patient understanding. *Advanced Emergency Nursing Journal*, *42*(1), 71–78.

Purpose

Patients have difficulty understanding and retaining education at the time of discharge, particularly if instructions are given only in the form of printed materials. The purpose of this study was to evaluate the effects of using video discharge instructions on patient understanding of the education provided upon discharge from an emergency department (ED).

Design

This was a prospective, randomized, controlled trial that used a convenience sample of patients admitted to the ED. Participants were randomized to receive either standard discharge procedures, or standard discharge procedures plus video discharge instructions. Ten minutes after receiving one of the education methods, participants were tested with a 5-question multiple choice test.

Findings

Participants included 60 adults with a mean age of 37 years, and with a medical diagnosis of either upper respiratory infection, pharyngitis, or gastroenteritis. Thirty participants received the video discharge instructions, while the other 30 received the standard discharge procedure. There was a significant difference in knowledge level, with those receiving the video instructions having a higher level of knowledge (4.53 vs. 4, $p = 0.009$) on the multiple choice test.

Nursing Implications

This study provides evidence that video discharge instructions have the potential to increase the knowledge level of patients receiving discharge education. Nurses who work in busy settings, such as EDs, should consider developing supplemental materials to augment standard written discharge instructions to help increase patients' understanding and retention of important information.

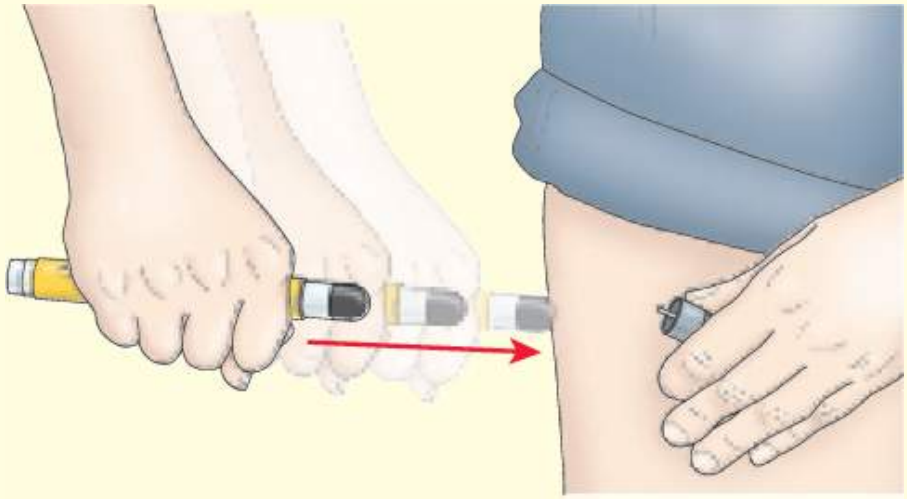
Chart 33-4 PATIENT EDUCATION

Self-Administration of Epinephrine

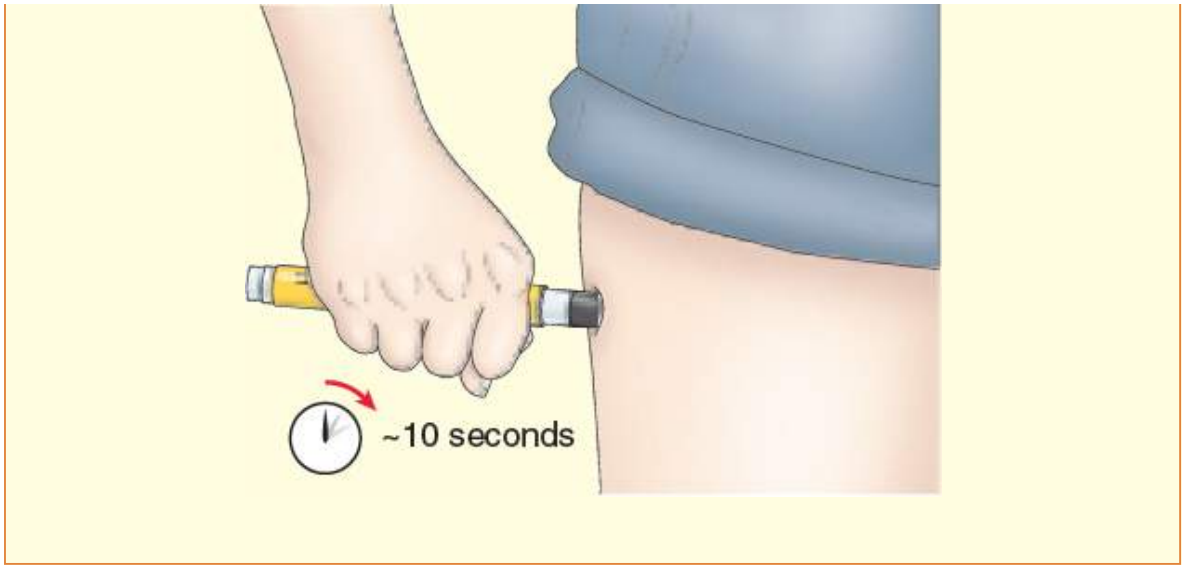
The nurse instructs the patient to:

1. After removing the autoinjector from its carrying tube, grasp the unit with the orange tip (injecting end) pointing downward. Form a fist around the unit with the orange tip down; with your other hand, remove the blue safety release cap.

2. Hold the black tip near outer thigh. Swing and jab firmly into the outer thigh until a click is heard with the device perpendicular (90-degree angle) to the thigh. Do NOT inject into buttocks.



3. Hold firmly against the thigh for approximately 10 seconds. Remove the unit from the thigh, and gently massage the injection area for 10 seconds. Call 911 and seek immediate medical attention. Carefully place the used autoinjector unit, needle-end first, into the device storage tube without bending the needle. Screw on the storage tube completely, and take it with you to the hospital emergency room.



Allergic Rhinitis

Allergic rhinitis (hay fever, seasonal allergic rhinitis) is the most common form of respiratory allergy, which is mediated by an immediate (type I hypersensitivity) immunologic reaction. In the United States approximately 20 million adults have allergic rhinitis (CDC, 2017). Early diagnosis and adequate treatment are essential to reduce complications and relieve symptoms.

Because allergic rhinitis is induced by airborne pollens or molds, it is characterized by the following seasonal occurrences (deShazo & Kemp, 2018a):

- Early spring—tree pollen
- Early summer—grass pollen
- Early fall—weed pollen (ragweed)

Each year, attacks begin and end at about the same time. Airborne mold spores require warm, damp weather. Although there is no rigid seasonal pattern, these spores appear in early spring, are rampant during the summer, then taper off and disappear by the first frost in areas that experience dramatic seasonal temperature variation. In temperate areas that do not experience freezing temperatures, these allergens, especially mold, can persist throughout the year.

Pathophysiology

Allergic rhinitis is caused by an allergen-specific IgE-mediated immunologic response. Sensitization most commonly begins by inhalation of antigen. IgE antibodies are stimulated and bind to mast cells in the respiratory mucosa, basophils in the peripheral blood, and eosinophils in the nasal and respiratory mucosa. Eosinophilia in the tissues is the key characteristic of allergic rhinitis.

When IgE antibodies bind to mast cells there is histamine release. Histamine is the major mediator of allergic reactions in the nasal mucosa. Inflammation, tissue edema, vasodilation, and increased capillary permeability occur (deShazo & Kemp, 2017).

Clinical Manifestations

Symptoms include sneezing, rhinorrhea, nasal itching, conjunctivitis, and nasal obstruction. Postnasal drip, cough, itching of the eyes, and fatigue are often present. If symptoms are severe, allergic rhinitis may interfere with sleep, leisure, school, work, and overall quality of life. Allergic rhinitis is commonly associated with chronic sinusitis, atopic dermatitis (eczema), and asthma. Infraorbital edema and dilation of peripheral vessels (due to histamine) can cause darkening under the eyes, sometimes referred to as "allergic shiners." A horizontal nasal crease can develop from constant rubbing of the nose; commonly referred to as the "allergic salute." The nasal mucosa can exhibit a grayish hue. Clear rhinorrhea, tonsillar hyperplasia, and postnasal rhinorrhea may be visible on examination of the throat. Tympanic membranes can be retracted or serous fluid may accumulate in the middle ear. Some patients can suffer oral allergy syndrome (OAS) with itching and irritation of the hard and soft palate. Allergic rhinitis and sinusitis can trigger migraine headache in some patients (deShazo & Kemp, 2018a).

Assessment and Diagnostic Findings

Diagnosis of seasonal allergic rhinitis is mainly based on history and physical examination. Blood or laboratory testing is usually unnecessary. Diagnostic testing can be done with immediate hypersensitivity skin testing (skin prick testing). In sensitive patients, testing with select diagnostic solutions of tree, grass, or weed pollen, mold, house dust mites, and animal allergens results in a wheal-and-flare reaction at the skin test site within 20 minutes. IgE immunoassay can provide similar information to skin prick test. Nasal cytology can be performed to differentiate rhinitis due to allergy from that due to infection, although it is relatively nonspecific and insensitive (deShazo & Kemp, 2018a).

Medical Management

The goal of therapy is to provide relief from symptoms. Therapy may include one or all of the following interventions: avoidance therapy, pharmacologic therapy, and immunotherapy. Verbal instructions must be reinforced by written information. Knowledge of general concepts regarding assessment and therapy

in allergic diseases is important so that the patient can learn to manage certain conditions as well as prevent severe reactions and illnesses.

Avoidance Therapy

In avoidance therapy, every attempt is made to remove the allergens that act as precipitating factors. Simple measures and environmental controls are often effective in decreasing symptoms. Examples include the use of air conditioners, air cleaners, humidifiers, and dehumidifiers; removal of dust-catching furnishings, carpets, and window coverings; removal of pets from the home or bedroom; the use of pillow and mattress covers that are impermeable to dust mites; and a smoke-free environment (Platts-Mills, 2019). Additional measures include changing clothing when coming in from outside, showering to wash allergens from hair and skin, and using an over-the-counter nasal irrigation device or saline nasal spray to reduce allergens in the nasal passages Because multiple allergens are often implicated, multiple measures to avoid exposure to allergens are often necessary. High-efficiency particulate air (HEPA) purifiers and vacuum cleaner filters may also be used to reduce allergens in the environment (Platts-Mills, 2019). Multiple avoidance strategies tailored to a person's risk factors can reduce the severity of symptoms, the number of work or school days missed because of symptoms, and the number of unscheduled health care visits for treatment. In many cases, it is impossible to avoid exposure to all environmental allergens, so pharmacologic therapy or immunotherapy is needed.

Pharmacologic Therapy

Many antihistamines, corticosteroid nasal sprays, adrenergic agents, mast cell stabilizers, nasal decongestant sprays, and corticosteroids are pharmacologic agents used in allergic rhinitis.

Antihistamines

First-generation antihistamines, which are readily absorbed, are most effective when administered orally at the first occurrence of symptoms because they prevent the development of new symptoms. Diphenhydramine is a common first-generation antihistamine available in over-the-counter (OTC) medications. Others include chlorpheniramine and hydroxyzine. First-generation antihistamines bind to histamine 1 receptors and can effectively relieve symptoms of hay fever, vasomotor rhinitis, urticaria (hives), and mild asthma. However, first-generation antihistamines cross the blood–brain barrier and cause significant sedation which impairs cognitive function and psychomotor performance. First-generation antihistamines can also have anticholinergic effects such as dry mouth, blurry vision, urinary hesitancy, and confusion. Due to their anticholinergic effects, first-generation antihistamines

should be avoided in older adults (Fick, Semla, Steinman, et al., 2019). First-generation antihistamines have a limited role in the treatment of allergy due to their adverse effects (deShazo & Kemp, 2018b).

Second-generation (nonsedating H_1-receptor antagonists) are antihistamines that do not cross the blood–brain barrier to the same extent as first-generation antihistamines. They mainly bind to peripheral rather than central nervous system H_1 receptors, causing less sedation. Examples of these OTC medications are loratadine, cetirizine, and fexofenadine (Sanchez-Borges & Ansotegui, 2019). Contraindications, major side effects, nursing implications, and patient education for select H_1 antihistamines can be found in Table 33-2.

If H_1 antihistamines are not completely effective, H_2 antihistamines such as famotidine, which blocks the H_2 receptors found in the stomach, vascular smooth muscle, and elsewhere, can be added to the drug regimen. It is given twice a day with the same total dose as for gastroesophageal reflux. H_2 antihistamines do not relieve urticaria on their own, but can augment the effect of H_1 antihistamines (Randall & Hawkins, 2018).

Antihistamines may also be combined with decongestants to reduce the nasal congestion associated with allergies. Most combination products are available as OTC medications; examples are loratadine/pseudoephedrine and cetirizine/pseudoephedrine. Decongestants can cause an increase in blood pressure; therefore, patients with a history of hypertension should be cautioned about long-term use of any medication that contains decongestants (Randall & Hawkins, 2018). Decongestants are contraindicated in patients receiving monoamine oxidase inhibitor therapy and should be used with caution in patients with closed-angle glaucoma, cardiovascular or cerebrovascular disease, hyperthyroidism, or bladder neck obstruction.

Antihistamine nasal sprays azelastine and olopatadine are available by prescription. They not only reduce inflammation and decrease nasal congestion, but also have rapid onset of action and can be used "on demand" (deShazo & Kemp, 2018b).

Corticosteroid Nasal Spray

Corticosteroid nasal sprays are recognized as the most effective pharmacotherapy for allergic rhinitis. These anti-inflammatory agents work directly on the nasal mucosa but take a few hours to work. The patient should understand that maximal therapeutic effectiveness of these agents can take 1 to 2 weeks. They are recommended as the best single therapy for patients with mild to moderate or moderate to severe symptoms (Berger & Melizer, 2015).

Corticosteroid nasal sprays are derived from hydrocortisone and are divided into first-generation and second-generation agents. Beclomethasone, flunisolide, triamcinolone, and budesonide are first-generation agents, whereas

flucatisone, mometasone, and ciclesonide are second-generation agents (deShazo & Kemp, 2018b).

Corticosteroid nasal spray therapy should begin with the maximal dose for patient age. Once patient symptoms are adequately controlled, the dose can be reduced at 1-week intervals to the lowest effective dose that controls symptoms. Patients with severe symptoms usually need daily use of the nasal spray. Some patients may find relief of symptoms with use of the nasal spray every other day or as needed. Newer second-generation corticosteroid spray preparations act rapidly (within 3 to 12 hours), and as-needed use appears to be effective. This kind of treatment may be adequate in patients with episodic symptoms (deShazo & Kemp, 2018b).

Adverse effects of corticosteroid nasal sprays are mild and include drying of the nasal mucosa and burning and itching sensations caused by the vehicle used to administer the medication. Beclomethasone, budesonide, flunisolide, and triamcinolone are deactivated rapidly after absorption, so they do not achieve significant blood levels. Inhaled corticosteroids do not affect the immune system to the same degree as systemic corticosteroids (i.e., oral corticosteroids). Because corticosteroids are inhaled into the upper respiratory tract, tuberculosis or untreated bacterial infections of the lungs may become apparent and progress. Whenever possible, patients with tuberculosis or other bacterial infections of the lungs should avoid corticosteroid nasal sprays (deShazo & Kemp, 2018b).

The combination of an antihistamine and a corticosteroid nasal spray may be helpful for patients who do not obtain sufficient relief with one agent. A combination spray containing azelastine and fluticasone is available (deShazo & Kemp, 2018b).

Adrenergic Agents

Alpha-adrenergic agonist (also called sympathomimetic) medications, such as pseudoephedrine, can be used as decongestants in allergies. These agents activate alpha-adrenergic receptor sites on the smooth muscle causing vasoconstriction of the nasal mucosal blood vessels, reducing local blood flow, fluid exudation, and mucosal edema. Oral alpha-adrenergic medications have a systemic effect and are not recommended as first-line treatment of allergic rhinitis (Laccourreye, et al., 2015). Oral alpha-adrenergic agents are also available in combination with antihistamines (e.g., diphenhydramine and pseudoephredine fexofenadine and pseudoephedrine). Alpha-adrenergic topical nasal spray (e.g., oxymetazoline) is also available. Alpha-adrenergic agonist ophthalmic drops, such as tetrahydrozoline, are commonly used for allergic conjunctivitis as they vasoconstrict the blood vessels of the eye.

There are many potential side effects of oral alpha-adrenergic agonists. These include hypertension, arrhythmias, palpitations, central nervous system stimulation, irritability, tremor, and tachyphylaxis. Oral adrenergic agents are

not first-line agents in allergy and have potential for cardiovascular and neurological adverse effects (deShazo & Kemp, 2018b). The topical preparations (i.e., drops and sprays) of alpha-adrenergic agonists cause fewer side effects than oral medications; however, the use of drops and sprays should be limited to a few days to avoid rebound congestion, also referred to as rhinitis medicamentosa.

The Combat Methamphetamine Epidemic Act of 2005 banned OTC sales of medications that contain the ingredients pseudoephedrine, ephedrine, or phenylpropanolamine as these can be used to make methamphetamine, a highly addictive stimulant. Laws to enforce this act vary state by state. There is a legal age requirement to purchase these drugs and pharmacists must limit and keep records of the amount purchased. Some states require a prescription (U.S. Food and Drug Administration [FDA], 2017).

TABLE 33-2 Select H_1 Antihistamines

H_1 Antihistamine	Contraindications	Major Side Effects	Nursing Implications and Patient Education
First-Generation H_1 Antihistamines (Sedating)			
Diphenhydramine	Allergy to any antihistamines Third trimester of pregnancy Lactation Use cautiously with narrow-angle glaucoma, asthma, stenosing peptic ulcer, benign prostatic hyperplasia (BPH) or bladder neck obstruction, first and second trimester of pregnancy, older patients, hypertension	Drowsiness, confusion, dizziness, dry mouth, nausea, vomiting, photosensitivity, urinary retention	Administer with food if gastrointestinal (GI) upset occurs. Caution patients to avoid alcohol, driving, or engaging in any hazardous activities until central nervous system (CNS) response to medication is stabilized. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Encourage the use of sunscreen and hat while outdoors. Assess for urinary retention; monitor urinary output.
Chlorpheniramine	Allergy to any antihistamines Third trimester of pregnancy Lactation Use cautiously with narrow-angle glaucoma, asthma, stenosing peptic ulcer, BPH or bladder neck obstruction, first and second trimesters of pregnancy, older patients, hypertension	Drowsiness, sedation, and dizziness, although less than other sedating agents; confusion, dry mouth, nausea, vomiting, urinary retention, epigastric distress, thickening of bronchial secretions	Caution patients to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to medication is stabilized. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Recommend the use of a humidifier.
Hydroxyzine	Allergy to hydroxyzine or cetirizine, pregnancy, lactation, hypertension	Drowsiness; dry mouth; involuntary motor activity, including	Caution patients to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to medication is stabilized. Suggest sucking

		tremor and seizures	on sugarless lozenges or ice chips for relief of dry mouth. Instruct patients to report tremors.
Second-Generation H_1 Antihistamines (Nonsedating)			
Cetirizine	Allergy to any antihistamines Narrow-angle glaucoma Asthma Stenosing peptic ulcer BPH or bladder neck obstruction Lactation Hypertension	Dry nasal mucosa, thickening of bronchial secretions	Can be taken without regard to meals. Instruct patients to use caution if driving or performing tasks that require alertness. Recommend the use of a humidifier.
Desloratadine	Allergy to loratadine Lactation Use cautiously with renal or hepatic impairment, pregnancy, hypertension	Somnolence, nervousness, dizziness, fatigue, dry mouth	Can be taken without regard to meals. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Recommend the use of a humidifier.
Loratadine	Allergy to any antihistamines Narrow-angle glaucoma Asthma Stenosing peptic ulcer BPH or bladder neck obstruction Hypertension	Headache, nervousness, dizziness, depression, edema, increased appetite	Instruct patients to take on empty stomach (1 h before or 2 h after meals or food). Instruct patients to avoid alcohol and to use caution if driving or performing tasks that require alertness. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Recommend the use of a humidifier.
Fexofenadine	Allergy to any antihistamines Pregnancy Lactation Use cautiously with hepatic or renal impairment, older patients, hypertension	Fatigue, drowsiness, GI upset	Should not be given within 15 min of ingestion of antacids. Instruct patients to use caution if driving or performing tasks that require alertness. Recommend the use of a humidifier.
Levocetirizine	Hypersensitivity to	Drowsiness, GI	Can be taken without regard

	any antihistamines End-stage kidney disease Hemodialysis Use cautiously with pregnancy, lactation, older patients	disturbance, headache	to meals. Instruct patients to use caution if driving or performing tasks that require alertness. Recommend the use of a humidifier.

Mast Cell Stabilizers

Intranasal cromolyn sodium is a spray that acts by stabilizing the mast cell membrane, thus reducing the release of histamine and other mediators of the allergic response. In addition, it inhibits macrophages, eosinophils, monocytes, and platelets involved in the immune response. Cromolyn interrupts the physiologic response to nasal antigens, and it is used prophylactically (before the exposure to allergens) to prevent the onset of symptoms and to treat symptoms once they occur. It is also used therapeutically in chronic allergic rhinitis. This spray is as effective as antihistamines but is less effective than corticosteroid nasal sprays in the treatment of seasonal allergic rhinitis. It is best to use this agent 30 minutes prior to exposure to allergen. Frequent use is necessary to obtain an effect (1 to 2 nasal sprays 4 times per day). The patient must be informed that the beneficial effects of the medication may take a week or longer to manifest. The medication is of no benefit in the treatment of nonallergic rhinitis. Adverse effects (e.g., sneezing, local stinging and burning sensations) are usually mild (deShazo & Kemp, 2018b).

Nasal Decongestant Sprays

Nasal decongestant sprays include phenylephrine, oxymetazoline, and naphazoline. These agents vasoconstrict blood vessels in the nasal mucosa by blocking alpha-adrenergic receptors. Nasal decongestant sprays are not recommended as monotherapy. After using these agents for 3 to 7 days, reduced sensitivity of alpha-adrenergic receptors develops which can cause worsening nasal congestion. This effect of worsening nasal congestion often causes patients to overuse these agents with less and less therapeutic effect. This is termed rhinitis medicamentosa and can lead to increased need for the agent and eventual dependency (Wahid & Shermetaro, 2019).

The combination of a topical nasal decongestant and topical corticosteroid may effectively treat symptoms without causing rhinitis medicamentosa. Nasal decongestants are helpful when used just before air travel in patients who have difficulties with middle ear or sinus equilibration with flying or in patients who have problems with altitude changes (deShazo & Kemp, 2018b).

Corticosteroids

Oral and parenteral corticosteroids can be used when conventional therapy has failed and symptoms are severe and of short duration. They can control symptoms of allergic reactions such as hay fever, medication-induced allergies, and allergic reactions to insect stings. However, corticosteroids have a delayed onset of action and cannot be used for immediate relief of allergic symptoms. The agents are not effective as singular treatment for severe allergic reactions such as anaphylaxis (deShazo & Kemp, 2018b). Oral corticosteroids in the lowest dose to control symptoms for the shortest period of time may be prescribed if other agents fail. However, corticosteroids are usually avoided because of their side effects.

Quality and Safety Nursing Alert

Patients who receive high-dose or long-term corticosteroid therapy must be cautioned not to stop taking the medication suddenly. Doses are tapered when discontinuing this medication to avoid adrenal insufficiency.

The patient should be cautioned about side effects, which include fluid retention, weight gain, hypertension, gastric irritation, glucose intolerance, osteoporosis, immunosuppression, and adrenal suppression. Further discussion of corticosteroids is provided in Chapter 45, Table 45-3.

Leukotriene Receptor Antagonists

Leukotrienes are inflammatory mediators that cause bronchospasm, vascular permeability, and activation of leukocytes. They are three to four times more potent than histamine in perpetuating inflammation in the upper respiratory tract (Castells, 2017). Leukotriene receptor antagonists (LTRAs), such as zafirlukast and montelukast, block the synthesis or action of leukotrienes and prevent the signs and symptoms associated with asthma (see Table 33-3). LTRAs are also used to counteract allergic rhinitis.

Montelukast efficacy has been compared to a second-generation antihistamine agent. In combination with a second-generation antihistamine such as loratadine, montelukast has shown to be more effective than montelukast alone. Adverse effects of montelukast include neuropsychiatric changes such as anxiety, depression, and insomnia. This agent may be not appropriate for patients with preexisting mood disorders (Badri & Takov, 2019).

Leukotriene receptor antagonists are for long-term use, and patients should be advised to take their medication daily. LTRAs are not effective as "rescue" medications. Patients take appropriate "rescue" medications for symptom

exacerbation but continue to take the LTRA on a daily basis. Studies report that using an LTRA in conjunction with an inhaled corticosteroid is effective for mild persistent asthma (Chauchan, Jeyaraman, Singh Mann, et al., 2017).

Allergen Immunotherapy

Allergen immunotherapy (AIT) is primarily used to treat IgE-mediated diseases by injections of allergen extracts. Immunotherapy, also referred to as allergy vaccine therapy, involves the administration of gradually increasing quantities of specific allergens to the patient until a dose is reached that is effective in reducing disease severity from natural exposure. This is an effective treatment for 80% to 90% of certain allergens such as grass and pollen. This type of therapy provides an adjunct to symptomatic pharmacologic therapy and can be used when avoidance of allergens is not possible. Specific immunotherapy has been used in the treatment of allergic disorders for many years. Goals of immunotherapy include reducing the level of circulating IgE, increasing the level of blocking antibody IgG, and reducing mediator cell sensitivity. Immunotherapy has been most effective for ragweed pollen, grass, tree pollen, cat dander, and house dust mite allergens (Akdis, 2018). Indications and contraindications for immunotherapy are presented in Chart 33-5.

TABLE 33-3 Leukotriene Receptor Antagonists

Leukotriene Receptor Antagonist	Available Formulations	Frequency of Dosing
Zafirlukast	Tablets: 10 mg; 20 mg	Taken twice a day
Montelukast	Tablets: 10 mg Chewable tablets: 4 mg; 5 mg Granules: 4 mg/packet	Taken once a day in PM
Zileuton	Tablets: 600 mg extended release	Taken twice a day within 1 h after morning and evening meals

Chart 33-5

IMMUNOTHERAPY: Indications and Contraindications

Indications

- Allergic rhinitis, conjunctivitis, or allergic asthma
- History of a systemic reaction to Hymenoptera and specific immunoglobulin E antibodies to Hymenoptera venom
- Desire to avoid the long-term use, potential adverse effects, or costs of medications
- Lack of control of symptoms by avoidance measures or the use of medications

Contraindications

- The use of beta-blocker or angiotensin-converting enzyme inhibitor therapy, which may mask early signs of anaphylaxis
- Presence of significant pulmonary or cardiac disease or organ failure
- Inability of the patient to recognize or report signs and symptoms of a systemic reaction
- Nonadherence of the patient to other therapeutic regimens and nonlikelihood that the patient will adhere to the immunization schedule (often weekly for an indefinite period)
- Inability to monitor the patient for at least 30 minutes after administration of immunotherapy
- Absence of equipment or adequate personnel to respond to allergic reaction if one occurs

Correlation of a positive skin test with a positive allergy history is an indication for immunotherapy if the allergen cannot be avoided. The benefit of immunotherapy has been fairly well established in instances of allergic rhinitis and bronchial asthma that are clearly due to sensitivity to one of the common pollens, molds, or household dust. Unlike antiallergy medication, allergen immunotherapy has the potential to alter the allergic disease course after 3 to 5 years of therapy. Because it may prevent the progression or development of asthma or multiple or additional allergies, it is also considered to be a potential preventive measure. The patient must understand what to expect and the importance of continuing therapy for several years before immunotherapy is accomplished. When skin tests are performed, the results are correlated with symptoms; treatment is based on the patient's needs rather than on the results of skin tests (Klimek, Pfaar, Bousquet, et al., 2017).

There are three methods of immunotherapy: subcutaneous immunotherapy (SCIT), sublingual immunotherapy (SLIT), and epicutaneous immunotherapy (EPIT).

Subcutaneous Immunotherapy

The most common method of treatment is SCIT, which consists of the serial injection of one or more antigens that are selected in each particular case on the basis of skin testing. This method provides a simple and efficient technique for targeting IgE antibodies to specific antigens. Specific treatment consists of injecting extracts of the allergens that cause symptoms in a particular patient. Injections begin with very small amounts and are gradually increased, usually at weekly intervals, until a maximum tolerated dose is attained. Although severe systemic reactions are rare, the risk of systemic and potentially fatal anaphylaxis exists. It tends to occur most frequently at the induction or "up-dosing" phase. Therefore, the patient must be monitored after administration of immunotherapy. Because of the risk of anaphylaxis, injections should not be given by a lay person or by the patient. The patient must remain in the office or clinic for at least 30 minutes after the injection and is observed for possible systemic symptoms. If a large, local swelling develops at the injection site, the next dose should not be increased, because this may be a warning sign of a possible systemic reaction (James & Bernstein, 2017).

Maintenance booster injections are given at 2- to 4-week intervals, frequently for a period of several years, before the maximum benefit is achieved, although some patients will note early improvement in their symptoms. Long-term benefit seems to be related to the cumulative dose of vaccine given over time (Nelson, 2018).

Quality and Safety Nursing Alert

Because the injection of an allergen may induce systemic reactions, such injections are given only in a setting where epinephrine is immediately available (i.e., primary provider's office, clinic).

Sublingual Immunotherapy

SLIT has been reported to have a 30% to 40% reduction in reactions and rescue medication usage in seasonal allergic rhinitis. Administration of SLIT includes a buildup phase that is followed by a treatment plan of three times per week with a rapid dissolving tablet or liquid containing allergen extracts. Recent studies show comparable efficacy of SLIT with SCIT (Chaaban, Mansi, Tripple, et al., 2019; Durham & Penagos, 2016). Systemic side effects are rare but have been reported in patients who also report systemic reactions with SCIT. Side effects include irritation, minor swelling or itching inside the mouth, and stomach upset and nausea.

Epicutaneous Immunotherapy

EPIT is an investigational alternative allergen immunotherapy with delivery of the allergen to the epidermis. Because the epidermis is less vascular, it is theorized that there is reduced risk of systemic allergic side effect. Epicutaneous allergen patches are applied to the upper inner arm or interscapular region of the back. Doses are lower than those used in SCIT or SLIT. The allergen is soluble and absorbed into the skin. Adverse reactions include localized erythema, pruritus, and urticaria at the site of allergen patch. Studies of EPIT have shown modest results compared to placebo, and there has been a higher rate of treatment-related mild to moderate anaphylactic reactions. Long-term studies of EPIT are currently in progress for peanut allergies (Nowak-Wegrzyn, 2019).

Immunotherapy should not be initiated during pregnancy; for patients who have been receiving immunotherapy before pregnancy, the dosage should not be increased during pregnancy.

Therapeutic failure is evident when a patient does not experience a decrease of symptoms within 12 to 24 months, fails to develop increased tolerance to known allergens, and cannot decrease the use of medications to reduce symptoms. Potential causes of treatment failure include misdiagnosis of allergies, inadequate doses of allergen, newly developed allergies, and inadequate environmental controls (Akdis, 2018).

NURSING PROCESS

The Patient with Allergic Rhinitis

Assessment

The examination and history of the patient reveal sneezing, often in paroxysms; thin and watery nasal discharge; itching eyes and nose; lacrimation; and occasionally headache. The health history includes a personal or family history of allergy. The allergy assessment identifies the nature of antigens, seasonal changes in symptoms, and medication history. The nurse also obtains subjective data about how the patient feels just before symptoms become obvious, such as the occurrence of pruritus, breathing problems, and tingling sensations. In addition to these symptoms, hoarseness, wheezing, hives, rash, erythema, and edema are noted. Any relationship between emotional problems or stress and the triggering of allergy symptoms is assessed (Kakli & Riley, 2016).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include:

- Impaired breathing associated with allergic reaction
- Lack of knowledge about allergy and the recommended modifications in lifestyle and self-care practices
- Difficulty coping with chronicity of condition and need for environmental modifications

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Anaphylaxis
- Impaired breathing
- Nonadherence to the therapeutic regimen

Planning and Goals

The goals for the patient may include restoration of a breathing pattern that provides adequate ventilation, increased knowledge about the causes and control of allergic symptoms, improved coping with alterations and modifications, and absence of complications.

Nursing Interventions

Improving Breathing Pattern

The patient is instructed and assisted to modify the environment to reduce the severity of allergic symptoms or to prevent their occurrence. The patient is also instructed to reduce exposure to people with upper respiratory tract

infections. Adherence to medication schedules and other treatment regimens is encouraged and reinforced.

Promoting Understanding of Allergy and Allergy Control

Instruction includes strategies to minimize exposure to allergens and explanation about desensitization procedures and correct use of medications. The nurse informs and reminds the patient of the importance of keeping appointments for desensitization procedures, because dosages are usually adjusted on a weekly basis, and missed appointments may interfere with the dosage adjustment (Pitsios & Dietis, 2019).

Patients need to understand the difference between rescue medications for allergy exacerbation and seasonal flares (e.g., antihistamines) and medications used for allergy control throughout the year (e.g., inhaled corticosteroids, leukotriene modifiers). Patients also need to understand that medications for allergy exacerbation and seasonal flares should be used only when the allergy is apparent. Continued use of these medications when not required can result in tolerance; consequently, the medications will be ineffective when needed (Pitsios & Dietis, 2019; Scadding, 2017).

Coping with a Chronic Disorder

Although allergic reactions are infrequently life-threatening, they require vigilance to avoid allergens and modification of the lifestyle or environment to prevent recurrence of symptoms. Allergic symptoms are often present year-round and create discomfort and inconvenience for the patient. Although patients may not feel ill during allergy seasons, they often do not feel well, either. The need to be alert for possible allergens in the environment may be tiresome, placing a burden on the patient's ability to lead a normal life. Stress related to these difficulties may in turn increase the frequency or severity of symptoms. To assist the patient in adjusting to these modifications, the nurse must have an appreciation of the difficulties encountered by the patient. The patient is encouraged to verbalize feelings and concerns in a supportive environment and to identify strategies to deal with them effectively (Scadding, 2017).

Monitoring and Managing Potential Complications

Anaphylaxis and Impaired Breathing. Respiratory and cardiovascular functioning can be significantly altered during allergic reactions by the reaction itself or by the medications used to treat reactions. Anaphylaxis is an acute, systemic reaction that causes vasodilation and bronchiole constriction which can lead to hypotensive shock and asphyxiation. The respiratory status is evaluated by monitoring the respiratory rate and pattern and by assessing for breathing difficulties or abnormal lung sounds. The pulse rate and rhythm and blood pressure are monitored to assess cardiovascular status regularly or any time the patient reports symptoms such as itching or difficulty breathing. In the event of signs and symptoms

suggestive of anaphylaxis, emergency medications and equipment must be available for immediate use. People with severe allergic reactions may be advised to carry an autoinjectable epinephrine device (Song & Lieberman, 2019). See Chapter 11 for treatment of anaphylactic shock.

Nonadherence to the Therapeutic Regimen. Knowledge about the treatment regimen does not ensure adherence. Having the patient identify potential barriers and explore acceptable solutions for effective management of the condition (e.g., installing tile floors rather than carpet, not gardening in the spring) can increase adherence to the treatment regimen (Pitsios & Dietis, 2019).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The patient is instructed about strategies to minimize exposure to allergens, the actions and adverse effects of medications, and the correct use of medications. The patient should know the name, dose, frequency, actions, and side effects of all medications taken.

Instruction about strategies to control allergic symptoms is based on the needs of the patient as determined by the results of tests, the severity of symptoms, and the motivation of the patient and family to deal with the condition (Pitsios & Dietis, 2019). Suggestions for patients who are sensitive to dust and mold in the home are given in Chart 33-6.

If the patient is to undergo allergen immunotherapy (AIT), the nurse reinforces the primary provider's explanation regarding the purpose and procedure. Instructions are given regarding the series of injections, which usually are given initially every week and then at 2- to 4-week intervals. These instructions include remaining in the primary provider's office or the clinic for at least 30 minutes after the injection, so that emergency treatment can be given if the patient has a reaction; avoiding rubbing or scratching the injection site; and continuing with the series for the period of time required. In addition, the patient and family are instructed about emergency treatment of severe allergic symptoms (James & Bernstein, 2017).

Because antihistamines may produce drowsiness, the patient is cautioned about this and other side effects applicable to the medication. Operating machinery, driving a car, and performing activities that require intense concentration should be postponed. The patient is also informed about the dangers of drinking alcohol when taking antihistamines, because they tend to exaggerate the effects of alcohol.

The patient must be aware of the effects caused by overuse of the sympathomimetic agents in nose drops or sprays, because rhinitis medicamentosa may result. After topical application of the medication, a rebound period occurs in which the nasal mucous membranes become more edematous and congested than they were before the medication was used.

Such a reaction encourages the use of more medication, and a cyclic pattern results. The topical agent must be discontinued immediately and completely to correct this problem (Wahid & Shermetaro, 2019).

Continuing and Transitional Care. Follow-up telephone calls to the patient are often reassuring to the patient and family and provide an opportunity for the nurse to answer any questions. The patient is reminded to keep follow-up appointments and informed about the importance of continuing with treatment. The importance of participating in health promotion activities and health screening is also emphasized.

Evaluation

Expected patient outcomes may include:

1. Exhibits a breathing pattern that provides adequate ventilation
    a. Demonstrates lungs clear on auscultation
    b. Exhibits absence of adventitious breath sounds (crackles, rhonchi, wheezing)
    c. Has a normal respiratory rate and pattern
    d. Reports no complaints of respiratory distress (shortness of breath, difficulty on inspiration or expiration)

Chart 33-6 HOME CARE CHECKLIST

Allergy Management

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of environmental allergens (e.g., dust, molds, perfumes, foods) on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in home environment necessary to minimize exposure to allergens.
  - Removing drapes, curtains, and venetian blinds and replacing them with pull shades; covering the mattress with a hypoallergenic cover that can be zipped; and removing rugs and replacing them with wood flooring or linoleum.
  - Reducing dust in the house as a whole by using steam or hot water for heating and using high-efficiency particulate air (HEPA) purifiers or air-conditioning.
  - Washing the floor and dusting and vacuuming daily, using clean filters, wearing a mask whenever cleaning is being done.
  - Replacing stuffed furniture with wood pieces that can easily be dusted.
  - Avoiding the use of tufted bedspreads, stuffed toys, and feather pillows and replacing them with washable cotton material.
  - Avoiding the use of any clothing that causes itching.
- Verbalize ways to reduce exposure to pollens or molds by identifying seasons of the year when pollen counts are high; wearing a mask at times of increased exposure (windy days and when grass is being cut); and avoiding contact with weeds, dry leaves, and freshly cut grass.
- State rationale for seeking air-conditioned areas at the height of the allergy season.
- State rationale for avoiding sprays and perfumes.
- State rationale for the use of hypoallergenic cosmetics.
- State rationale for taking prescribed medications as prescribed.
- Identify specific foods that may cause allergic symptoms and develop a list of foods to avoid (e.g., fish, nuts, eggs, chocolate).
- Verbalize ways to cope with stress successfully, plans for regular exercise, and rationale for obtaining adequate rest.
- State how to reach primary provider with questions or complications.
- State time and date of follow-up appointments, testing.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

2. Demonstrates knowledge about allergy and strategies to control symptoms
   a. Identifies causative allergens, if known
   b. States methods of avoiding allergens and controlling indoor and outdoor precipitating factors
   c. Removes from the environment items that retain dust
   d. Wears a dampened mask if dust or mold may be a problem
   e. Avoids smoke-filled rooms and dust-filled or freshly sprayed areas
   f. Uses air-conditioning for a major part of the day when allergens are high
   g. Takes antihistamines as prescribed; participates in allergen immunotherapy program, if applicable
   h. Describes name, purpose, side effects, and method of administration of prescribed medications
   i. Identifies when to seek immediate medical attention for severe allergic responses
   j. Describes activities that are possible, including ways to participate in activities without activating the allergies
3. Adapts to the inconveniences of an allergy
   a. Relates the emotional aspects of the allergic response
   b. Demonstrates the use of measures to cope positively with allergy
4. Demonstrates absence of complications
   a. Exhibits vital signs within normal limits
   b. Reports no symptoms or episodes of anaphylaxis (urticaria, itching, peripheral tingling, fullness in the mouth and throat, flushing, difficulty swallowing, coughing, wheezing, or difficulty breathing)
   c. Demonstrates correct procedure to self-administer emergency medications to treat severe allergic reaction
   d. Correctly states medication names, dose and frequency of administration, and medication actions
   e. Correctly identifies side effects and untoward signs and symptoms to report to primary provider
   f. Discusses acceptable lifestyle changes and solutions for identified potential barriers to adherence to treatment and medication regimen

Contact Dermatitis

Contact dermatitis is an inflammatory reaction of the skin due to contact with an exogenous substance. There are two basic types of contact dermatitis: irritant contact dermatitis and allergic contact dermatitis (see Table 33-4). Irritant contact dermatitis is an inflammatory response of the skin to direct chemical damage that releases mediators predominantly from epidermal cells. Allergic contact dermatitis is a delayed (type 4) hypersensitivity reaction to exogenous contact antigens that involves activation of T cells (Litchman, Nair, & Atwater, 2019). Eighty percent of contact dermatitis is irritant type and 20% is allergic type (Fornacier & Noor, 2018). Most cases are caused by excessive exposure to or additive effects of irritants (e.g., soaps, detergents, metals, organic solvents, cosmetics). Skin sensitivity may develop after brief or prolonged periods of exposure, and the clinical picture may appear hours or weeks after the sensitized skin has been exposed.

Clinical Manifestations

Symptoms of acute contact dermatitis include itching, burning, erythema, skin lesions (vesicles and bullae), and oozing (Goldner & Fransway, 2018). The reaction is limited to the site of contact. Chronic contact dermatitis symptoms can include scaling, lichenification, thickening of the skin, and pigmentary changes. Secondary invasion by bacteria may develop in skin that is abraded by rubbing or scratching. Usually, there are no systemic symptoms unless the eruption is widespread.

Assessment and Diagnostic Findings

Determining allergens responsible requires a history, physical examination, and patch testing.

Assessment includes the date of onset and any identifiable relationship to work environment and skin care products. The location of the lesions, distribution of the dermatitis, absence of other etiologies, and the history of exposure aid in determining the condition (Goldner & Fransway, 2018). Patch testing and environmental history of exposure to contact allergens are required to verify the diagnosis. Patch testing is the standard test for identification of culprit allergens in persons with allergic contact dermatitis. The patch test most commonly used is the thin-layer rapid use epicutaneous (TRUE) test. An extended screening panel (North American screening series) has increased sensitivity. Researchers reported an extended screening panel identified an additional 10.8% of patients with positive tests that were negative to TRUE test allergens (Sundquist, Lang, & Pasha, 2019).

TABLE 33-4 Types, Testing, and Treatment of Contact Dermatitis

Type	Etiology	Clinical Presentation	Diagnostic Testing	Treatment
Allergic	Results from contact of skin and allergenic substance; has a sensitization period of 10–14 days	Vasodilation and perivascular infiltrates on the dermis Intracellular edema Usually seen on dorsal aspects of hand	Patch testing (contraindicated in acute, widespread dermatitis)	Avoidance of offending material Aluminum acetate (Burow Solution, Domeboro Powder) or cool water compress Systemic corticosteroids (prednisone) for 7–10 days Topical corticosteroids for mild cases Oral antihistamines to relieve pruritus
Irritant	Results from contact with a substance that chemically or physically damages the skin on a nonimmunologic basis; occurs after first exposure to irritant or repeated exposures to milder irritants over an extended time	Dryness lasting days to months Vesiculation, fissures, cracks Hands and lower arms most common areas	Clinical picture Appropriate negative patch tests	Identification and removal of source of irritation Application of hydrophilic cream or petrolatum to soothe and protect Topical corticosteroids and compresses for weeping lesions Antibiotics for infection and oral antihistamines for pruritus

Adapted from Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer.

Atopic Dermatitis

Atopic dermatitis (commonly called eczema) is a chronic, inflammatory allergic skin disorder that is triggered by environmental factors in individuals who are genetically susceptible. This disorder affects 7% of adults in the United States (Weston & Howe, 2019). More than half of patients are also affected by asthma, allergic rhinitis, and food allergies.

Atopic dermatitis is a type I immediate hypersensitivity disorder involving IgE antibodies that causes dry, pruritic, hypersensitive skin. It often begins with small red pruritic papules that stimulate intense itching, leaving erythematous, excoriated areas of skin. This often triggers an "itch-scratch cycle" where rubbing or scratching the skin causes further irritation, redness, and skin breakdown. Skin thickening from chronic scratching (lichenification) and fissuring may develop over time. In many patients, lesions in different stages may be present at the same time (Weston & Howe, 2019). Atopic dermatitis in adults often occurs at the hands, wrists, elbows, knees, ankles, face, and neck.

Atopic dermatitis is due to a "leaky" skin barrier that allows water to leave the skin dried out and hypersensitive. Exposure of the hypersensitive skin to soaps, detergent, house dust mites, pollen, animal dander, and some bacteria break down the skin barrier (Weston & Howe, 2019).

Defective filaggrin (FLG) genes at chromosome 1q21.3 are common in persons with the disorder. Filaggrin is a protein produced by keratinocytes in the skin that is encoded by the FLG gene (Løset, Brown, Saunes, et al., 2019). Currently, there is ongoing investigation into the etiology of atopic dermatitis, including other genes involved in processing of filaggrin.

Nurses should be aware that atopic dermatitis is often linked to a process called the **atopic march** that refers to the natural history of allergic diseases as they begin in infancy and through childhood. Atopic march begins with atopic dermatitis and progresses to IgE-mediated food allergy, asthma, and allergic

rhinitis. It is the result of interactions between susceptibility genes, the environment, defective function of the skin barrier, and immunologic responses (AAAAI, 2019a; Hill & Spergel, 2018).

The diagnosis of atopic dermatitis is based on the health history, morphology and distribution of skin lesions, and associated clinical signs. Laboratory testing, patch testing, and skin biopsy may be necessary if there is a need to rule out other skin conditions.

Medical Management

Treatment of patients with atopic dermatitis involves avoidance of irritative agents, use of anti-inflammatory topical agents, and moisturization of the skin. Patients should avoid potential triggers of atopic dermatitis, which include excessive bathing without subsequent moisturization, low humidity environments, animal dander, dust mites, xerosis (dry skin), overheating of skin, and exposure to solvents and detergents. Individuals are commonly hypersensitive to fragrances, perfumes, and contact allergens such as nickel.

Topical corticosteroids are the mainstay of treatment of atopic dermatitis. If mild OTC corticosteroids are not adequate, more potent corticosteroids such as fluocinoline 0.025%, triamcinolone, 0.1%, or betamethasone, 0.05% are prescribed. These agents should not be used on the face as they can cause skin atrophy. Topical calcineurin inhibitors, which are nonsteroidal immunomodulating agents (e.g., tacrolimus, pimecrolimus), are best for the facial area. Treatment of severe flare-ups of chronic disease can be treated with a short course of systemic corticosteroids (Weston & Howe, 2019).

Dupilumab is an interleukin (IL)-4 and IL-13 receptor-alpha antagonist that was approved by the FDA for the treatment of patients aged 12 years and older with moderate to severe atopic dermatitis not adequately controlled with topical prescription therapies (Spergel & Lio, 2019).

Colonization with *Staphylococcus aureus* occurs more frequently in individuals with atopic dermatitis than in the general population, and *S. aureus* is a common cause of secondary infection in these patients. The presence of purulence or honey-colored crusts suggests *S. aureus* infection. Antibiotic treatment is needed to eradicate infection (Spergel & Lio, 2019).

Nursing Management

Patients who experience atopic dermatitis and their families require assistance and support from the nurse to cope with the disorder. The symptoms are often disturbing to the patient and disruptive to the family. The appearance of the skin may affect the patient's self-esteem and their willingness to interact with others. Instructions and counseling about strategies to incorporate preventive measures and treatments into the lifestyle of the family may be helpful.

Skin hydration is a key component of treatment as atopic skin is low in moisture. Thick cream moisturizers and emollients that contain glycerol or urea should be used as these will keep the skin hydrated. A hydrating bath with mild soap followed by immediate emollient application is recommended, or a shower of short duration (Spergel & Lio, 2019).

Itching can be decreased by wearing cotton fabrics, washing clothes with a mild detergent, and humidifying dry heat in winter. Antihistamines such as diphenhydramine may be used as treatment, but since they are sedating, the patient can be advised that it is best to use them at bedtime.

The patient and family need to be aware of signs of secondary infection and of the need to seek treatment if infection occurs. The nurse also educates the patient and family about the side effects of medications used in treatment.

Drug Hypersensitivity

Drug hypersensitivity is the leading cause of fatal anaphylaxis, comprising 43% of deaths from anaphylaxis. All routes of administration are potentially fatal, but drugs given parenterally incur the greatest risk. Cutaneous rashes are among the most common reactions to medications and occur in approximately 2% to 3% of hospitalized patients (Habif, 2016).

A drug hypersensitivity reaction is defined by the time of appearance, possible mode of action (mechanism of immune stimulation), and resulting pathophysiology. According to the World Allergy Organization, immunologic drug reactions can be divided into immediate reactions (i.e., onset within 1 hour of exposure) and delayed reactions (onset after 1 hour), based on the timing of the appearance of symptoms (Tanno, Torres, Castells, et al., 2018).

IgE-mediated immediate type 1 hypersensitivity reactions to a drug occur within 1 hour of administration of the agent. Delayed hypersensitivity reactions occur after 1 hour; most occur after 6 hours or days of treatment. These reactions can also occur after the course of medication is finished. These reactions may be caused by several different mechanisms, but they are not IgE mediated. Types II, III, and IV immunologic reactions are all considered delayed reactions (Pichler, 2019).

A disorder known as drug rash with eosinophilia and systemic symptoms (DRESS) can occur after weeks of continuous treatment. Also known as "drug-induced hypersensitivity syndrome" (DiHS), it is characterized by fever, rash, and multiorgan involvement, and may or may not be associated with eosinophilia and lymphocytosis. Hepatitis and myocarditis can be part of DRESS. These reactions can persist for weeks to months, even after the medication is stopped (Mockenhaupt, 2019). Anticonvulsant agents (e.g., lamotrigine, phenytoin, phenobarbital) and allopurinol are the most frequently reported causes of DRESS (Mockenhaupt, 2019).

Anaphylaxis is the most severe presentation of an IgE-mediated drug reaction. Medications administered IV may cause symptoms in seconds to minutes, while the same drug administered orally may cause symptoms in 3 to 30 minutes if taken on an empty stomach, and in 10 to 60 minutes if taken with food. The agents that most commonly exhibit this type of reaction include the following (Pichler, 2019):

- Beta-lactam drugs (e.g., penicillins and cephalosporins)
- Neuromuscular blocking agents (e.g., pancuronium)
- Quinolones (e.g., ciprofloxacin)
- Platinum-containing chemotherapeutic agents (e.g., carboplatin)
- Foreign proteins such as monoclonal antibodies (e.g., rituximab)

Type II cytotoxic reactions involve antibody-mediated cell destruction. Type II reactions may arise when drugs bind to surfaces of certain cell types and act as antigens. Clinical manifestations include hemolytic anemia, thrombocytopenia, or neutropenia, since these are the cell types that are most often affected. The drugs most commonly implicated in hemolytic anemia are cephalosporins, penicillins, nonsteroidal anti-inflammatory drugs (NSAIDs), and quinine and quinidine. Drugs implicated in thrombocytopenia include heparin, abciximab, quinine and quinidine, sulfonamides, vancomycin, gold compounds, beta-lactam antibiotics, carbamazepine, and NSAIDs. Severe neutropenia due to type II drug reactions presents days to weeks after beginning the medication. Clinical manifestations include symptoms of infection, such as fever, stomatitis, pharyngitis, pneumonia, or sepsis. Propylthiouracil, amodiaquine, and flecainide can cause these reactions (Pichler, 2019).

Type III reactions are mediated by antigen–antibody complexes that deposit on basement membranes and usually present as serum sickness, vasculitis, or drug fever. Signs and symptoms take 1 or more weeks to develop after drug exposure, since significant quantities of antibody are needed to generate symptoms related to antigen–antibody complexes. These are uncommon reactions but are seen with antitoxins for rabies, botulism, and venoms, tetanus, hepatitis, and diphtheria vaccines (Pichler, 2019).

Type IV reactions involve activated T cells, which take time to develop. Type IV reactions usually take at least 48 to 72 hours and sometimes days to weeks to develop following exposure to the drug. Type IV reactions can vary from a nonurticarial, maculopapular rash (drug fever) to Stevens–Johnson syndrome and toxic epidermal necrolysis (see Chapter 56), or drug rash with eosinophilia and systemic symptoms, or DRESS/DiHS. Type IV reactions can appear after weeks of drug treatment (Pichler, 2019).

Medications are the most common agent responsible for approximately 90% of all drug rashes. Commonly prescribed medications (e.g., antibiotics, sulfonamides) are implicated in most cases (Samel & Chu, 2019).

Drug fever, which usually causes fever and rash, is associated with azathioprine, sulfasalazine, minocycline, trimethoprim-sulfamethoxazole, sirolimus, and tacrolimus (McDonald & Sexton, 2019). Contact dermatitis skin reactions can result from topical anesthetics such as benzocaine, topical antibiotics such as neomycin or bacitracin, and topic corticosteroids.

Symmetrical drug-related intertriginous and flexural exanthem (SDRIFE), formerly called baboon syndrome, is a distinctive drug eruption that typically develops within a few hours to days of drug exposure and presents with demarcated, V-shaped erythema in the gluteal/perianal or inguinal/perigenital areas, often with involvement of at least one other flexural area, such as the axillae, elbows, or knees. Aminopenicillins are a common trigger of SDRIFE (Bircher, 2018).

Acute generalized exanthematous pustulosis (AGEP) is a rare type of reaction characterized by superficial pustules, usually appearing within 24 hours after the administration of the culprit drug. Antimicrobial drugs (amoxicillin), antimalarials, and calcium channel blockers are the most frequently reported triggers of AGEP (Cho & Chu, 2017).

Stevens–Johnson syndrome and toxic epidermal necrolysis are severe reactions commonly triggered by medications. The disorder can evolve into extensive epidermal necrosis and become life-threatening. Mucous membranes are affected in over 90% of patients, usually at two or more distinct sites (ocular, oral, and genital). In some patients, an exanthematous eruption can be the heralding sign of Stevens–Johnson syndrome and toxic epidermal necrolysis. Fever, often exceeding 39°C (102.2°F), and influenzalike symptoms precede development of mucocutaneous lesions and erythematous macules with purpuric centers that evolve into blisters and bullae. Photophobia, conjunctival itching or burning, and pain on swallowing may be due to mucosal involvement. Malaise, myalgia, and arthralgia are present in most patients. The following agents are most commonly implicated in Stevens–Johnson syndrome and toxic epidermal necrolysis (High, 2019):

- Allopurinol
- Aromatic antiepileptic drugs and lamotrigine
- Antibacterial sulfonamides (including sulfasalazine)
- Nevirapine
- Oxicam NSAIDs

Some conventional and targeted anticancer drugs have been associated with these syndromes including thalidomide, capecitabine, afatinib, vemurafenib, tamoxifen, and immune checkpoint inhibitors ipilimumab, pembrolizumab, and nivolumab. Radiation treatment in combination with antiepileptic drugs (e.g., phenytoin, phenobarbital, carbamazepine) can trigger Stevens–Johnson syndrome and toxic epidermal necrolysis (High, 2019).

Pharmacogenetic studies suggest that there is a genetic predisposition to drug allergy. In some populations, individuals with HLA-B*1502, HLA-B*5801, or HLA-B*5701 have an increased risk of developing Stevens–Johnson syndrome and toxic epidermal necrolysis to aromatic anticonvulsants such as carbamazepine, allopurinol, cotrimoxazole, and abacavir, respectively (Bircher, 2018).

Pseudoallergic Drug Reactions

Pseudoallergic drug reactions are adverse drug reactions with signs and symptoms that mimic immunologic drug allergies, but no immunologic mechanisms are occurring. They are referred to as nonimmunologic hypersensitivity reactions or anaphylactoid reactions. It is unclear how certain drugs elicit pseudoallergic reactions. However, degranulation of mast cells occurs. Some affected patients have underlying dermographism which indicates an "instability" of their mast cells. In dermographism, when pressure is applied to the skin, the skin reddens for a prolonged time in the same pattern as the pressure was applied. The following drugs may cause a pseudoallergic drug reaction (Pichler, 2019):

- Radiocontrast agents
- Opioids (e.g., morphine and meperidine)
- NSAIDs (e.g., ibuprofen) and aspirin
- Vancomycin
- Local anesthetic agents (e.g., lidocaine, benzocaine)
- Chemotherapeutic agents (e.g., platinum-based drugs)

The patient should be educated about avoidance and provided with a written list of the generic and brand names of the causative agents to avoid in the future (Pichler, 2019).

Urticaria and Angioedema

Urticaria (hives) is a type I hypersensitive allergic reaction of the skin that is characterized by the sudden appearance of intensely pruritic pink or red discrete papules that progress to wheals of variable size. Urticarial lesions coalesce and evolve into large erythematous plaques (AAAAI, 2019b). This is a common condition with up to 20% of people having at least one episode of hives during their lifetime. Urticaria is most commonly instigated by infections, allergic reactions to food, insect stings, and medications (Asero, Tedeschi, Marzano, et al., 2017).

Acute urticaria evolves over a time span of minutes to hours and disappears by 24 hours; lesions can be in different stages over this time. Urticaria is

considered acute if it has been present for less than 6 weeks. However, if urticaria occurs frequently and reoccurs daily for longer than 6 weeks, the condition is called chronic urticaria. In urticaria, mast cells and basophils within the skin are activated and release histamine and inflammatory mediators that cause vasodilation (AAAAI, 2019b).

Common causes of urticaria include allergic reactions to medications or contact allergens, foods, insect stings and bites; reactions to medications that cause nonallergic mast cell activation (e.g., opioids); latex allergy; transfusions; and NSAIDs. Physical urticarial syndromes are forms of chronic urticaria that are triggered by specific physical and environmental factors, such as cold exposure, sudden changes in body temperature, pressure or vibration against the skin, exercise, exposure to sunlight, or other stimuli (Asero, 2017). Serum sickness, a type III hypersensitivity reaction, commonly due to medication, can also cause urticaria. Serum sickness classically causes rash, fever, and polyarthralgias or polyarthritis, which begin 1 to 2 weeks after the first exposure to the responsible agent and resolve within a few weeks of discontinuation (Wener, 2018).

The diagnosis of urticaria can usually be made by health history and physical examination. Laboratory testing is usually not necessary.

Management of the condition includes eliminating the causative agent; avoiding the use of NSAIDs; and minimizing potential aggravators, including heat, stress, alcohol, and tight clothes. Treatment with second-generation H_1 antihistamine agents (e.g., cetirizine, fexofenadine, loratadine) is the mainstay of treatment. These agents are better tolerated as they have less sedating effects than first-generation H_1 antihistamines (e.g., diphenhydramine, chlorpheniramine, hydroxyzine). Doses of second-generation antihistamines may be increased as high as four times the standard dose (Khan, 2019a). Oral corticosteroids given in a decreasing dose schedule may be prescribed to relieve severe symptoms for a few days. About 50% of cases of chronic spontaneous urticaria will respond to treatment with antihistamines, as discussed above. For those patients who do not improve with antihistamines, 65% might respond to prescribed omalizumab. Omalizumab, a monoclonal antibody that acts against IgE antibodies, is injected under the skin every 2 to 4 weeks by a primary provider. Therapeutic effects can be seen within 3 to 6 months (AAAAI, 2019b; Stokes & Casale, 2018).

Angioedema is an allergic reaction that involves the infiltration of fluid in subcutaneous tissue and mucous membranes resulting in diffuse swelling. It is manifested by nonpruritic, brawny, widespread, nonpitting edema. Urticaria and angioedema often occur together (AAAAI, 2019b; Habif, 2016).

The regions most often involved in angioedema are the lips, eyelids, cheeks, hands, feet, genitalia, and tongue; the mucous membranes of the larynx, bronchi, and gastrointestinal tract may also be affected, particularly in the hereditary type (see discussion in the following section). On occasion, this

reaction covers the entire back or large area of the body. Swellings may appear suddenly, in a few seconds or minutes, or slowly over 1 or 2 hours. It usually resolves within 24 hours. Angioedema is usually a benign and transient condition, although it can be life-threatening when severe angioedema of the larynx, upper airway, or tongue results in airway obstruction (Zuraw, 2019).

Two types of angioedema can be distinguished: mast cell–mediated, also called histaminergic angioedema, and bradykinin-mediated angioedema. Allergic reactions to foods, latex, certain drugs, or insect stings are common examples of mast cell–mediated angioedema. Histamine is the main inflammatory mediator and signs and symptoms include urticaria, flushing, generalized pruritus, bronchospasm, throat tightness, and/or hypotension. Patients may be experiencing anaphylaxis and should be treated immediately with epinephrine. Mast cell–mediated angioedema usually begins within minutes of exposure to the allergen, builds over a few hours, and resolves in 24 to 48 hours (Zuraw, 2019).

Alternatively, bradykinin-induced angioedema does not involve histamine and is not associated with urticaria, bronchospasm, or other symptoms of allergic reactions. Bradykinin is a potent vasodilator which also increases vasopermeability (Cicardi & Zuraw, 2018a). The fluid infiltration of the tissues usually develops over 24 to 36 hours and resolves within 2 to 4 days. The relationship between the trigger and the onset of symptoms is often not apparent. Angiotensin-converting enzyme inhibitors (e.g., captopril) are common causes of bradykinin-induced angioedema; swelling may appear within a week of starting the medication or after years of use (Zuraw, 2019).

Second-generation H_1 antihistamines and corticosteroids are the mainstay of treatment for mast cell–mediated angioedema. If angioedema is part of an anaphylactic reaction, intramuscular epinephrine is an important part of treatment (Guyer & Banerji, 2019).

Treatment of bradykinin-induced angioedema involves avoidance of drug, icatibant, C1 inhibitor concentrate, ecallantide, and possibly administration of fresh-frozen plasma. Antihistamines are ineffective (Cicardi & Zuraw, 2018b). Icatibant is a synthetic bradykinin beta-2-receptor antagonist. C1 inhibitor concentrate and exallantide inhibit kallikrein which is a protease involved in bradykinin production. Fresh-frozen plasma contains angiotensin-converting enzyme, and the administration of plasma is thought to degrade high levels of bradykinin (Guyer & Banerji, 2019).

Hereditary Angioedema

Hereditary angioedema (HAE) is a rare, potentially life-threatening, autosomal dominant genetic disorder. It is a bradykinin-mediated type of angioedema that is due to a lack of C1 inhibitor activity, a specific protein that takes part in

kinin generation. Kinins are inflammatory mediators; bradykinin is one of these. C1INH usually plays a role in limiting bradykinin production, so when C1INH is deficient or dysfunctional, bradykinin production is relatively unchecked (AAAAI, 2019c).

There are two different types of HAE; HAE type I is due to C1 inhibitor (C1INH) deficiency, and type II is caused by C1INH dysfunction (Cicardi & Zuraw, 2018a).

Clinical Manifestations

HAE is commonly categorized as laryngeal, gastrointestinal, or cutaneous. Swelling of the skin is usually diffuse, nonpruritic, and not accompanied by urticaria. Attacks of swelling in patients with HAE generally involve the extremities, abdomen, genitourinary tract, face, oropharynx, or larynx and follow a stereotypical pattern in which the swelling worsens over 24 hours, peaks, and then slowly resolves over the following 48 hours. Gastrointestinal edema may cause abdominal pain severe enough to be incapacitating. Typically, attacks last 2 to 4 days and resolve without intervention; however, attacks can occasionally affect the subcutaneous and submucosal tissues in the region of the upper airway and can be associated with respiratory obstruction and asphyxiation (Cicardi & Zuraw, 2018a).

Medical Management

Attacks usually subside within 2 to 4 days, but during this time the patient should be observed carefully for signs of laryngeal obstruction, which may necessitate tracheostomy as a lifesaving measure. Epinephrine, antihistamines, and corticosteroids are commonly administered in an attempt to relieve HAE; however, these are often ineffective. A trial of high doses of second-generation H_1 antihistamines for 1 month may be effective in some patients. If this proves unsuccessful, C1INH concentrate, derived from human plasma, recombinant human C1INH (rhC1INH, conestat alfa), icatibant, a synthetic bradykinin beta-2-receptor antagonist and ecallantide, a recombinant plasma kallikrein inhibitor are agents that are available (Cicardi & Zuraw, 2018b). Nurses need to be prepared to use different emergency approaches in the treatment of HAE and to have lifesaving equipment readily available.

Cold Urticaria

Cold urticaria is a type of physical urticaria. Physical urticarias are inducible urticarias that are stimulated by environmental triggers. Cold urticaria is the development of wheals (hives) or angioedema due to exposure to cold. Mast

cells release histamine and inflammatory mediators are stimulated in response to skin contact with cold objects, cold fluids, or cold air. It is an IgE-mediated atopic immune reaction. Cold urticaria most commonly affects young adults as a self-limited disorder that occurs over a period of 5 to 6 years.

Clinical Manifestations

The patient feels a burning or pruritic sensation and the skin is erythematous due to activation of sensory nerves and vasodilation of arterioles. Most commonly it is a localized reaction in areas exposed to cold. However, extensive cold contact, such as swimming in cold water, may result in systemic reactions, ranging from generalized urticaria to anaphylaxis, with symptoms involving the respiratory, gastrointestinal, and/or cardiovascular systems. Oropharyngeal angioedema, which can cause suffocation and severe hypotension, has been observed in some persons with the disorder (Maurer, 2019).

Medical Management

Cold urticaria is diagnosed by cold stimulation testing. An ice cube within a thin plastic bag of cold water is applied to the volar aspect of the forearm for 1 to 5 minutes. A positive test results in development of urticaria at the site. The test is considered positive if the test site shows a palpable and clearly visible wheal-and-flare skin reaction upon rewarming. All patients with any form of cold urticaria should carry an autoinjectable epinephrine device for emergency use because hives can progress to anaphylaxis. Pretreatment with an antihistamine prior to predictable cold exposure is recommended, because clinical experience suggests that antihistamine pretreatment can prevent skin reactions and systemic reactions (Maurer, 2019). Patients with cold urticaria refractory to antihistamines can be treated with immunomodulator agents, such as omalizumab, certain antibiotics, leukotriene receptor antagonists, or cold desensitization therapy (Khan, 2019b).

Nursing Management

Prevention involves avoidance of cold stimuli. Patient education is needed about what environmental conditions can stimulate a reaction. For instance, patients should be instructed to expose a small section of the body to the water of a swimming pool prior to submerging the body in water. A wet suit can be used during swimming. Patients should understand that cold foods and beverages can stimulate oropharyngeal angioedema or anaphylaxis and should be avoided. Patients anticipating surgery may develop a reaction to the cold air within operating rooms and are instructed to alert surgical personnel that they

have cold uriticaria and should be kept warm during any procedures. Cold intravenous solutions can also provoke a reaction (Singleton & Halverstam, 2016).

Food Allergy

Food allergy is an adverse reaction to certain foods due to immunologic mechanisms. Food allergies are categorized as either IgE-mediated or non–IgE-mediated allergies. IgE-mediated food allergy, a type I hypersensitivity reaction, occurs in about 5% of adults. IgE-mediated food allergy is more common and better understood than non–IgE-mediated food allergy (Commins, 2019). Recent studies show that within the population there are many with the misconception that they have a food allergy (19%) compared to persons with true immune-mediated food allergy (10%) (Gupta, Warren, & Smith, 2019).

Almost any food can cause an IgE-mediated allergic reaction. Allergic reactions can range from cutaneous urticaria to anaphylaxis. Fish and shellfish (e.g., lobster, shrimp, crab, clams, fin fish) as well as peanuts and tree nuts (e.g., cashew, walnut) are the two food groups that cause the majority of adult food allergies (Gupta et al., 2019). Other common foods causing allergy include cow's milk, eggs, soy, and wheat. Allergens are proteins and there is a danger that cross-reactivity can occur in foods containing similar proteins (AAAAI, 2018).

OAS, or pollen-food allergy syndrome (PFAS or PFS), is the most common form of IgE-mediated food allergy in adults. OAS often occurs in persons who are also allergic to pollen that causes seasonal allergic rhinitis. Raw fruits and vegetables often cause OAS but cooked fruit and vegetables do not (Burks, 2019).

Non–IgE-mediated food allergies present as more subacute and/or chronic symptoms that are typically isolated to the gastrointestinal tract and/or skin.

Clinical Manifestations

Acute urticaria and angioedema (swelling of the mouth, face, lips, tongue, and throat) are the most common clinical manifestations of food allergy. The reaction develops within minutes to hours after eating the offending food. The clinical symptoms may include wheezing, cough, laryngeal edema, and gastrointestinal symptoms (abdominal pain, nausea, cramps, vomiting, and diarrhea). Tree nuts and peanuts can cause the most severe allergic reactions evolving into anaphylaxis.

Assessment and Diagnostic Findings

Diagnosis of food allergy requires clinical history, physical examination, trial elimination diets, diet diaries, skin prick testing (SPT), and allergen-specific serum IgE immunoassay. A patch test is used if non–IgE-mediated food allergy is suspected. However, the standard is clinician-supervised oral food challenges to confirm or rule out the diagnosis. SPT is used to identify the source of symptoms and assists in identifying specific foods as causative agents. The patient is injected with a minute quantity of food antigen under the skin. Then the patient and primary provider wait to observe if hives and erythema arise within the 15 minute period. If the allergen triggers mast cells to release histamine, a localized wheal will be raised in the skin. A positive skin prick test for IgE-mediated food allergy is diagnosed when a wheal of 3 mm in diameter is raised within 15 minutes. A different kind of test, referred to as a 48-hour atopy patch test, is used for non–IgE-mediated food allergy. This is a topical application of food allergen that is applied to the small surface area of skin. This is a delayed reaction that requires 48 hours of observation (Andreae & Schreffler, 2019).

Medical Management

Therapy for food hypersensitivity includes avoidance of the food responsible for the hypersensitivity. Pharmacologic therapy is necessary for patients who cannot avoid exposure to offending foods and for patients with multiple food sensitivities not responsive to avoidance measures. Medication therapy involves the use of H_1 blockers, antihistamines, adrenergic agents, corticosteroids, and cromolyn sodium. All patients with food allergies, especially seafood and nuts, should have an autoinjectable epinephrine device prescribed. Another essential aspect of management is educating patients and family members about how to recognize and manage the early stages of an acute anaphylactic reaction.

Oral immunotherapy (OIT), or tolerance induction, is an increasingly used treatment. The patient ingests very small amounts of the allergen in increasing dosages over several months. OIT is not a curative treatment. The goal of OIT is to increase the threshold that triggers a reaction. OIT can be used to achieve desensitization or sustained unresponsiveness to a food allergen (AAAAI, 2018).

Initially, OIT has to be administered in a clinical setting equipped for treatment of potential anaphylaxis. Patients are generally started on a very small daily dose of the food (e.g., 3 to 6 mg of food protein) and advanced periodically (usually every 2 weeks) to a maintenance dose (e.g., 300 mg or, depending on the food and goals, 1 to 2 g of food protein daily) over several months (Nowak-Wegrzyn, 2019).

Peanut, egg, and milk OIT have been shown to desensitize approximately 60% to 80% of patients studied. OIT has not cured food allergy in these

individuals; it has raised the patient's tolerance of the offending food. Most children outgrow their allergies to cow's milk, egg, soy and wheat, even if they have a history of a severe reaction. However, peanut, tree nuts, fish, and shellfish allergies tend to persist through adulthood (AAAAI, 2018).

Chart 33-7 HOME CARE CHECKLIST

Managing Food Allergies

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of food allergies on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Verbalize understanding of the need to maintain an allergen-free diet.
- Demonstrate reading of food labels to identify hidden allergens in food.
- Identify ways to manage an allergen-free diet when eating away from home.
- State the need to wear medical identification bracelet or necklace.
- List symptoms of food allergy.
- Demonstrate emergency administration of epinephrine.
- State the importance of replacing epinephrine when outdated.
- State the importance of prompt treatment of allergic reactions and health care follow-up.
- State how to reach primary provider with questions or complications.
- State time and date of follow-up appointments, testing.
- Verbalize ways to cope with stress successfully, plans for regular exercise, and rationale for obtaining adequate rest.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Nursing Management

In addition to participating in management of the allergic reaction, the nurse focuses on preventing future exposure of the patient to the food allergen. The nurse should educate the patient about the signs of anaphylaxis and devise an action plan with the patient. If a severe allergic or anaphylactic reaction to food allergens has occurred, the nurse must instruct the patient and family about avoidance strategies to prevent its recurrence (see Chart 33-7). All patient allergies, including food allergies, should be noted on patient medical

records, as dietary restrictions would be necessary in the case of hospitalization. Also, there may be risk of cross-reactivity with some medications containing similar substances. The patient also needs to understand how to select and specify preparation of restaurant food (Sicherer, 2019).

Latex Allergy

Latex allergy—the allergic reaction to the proteins in the saplike fluid of a rubber tree—has been implicated in rhinitis, conjunctivitis, contact dermatitis, urticaria, asthma, and anaphylaxis. The prevalence is estimated at 4% to 7% of the population, but this has been steadily declining because of the use of nonpowdered latex and latex-free gloves (Hamilton, 2017a).

The sap of the rubber tree (*Hevea brasiliensis*) contains 250 different polypeptides that can react with IgE. The polypeptides and proteins in natural rubber latex (Hevea proteins) or the various chemicals that are used in the manufacturing process are thought to be the source of the allergic reactions.

Those at risk include health care workers, patients who have undergone multiple surgeries, people working in factories that manufacture latex products, and patients with spina bifida. Patients with spina bifida are at risk because they have had multiple surgeries, multiple urinary catheterization procedures, and other treatments involving use of latex products (Hamilton, 2017a). Because food handlers, hairdressers, automobile mechanics, and police may wear latex gloves and use latex products, they are also at risk for latex allergy. Increasingly, however, nonlatex gloves are being used in various occupational settings. Risk factors include occupational exposure to latex and atopic tendency in the affected person. Patients are at risk for anaphylactic reactions as a result of contact with latex during medical treatments, particularly surgical procedures (AAAAI, 2019d).

Persons with latex allergy are also prone to cross-reactions to pollen and some fruits; such as kiwis, bananas, pineapples, mangoes, passion fruit, avocados, and chestnuts (Hamilton, 2017a).

Routes of exposure to latex products can be cutaneous, percutaneous, mucosal, parenteral, or aerosol. The most frequent source of exposure is cutaneous, which usually involves the wearing of natural latex gloves. The powder used to facilitate putting on latex gloves can become a carrier of latex proteins from the gloves; when the gloves are put on or removed, the particles become airborne and can be inhaled or settle on skin, mucous membranes, or clothing (AAAAI, 2019d). Mucosal exposure can occur from the use of latex condoms, catheters, airways, and nipples. Parenteral exposure can occur from intravenous lines or hemodialysis equipment. In addition to latex-derived medical devices, many household items also contain latex. Examples of

medical and household items containing latex and a list of alternative products are found in Table 33-5. It is estimated that more than 40,000 medical devices and nonmedical products contain latex (AAAAI, 2019d).

Clinical Manifestations

Many different types of reactions to latex are possible (see Table 33-6). Irritant contact dermatitis, a nonimmunologic response, may be caused by mechanical skin irritation or an alkaline pH associated with latex gloves. Common symptoms of irritant dermatitis include erythema and pruritus.

Delayed hypersensitivity to latex, a type IV reaction mediated by T cells, is localized to the area of exposure and is characterized by symptoms of contact dermatitis. These include vesicular skin lesions, papules, pruritus, edema, erythema, and crusting and thickening of the skin. These symptoms usually appear on the back of the hands 1 to 4 days postcontact. It is the most common allergic reaction to latex. Although usually not life-threatening, delayed hypersensitivity reactions often require major changes in the patient's home and work environment to avoid further exposure (AAAAI, 2019d).

TABLE 33-5 Select Products Containing Natural Rubber Latex and Latex-Free Alternatives

Products Containing Latex	Examples of Latex-Safe Alternatives[a]
Hospital Environment	
Ace bandage (brown)	Ace bandage, white all cotton
Adhesive bandages, Band-Aid dressing, Telfa	Cotton pads and plastic or silk tape, Active Strips (3M), DuoDERM
Anesthesia equipment	Neoprene anesthesia kit (King)
Blood pressure cuff, tubing, and bladder	Clean Cuff, single-use nylon or vinyl blood pressure cuffs or wrap with stockinette or apply over clothing
Catheters	All-silicone or vinyl catheters
Catheter leg bag straps	Velcro straps
Crutch axillary pads and hand grips, tips	Cover with cloth, tape
ECG pads	Baxter, Red Dot 3M ECG pads
Elastic compression stockings	Kendall SCD stockings with stockinette
Gloves	Derma Prene, neoprene, polymer, or vinyl gloves
IV catheters	Jelco, Deseret IV catheters
IV rubber injection ports	Cover Y-sites and ports; do not puncture. Use three-way stopcocks on plastic tubing
Levin tube	Salem sump tube
Medication vials	Remove rubber stopper
Penrose drains	Jackson-Pratt, Zimmer Hemovac drains
Prepackaged enema kits	Therevac, Fleet Ready-to-Use
Pulse oximeters	Noninoximeters
Resuscitation bags	Laerdal, Puritan Bennett, *certain* Ambu
Stethoscope tubing	PVC tubing; cover with latex-free stockinette
Suction tubing	PVC (Davol, Laerdal)
Syringes—single use (Monoject, BD)	Terumo syringes, Abbott PCA Abboject
Tapes	Dermicel, Micropore
Theraband	New Thera-band Exercisers, plastic tubing
Thermometer probes	Diatek probe covers
Tourniquets	X-Tourn straps (Avcor)
Home Environment	
Balloons	Mylar balloons
Condoms, diaphragms	Polyurethane products, Durex Avanti and Reality products (female condom)
Diapers, incontinence pads	Huggies, Always, *some* Attends

Feminine hygiene pads	Kimberly-Clark products
Wheelchair cushions	ROHO cushions, Sof Care bed/chair cushions

[a]Confirmation is essential to verify that all items are latex free before using, especially if risk of latex allergy is present.

ECG, electrocardiogram; IV, intravenous; PVC, polyvinyl chloride.

Adapted from Centers for Disease Control and Prevention (CDC). (2014). Latex allergy: A prevention guide. Retrieved on 12/2/2019 at: www.cdc.gov/niosh/docs/98-113/default.html; Mayo Foundation for Medical Education and Research. (2019). Diseases and conditions: Latex allergy. Retrieved on 12/2/2019 at: www.mayoclinic.org/diseases-conditions/latex-allergy/basics/definition/CON-20024233

Latex allergy can also be an immediate hypersensitivity, type I allergic reaction, mediated by IgE. Localized itching, erythema, or local urticaria within 10 to 15 minutes after exposure to latex are often the initial symptoms (Hamilton, 2017a). Symptoms commonly include rhinitis, conjunctivitis, and nasal congestion. An asthma attack can be triggered. Severe anaphylaxis can occur, which includes generalized urticaria, angioedema, bronchospasm, and hypotension minutes after dermal or mucosal exposure to latex.

Assessment and Diagnostic Findings

The diagnosis of latex allergy is based on the history, physical examination, and diagnostic test results. Sensitization is detected by skin testing; serum-specific IgE, EIA, or ELISA; or the level of Hevea latex-specific IgE antibody in the serum. Testing for the chemicals found in the rubber production that makes latex is performed using the patch test. Skin patch testing is the preferred method for patients with contact allergies. The TRUE test and other skin tests should be performed only by primary providers who have expertise in their administration and interpretation and who have the necessary equipment available to treat local or systemic allergic reactions to the reagent (Hamilton, 2017a).

Medical Management

The best prevention strategy for latex allergy is the avoidance of latex-based products. A new, natural derivative from the desert plant guayule is now being used as a replacement for latex in many products. The predominant nonsterile, nonlatex examination gloves used in medical institutions today are made of nitrile, neoprene, vinyl, or synthetic polyisoprene rubber that is extracted from oil. Nonlatex condoms are available for contraception but these do not prevent transmission of HIV or other sexually transmitted infections (STIs). Persons allergic to latex should be cautioned to not blow up latex balloons or be in

enclosed spaces where these are used, as these balloons are still used as decorations (AAAAI, 2019d).

Patients at risk for an anaphylactic reaction to latex should be instructed to carry auto-injectable epinephrine in case of a reaction (Hamilton, 2017b).

Patients should report their allergy prior to any medical, dental, gynecologic, or surgical procedure and request a latex-safe environment (Hamilton, 2017b).

TABLE 33-6 Types of Reactions to Latex

Type of Reaction	Cause	Signs/Symptoms	Treatment
Irritant contact dermatitis	Damage to skin because of irritation and loss of epidermoid skin layer; not an allergic reaction. Can be caused by excessive use of soaps and cleansers, repeated handwashing, inadequate hand drying, mechanical irritation (e.g., sweating, rubbing inside powdered gloves), exposure to chemicals added during the manufacturing of gloves, and alkaline pH of powdered gloves. Reaction may occur with first exposure, is usually benign, and is not life-threatening.	*Acute:* Redness, edema, burning, discomfort, itching *Chronic:* Dry, thickened, cracked skin	Referral for diagnostic testing Avoidance of exposure to irritant Thorough washing and drying of hands Use of powder-free gloves with more frequent changes of gloves Changing glove types Use of water- or silicone-based moisturizing creams, lotions, or topical barrier agents Avoidance of oil- or petroleum-based skin agents with latex products, because they cause breakdown of the latex product
Allergic contact dermatitis	Delayed hypersensitivity (type IV) reaction. Usually affects only area in contact with latex; reaction is usually to chemical additives used in the manufacturing process rather than to latex itself. Cause of reaction is T-cell–mediated sensitization to additives of latex. Reaction is not life-threatening and is far more common than a type I reaction.	Pruritus, erythema, swelling, crusty thickened skin, blisters, other skin lesions	Referral for diagnosis (patch tests) and treatment Thorough washing and drying of hands Use of water- or silicone-based moisturizing creams,

	Slow onset; occurs 18–24 h after exposure. Resolves within 3–4 days after exposure. More severe reactions may occur with subsequent exposures.		lotions, or topical barrier agents Avoidance of oil- or petroleum-based products unless they are latex compatible Avoidance of identified causative agent, because continued exposure to latex products in presence of breaks in skin may contribute to latex protein sensitization
Latex allergy	Type I IgE-mediated immediate hypersensitivity to plant proteins in natural rubber latex. In sensitized people, antilatex IgE antibody stimulates mast cell proliferation and basophil histamine release. Exposure can be through contact with the skin, mucous membranes, or internal tissues, or through inhalation of traces of powder from latex gloves. Severe reactions usually occur shortly after parenteral or mucous membrane exposure. People with any type I reaction to latex are at high risk for anaphylaxis. Local swelling, redness, edema, itching, and systemic reactions, including anaphylaxis, occur within minutes after exposure.	Rhinitis, flushing, conjunctivitis, urticaria, laryngeal edema, bronchospasm, asthma, severe vasodilation angioedema, anaphylaxis, cardiovascular collapse, death	Immediate treatment of reaction with epinephrine, fluids, vasopressors, and corticosteroids, and airway and ventilator support, with close monitoring for recurrence for the next 12–14 h Prompt referral for diagnostic evaluation Treatment and diagnostic evaluation in latex-free environment Assessment of all patients for symptoms of latex allergy

	Educating patients and family members about the disorder and the importance of preventing future reactions by avoiding latex (e.g., wearing medical identification, carrying and autoinjector of epinephrine)

IgE, immunoglobulin E.

Nursing Management

The nurse can assume a pivotal role in the management of latex allergies in both patients and staff. All patients should be asked about latex allergy. Every time an invasive procedure must be performed, the nurse should consider the possibility of latex allergies. Nurses working in operating rooms, intensive care units, short procedure units, and EDs need to pay particular attention to latex allergy (Hamilton, 2017b). See Chapter 14, Figure 14-2, for a sample latex allergy assessment form.

Although the type I reaction is the most significant of the reactions to latex, care must be taken in the presence of irritant contact dermatitis and delayed hypersensitivity reaction to avoid further exposure of the person to latex. Patients with latex allergy are advised to notify their health care providers and to wear medical identification. Patients must become knowledgeable about what products contain latex and what products are safe, nonlatex alternatives. They must also become knowledgeable about signs and symptoms of latex allergy and emergency treatment and self-injection of epinephrine in case of allergic reaction (Hamilton, 2017b).

CRITICAL THINKING EXERCISES

1 ipc You are the nurse working in an outpatient walk-in clinic. A 28-year-old patient is newly diagnosed with allergic rhinitis. What nursing and interprofessional assessments are indicated? What interventions, including patient education, will you implement? What interprofessional referrals would be appropriate?

2 ebp A 44-year-old presents to the emergency department (ED) complaining of dyspnea after eating at a new restaurant. The patient states that this has happened two other times in the past and seems to be worse each time. What is the evidence for management of this patient? Describe the strength of the evidence and criteria used to assess its strength.

34 Assessment and Management of Patients with Inflammatory Rheumatic Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Explain the pathophysiology of inflammatory rheumatic diseases and describe the assessment and diagnostic findings seen in patients with these disorders.
2. Use the nursing process as a framework for care of the patient with an inflammatory rheumatic disorder.
3. Devise an education plan for the patient with newly diagnosed inflammatory rheumatic disease.
4. Identify modifications in interventions to accommodate changes in patients' functional ability that may occur with disease progression.

Immunity
Infection
Inflammation

GLOSSARY

arthritis: inflammation of a joint
cytokines: cell signaling proteins that are vital to regulation of hematopoiesis, apoptosis, and immune responses
exacerbation: period when disease symptoms occur or increase
pannus: proliferation of newly formed synovial tissue infiltrated with inflammatory cells
remission: period when disease symptoms are reduced or absent
rheumatic diseases: numerous disorders affecting skeletal muscles, bones, cartilage, ligaments, tendons, and joints
rheumatoid arthritis: a systemic autoimmune disease with symmetric arthritic manifestations and multiple extra-articular features
subchondral bone: bony plate that supports the articular cartilage
tophi: accumulation of crystalline deposits in articular surfaces, bones, soft tissue, and cartilage

The **rheumatic diseases** encompass autoimmune, degenerative, inflammatory, and systemic conditions that affect the joints, muscles, and soft tissues of the body. Rheumatic diseases most commonly manifest the clinical features of **arthritis** (inflammation of a joint) and pain. There are more than 100 types of rheumatic diseases. The problems caused by rheumatic diseases include limitations in mobility and activities of daily living, pain, fatigue, altered self-image, and sleep disturbances, as well as systemic effects that can lead to organ failure and death. An understanding of inflammatory rheumatic diseases and their effects on a patient's function and well-being is essential to developing an appropriate plan of nursing care.

Rheumatic Diseases

Rheumatic disease processes affect males and females of all ages and ethnic groups. Some disorders are more likely to occur at a particular time of life or

to affect one gender more often than the other. In general, women are two to nine times more commonly affected by rheumatic diseases than men (Norris, 2019). Arthritis and other rheumatic diseases and the physical limitations that occur with them are becoming more prominent and a larger public health issue, which can be attributed to the increased number of older adults in the United States.

The onset of these conditions may be acute or insidious, with a course possibly marked by periods of **remission** (a period when disease symptoms are reduced or absent) and **exacerbation** (a period when symptoms occur or increase). Treatment can be simple, aimed at localized relief, or it can be complex, directed toward relief of systemic effects. Permanent changes and disability may result from these disorders.

Nurses need to understand the classification of rheumatic diseases. One system is to classify disease as either monoarticular (affecting a single joint) or polyarticular (affecting multiple joints). Another system is to classify the disease as either inflammatory or noninflammatory. This chapter focuses on inflammatory rheumatic diseases, while noninflammatory rheumatic diseases (i.e., osteoarthritis) are covered in Chapter 36. Conditions that may secondarily affect the musculoskeletal structure are also considered in disease classification.

Pathophysiology

Each of the inflammatory rheumatic diseases exhibits unique pathophysiologic features. Three distinct characteristics of pathophysiology include inflammation, autoimmunity, and degeneration.

Inflammation

Inflammation is a complex physiologic process mediated by the immune system that occurs in response to harmful stimuli like damaged cells or antigens, which may include pathogens (e.g., viruses, bacteria). Inflammation is meant to protect the body from insult by removing the triggering antigen or event. In response to a triggering episode, the antigen stimulus activates the body's immune system to form antibodies like monocytes and T lymphocytes (also referred to as T cells). Next, the immunoglobulin antibodies form immune complexes with antigens. Phagocytosis of the immune complexes is initiated, generating an inflammatory reaction (joint effusion, pain, and edema) (see Fig. 34-1). Phagocytosis produces chemicals such as leukotrienes and prostaglandins. Leukotrienes contribute to the inflammatory process by attracting other white blood cells to the area. Prostaglandins act as modifiers to inflammation. In some cases, they increase inflammation; in other cases, they decrease it. Leukotrienes and prostaglandins produce enzymes such as collagenase that break down collagen, which is a vital part of a normal joint.

The release of these enzymes in the joint causes edema and proliferation of synovial membrane. In patients with chronic inflammation, the immune response can deviate from normal. Instead of resolution of swelling and joint pain once the triggering event has subsided, **pannus** (proliferation of newly formed synovial tissue infiltrated with inflammatory cells) formation occurs. Destruction of the joint's cartilage and erosion of bone soon follow (Norris, 2019).

The immunologic inflammatory process begins when antigens are presented to T lymphocytes, leading to a proliferation of T and B cells. B cells (also referred to as plasma cells) are a source of antibody-forming cells. In response to specific antigens, plasma cells produce and release antibodies. Antibodies combine with corresponding antigens to form pairs, or immune complexes. The immune complexes build up and are deposited in synovial tissue or other organs in the body, triggering the inflammatory reaction that can ultimately damage the involved tissue (Norris, 2019).

Autoimmunity

A hallmark of inflammatory rheumatic diseases is autoimmunity, where the body mistakenly recognizes its own tissue as a foreign antigen. Autoimmunity leads to destruction of tissue via the same inflammatory process as discussed earlier, along with chronic and long-standing pain. Although focused in the joints, inflammation and autoimmunity also involve other areas. The blood vessels (vasculitis and arteritis), lungs, heart, and kidneys may be affected by the autoimmunity and inflammation. See Chapter 32 for more information on autoimmune disease. A large group of genes, called *human leukocyte antigen* (HLA) genes, has been linked to the immune response and the development of multiple rheumatic diseases (Norris, 2019).

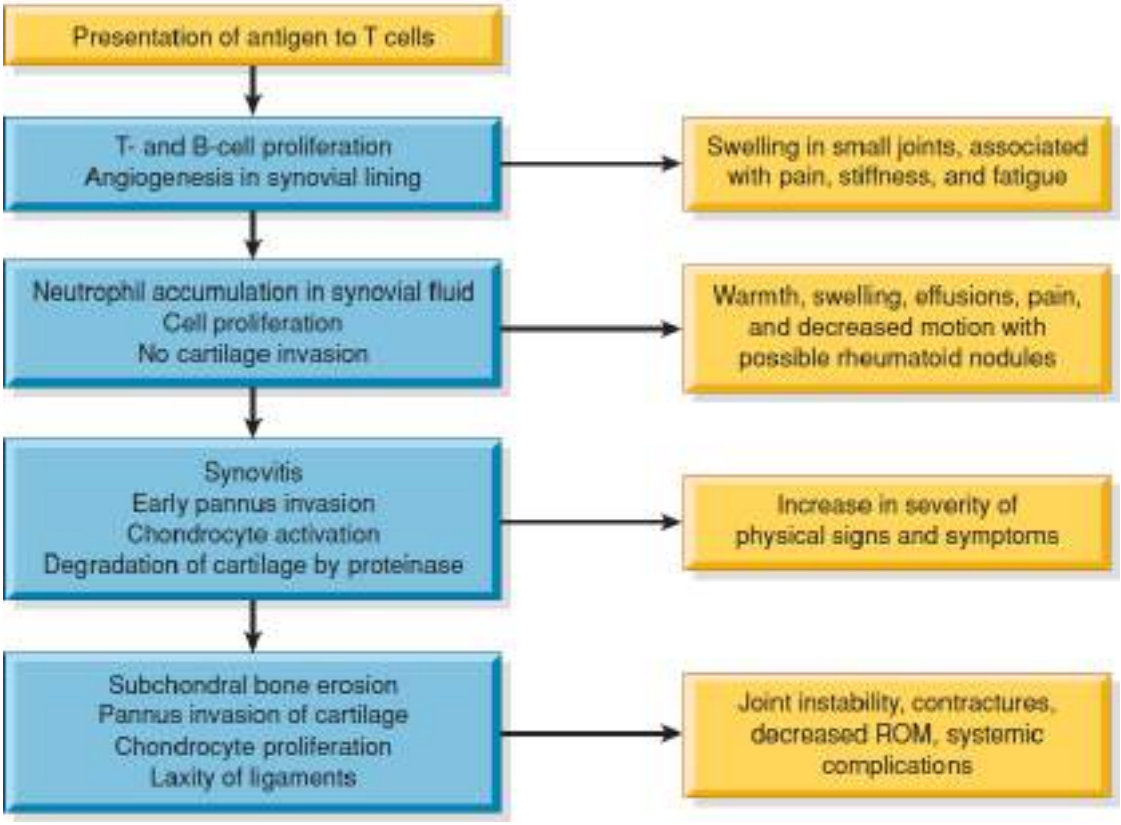

Figure 34-1 • Pathophysiology and associated physical signs of rheumatoid arthritis. ROM, range of motion.

Degeneration

In degenerative rheumatic diseases, inflammation also occurs, but as a secondary process. Although the cause of degeneration of the articular cartilage is poorly understood, the process is known to be metabolically active and therefore is more accurately called *degradation.* One theory of degradation is that genetic or hormonal influences, mechanical factors, and prior joint damage cause cartilage failure. Degradation of cartilage ensues, and increased mechanical stress on bone ends causes stiffening of bone tissue. Another theory is that bone stiffening occurs and results in increased mechanical stress on cartilage, which in turn initiates the processes of degradation. See Chapter 35 for more information on the structure and function of the articular system.

Clinical Manifestations

The most common symptom in the rheumatic diseases is pain. Other common symptoms include joint swelling, limited movement, stiffness, weakness, and fatigue.

Assessment and Diagnostic Findings

Assessment begins with a general health history, which includes the onset of symptoms and how they evolved, family history, past health history, and any other contributing factors. Because many of the rheumatic diseases are chronic conditions, the health history should also include information about the patient's perception of the problem, previous treatments and their effectiveness, the patient's support systems, and the patient's current knowledge base and the source of that information. A complete health history is followed by a complete physical assessment (see Chapter 4).

Assessment for rheumatic diseases combines the physical examination with a functional assessment (Eliopoulos, 2021). Inspection of the patient's general appearance occurs during the initial contact. Gait, posture, and general musculoskeletal size and structure are observed. Gross deformities and abnormalities in movement are noted. The symmetry, size, and contour of other connective tissues, such as the skin and adipose tissue, are also noted and recorded (Weber & Kelley, 2019). Chart 34-1 outlines the important areas for consideration during the physical assessment. The functional assessment is a combination of history (what the patient reports that they can and cannot do) and examination (observation of activities, in which the patient demonstrates what they can and cannot do, such as dressing and getting in and out of a chair). Observation also includes the adaptations and adjustments the patient may have made (sometimes without awareness)—for example, with shoulder or elbow involvement, the person may bend over to reach a fork rather than raising the fork to the mouth.

Laboratory Studies

In Table 34-1 common laboratory studies are listed with their corresponding normal ranges and significance. Many of the tests require special laboratory techniques and may not be performed in every health care facility. The primary provider determines which tests are necessary based on symptoms, stage of disease, cost, and likely benefit. In some instances, tests are used to monitor the course of the disease.

Other Diagnostic Studies

Imaging studies commonly used for patients with rheumatic diseases include x-ray studies, computed tomography (CT) scans, magnetic resonance imaging (MRI) scans, and arthrography. See Chapter 35 for further information about these and other diagnostic studies.

Medical Management

The chronic nature of rheumatic conditions requires cooperation between the patient and the provider. Patient education regarding the disease process and treatment options is imperative to enable patients to make informed decisions regarding their care. Management of rheumatic diseases is based on a shared decision process between the provider and patient that takes into account the patient's values, preferences, and comorbidities (Singh, Saag, Bridges, et al., 2016).

Pharmacologic Therapy

Medications are used with the rheumatic diseases to manage symptoms, to control inflammation, and, in some instances, to modify the disease. Useful medications include the salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), and both biologic and nonbiologic disease-modifying antirheumatic drugs (DMARDs). As their name suggests, DMARDs have the ability to suppress the autoimmune response; alter disease progression; and stop or decrease further tissue damage on the joints, cartilage, and organs. DMARDs have been found to halt the progression of bone loss and destruction and can induce remission (Singh et al., 2016). Nonbiologic DMARDs are thought to reduce proinflammatory **cytokines** (cell signaling proteins vital to regulation of hematopoiesis, apoptosis, and immune responses) and increase anti-inflammatory cytokines. Biologic DMARDs, in contrast, have been specifically engineered to target a certain cell or molecule within the immune system to treat the specific rheumatic condition. Specific biologic DMARDs target tumor necrosis factor alpha (TNF-α), B cells, T cells, interleukin 1 (IL-1), and interleukin 6 (IL-6). Table 34-2 reviews select medications.

Controlling the inflammation related to the disease process helps manage pain, but this is often a delayed response. Nonopioid medications are often used for pain management, especially early in the treatment program, until other measures can be instituted.

Nonpharmacologic Pain Management

Nonpharmacologic methods of pain management are important. Heat applications are helpful in relieving pain, stiffness, and muscle spasm (Kapale, Vardharajulu, & Warude, 2017). Superficial heat may be applied in the form of warm tub baths or showers and warm moist compresses. Paraffin baths (dips), which offer concentrated heat, are helpful to patients with wrist and small-joint involvement. Maximum benefit is achieved within 20 minutes after application. More frequent use for shorter lengths of time is most beneficial. Therapeutic exercises can be carried out more comfortably and effectively after heat has been applied (Kapale et al., 2017).

Chart 34-1 ASSESSMENT

Assessing for Rheumatic Disorders

In addition to the head-to-toe assessment or systems review, the following are important areas of consideration to be noted when performing the complete physical assessment of a patient with a known or suspected rheumatic disorder.

Manifestation	Significance
Skin (inquire and inspect)	
Rash, lesions	Associated with systemic lupus erythematosus (SLE) vasculitis, adverse effect of medication
Increased bruising	Associated with several rheumatic diseases and adverse effect of medication
Erythema	Sign of inflammation
Thinning	Adverse effect of medication
Warmth	Sign of inflammation
Photosensitivity	Associated with SLE, dermatomyositis, adverse effect of medication
Hair (inquire and inspect)	
Alopecia or thinning	Associated with rheumatic diseases or adverse effect of medication
Eye (inquire and inspect)	
Dryness, grittiness	Associated with Sjögren's syndrome (commonly occurring with rheumatoid arthritis [RA] and SLE)
Decreased acuity or blindness	Associated with temporal arteritis, medication complications
Cataracts	Adverse effect of medication
Decreased peripheral vision	Adverse effect of medication
Conjunctivitis, uveitis	Associated with ankylosing spondylitis and Reiter's syndrome
Ear (inquire)	
Tinnitus	Adverse effect of medication
Decreased acuity	Adverse effect of medication
Mouth (inquire and inspect)	
Buccal, sublingual lesions	Associated with vasculitis, dermatomyositis, adverse effect of medication
Altered sense of taste	Adverse effect of medication
Dryness	Associated with Sjögren's syndrome
Dysphagia	Associated with myositis
Difficulty chewing	Associated with decreased range of motion of jaw
Chest (inspect and inquire)	
Pleuritic pain	Associated with RA and SLE
Decreased chest expansion	Associated with ankylosing spondylitis
Activity intolerance (dyspnea)	Associated with pulmonary hypertension in scleroderma
Cardiovascular system (inquire, inspect, palpate)	

Blanching of fingers on exposure to cold	Associated with Raynaud's phenomenon
Peripheral pulses	Deficit may indicate vascular involvement or edema associated with medication effect or rheumatic diseases, especially SLE or scleroderma
Abdomen (inquire and palpate)	
Altered bowel habits	Associated with scleroderma, spondylosis, ulcerative colitis, decreased physical mobility, medication effect
Nausea, vomiting, bloating, and pain	Adverse effect of medication
Weight change (measure)	Associated with RA (decreased), adverse effect of medication (increased or decreased)
Genitalia (inquire and inspect)	
Dryness, itching	Associated with Sjögren's syndrome
Abnormal menses	Adverse effect of medication
Altered sexual performance	Fear of pain (or of pain caused by partner) and limitation of motion may affect sexual mobility
Hygiene	Poor hygiene may be related to limitations in activities of daily living
Urethritis, dysuria	Associated with ankylosing spondylitis and Reiter's syndrome
Lesions	Associated with vasculitis
Neurologic (inquire and inspect)	
Paresthesias of extremities; abnormal reflex pattern	Nerve compressions (e.g., carpal tunnel syndrome, spinal stenosis)
Headaches	Associated with temporal arteritis, adverse effect of medication
Musculoskeletal (inspect and palpate)	
Joint redness, warmth, swelling, tenderness, deformity—location of first joint involved, pattern of progression, symmetry, acute vs. chronic nature	Signs of inflammation
Joint range of motion	Decreased range of motion may indicate severity or progression of disease
Surrounding tissue findings	
Muscle atrophy, subcutaneous nodules, popliteal cyst	Extra-articular manifestations
Muscle strength (grip)	Muscle strength decreases with increased disease activity

Adapted from Weber, J. R., & Kelley, J. H. (2019). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

TABLE 34-1 Common Blood Studies for Rheumatic Diseases

Test	Normal Value	Significance
Serum		
Creatinine		
Metabolic waste excreted through the kidneys	*Men*: 0.6–1.2 mg/dL (71–106 mmol/L) *Women*: 0.4–1.0 mg/dL (36–90 mmol/L)	Increase may indicate kidney damage in SLE, scleroderma, and polyarteritis.
Erythrocyte Count		
Measures circulating erythrocytes	*Men:* 4,200,000–5,400,000/mm^3 ($4.2–5.4 \times 10^{12}$/L) *Women:* 3,600,000–5,000,000/mm^3 ($3.6–5.0 \times 10^{12}$/L)	Decrease can be seen in RA, SLE.
Erythrocyte Sedimentation Rate (ESR)		
Measures the rate at which RBCs settle out of unclotted blood in 1 hour	Westergren: Men under 50 yr: <15 mm/h Men over 50 yr: <20 mm/h Women under 50 yr: <20 mm/h Women over 50 yr: <30 mm/h	Increase is usually seen in inflammatory connective tissue diseases. An increase indicates rising inflammation, resulting in clustering of RBCs, which makes them heavier than normal. The higher the ESR, the greater the inflammatory activity.
Hematocrit		
Measures the size, capacity, and number of cells present in blood	*Men:* 42–52% *Women:* 36–48%	Decrease can be seen in chronic inflammation (anemia of chronic disease); also, blood loss through GI bleed.
White Blood Cell Count		
Measures circulating leukocytes	4,500–11,000 cells/mm^3	Decrease may be seen in SLE.
Uric Acid		
Measures level of uric acid in serum	*Men:* 3.4–7 mg/dL (202–416 µmol/L) *Women:* 2.4–6 mg/dL (143–357 µmol/L)	Increase is seen with gout. During acute flare, levels may be normal. After flare has subsided, levels will be elevated in gout.

Serum Immunology		
Antinuclear Antibody (ANA)		
Measures antibodies that react with a variety of nuclear antigens If antibodies are present, further testing determines the type of ANA circulating in the blood (anti-DNA, anti-RNP).	Negative Healthy adults may also have a positive ANA.	Positive test may be associated with SLE, RA, scleroderma, Raynaud's disease, Sjögren's syndrome, necrotizing arteritis. The higher the titer, the greater the inflammation. The pattern of immunofluorescence (speckled, homogeneous, or nucleolar) helps determine the diagnosis.
Anti-DNA, DNA Binding		
Titer measurement of antibody to double-stranded DNA	Negative	High titer is seen in SLE; increases in titer may indicate an increase in disease activity.
C-Reactive Protein (CRP)		
Shows presence of abnormal glycoprotein due to inflammatory process	<1 mg/dL (<10 mg/L)	A positive reading indicates active inflammation.
Immunoglobulin Electrophoresis		
Measures the values of immunoglobulins	*IgA:* 60–400 mg/dL (600–4000 mg/L) *IgG:* 700–1,500 mg/dL (7–15 g/L) *IgM:* 60–300 mg/dL (600–3000 mg/L)	Increased levels are found in people who have autoimmune disorders.
Rheumatoid Factor (RF)		
Determines the presence of abnormal antibodies seen in connective tissue disease	Negative	Positive titer >1:80 Present in 80% of those with RA Positive RF may also suggest SLE, Sjögren's syndrome, or mixed connective tissue disease. The higher the titer (number at right of colon), the greater the inflammation.
Tissue Typing		
HLA-B27 Antigen		
Measures presence of HLA antigens, which are used for tissue recognition	Negative	Found in 80–90% of those with ankylosing spondylitis and Reiter's syndrome

DNA, deoxyribonucleic acid; GI, gastrointestinal; HLA, human leukocyte antigen; IgA, immunoglobulin A; IgG, immunoglobulin G; IgM, immunoglobulin M; RA, rheumatoid arthritis; RBCs, red blood cells; RNP, ribonucleoprotein; SLE, system lupus erythematosus.

Adapted from Fischbach, F. T., & Fischbach, M. A. (2018). *A manual of laboratory and diagnostic tests* (10th ed.). Philadelphia, PA: Wolters Kluwer.

TABLE 34-2 Select Medications Used in Rheumatic Diseases

Medication	Action, Use, and Indication	Nursing Considerations
Salicylates		
Acetylated: aspirin *Nonacetylated:* choline trilisalicylate, salsalate, sodium salicylate	*Action:* Anti-inflammatory, analgesic, antipyretic Acetylated salicylates are platelet aggregation inhibitors	Administer with food, milk, antacids or large glass of water to reduce GI effects. Assess for tinnitus, gastric intolerance, GI bleeding, and purpura. Administer enteric coated or extended release whole, do not crush.
Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)		
diclofenac, diflunisal, etodolac, ibuprofen, ketoprofen, meloxicam, nabumetone, naproxen, piroxicam, sulindac *COX-2 enzyme blockers:* celecoxib	*Action:* Anti-inflammatory, analgesic, antipyretic, platelet aggregation inhibitor Anti-inflammatory effect occurs 2–4 wk after initiation All NSAIDs are useful for short-term treatment of acute gout attack NSAIDs are an alternative to salicylates for first-line therapy in several rheumatic diseases *Action:* Inhibit only COX-2 enzymes, which are produced during inflammation, and spare COX-1 enzymes, which can be protective to the stomach	Administer NSAIDs with food. Monitor for GI, CNS, cardiovascular, renal, hematologic, and dermatologic adverse effects. Avoid salicylates; use acetaminophen for additional analgesia. Watch for possible confusion in older adults. Monitoring is the same as for other NSAIDs. Increased risk of cardiovascular events, including myocardial infarction and stroke. Appropriate for older adults and patients who are at high risk for gastric ulcers.
Disease-Modifying Antirheumatic Drugs (DMARDs)		
Antimalarials: hydroxychloroquine, chloroquine	*Action:* Anti-inflammatory, inhibit lysosomal enzymes Slow acting; onset may take 2–4 mo. May be used in conjunction with other DMARD therapy. Useful in RA and SLE.	May be administered concurrently with NSAIDs. Assess for visual changes, GI upset, skin rash, headaches, photosensitivity, bleaching of hair. Emphasize need for ophthalmologic

		examinations (every 6–12 mo).
Janus Kinase (JAK) inhibitors		
tofacitinibic, baricitinic	*Action*: Enters the cell and binds to the active JAK site, inhibits autophosphorylation and JAK activation that inhibits cytokine production. May be used in combination with methotrexate or other nonbiologic DMARDs. May also be used as monotherapy.	Administer twice a day (immediate release) or once daily (extended release). Do not administer with biologic DMARDs or potent immunosuppressants. Test for latent TB before initiation of therapy. Monitor liver enzymes routinely.
sulfasalazine	*Action:* Anti-inflammatory, reduces lymphocyte response, inhibits angiogenesis Useful in RA, seronegative spondyloarthropathies	Administer concurrently with NSAIDs. Do not use in patients with allergy to sulfa medications or salicylates. Emphasize adequate fluid intake. Assess for GI upset, skin rash, headache, liver abnormalities, anemia.
Immunosuppressives: methotrexate, azathioprine, cyclophosphamide	*Action:* Nonbiologic immune suppression, affect DNA synthesis and other cellular effects Have teratogenic potential; azathioprine and cyclophosphamide reserved for more aggressive or unresponsive disease Methotrexate is generally the first-line agent for RA treatment; also useful in SLE. Methotrexate may be given orally or by intramuscular or subcutaneous injection	Assess for bone marrow suppression, GI ulcerations, skin rashes, alopecia, bladder toxicity, increased infections. Monitor CBC, liver enzymes, creatinine at 6 wk after initiation, then every 2–3 mo or accordingly. Advise patient of contraceptive measures because of teratogenicity.
cyclosporine	*Action:* Nonbiologic immune suppression by inhibiting T lymphocytes Used for severe, progressive RA, unresponsive to other DMARDs Used in combination with methotrexate	Assess slow dose titration upward until response noted or toxicity occurs. Assess for toxic effects, such as bleeding gums,

		fluid retention, hair growth, tremors. Monitor blood pressure and renal function (creatinine) every 2 wk until stable.
Immunomodulators		
Pyrimidine synthesis inhibitor: leflunomide	*Action:* Nonbiologic with antiproliferative and anti-inflammatory effects; used in moderate to severe RA May be used alone or in combination with other DMARDs	Long half-life; requires loading dose followed by daily administration. Assess for diarrhea, hair loss, skin rash, mouth sores. Monitor liver function tests. Contraindicated in pregnancy and breast-feeding. Given orally.
TNF-blocking agents: adalimumab, certolizumabpegol, etanercept, infliximab, golimumab	*Action:* Biologic response modifier that binds to TNF, a cytokine involved in inflammatory and immune responses. Used in moderate to severe RA. Can be used alone or with methotrexate or other nonbiologic DMARDs. Adalimumab is given by subcutaneous injection every 2 wk, but may be used every week if efficacy not reached. Certolizumabpegol is given by subcutaneous injection every 2 wk. Etanercept is given by subcutaneous injection weekly. Infliximab is given intravenously over 2 h or more. Medication must be refrigerated. Golimumab is given by subcutaneous injection once a month. Golimumab SQ is a second alternative that is administered intravenously every 8 wk after initial 2 loading doses	Patient should be tested for tuberculosis before beginning this medication. Educate patient about subcutaneous self-injection. Monitor for injection site reactions. Educate patient about increased risk for infection and to withhold medication if fever occurs. Notify provider if any illness or infection occurs and medication is held.
T-cell costimulation modulator: abatacept	*Action:* Blocks one of the pathways needed to fully activate T cells, decreasing inflammatory and immunologic responses. Used in moderate to severe RA	Administered IV initially, then transitions to subcutaneous dosage once weekly. Educate patient about

	unresponsive to TNF inhibitors. Used with methotrexate or DMARDs other than TNF inhibitors or anakinra.	subcutaneous self-injections given daily. Monitor for injection site reactions. Educate patient about increased risk of infection and to withhold medication if fever occurs. IV infusions are given every 4 wk over 30-min infusion.
B-cell production blocker: rituximab	*Action:* Binds to B-lymphocyte CD20 surface antigens. Used in refractory RA in patients with inadequate response to TNF antagonist. Given with methotrexate.	Rituximab is given as two 1000-mg doses via IV infusion separated by 2 wk. Given on wk 0 and 2, and then subsequent doses are infused 24 wk later or based on clinical diagnosis (commonly given every 6 mo). Premedicate with acetaminophen, antihistamine, and methylprednisolone 30 min prior to infusion of rituximab. Educate patient about increased risk of infection.
Human IL-1 receptor antagonist: anakinra	*Action:* Blocks IL-1 receptors, decreasing inflammatory and immunologic responses. Used in moderate to severe RA. Can be used alone or with methotrexate or DMARDs other than TNF-blocking agents	Given daily by subcutaneous injection. Educate patient about subcutaneous self-injections given daily. Medication must be refrigerated. Monitor for injection site reactions. Educate patient about increased risk of infection and to withhold medication if fever occurs.
Human IL-6 receptor antagonist: tocilizumab	*Action:* Binds to and inhibits IL-6 receptors, decreasing inflammatory and immunologic responses. Can be used alone or with methotrexate or in combination with other nonbiologic DMARDs	Administered IV every 4 wk. Educate patient about increased risk of infection.

Corticosteroids		
prednisone, prednisolone, hydrocortisone	*Action:* Anti-inflammatory. Used for shortest duration and at lowest dose possible to minimize adverse effects. Useful for unremitting RA, SLE, polymyalgia rheumatica, myositis, arteritis Fast acting; onset in days Intra-articular injections useful for joints unresponsive to NSAIDs	Assess for toxicity: Cataracts, GI irritation, hyperglycemia, hypertension, fractures, avascular necrosis, hirsutism, psychosis. Joints most amenable to injections include ankles, knees, hips, shoulders, and hands. Repeated injections can cause joint damage. Use caution in patients diagnosed with diabetes, due to effects causing elevation in blood sugar.

CBC, complete blood count; CNS, central nervous system; COX, cyclo-oxygenase; GI, gastrointestinal; IL-1, interleukin 1; IL-6, interleukin 6; IV, intravenous; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; TNF, tumor necrosis factor.

Adapted from Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer; Mogul, A., Corsi, K., & McAuliffe, L. (2019). Baricitinic: The second FDA approved JAK inhibitor for the treatment of rheumatoid arthritis. *Annals of Pharmacotherapy*, *53*(9), 947–953.

Devices such as braces, splints, and assistive devices for ambulation (e.g., canes, crutches, walkers) ease pain by limiting movement or stress from putting weight on painful joints. Acutely inflamed joints can be rested by applying splints to limit motion. Splints also support the joint to relieve spasm. Canes and crutches can relieve stress from inflamed and painful weight-bearing joints while promoting safe ambulation. Cervical collars may be used to support the weight of the head and limit cervical motion. A metatarsal bar or special pads may be put into the patient's shoes if foot pain or deformity is present. A combination of methods may be required, because different methods often work better at different times.

Exercise and Activity

The ongoing nature of most rheumatic diseases makes it important to maintain and, when possible, improve joint mobility and overall functional status. Appropriate programs of exercise have been shown to decrease pain and improve function (Eliopoulos, 2021). Changes in gait as well as joint limitations commonly require referral for rehabilitation therapy. An individualized exercise program is crucial to improve movement. Table 34-3

summarizes the exercises appropriate for patients with rheumatic diseases. Physical and occupational therapy programs and interventions are beneficial in improving physical activity and maintaining range of motion. Such interventions may include stretching exercises, muscle conditioning, aerobic exercise, massage, acupuncture, and chiropractic and osteopathic manipulation. Other strategies for decreasing pain include muscle relaxation techniques, imagery, self-hypnosis, and distraction. A mild analgesic agent may be suggested before exercise to improve pain during exercise. A weight reduction program may be recommended to relieve stress on painful joints for patients who are overweight. Any patient who experiences acute or prolonged pain associated with exercise should report the symptoms to their primary provider for evaluation.

TABLE 34-3 Exercise to Promote Mobility

Type of Exercise	Purpose	Recommended Performance	Precautions
Range of motion	Maintain flexibility and joint motion	Active or active/self-assisted at least daily	Reduce the number of repetitions when inflammation is present
Isometric exercise	Improve muscle tone, static endurance, and strength; prepare for dynamic and weight-bearing exercises	Perform at 70% of maximal voluntary contraction daily	Monitor blood pressure; isometric exercises may increase blood pressure and decrease blood flow to muscles
Dynamic exercise	Maintain or increase dynamic strength and endurance; increase muscle power; enhance synovial blood flow; promote strength of bone and cartilage	Start with repetitions against gravity and add progressive resistance; perform 2–3 days per week	May increase biomechanical stress on unstable or misaligned joints
Aerobic exercise	Improve cardiovascular fitness and endurance	Perform 3–5 days per week for 20–30 min of moderate-intensity exercise	Progress slowly as activity tolerance and fitness improve
Pool exercise	Water supports or resists movement; warm water may provide muscle relaxation	Provide buoyant medium for performance of dynamic or aerobic exercise	Heated swimming pool; deep water to minimize joint compression; nonslip footwear for safety and comfort. Receive appropriate education in a program designed for people with arthritis

Adapted from Kapale, P., Vardharajulu, G., & Warude, T. (2017). Effect of free exercise and rheumatoid arthritis. *Indian Journal of Physiotherapy and Occupational Therapy*, *11*(3), 62–65.

The major challenge for the patient and the health care provider is the need to adjust all aspects of treatment according to the activity of the disease. Especially for the patient with an active diffuse connective tissue disease, such as rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE), activity levels may vary from day to day and even within a single day.

Sleep

Short-term use of low-dose antidepressant medications, such as amitriptyline, may be prescribed to reestablish adequate sleep patterns and improve pain management (Comerford & Durkin, 2020). Patients need restful sleep so that they can cope with pain, minimize physical fatigue, and deal with the changes related to having a chronic disease. In patients with acute disease, sleep time is frequently reduced and fragmented by prolonged awakenings. Stiffness, depression, and medications may also compromise the quality of sleep and increase daytime fatigue. A sleep-inducing routine, medication, and comfort measures may help improve the quality of sleep.

Education about sleep hygiene strategies may help promote restorative sleep. These strategies include establishing a set time to sleep and a regular wake-up time, creating a quiet sleep environment with a comfortable room temperature, avoiding factors that interfere with sleep (e.g., the use of alcohol and caffeine), using relaxation exercises, and getting out of bed and engaging in another activity (e.g., reading) if unable to sleep.

Nursing Management

Much of the care of patients with arthritis involves self-management; thus, using a standardized assessment of self-management behaviors will help plan effective on-going care and treatment targets (Oh, Han, Kim, et al., 2018). The Nursing Research Profile in Chart 34-2 describes one such tool. Chart 34-3 details the nursing diagnoses, interventions, and expected outcomes for the patient with a rheumatic disorder.

Gerontologic Considerations

The various rheumatic disease conditions in the older adult pose unique challenges. These challenges relate to disability, cognitive changes, comorbid conditions, and diagnosis. Musculoskeletal problems are the most frequently reported conditions in older adults (Eliopoulos, 2021) and will be seen more frequently by health professionals in the coming years along with associated disability, especially among frail older adults.

Comorbid conditions pose a unique challenge in diagnosing rheumatic disease in older adults because they have the potential to mask or alter presenting symptoms. The frequency, pattern of onset, clinical features, severity, and effects on function of the rheumatic disease in older patients needs to be assessed. One study reported that functional disability was correlated with disease state and thus must be addressed in planning care (Omma, Celik, Bes, et al., 2018). Additional medical conditions may take precedence over the rheumatic disease, causing it to become a secondary diagnosis and concern. Decreased vision and altered balance, often present in older adults, may be problematic if rheumatic disease in the lower extremities

affects locomotion. The combination of decreased hearing and visual acuity, memory loss, and depression contributes to failure to follow the treatment regimen in older adult patients as well (Eliopoulos, 2021). Special techniques for promoting patient safety, self-management, and strategies such as memory aids for medications may be necessary.

Chart 34-2 NURSING RESEARCH PROFILE

Assessing Self-Management in Patients with Arthritis

Oh, H. S., Han, S. Y., Kim, S. H., et al. (2018). Development and validity testing of an arthritis self-management assessment tool. *Orthopaedic Nursing*, *37*(1), 24–35.

Purpose

Self-management is central to arthritis treatment; yet, no instrument existed to measure arthritis self-management ability. Therefore, the purpose of this research was to develop and test the reliability and validity of a comprehensive tool to assess self-management in patients with arthritis.

Design

A nonexperimental correlational design was used for this study. Items for inclusion on the Arthritis Self-Management Assessment Tool (ASMAT) were generated using a chronic illness management model. Content validity of the initial 42 items were reviewed by a panel of experts and decreased to 32 items. The tool was then tested with 150 patients with arthritis in an outpatient setting. Factor analysis was used to test construct validity.

Findings

The mean age of participants was 52 years and approximately 60% were male. There were 32 items generated and tested in the final version of the ASMAT. The 32 items were validated and the scale was found to have 3 subscales: that of medical management tasks (10 items), behavioral management tasks (13 items), and psycho-emotional management tasks (9 items). Confirmatory factor analysis showed construct validity for the 32 item tool. Cronbach α levels showed the overall toll and the 3 subscales to be reliable.

Nursing Implications

Nurses are in a key position to assist patients with arthritis to self-manage their care. Performing an ASMAT helps evaluate the patient's self-management abilities and the effectiveness of self-management interventions. Early identification of barriers to adoption of self-management strategies can lead to improved symptom management, independence, and improved quality of life.

Behavioral clues such as gait patterns, guarding, and joint flexion may aid the nurse in assessing the patient's pain when cognitive impairment is present. Older adults, especially men, may also neglect to communicate their pain unless elicited by the provider. Pain, in general, in this population that is not treated or undertreated may impact the quality of life for these patients, which can exacerbate all other medical conditions.

Chart 34-3 PLAN OF NURSING CARE

Care of the Patient with a Rheumatic Disorder

Nursing Diagnosis: Acute and chronic pain associated with inflammation and increased disease activity, tissue damage, fatigue, or lowered tolerance level

Goal: Improvement in comfort level; incorporation of pain management techniques into daily life

Nursing Interventions	Rationale	Expected Outcomes
1. Provide variety of comfort measures: a. Application of heat or cold b. Massage, position changes, rest c. Foam mattress, supportive pillow, splints d. Relaxation techniques, diversional activities 2. Administer anti-inflammatory, analgesic, and slow-acting antirheumatic medications as prescribed. 3. Individualize medication schedule to meet patient's need for pain management. 4. Encourage verbalization of feelings about pain and chronicity of disease. 5. Assess for subjective changes in pain.	1. Pain may respond to nonpharmacologic interventions, such as exercise, relaxation, and thermal modalities. 2. Pain of rheumatic disease responds to monotherapy or combination medication regimens. 3. Previous pain experiences and management strategies may be different from those needed for persistent pain. 4. Verbalization promotes coping. 5. The impact of pain on an individual's life often leads to misconceptions about pain and pain management techniques. The individual's description of pain is a more reliable indicator than objective measurements	• Identifies factors that exacerbate or influence pain response • Identifies and uses pain management strategies • Verbalizes decrease in pain • Reports signs and symptoms of side effects in timely manner to prevent additional problems • Verbalizes that pain is characteristic of rheumatic disease • Establishes realistic pain relief goals • Identifies changes in quality or intensity of pain

	such as change in vital signs, body movement, and facial expression.	
NURSING DIAGNOSIS: Fatigue associated with increased disease activity, pain, inadequate sleep/rest, deconditioning, inadequate nutrition, emotional stress, anxiety, and depressive symptoms **Goal:** Incorporates as part of daily activities strategies necessary to modify fatigue		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Provide education about fatigue. a. Describe relationship of disease activity to fatigue. b. Describe comfort measures while providing them. c. Develop and encourage a sleep routine (warm bath and relaxation techniques that promote sleep). d. Explain importance of rest for relieving systematic, articular, and emotional stress. e. Explain how to use energy conservation techniques (pacing, delegating, setting priorities). f. Identify physical and emotional factors that can cause fatigue.	1. The patient's understanding of fatigue will affect their actions. a. The amount of fatigue is directly related to the activity of the disease. b. Relief of discomfort can relieve fatigue. c. Effective bedtime routine promotes restorative sleep. d. Different kinds of rest are needed to relieve fatigue and are based on patient's need and response. e. A variety of measures can be used to conserve energy.	• Self-evaluates and monitors fatigue pattern • Verbalizes the relationship of fatigue to disease activity • Uses comfort measures as appropriate • Practices effective sleep hygiene and routine • Makes use of various assistive devices (splints, canes) and strategies (bed rest, relaxation techniques) to ease different kinds of fatigue • Incorporates time management

2. Facilitate development of appropriate activity/rest schedule. 3. Encourage adherence to the treatment program. 4. Refer to and encourage a conditioning program. 5. Encourage adequate nutrition, including source of iron from food and supplements.	f. Awareness of the various causes of fatigue provides the basis for measures to modify the fatigue. 2. Alternating rest and activity conserves energy while allowing most productivity. 3. Overall control of disease activity can decrease the amount of fatigue. 4. Deconditioning resulting from lack of mobility, understanding, and disease activity contributes to fatigue. 5. A nutritious diet can help counteract fatigue.	strategies in daily activities • Uses appropriate measures to prevent physical and emotional fatigue • Has an established plan to ensure well-paced, therapeutic activity schedule • Adheres to therapeutic program • Follows a planned conditioning program • Consumes a nutritious diet consisting of the five major groups and recommended daily allowance of vitamins and minerals

Nursing Diagnosis: Impaired mobility associated with decreased range of motion, muscle weakness, pain on movement, limited endurance, lack of or improper use of ambulatory devices

Goal: Attains and maintains optimal functional mobility

Nursing Interventions	Rationale	Expected Outcomes
1. Encourage verbalization	1. Mobility is not necessarily	• Identifies factors that

regarding limitations in mobility. 2. Assess need for occupational or physical therapy consultation. a. Emphasize range of motion of affected joints. b. Promote the use of assistive ambulatory devices. c. Explain the use of safe footwear. d. Use individual appropriate positioning/posture. 3. Assist to identify environmental barriers. 4. Encourage independence in mobility and assist as needed. a. Allow ample time for activity. b. Provide rest period after activity. c. Reinforce principles of pacing and work simplification. 5. Initiate referral to community health agency.	related to deformity. Pain, stiffness, and fatigue may temporarily limit mobility. The degree of mobility is not synonymous with the degree of independence. Decreased mobility may influence a person's self-concept and lead to social isolation. 2. Therapeutic exercises, proper footwear, and assistive equipment may improve mobility. Correct posture and positioning are necessary for maintaining optimal mobility. 3. Furniture and architectural adaptations may enhance mobility. 4. Changes in mobility may lead to a decrease in personal safety. 5. The degree of mobility may be slow to improve or may not improve with intervention.	interfere with mobility • Describes and uses measures to prevent loss of motion • Identifies environmental (home, school, work, community) barriers to optimal mobility • Uses appropriate techniques, assistive equipment, or both to aid mobility • Identifies community resources available to assist in managing decreased mobility
Nursing Diagnosis: Able to perform self care associated with contractures, fatigue, or loss of motion		

Goal: Performs self-care activities independently or with the use of resources

Nursing Interventions	Rationale	Expected Outcomes
1. Assist patient to identify self-care deficits and factors that interfere with ability to perform self-care activities. 2. Develop a plan based on the patient's perceptions and priorities on how to establish and achieve goals to meet self-care needs, incorporating energy conservation, and work simplification concepts. a. Provide appropriate assistive devices. b. Reinforce correct and safe use of assistive devices. c. Allow patient to control timing of self-care activities. d. Explore with the patient different ways to perform difficult tasks or ways to enlist the help of someone else. 3. Consult with community health care agencies when individuals have attained a maximum level of self-care yet still have some	1. The ability to perform self-care activities is influenced by the disease activity and the accompanying pain, stiffness, fatigue, muscle weakness, loss of motion, and depression. 2. Assistive devices may enhance self-care abilities. Effective planning for changes must include the patient, who must accept and adopt the plan. 3. Individuals differ in ability and willingness to perform self-care activities. Changes in ability to care for self may lead to a decrease in personal safety.	• Identifies factors that interfere with the ability to perform self-care activities • Identifies alternative methods for meeting self-care needs • Uses alternative methods for meeting self-care needs • Identifies and uses other health care resources for meeting self-care needs

deficits, especially regarding safety.

Nursing Diagnosis: Disturbed body image associated with physical and psychological changes and dependency imposed by chronic illness
Goal: Adapts to physical and psychological changes imposed by the rheumatic disease

Nursing Interventions	Rationale	Expected Outcomes
1. Help patient identify elements of control over disease symptoms and treatment. 2. Encourage patient's verbalization of feelings, perceptions, and fears. a. Help to assess present situation and identify problems.	1. The individual's self-concept may be altered by the disease or its treatment. 2. The individual's coping strategies reflect the strength of their self-concept.	• Verbalizes an awareness that changes taking place in self-concept are normal responses to rheumatic disease and other chronic illnesses • Identifies strategies to cope with altered self-concept

Nursing Diagnosis: Difficulty coping associated with actual or perceived lifestyle or role changes

Goal: Use of effective coping behaviors for dealing with actual or perceived limitations and role changes

Nursing Interventions	Rationale	Expected Outcomes
1. Identify areas of life affected by disease. Answer questions and dispel possible myths. a. Assist to identify past coping mechanisms. b. Assist to identify effective coping mechanisms. 2. Develop plan for managing symptoms and enlisting support of family and friends to promote daily function.	1. The effects of disease may be more or less manageable once identified and explored reasonably. 2. By taking action and involving others appropriately, patient develops or draws on coping skills and community support.	• Names functions and roles affected and not affected by disease process • Describes therapeutic regimen and states actions to take to improve, change, or accept a particular situation, function, or role

Collaborative Problems: Complications secondary to effects of medications

Goal: Absence or resolution of complications

Nursing Interventions	Rationale	Expected Outcomes
1. Perform periodic clinical assessment and laboratory evaluation.	1. Skillful assessment helps detect early symptoms of side effects of medications.	• Adheres to monitoring procedures and experiences minimal side effects

Provide 2. education about correct self-administration, potential side effects, and importance of monitoring. 3. Counsel regarding methods to reduce side effects and manage symptoms. 4. Administer medications in modified doses as prescribed if complications occur.	2. The patient needs accurate information about medications and potential side effects to avoid or manage them. 3. Appropriate identification and early intervention may minimize complications. 4. Modifications may help minimize side effects or other complications.	Takes medication as • prescribed and lists potential side effects • Identifies strategies to reduce or manage side effects • Reports that side effects or complications have subsided

Pharmacologic therapy (including analgesic agents), exercise, postural assistance, modification of activities of daily living, and psychological support are useful components of a self-management program for the older adult (Oh et al., 2018).

Identifying the effects of the rheumatic disease on the patient's lifestyle, independence, and psychological status is important and can improve the quality of life for older adults. Depressed mood is routinely found in those suffering from chronic joint disease. The body image and self-esteem of the older adult with rheumatic disease, combined with underlying depression, may interfere with the use of assistive devices such as canes. The use of adaptive equipment such as long-handled reachers or tongs may be viewed by the older adult as evidence of aging rather than as a means of increasing independence.

Because most rheumatic diseases involve pain, especially with joints, some older adults may consider their symptoms as inevitable consequences of aging. In fact, many older adults expect and accept the immobility and self-care problems related to the rheumatic diseases and do not seek help, thinking that nothing can be done.

The older adult usually has a lifelong pattern of dealing with the stresses of daily life. Depending on the success of that pattern, the older adult can often maintain a positive attitude and self-esteem when faced with a rheumatic disease, especially if support is available. Previous stress management strategies are assessed. If these strategies have been effective, the patient is

encouraged and supported in their use. If they were ineffective, the nurse assists the patient in identifying alternative strategies, encourages the use of new strategies, and assesses their effectiveness.

Pharmacologic treatment of rheumatic disease in older patients is more difficult than in younger patients. If therapeutic medications have an effect on the senses (hearing, cognition), this effect is intensified in the older adult. The cumulative effect of medications, in general, is accentuated because of the physiologic changes of aging. For example, decreased renal function in the older adult alters the metabolism of certain medications, such as NSAIDs. Older adults are more prone to side effects associated with the use of multiple-drug therapy.

Partly because of the more frequent contact of older adults with health care providers for a variety of health issues, overtreatment or inappropriate treatment is possible. Complaints of pain may be met with a prescription for analgesic agents rather than instructions for rest, the use of an assistive device, and local comfort measures such as heat or cold. Acetaminophen may be appropriate and worth trying before other medications that pose a greater chance of side effects. NSAIDs can be used; however, long-term use of NSAIDs can increase the risks of peptic ulcers, hemorrhage, and cardiovascular toxicity (Comerford & Durkin, 2020).

Intra-articular corticosteroid injections, with their usually rapid relief of symptoms, may be requested by the patient who is unaware of the consequences of too-frequent use of this treatment. In addition, exercise programs may not be instituted or may be ineffective because the patient expects results to occur quickly or fails to appreciate the effectiveness of a program of exercise. In fact, strength training is encouraged in the older adult with chronic diseases.

Diffuse Connective Tissue Diseases

Diffuse connective tissue disease refers to a group of systemic disorders that are chronic in nature and are characterized by diffuse inflammation and degeneration in the connective tissues. These disorders share similar clinical features and may affect some of the same organs. The characteristic clinical course is one of exacerbations and remissions. Although diffuse connective tissue diseases have unknown causes, they are thought to be the result of immunologic abnormalities. They include RA, SLE, Sjögren's syndrome, scleroderma, polymyositis, polymyalgia rheumatica (PMR), and giant cell arteritis (GCA).

Rheumatoid Arthritis

Rheumatoid arthritis is an autoimmune disease of unknown origin that affects 1% to 2% of the population worldwide, with females having a three times greater incidence than males. It may occur at any age but the onset commonly occurs between the third and sixth decade of life. The incidence of RA increases after the sixth decade of life (Norris, 2019). RA that occurs after the age of 65 is referred to as elderly onset RA (Norris, 2019). Additional risks that have been identified include family history, environmental influences such as diet or geographic location, nulliparity, as well as the modifiable factors of smoking and obesity (Mogul, Corsi, & McAuliffe, 2019).

Pathophysiology

The exact mechanism of action for the etiology of RA is unknown. Evidence points to a genetic predisposition and the development of immunologically mediated joint inflammation (Eliopoulos, 2021; Norris, 2019). An autoimmune reaction (see Fig. 34-1) occurs in the synovial tissue. RA synovium breaks down collagen, causing edema, proliferation of the synovial membrane, and ultimately pannus formation. Pannus destroys cartilage and erodes the bone. The consequence is the loss of articular surfaces and joint motion. Muscle fibers undergo degenerative changes. Tendon and ligament elasticity and contractile power are lost.

The RA inflammatory process has also been implicated in other disease processes (i.e., arteriosclerosis). It is hypothesized that the RA disease process somehow interferes with the production of high-density lipoprotein cholesterol, which is the form of cholesterol responsible for decreasing cellular lipids and, therefore, is considered antiatherosclerotic.

The nervous system is also affected by the RA inflammatory process. The synovial inflammation can compress the adjacent nerve, causing neuropathies and paresthesias. Axonal degeneration and neuronal demyelination are also possible due to the infiltration of polymorphonuclear leukocytes, eosinophils, and mononuclear cells, causing necrotizing or occlusive vasculitis (Norris, 2019).

Clinical Manifestations

The American College of Rheumatology and the European League Against Rheumatism have collaborated and established criteria for classifying RA. These criteria are based on a point system where a total score of 6 or greater is required for the diagnosis of RA. The scoring system is based on joint involvement (number of joints affected), serology (low positive or high positive rheumatoid factor [RF] or anti-citrullinated peptide antibody [ACPA]), abnormal results of the acute phase reactants (erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP]), and duration of symptoms greater than 6

weeks. Patients diagnosed with RA who are excluded from these diagnostic criteria include: (1) patients who have one joint with synovitis that is not related to any other clinical disease and who also score at least 6 to 10 points on the scale, and (2) patients diagnosed with bony erosions on x-ray (Aletaha, Neogi, Silman, et al., 2010; Molano-Gonzalez, Olivares-Matinez, Anaya, et al., 2019).

The initial clinical manifestations of RA include symmetric joint pain and morning joint stiffness lasting longer than 1 hour. Over the course of the disease, clinical manifestations of RA vary, usually reflecting the stage and severity of the disease. Symmetric joint pain, swelling, warmth, erythema, and lack of function are classic symptoms. Palpation of the joints reveals spongy or boggy tissue. Often, fluid can be aspirated from the inflamed joint. Characteristically, the pattern of joint involvement begins in the small joints of the hands, wrists, and feet (Omma et al., 2018). As the disease progresses, the knees, shoulders, hips, elbows, ankles, cervical spine, and temporomandibular joints may be affected. The onset of symptoms is usually acute. Symptoms are usually bilateral and symmetric.

In the early stages of disease, even before the presentation of bony changes, limitation in function can occur when there is active inflammation in the joints. Joints that are hot, swollen, and painful are not easily moved. The patient tends to guard or protect these joints by immobilizing them. Immobilization for extended periods can lead to contractures, creating soft tissue deformity.

Deformities of the hands (e.g., ulnar deviation and swan neck deformity) and feet are common in RA (see Chapter 35, Fig. 35-6). The deformity may be caused by misalignment resulting from swelling, progressive joint destruction, or the subluxation (partial dislocation) that occurs when one bone slips over another and eliminates the joint space. Deformities of RA differ from those seen with osteoarthritis (OA), such as Heberden's and Bouchard's nodes (see Chapter 36).

RA is a systemic disease with multiple extra-articular features. Most common are fever, weight loss, fatigue, anemia, lymph node enlargement, and Raynaud's phenomenon (cold- and stress-induced vasospasm causing episodes of digital blanching or cyanosis). Rheumatoid nodules are common in patients with more advanced RA. These nodules are usually nontender and movable in the subcutaneous tissue. They usually appear over bony prominences such as the elbow, are varied in size, and can disappear spontaneously or progress to ulceration (Weber & Kelley, 2019; Young, 2019). Nodules occur only in people who have rheumatoid factor. Other extra-articular features include arteritis, neuropathy, pericarditis, splenomegaly, and Sjögren's syndrome (dry eyes and dry mucous membranes).

Assessment and Diagnostic Findings

Several assessment findings are associated with RA: rheumatoid nodules, joint inflammation detected on palpation, and certain laboratory findings. The history and physical examination focus on manifestations, such as bilateral and symmetric stiffness, tenderness, swelling, and temperature changes in the joints (Weber & Kelley, 2019). The patient is also assessed for extra-articular changes; these often include weight loss, sensory changes, lymph node enlargement, and fatigue. Symptoms and examination findings are often recorded using a disease activity score, a variety of which are in use, to evaluate disease activity, help guide treatment decisions, and monitor treatment efficacy (Mahmood, van Tuyl, Schoonmade, et al., 2019).

Rheumatoid factor is present in many patients with RA, but its presence alone is not diagnostic of RA, and its absence does not rule out the diagnosis. Antibodies to cyclic citrullinated peptide (anti-CCP) have a specificity of approximately 95% at detecting RA (Norris, 2019). The ESR and CRP tend to be significantly elevated in the acute phases of RA and are therefore useful in monitoring active disease and disease progression. The complete blood count (CBC) should be assessed to establish a baseline count especially prior to starting medications (Fischbach & Fischbach, 2018). Patients may exhibit anemia, and platelets may be elevated due to the inflammatory process. A tuberculin (TB) skin test should be done prior to the initiation of certain medications to rule out tuberculosis. In the event the patient has latent TB and has never been treated, the infection can be reactivated. The patient should also be assessed for hepatitis B and hepatitis C, which could impact treatment strategies if positive. If the client tests positive for hepatitis, the infection should be treated prior to starting medication. Liver and kidney monitoring are recommended for most DMARD therapy because it can cause elevation of the liver enzymes and can also affect kidney function.

X-ray, ultrasound, or both of the hands, wrists, and feet can be useful in establishing a baseline for joint evaluation, and assessing the joints for erosions and synovitis. Joint damage may occur within the first 6 to 12 months of diagnosis and should be followed as indicated. Plain x-ray is the most common radiographic study used to track disease progression as it is inexpensive, reliable, and reproducible (Mahmood et al., 2019). MRI can also be useful to detect small erosions that may not be visible on x-ray or ultrasound.

Medical Management

The goal of treatment at all phases of the RA disease process is to decrease joint pain and swelling, achieve clinical remission, decrease the likelihood of joint deformity, and minimize disability. Initial treatment delays have been implicated in greater long-term joint deformity. Aggressive and early treatment

regimens are warranted. The use of a targeted pharmacologic treatment strategy is recommended to decrease RA disease activity (Singh et al., 2016).

Early Rheumatoid Arthritis

Once the diagnosis of RA is made, treatment should begin with either a nonbiologic or biologic DMARD. The goal of using DMARD therapy is preventing inflammation and joint damage.

Recommended treatment guidelines include beginning with the nonbiologic DMARDs (methotrexate is the preferred agent but leflunomide, sulfasalazine, or hydroxychloroquine are also used) biologics, or tofacitinibic within 3 months of disease onset. Care should be used with each of these medications by performing routine blood testing for liver and kidney function, along with monitoring the CBC for anemia. Dosage may need to be modified for patients with renal impairment (Comerford & Durkin, 2020).

Another treatment approach for RA is the use of biologic DMARDs. These agents have been specifically engineered to target the most prominent proinflammatory mediators in RA—TNF-α, B cells, T cells, IL-1, and IL-6 (see Table 34-2). Biologic DMARDs are the first targeted therapy for RA. Clinical evidence suggests that biologic DMARDs work more quickly and show a greater delay in radiologic disease progression when compared to nonbiologic DMARDs. The biologic DMARDs are more expensive and have fewer years of usage with the RA population. Therefore, they tend to be reserved for patients with persistent moderate to severe RA who have not responded adequately to synthetic DMARDs (Singh et al., 2016).

After initiating treatment with a DMARD, patients generally report a beneficial effect within 6 weeks and tolerate the medication relatively well. However, some patients may take longer to see improvement. Corticosteroids are recommended as a "bridge" in the early treatment but are not recommended for long-term therapy due to side effects (Singh et al., 2016).

A newer class of drugs, the Janus Kinase (JAK) inhibitors, bind to the active JAK enzyme sites, inhibiting autophosphorylation and thus inhibiting cytokine production and decreasing the immune response (Mogul et al., 2019). JAK inhibitors are used in combination with methotrexate or other nonbiologic DMARDs. They may also be used as monotherapy (Mogul et al., 2019; Singh et al., 2016).

NSAIDs and specifically the cyclo-oxygenase 2 (COX-2) enzyme blockers are used for pain and inflammation relief. NSAIDs, such as ibuprofen and naproxen, are commonly prescribed because of their low cost and analgesic properties. They must be used with caution, however, in long-term chronic diseases because of the possibility of gastric ulcers. Several COX-2 enzyme blockers have been approved for treatment of RA. Cyclo-oxygenase is an enzyme that is involved in the inflammatory process. COX-2 medications block the enzyme involved in inflammation (COX-2) while leaving intact the

enzyme involved in protecting the stomach lining (COX-1). As a result, COX-2 enzyme blockers are less likely to cause gastric irritation and ulceration than other NSAIDs; however, they are associated with increased risk of cardiovascular disease and must be used with caution (Comerford & Durkin, 2020). The nurse should be aware that NSAIDs do not prevent erosions or alter disease progression and, consequently, are medications useful only for symptom relief (Singh et al., 2016).

Additional analgesia may be prescribed for periods of extreme pain. Opioid analgesic agents are avoided because of the potential for continuing need for pain relief. Nonpharmacologic pain management techniques (e.g., relaxation techniques, heat and cold applications) are taught.

Established Rheumatoid Arthritis

In patients with established RA, a formal program with occupational and physical therapy is prescribed to educate the patient about principles of pacing activities, work simplification, range of motion, and muscle-strengthening exercises. The patient is encouraged to participate actively in the management program. The medication program is reevaluated periodically, and appropriate changes are made if disease progression is occurring despite pharmacologic treatment. Additional agents may be added to enhance the disease-modifying effect of methotrexate. Combination therapy using one nonbiologic DMARD and one biologic DMARD is common (Singh et al., 2016).

For more established RA, reconstructive surgery and corticosteroids are often used. Reconstructive surgery is indicated when pain cannot be relieved by conservative measures and the threat of loss of independence is eminent. Surgical procedures include synovectomy (excision of the synovial membrane), tenorrhaphy (suturing of a tendon), arthrodesis (surgical fusion of the joint), surgical repair, and replacement of the joint. Surgery is not performed during exacerbations.

Systemic corticosteroids are used when the patient has unremitting inflammation and pain or needs a “bridging” medication while waiting for the slower DMARDs (e.g., methotrexate) to begin taking effect. Low-dose corticosteroid therapy is prescribed for the shortest time necessary to minimize side effects (Singh et al., 2016). Single large joints that are severely inflamed and fail to respond promptly to the measures outlined previously may be treated by local injection of a corticosteroid.

Topical analgesic agents such as capsaicin and methylsalicylate are often prescribed. Topical diclofenac sodium gel may help with joint pain in the hands and knees (Comerford & Durkin, 2020).

For most patients with RA, the emotional and possible financial burden of the disease can lead to depressive symptoms and sleep deprivation. The patient may require the short-term use of low-dose antidepressant medications, such as amitriptyline, paroxetine, or sertraline, to reestablish an adequate sleep

pattern and manage depressive symptoms. Patients may benefit from referrals for talk therapy or group support.

Obesity Considerations

The prevalence of obesity is increasing in the general population and in patients with RA. One large study reported that the prevalence of obesity, diagnosed with a body mass index (BMI) of greater than or equal to 30 kg/m^2, was approximately 20% at diagnosis and increased each year (Nikiphorou, Norton, Young, et al., 2018). Furthermore, the presence of obesity adversely affected disease progression, function, and quality of life in patients with RA followed for 10 to 25 years (Nikiphorou et al., 2018). Management of obesity in the patient with RA is essential.

Certain medications (i.e., oral corticosteroids) used in RA treatment stimulate the appetite and, when combined with decreased activity, may lead to weight gain. In fact, one study reported that approximately half the increase in BMI within the first year of diagnosis with RA could be attributed to steroid use (Nikiphorou et al., 2018).

A dietician can counsel the patient about better food choices. Food selection should include the five major groups (grains, vegetables, fruits, dairy, and protein), with emphasis on foods high in vitamins, protein, and iron for tissue building and repair. Patients who are overweight or have obesity need to be counseled about eating a healthy, calorie-restricted diet.

Nursing Management

Nursing care of the patient with RA follows the basic plan of care presented earlier (see Chart 34-3). The most common issues for the patient with RA include pain, sleep disturbance, fatigue, altered mood, and limited mobility. The patient with newly diagnosed RA needs information about the disease to make daily self-management decisions and cope with having a chronic disease. Consultation with a dietician for assessment and assistance with appropriate food choices may be helpful.

Monitoring and Managing Potential Complications

Patients commonly have comorbid conditions such as cardiovascular disease that can lead to complications. It has been estimated that the primary cause of death for up to 40% of patients diagnosed with RA is cardiovascular disease. The cause of cardiovascular disease in these patients is thought to be due to elevated lipid values, chronic inflammation, dysfunction of the endothelium, and/or abnormal homocysteine levels (Norris, 2019).

Medications used for treating RA may cause serious and adverse effects. The primary provider bases the prescribed medication regimen on clinical findings and past medical history, and then, with the help of the nurse, monitors for side effects using periodic clinical assessments and laboratory testing. The nurse, who can be available for consultation between visits with the primary provider, works to help the patient recognize and deal with these side effects (see Table 34-2). Medication may need to be stopped or the dose reduced. If the patient experiences an increase in symptoms while the complication is being resolved or a new medication is being initiated, the nurse's counseling regarding symptom management may relieve potential anxiety and distress.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Patient education is an essential aspect in nursing care of the patient with RA to enable the patient to maintain as much independence as possible, to take medications accurately and safely, and to use adaptive devices correctly (Oh et al., 2018). Patient education focuses on self-management related to the disorder, the therapeutic regimen prescribed to treat it, and the potential side effects of medications. Patients undergoing surgery need education as well. The nurse works with the patient and family on strategies to maintain independence, function, and safety in the home (see Chart 34-4).

The patient and family are encouraged to verbalize their concerns and ask questions. Because RA commonly affects young women, major concerns may be related to the effects of the disease on childbearing potential, caring for family, or work responsibilities. The patient with a chronic illness may seek a "cure" or have questions about alternative therapies. Research indicates that acupuncture is safe and may be beneficial for patients with RA (Chou & Chu, 2018). There is not enough evidence of the effectiveness of other complementary, alternative, and integrative health therapies, and more rigorous research is needed (Chou & Chu, 2018; Katz-Talmor, Katz, Porta-Katz, et al., 2018).

The nurse educates patients using topical analgesic agents to apply sparingly, avoid areas of open skin, and avoid contact with eyes and mucous membranes. Patients should also wash their hands carefully after application and assess for local skin irritation. Pain, fatigue, and depressive symptoms can interfere with the patient's ability to learn and should be addressed before the education is initiated. Various educational strategies may then be used, depending on the patient's previous knowledge base, interest level, degree of comfort, social or cultural influences, and readiness to learn. The nurse

educates the patient about basic disease management and necessary adaptations in lifestyle. Some types of aerobic exercise and strength training should be discussed (Kapale et al., 2017). Because suppression of inflammation and autoimmune responses require the use of anti-inflammatory, disease-modifying antirheumatic, and immunosuppressive agents, the patient is taught about prescribed medications, including type, dosage, rationale, potential side effects, self-administration, and required monitoring procedures. If hospitalized, the patient is encouraged to practice new self-management skills with support from caregivers and significant others. The nurse then reinforces disease management skills during each patient contact. Barriers are assessed, and measures are taken to promote adherence to medications and the treatment program.

Chart 34-4 HOME CARE CHECKLIST

The Patient with Rheumatoid Arthritis

At the completion of education, the patient and/or caregiver will be able to:

State the impact of rheumatoid arthritis on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.

- State changes in lifestyle (e.g., diet, activity, rest) necessary to maintain health.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Demonstrate accurate and safe self-administration of medications.
- Describe and demonstrate the use of pain management techniques.
- Demonstrate ability to perform ADLs independently or with assistive devices/adaptive equipment.
- Verbalize ways to cope with stress successfully, plans for regular, safe exercise, and rationale for obtaining adequate rest. Demonstrate a relaxation technique.
- Verbalize a dietary plan that includes maintaining or losing weight while maximizing vitamins, protein, and iron for tissue building and repair
- State how to reach primary provider with questions or complications
- State time and date of follow-up appointments, testing
- Identify the need for health promotion, disease prevention, and screening activities
- Identify community resources for peer and caregiver/family information and support:
  - Identify sources of support (e.g., friends, relatives, faith community)
  - Identify the contact details for support services for patients and their caregivers/families

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Continuing and Transitional Care

Depending on the severity of the disease and the patient's resources and supports, referral for home care may be warranted. For example, the patient who is an older adult or frail, has RA that limits function significantly, and lives alone may need referral for home care.

The impact of RA on everyday life is not always evident when the patient is seen in the hospital or in an ambulatory care setting. The increased frequency with which nurses see patients in the home provides opportunities for recognizing problems and implementing interventions aimed at improving the quality of life of patients with RA.

During home visits, the nurse has the opportunity to assess the home environment and its adequacy for patient safety and management of the disorder. Adherence to the treatment program can be more easily monitored in the home setting, where physical and social barriers to adherence are more readily identified. For example, a patient who also has diabetes and requires insulin may be unable to fill the syringe accurately or unable to administer the insulin because of impaired joint mobility. Appropriate adaptive equipment needed for increased independence is often identified more readily when the nurse sees how the patient functions in the home. Any barriers to adherence are identified, and appropriate referrals are made.

For patients at risk for impaired skin integrity, the home health nurse can closely monitor skin status and also educate, provide, or supervise the patient and family in preventive skin care measures. The nurse also assesses the patient's need for assistance in the home and supervises home health aides, who may meet many of the needs of the patient with RA. Referrals to physical and occupational therapists may be made as problems are identified and limitations increase. A home health nurse may visit the home to make sure that the patient can function as independently as possible despite mobility problems and can safely manage treatments, including pharmacotherapy. The patient and family should be informed about support services such as Meals on Wheels and local Arthritis Foundation chapters.

Because many of the medications used to suppress inflammation are injectable, the nurse may administer the medication to the patient or educate about self-injection. These frequent contacts allow the nurse to reinforce other disease management techniques.

The nurse also assesses the patient's physical and psychological status, adequacy of symptom management, and adherence to the management plan. Patients should know which type of rheumatic disease they have, not just that they have "arthritis" or "arthritis of the knee." The importance of attending follow-up appointments is emphasized to the patient and family, and they should be reminded about the importance of participating in other health promotion activities and health screening.

Systemic Lupus Erythematosus

SLE is an inflammatory, autoimmune disorder that affects nearly every organ in the body. The overall incidence of SLE is estimated to be 1.8 to 7.6 per 100,000 people (Centers for Disease Control and Prevention [CDC], 2018). It occurs 4 to 12 times more frequently in women than in men and occurs more often in African Americans, Hispanics/Latino Americans, Asians, and American Indians/Alaska Natives than among White Americans (CDC, 2018). In addition to SLE, other forms of adult lupus exist, including subacute

cutaneous or discoid lupus erythematous, and drug-induced lupus (Aringer, Costenbader, Daikh, et al., 2019).

Pathophysiology

While the exact cause is not known, SLE starts with the body's immune system inaccurately recognizing one or more components of the cell's nucleus as foreign, seeing it as an antigen. The immune system starts to develop antibodies to the nuclear antigen. In particular, B cells begin to overproduce antibodies with the help of multiple cytokines such as B-lymphocyte stimulator (BLyS), which is overexpressed in SLE. The antibodies and antigens form antigen–antibody complexes and have the propensity to get trapped in the capillaries of visceral structures. The antibodies also act to destroy host cells. It is thought that those two mechanisms are responsible for the majority of the clinical manifestations of this disease process. The immunoregulatory disturbance is thought to be brought about by some combination of four distinct factors: genetic, immunologic, hormonal, and environmental (Norris, 2019).

Research into the genetic origins of SLE has thus far revealed that multiple genes are likely implicated in the development of SLE (Norris, 2019). The large majority of SLE cases, however, remain sporadic and unrelated to family medical history.

Given the high number of women with SLE compared with men, it is hypothesized that female sex hormones (estrogen) play a role in the predisposition to SLE. Estrogen may contribute to the body's response of overreacting to the body's own tissues.

Although genetics and hormones likely play a role in the predisposition of SLE, it is hypothesized that exogenous or environmental triggers are also implicated in the onset of the disease process. These triggers may include cigarette smoke, ultraviolet rays, exposure from sunlight and fluorescent light bulbs, medications (hydralazine, minocyline, or procainamide), viral infections, emotional stress, stress on the body (e.g., surgery, pregnancy), and silica dust exposure in the occupational setting (Norris, 2019).

Clinical Manifestations

SLE is an autoimmune, systemic disease that can affect any body system (Fig. 34-2). The disease process involves chronic states where symptoms are minimal or absent and acute flares where symptoms and lab results are elevated. Symptoms most often include fever, fatigue, skin rashes, as well as joint pain and swelling (Aringer et al., 2019; CDC, 2018). The mucocutaneous, musculoskeletal, renal, nervous, cardiovascular, and respiratory systems are

most commonly involved. Less commonly affected are the gastrointestinal tract and liver as well as the ocular system.

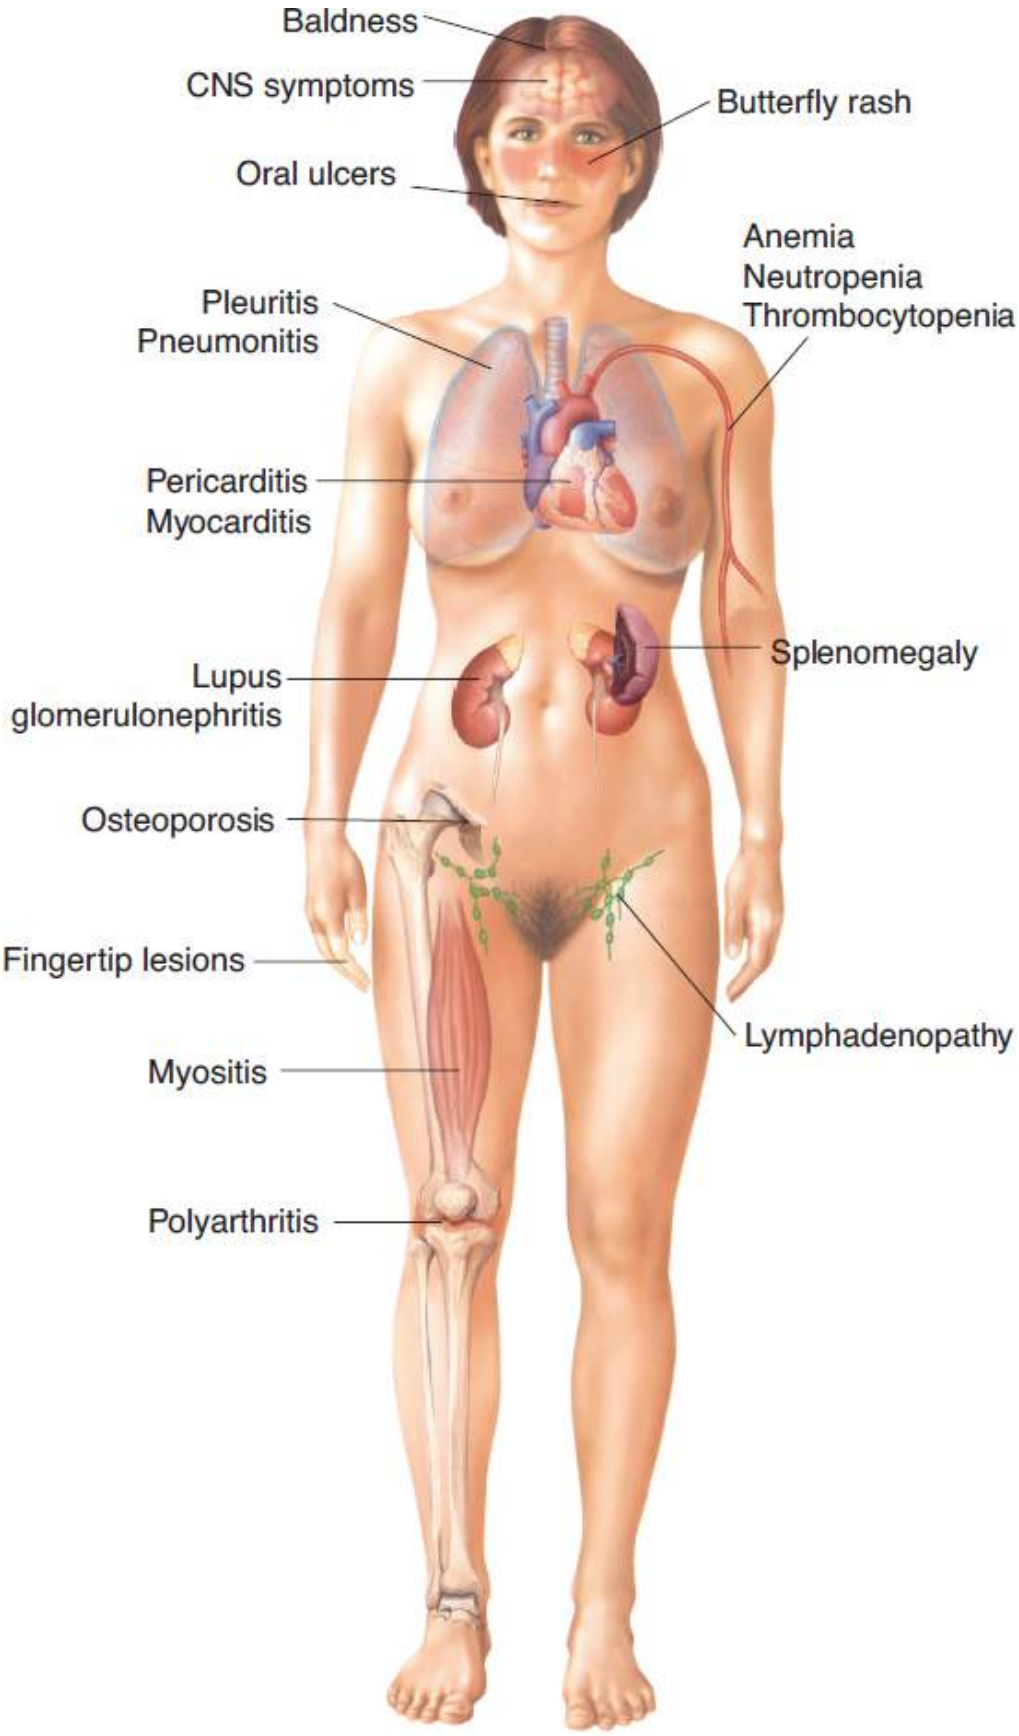

Figure 34-2 • Clinical manifestations of SLE. Reprinted with permission from Norris, T. L. (2019). *Porth's pathophysiology:*

Concepts of altered health states (10th ed., Fig. 50.5). Philadelphia, PA: Wolters Kluwer.

Some type of cutaneous system manifestation is experienced in up to 85% of patients with SLE (Norris, 2019). Several skin manifestations may occur in patients with SLE, including subacute cutaneous lupus erythematosus, which involves papulosquamous or annular polycyclic lesions, and a discoid rash, which is a chronic rash with erythematous papules or plaques and scaling and can cause scarring and pigmentation changes (Aringer et al., 2019). In some cases, the only skin involvement may be a discoid rash. In some patients with SLE, the initial skin involvement is the precursor to more systemic involvement. The lesions often worsen during **exacerbations** (flares) of the systemic disease and possibly are provoked by sunlight or artificial ultraviolet light (Norris, 2019). Oral ulcers, which may accompany skin lesions, may involve the buccal mucosa or the hard palate, occur in crops, and are often associated with exacerbations. Other cutaneous manifestations include splinter hemorrhages, alopecia, and Raynaud's phenomenon.

Joint pain and swelling occur in more than 90% of patients with SLE (Norris, 2019). Joint swelling, tenderness, and pain on movement are also common. Frequently, these are accompanied by morning stiffness.

The cardiac system is also commonly affected in SLE. Pericarditis is the most common cardiac manifestation (Norris, 2019). Patients may present with substernal chest pain that is aggravated by movement or inspiration. Symptoms can be acute and severe or last for weeks at a time. Other cardiac symptoms may involve myocarditis, hypertension, cardiac arrhythmias, and valvular incompetence.

Nephritis as a result of SLE, also referred to as lupus nephritis, occurs due to a buildup of antibodies and immune complexes that cause damage to the nephrons. Serum creatinine levels and urinalysis are used in screening for renal involvement. Early detection allows for prompt treatment so that renal damage can be prevented. Renal involvement may lead to hypertension, which also requires careful monitoring and management (see Chapter 27).

Central nervous system involvement is widespread, encompassing the entire range of neurologic disease. The varied and frequent neuropsychiatric presentations of SLE are now widely recognized and include psychosis, cognitive impairment, seizures, peripheral and cranial neuropathies, transverse myelitis, and strokes. These are generally demonstrated by subtle changes in behavior patterns or cognitive ability.

Assessment and Diagnostic Findings

Diagnosis of SLE is based on a complete history, physical examination, and blood tests. In addition to the general assessment performed for any patient

with a rheumatic disease, assessment for known or suspected SLE has special features. The skin is inspected for erythematous rashes. Cutaneous erythematous plaques with an adherent scale may be observed on the scalp, face, or neck. Areas of hyperpigmentation or depigmentation may be noted, depending on the phase and type of disease. The patient should be questioned about skin changes (because these may be transitory) and specifically about sensitivity to sunlight or artificial ultraviolet light. The scalp should be inspected for alopecia and the mouth and throat for ulcerations reflecting gastrointestinal involvement.

Cardiovascular assessment includes auscultation for pericardial friction rub, possibly associated with myocarditis and accompanying pleural effusions. The pleural effusions and infiltrations, which reflect respiratory insufficiency, are demonstrated by abnormal lung sounds. Papular, erythematous, and purpuric lesions developing on the fingertips, elbows, toes, and extensor surfaces of the forearms or lateral sides of the hand that may become necrotic suggest vascular involvement.

Joint swelling, tenderness, warmth, pain on movement, stiffness, and edema may be detected on physical examination. The joint involvement is often symmetric and similar to that found in RA.

The neurologic assessment is directed at identifying and describing any central nervous system changes. The patient and family members are asked about any behavioral changes, including manifestations of neurosis or psychosis. Signs of depression are noted, as are reports of seizures, chorea, or other central nervous system manifestations.

The antinuclear antibody (ANA) is positive in more than 95% of patients with SLE, indicating exceptional specificity (Aringer et al., 2019). Other laboratory tests include anti-DNA (antibody that develops against the patient's own DNA), anti-ds DNA (antibody against DNA that is highly specific to SLE, which helps differentiate it from drug-induced lupus), and anti-Sm (antibody against Sm, which is a specific protein found in the nucleus). Other blood work includes the CBC, which may reveal anemia, thrombocytopenia, leukocytosis, or leukopenia.

Medical Management

SLE can be life-threatening, but advances in its treatment have led to improved survival and reduced morbidity. Acute disease requires interventions directed at controlling increased disease activity or exacerbations that can involve any organ system. Disease activity is a composite of clinical and laboratory features that reflect active inflammation secondary to SLE. Management of the more chronic condition involves periodic monitoring and recognition of meaningful clinical changes requiring adjustments in therapy.

The goals of treatment include preventing progressive loss of organ function, reducing the likelihood of acute disease, minimizing disease-related disability, and preventing complications from therapy. Management of SLE involves regular monitoring to assess disease activity and therapeutic effectiveness.

Pharmacologic Therapy

The mainstay of SLE treatment is based on pain management and nonspecific immunosuppression. Therapy includes monoclonal antibodies, corticosteroids, antimalarial agents, NSAIDs, and immunosuppressive agents. Each of these medications has potentially serious side effects, including organ damage.

Belimumab is a monoclonal antibody that specifically recognizes and binds to BLyS. BLyS acts to stimulate B cells to produce antibodies against the body's own nuclei, which is an integral part of the disease process in SLE. Belimumab acts to render BLyS inactive, preventing it from binding to B-cell surfaces and stimulating B-cell activity. This action then halts the production of unnecessary antibodies and decreases disease activity in SLE. Live vaccines are contraindicated for 30 days before taking this medication (Comerford & Durkin, 2020). Rituximaub is an additional monoclonal antibody used in the treatment of SLE for its immune modulating effects (MacIsaac, Siddiqui, Jamula, et al., 2018).

Corticosteroids are another medication used topically for cutaneous manifestations, in low oral doses for minor disease activity, and in high doses for major disease activity. Intravenous (IV) administration of corticosteroids is an alternative to traditional high-dose oral administration. One of the most important risk factors associated with the use of corticosteroids in SLE is osteoporosis and fractures (Comerford & Durkin, 2020).

An antimalarial medication, hydroxychloroquine, is effective for managing cutaneous, musculoskeletal, and mild systemic features of SLE (Comerford & Durkin, 2020). The NSAIDs used for minor clinical manifestations are often used in conjunction with corticosteroids in an effort to minimize corticosteroid requirements.

Immunosuppressive agents (alkylating agents and purine analogues) are used because of their effect on overall immune function. These medications are generally reserved for patients who have serious forms of SLE that have not responded to conservative therapies. Examples include cyclophosphamide, azathioprine, mycophenolic acid, and methotrexate, which are contraindicated in pregnancy and have been used most frequently in SLE nephritis (Comerford & Durkin, 2020).

Nursing Management

Nursing care of the patient with SLE is based on the fundamental plan presented earlier in the chapter (see Chart 34-3). The most common nursing diagnoses include fatigue, impaired skin integrity, body image disturbance, and lack of knowledge for self-management decisions. The disease or its treatment may produce dramatic changes in appearance and considerable distress for the patient. The changes and the unpredictable course of SLE necessitate expert assessment skills and nursing care with sensitivity to the psychological reactions of the patient. The patient may benefit from participation in support groups, which can provide disease information, daily management tips, and social support. Because sun and ultraviolet light exposure can increase disease activity or cause an exacerbation, patients should be instructed to avoid exposure or to protect themselves with sunscreen and appropriate clothing.

Because of the increased risk of involvement of multiple organ systems, patients should understand the need for routine periodic screenings as well as health promotion activities. A dietary consultation may be indicated to ensure that the patient is knowledgeable about dietary recommendations, given the increased risk of cardiovascular disease, including hypertension and atherosclerosis.

In the healthy population, smoking and using electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars clearly poses health risks. Smoking increases the incidence of respiratory infections, lung cancer, risk of coronary artery disease; increases blood pressure, which can worsen kidney function; inhibits liver function (which can also inhibit treatment medications from working appropriately, such as hydroxychloroquine); increases the risk for skin diseases; and increases the risk for osteoporosis. The health risks of ENDS use is under investigation. Patients diagnosed with SLE are at even higher risk of developing lung cancer and other rare cancers. Therefore, smoking cessation programs should be offered to all patients who report smoking habits (Montes, Mocarzel, Lanzieri, et al., 2016).

The nurse educates the patient about the importance of continuing prescribed medications and addresses the changes and potential side effects that are likely to occur with their use. The patient is reminded of the importance of monitoring because of the increased risk of systemic involvement, including renal and cardiovascular effects.

Because of the immunosuppression associated with systemic corticosteroid usage, the nurse must watch for signs and symptoms of infection, especially with patients who are acutely ill.

The nurse should also screen the patient for osteoporosis, because long-term use of corticosteroids increases the incidence of osteoporosis. Patients should have a bone mineral density test performed at diagnosis and prior to beginning steroid use to determine a baseline status and then every 2 years thereafter. Educating the patient regarding calcium and vitamin D supplementation daily

is encouraged, along with the benefits of weight-bearing activities to support bone health.

Primary Sjögren's Syndrome

Primary Sjögren's syndrome is a rare systemic autoimmune disease that predominantly affects middle-aged women (Cornec, Devauchelle-Pensec, Mariette, et al., 2017).

Sjögren's syndrome often manifests in conjunction with other autoimmune diseases, most commonly autoimmune thyroid disease, RA, and SLE (MacIsaac et al., 2018; Molano-Gonzalez et al., 2019).

Pathophysiology

Primary Sjögren's is a multisystem disease characterized by lymphocytic infiltration leading to failure of the lacrimal and salivary glands (Cui, Li, Yin, et al., 2018).

Clinical Manifestations

The most common symptoms involve kerotoconjunctivitis sicca (dry eyes), xerostomia (dry mouth), pain, and fatigue (Cornec et al., 2017; Cui et al., 2018). Some patients will complain that their eyes feel "gritty," as if there is sand present. The patient's eyes will exhibit increased redness and lack of tearing. The mouth will have dry and sticky mucous membranes. The reduced saliva production may lead to difficulty swallowing.

Sjögren's syndrome can also exhibit symptoms in many other organ systems. Lesions may ulcerate and can be painful. Optic neuritis, trigeminal neuralgia, and sensory neuropathy may be present, with symptoms such as burning pain in the extremities, numbness, vertigo, arthralgia, and/or myalgia. Raynaud's phenomenon, which involves blood vessel spasms leading to decreased circulation to the toes, fingers, nose, and ears, may be reported. Patients experience symptoms of pain, fatigue, depression, and anxiety (Cui et al., 2018). Sleep disturbances are frequently reported and may be related to pain, fatigue, and depressive symptoms (Hackett, Gotts, Ellis, et al., 2017).

Assessment and Diagnostic Findings

The classification criteria for diagnosis of Sjögren's syndrome identify six distinct indices (Klippel, Stone, Crofford, et al., 2008):

- Ocular symptoms such as chronic dry eye (Kerotoconjunctivitis Sicca).

- Positive ocular tests (evaluating tear production, corneal, and conjunctival damage). Ocular testing may include Schemer tear test or Rose Bengal tests.
- Oral symptoms, dry mouth.
- Histopathology evaluation (of salivary glands). This will help differentiate the cause of dry mouth from other causes, such as infection, malignancy, stones, and sarcoidosis.
- Salivary gland involvement.

Laboratory tests include autoantibodies to ribonucleoprotein particles (Ro[SS-A] and/or La[SS-B]), which act as antigens in this disease process. Other laboratory indices are also useful in diagnosing Sjögren's syndrome. Rheumatoid factor is present in 50% to 70% of patients. ANA, circulating DNA (cDNA), anti-CCP, ACPA, and anticentromere antibody (ACA) are all potentially present in Sjögren's syndrome and in some cases may act as markers for disease activity (Molano-Gonzalez et al., 2019).

For vasculitis manifestations, a skin biopsy can yield useful information such as leukocytoclastic vasculitis found on histologic examination. If neurologic symptoms are present, nerve conduction studies, MRI, electroencephalograms, and cerebrospinal fluid testing may be used to aid in diagnosis and treatment planning.

Medical Management

There is no cure for Sjögren's syndrome, and treatment is aimed at symptom management and improving quality of life (Cornec et al., 2017; Cui et al., 2018; Hackett et al., 2017). Artificial tears, drops such as pilocarpine, and ocular ointments such as topical cyclosporine are used for dry eyes. Tears normally drain through the lacrimal puncta to the nose, which can render artificial tears ineffective. Therefore, punctum plugs may be a useful management tool. One systematic review reported that pilocarpine is highly effective in decreasing symptoms of dry mouth by increasing salivary flow (Hamad, Lodi, Porter, et al., 2018). Biotene oral rinse may also be useful for some patients. Additional suggestions include eating small frequent meals; omitting spicy, salty, and irritating food; and avoiding smoking (including ENDS), excessive alcohol use, and drugs with anticholinergic side effects. There is some evidence for the effectiveness of rituximab and interferone (Cornec et al., 2017; Hamad et al., 2018; MacIsaac et al., 2018). Patients need to be screened for depression and sleep disturbances, then appropriate referrals made when these comorbid conditions are present (Cui et al., 2018; Hackett et al., 2017).

Nursing Management

Nursing care is based on the fundamental plan of nursing care presented earlier (see Chart 34-3). The primary issues for the patient with Sjögren's syndrome are pain, fatigue, and inadequate knowledge of self-management techniques. The nurse is in the unique position to educate and reinforce the treatment regimen with the patient, especially involving the ocular treatments to avoid eye infections secondary to the dry eyes. The high prevalence of pain, fatigue, and depressive symptoms may interfere with the patient's ability to learn and engage in self-management techniques and should be addressed (Cui et al., 2018).

Scleroderma

Scleroderma is a rare autoimmune disease affecting the connective tissue of the skin, blood vessel walls, and internal organs. There are two general types: localized (affecting only the cutaneous system) or diffuse (routinely referred to as systemic sclerosis and affecting multiple organ systems). Similar to other autoimmune diseases, women are affected four times more than men, and the onset occurs typically between the ages of 25 and 50 years (Norris, 2019). Scleroderma has a variable course with remissions and exacerbations.

Pathophysiology

The pathogenesis is poorly understood. Scleroderma commonly begins with skin involvement. Mononuclear cells cluster on the skin and stimulate lymphokines to stimulate procollagen. Insoluble collagen is formed and accumulates excessively in the tissues (Norris, 2019). Initially, the inflammatory response causes edema, with a resulting taut, smooth, and shiny skin appearance. The skin then undergoes fibrotic changes, leading to loss of elasticity and movement. Eventually, the tissue degenerates and becomes nonfunctional. This chain of events, from inflammation to degeneration, also occurs in blood vessels, major organs, and body systems (Norris, 2019).

Clinical Manifestations

The skin and subcutaneous tissues become increasingly hard and rigid due to excess collagen and cannot be pinched up from the underlying structures. Wrinkles and lines are obliterated. The skin is dry because sweat secretion over the involved region is suppressed. The extremities stiffen and lose mobility. The condition spreads slowly; for years, these changes may remain localized in the hands and the feet. The face appears masklike, immobile, and expressionless, and the mouth becomes rigid; referred to as "stone facies" (Norris, 2019).

The changes within the body, although not visible directly, are vastly more important than the visible changes. The esophagus hardens, interfering with swallowing. The lungs become scarred, impeding respiration. Digestive disturbances occur because of sclerosing (hardening) of the intestinal mucosa. Vascular involvement of the kidneys leads to malignant hypertension and renal insufficiency. Cardiac disorders include pericarditis, heart block, and myocardial fibrosis (Norris, 2019).

The patient may manifest a variety of symptoms referred to as the CREST syndrome. *CREST* stands for *c*alcinosis (calcium deposits in the tissues), *R*aynaud's phenomenon, *e*sophageal dysmobility, *s*clerodactyly (scleroderma of the digits), and *t*elangiectasia (capillary dilation that forms a vascular lesion) (Norris, 2019).

Assessment and Diagnostic Findings

Assessment focuses on the sclerotic changes in the skin, contractures in the fingers, and color changes or lesions in the fingertips. Assessment of systemic involvement requires a systems review with special attention to gastrointestinal, pulmonary, renal, and cardiac symptoms. Limitations in mobility and self-care activities should be assessed, along with the impact the disease has had (or will have) on body image.

There is no one conclusive diagnostic test used to diagnose scleroderma. Generally, the patient is diagnosed with the CREST type of scleroderma if they have four of the five symptoms in the syndrome (Norris, 2019).

Medical Management

Treatment of scleroderma is mainly symptomatic and supportive. No medication regimen is effective in modifying the disease process in scleroderma, but various medications are used to treat organ system involvement. The use of angiotensin-converting enzyme inhibitors when there is kidney involvement has led to a substantial decrease in mortality from hypertensive kidney disease (Norris, 2019).

All patients require counseling, during which realistic individual goals may be determined. Support measures include strategies to decrease pain and limit disability. A moderate exercise program is encouraged to prevent joint contractures. Patients are advised to avoid extreme temperatures and to use lotion to minimize skin dryness.

Nursing Management

Nursing care of the patient with scleroderma is based on the fundamental plan of nursing care presented earlier (see Chart 34-3). The primary nursing

diagnoses are impaired skin integrity; self care deficits; impaired nutritional status; and disturbed body image. The patient with advanced disease may also have impaired gas exchange, impaired cardiac output, impaired swallowing, and constipation.

Providing meticulous skin care and preventing the effects of Raynaud's phenomenon are major nursing challenges. See Chapter 26 for further discussion of Raynaud's phenomenon.

Polymyositis

Polymyositis is a group of diseases that are termed *idiopathic inflammatory myopathies* (Klippel et al., 2008). They are rare chronic conditions, with an incidence estimated at 2 cases per 10,000 adults per year. Polymyositis is most commonly seen in women versus men (2:1) and usually seen between 40 and 50 years of age (Miller & Vleugels, 2019).

Pathophysiology

Polymyositis is classified as autoimmune because autoantibodies are present. However, these antibodies do not cause damage to muscle cells, indicating only an indirect role in tissue damage. The pathogenesis is multifactorial, including cellular and humoral immune mechanisms (Norris, 2019).

Clinical Manifestations

The onset may be very slow and insidious, with symptoms gradually worsening over weeks to months. Proximal muscle weakness is typically the first symptom. Muscle weakness is usually symmetric and diffuse. Common complaints include having difficulty rising from a chair, climbing steps, or holding up the head. Myalgia and muscle tenderness occur in 25% to 50% of patients. Dermatomyositis, a related condition, is most commonly identified by an erythematous smooth or scaly lesion found over the joint surface, which often occurs prior to symptoms of weakness in 50% to 60% of patients (Miller & Vleugels, 2019).

Assessment and Diagnostic Findings

A complete history and physical examination help exclude other muscle-related disorders. As with other diffuse connective tissue disorders, no single test confirms polymyositis. An electromyogram is performed to rule out degenerative muscle disease. A muscle biopsy may reveal inflammatory infiltrate in the tissue. Serum studies indicate increased muscle enzyme activity.

Medical Management

Corticosteroid therapy is the mainstay of medical management (Norris, 2019). IV immune globulin, plasmapheresis, lymphapheresis, and total-body irradiation have been used if there is no response to corticosteroids. The goal is to control inflammation and prevent long-term damage to muscles, joints, and internal organs (Norris, 2019). The antimalarial agent hydroxychloroquine may be effective for skin rashes. Physical therapy is initiated slowly, with range-of-motion exercises to maintain joint mobility, followed by gradual strengthening exercises (Klippel et al., 2008).

Nursing Management

Nursing care is based on the fundamental plan of nursing care presented earlier (see Chart 34-3). The primary nursing diagnoses for the patient with polymyositis are impaired mobility, fatigue, self care deficit, and lack of knowledge of self-management techniques.

Patients with polymyositis may have symptoms similar to those of other inflammatory diseases. However, proximal muscle weakness is characteristic, making activities such as combing the hair, reaching overhead, and using stairs difficult. Therefore, the use of assistive devices may be recommended, and referral to occupational or physical therapy may be warranted.

Polymyalgia Rheumatica and Giant Cell Arteritis

PMR involves stiffness of muscles and pain in the neck, shoulder, and pelvic girdle. GCA is a form of vasculitis affecting the medium-sized and large arteries of the body (Klippel et al., 2008). GCA is also sometimes referred to as temporal arteritis (Hill, Black, Nossent, et al., 2017). PMR and GCA represent a spectrum of one disease. Both primarily affect individuals older than 50 years and are associated with the same HLA haplotype genetic markers. PMR and GCA occur predominately in Caucasians and often in first-degree relatives. PMR has an annual incidence rate of 52 cases per 100,000 people older than 50 years. GCA varies by geographic location and has the highest incidence in Scandinavian countries. PMR is two to three times more common than GCA (Klippel et al., 2008).

Pathophysiology

The underlying mechanism of action involved with PMR and GCA is unknown. It is clear, however, that the immune system is abnormally activated in both disease processes with increases in circulating monocytes that produce IL-1 and IL-6. These circulating monocytes make the endothelial linings of

blood vessels more vulnerable to vasculitis (Klippel et al., 2008). Immunoglobulin deposits in the walls of inflamed temporal arteries suggest that an autoimmune process is at work.

Clinical Manifestations

PMR is characterized by severe proximal muscle discomfort with mild joint swelling. Severe aching in the neck, shoulder, and pelvic muscles is common. Stiffness is noticeable most often in the morning and after periods of inactivity. This stiffness can become so severe that patients struggle putting on a coat or combing their hair. Systemic features include low-grade fever, weight loss, malaise, anorexia, and depression. Because PMR usually occurs in people 50 years and older, it may be confused with, or dismissed as, an inevitable consequence of aging.

GCA may cause headaches, changes in vision, and jaw claudication. These symptoms should be evaluated immediately because of the potential for blindness and stroke if left untreated (Hill et al., 2017). PMR and GCA have a self-limited course, lasting several months to several years (Klippel et al., 2008).

Assessment and Diagnostic Findings

Assessment focuses on musculoskeletal tenderness, weakness, and decreased function. Careful attention should be directed toward assessing the head (for changes in vision, headaches, and jaw claudication). An MRI scan may be used in the assessment of extra-articular synovitis in patients with PMR, regardless of symptoms.

Often, diagnosis is difficult because of the lack of specificity of tests. A markedly high ESR is a screening test but is not definitive. The CRP level and platelet count also provide valuable data. In fact, simultaneous elevation in the ESR and CRP has a sensitivity of 98.6% and a specificity of 75.7% in making the diagnosis of GCA when coupled with clinical findings (Seetharaman, 2019). Diagnosis of both GCA and PMR is more likely to be made by eliminating other potential diagnoses. The dramatic and immediate response to treatment with corticosteroids is considered by some to be diagnostic.

In the case of GCA, biopsy of the temporal artery is the definitive diagnostic tool (Seetharaman, 2019). High-resolution MRI is an alternative or adjunct to the traditional temporal artery biopsy.

Medical Management

The treatment for patients with PMR (without GCA) is moderate doses of corticosteroids. Longer durations of corticosteroid treatment are required with

patients who have higher baseline inflammatory markers. Gradual tapering of the corticosteroid treatment should be monitored. NSAIDs are sometimes given in mild disease. The treatment for patients with GCA is rapid initiation of and strict adherence to a regimen of corticosteroids. This is essential to avoid the complication of blindness (Hill et al., 2017). Aspirin is an adjunctive treatment may help reduce the risk of visual loss.

Nursing Management

Nursing care of the patient with PMR is based on the fundamental plan of nursing care presented earlier (see Chart 34-3). The most common nursing diagnoses are pain and lack of knowledge of medications.

A management concern is that the patient will take the prescribed medication, frequently corticosteroids, until symptoms improve and then discontinue the medication. The decision to discontinue the medication should be based on clinical and laboratory findings and the prescription. Nursing implications are related to helping the patient prevent and monitor adverse effects of medications (e.g., infections, diabetes, gastrointestinal problems, and depression) and adjust to those side effects that cannot be prevented (e.g., increased appetite and altered body image).

Quality and Safety Nursing Alert

The nurse must emphasize to the patient the need for continued adherence to the prescribed medication regimen to avoid complications of GCA, such as blindness and stroke.

The loss of bone mass with corticosteroid use increases the risk of osteoporosis in this already at-risk population. Interventions to promote bone health, such as adequate dietary calcium and vitamin D, measurement of bone mineral density, weight-bearing exercise, smoking and ENDS cessation, and reduction of alcohol consumption if indicated, should be emphasized.

Spondyloarthropathies

The spondyloarthropathies are another category of systemic inflammatory disorders of the skeleton. The spondyloarthropathies include ankylosing spondylitis (AS), reactive arthritis (formerly known as Reiter's syndrome), and psoriatic arthritis. Spondyloarthritis is also associated with inflammatory bowel diseases such as Crohn's disease (regional enteritis) and ulcerative colitis (Norris, 2019).

These rheumatic diseases share several clinical features. The inflammation tends to occur peripherally at the sites of attachment—at tendons, joint capsules, and ligaments. Periosteal inflammation may be present. Many patients have arthritis of the sacroiliac joints. The onset tends to occur during young adulthood, with the disease affecting men more often than women. There is a strong tendency for these conditions to occur in families. Frequently, the HLA-B27 genetic marker is found. In addition, more than one of these conditions can be found simultaneously in the same person or another family member (Norris, 2019).

As with other inflammatory conditions, patients with spondyloarthropathies have an increased risk for cardiovascular disease. These findings may be related to a state of chronic systemic inflammation and an increase in traditional cardiac risk factors, such as lack of exercise due to increased pain (Norris, 2019).

Ankylosing Spondylitis

AS is a chronic inflammatory disease of the spine. It is more prevalent in males than in females and is usually diagnosed in the second or third decade of life. The disease is also more severe in males, and significant systemic involvement is likely (Norris, 2019).

AS affects the cartilaginous joints of the spine and surrounding tissues, making them rigid, decreasing mobility, and leading to kyphosis (a stooped position). This kyphosis can, in turn, lead to decreased stability and balance. Back pain is the characteristic feature. The back pain can be so severe that it may mask symptoms of a cervical fracture, which can lead to neurologic problems if left untreated. Occasionally, the large synovial joints, such as the hips, knees, or shoulders, may be involved (Norris, 2019).

AS also exhibits systemic effects as the heart and lungs become constricted in the chest cavity (Norris, 2019). Another potential complication of AS is the risk of osteoporosis, which appears to be related to the inflammatory process as well as bone turnover and low vitamin D levels. Other complications involve atrioventricular conduction defects, aortic insufficiency, and pulmonary fibrosis. As the disease progresses, ankylosis (i.e., fixation or immobility) of the entire spine may occur, leading to respiratory compromise and further complications.

Reactive Arthritis (Reiter's Syndrome)

The disease process involved in reactive arthritis is called *reactive* because the arthritis occurs after an infection, primarily gastrointestinal or genitourinary (Norris, 2019). It mostly affects young adult males and is characterized

primarily by urethritis, arthritis, and conjunctivitis. Dermatitis and ulcerations of the mouth and penis may also be present. Low back pain is common.

Psoriatic Arthritis

Psoriatic arthritis is an inflammatory arthritis associated with the skin disease psoriasis. Approximately 7% of people with psoriasis develop psoriatic arthritis (Norris, 2019). Psoriasis is the most common autoimmune disease in the United States, affecting 2% to 3% of the population. Psoriatic arthritis onset occurs between 30 and 50 years of age and affects equal numbers of men and women (Dewing, 2015). See Chapter 56 for more information on psoriasis.

Psoriatic arthritis is characterized by synovitis, polyarthritis, and spondylitis. Inflammatory back pain is a common symptom, which is differentiated from other back pain by symptoms of back pain presenting at a young age, pain improving with activity, and pain occurring at night. Radiographic evidence of asymetrical sacroilitis or spondylitis may also assist with diagnosing psoriatic arthritis (Dewing, 2015). Other sites of pain commonly seen in these patients are the Achilles tendon, plantar fascia, or tibial tuberosity areas. Pain in these areas is common from the inflammation that occurs at the entheses, where tendons and ligaments attach to the bone.

Medical Management

Medical management of spondyloarthropathies focuses on treating pain and maintaining mobility by suppressing inflammation. For the patient with AS, good body positioning and posture are essential so that if ankylosis does occur, the patient is in the most functional position. Maintaining range of motion with regular exercise and a muscle-strengthening program is especially important and has been linked with higher quality of life for patients.

Pharmacologic Management

NSAIDs are the first-line therapy for treating all spondylarthropathies. All chronic conditions (cardiac, renal, and gastrointestinal) should be taken into consideration when prescribing long-term NSAIDs. Methotrexate, sulfasalazine, and leflunomide may also be used; these drugs may help with skin and peripheral joint disease but may not prevent spinal changes. Corticosteroid injections may be used for periodic flares; however, oral and long-term use of steroids is not recommended due to the possibility of psoriatic skin flare when discontinuing use.

Disease remission is now the target for psoriatic arthritis (Mease & Coates, 2018). Anti-TNF medications that have been used effectively include etanercept, infliximab, adalimumab, golimumab, and certolizumabpegol.

Additional agents include apremilast, which is a PDE4 inhibitor, and ustekinumab, an anti-IL12/anti-IL23 agent (Mease & Coates, 2018).

Surgical Management

With advanced AS and subsequent debilitating kyphosis, an osteotomy of the spine can be done. One study showed that an average correction of 45 degrees in the cervical spine was obtained and that quality of life also improved. Surgical management may also include total joint replacement (see Chapter 36).

Nursing Management

Major nursing interventions in the spondyloarthropathies are related to symptom management and maintenance of optimal functioning. Affected patients are primarily young men. Their major concerns are often related to prognosis and job modification, especially among those who perform physical work. Patients may also express concerns about leisure and recreational activities. Focusing on physical activity and staying active and maintaining good posture will help to prevent chronic changes that may lead to deformities. It is important to address psychological changes, such as depression and emotional stress, that can occur with the diagnosis and chronic nature of the disease. If symptoms are present, the primary provider should assess for emotional stress and treat as appropriate.

Metabolic and Endocrine Diseases Associated with Rheumatic Disorders

Metabolic and endocrine diseases may be associated with rheumatic disorders. These include biochemical abnormalities (amyloidosis and scurvy), endocrine diseases (diabetes and acromegaly), immune deficiency diseases (human immune deficiency virus infection, acquired immune deficiency syndrome), and some inherited disorders (hypermobility syndromes). However, the most common conditions are the crystal-induced arthropathies, in which crystals such as monosodium urate (gout) or calcium pyrophosphate (calcium pyrophosphate dihydrate disease or pseudogout) are deposited within joints and other tissues (Norris, 2019).

Gout

Gout is the most common form of inflammatory arthritis. More than 8.3 million Americans self-report the diagnosis of gout (CDC, 2019). The prevalence is reported to be about 3.9% and appears to be on the rise. Men are

three to four times more likely to be diagnosed with gout than women. The incidence of gout increases with age, body mass index, alcohol consumption, hypertension, and diuretic use (CDC, 2019). Evidence links the consumption of fructose-rich beverages with the risk of gout for both men and women (CDC, 2019). Patients with gout have an increased risk of cardiovascular disease. Comorbid conditions such as hypertension, dyslipidemia, diabetes, osteoarthritis, kidney disease, and depression may be present in patients with gout (Lin, Zhang, & Ma, 2018; Norris, 2019).

Pathophysiology

Gout is caused by hyperuricemia (increased serum uric acid). Uric acid is a by-product of purine metabolism; purines are basic chemical compounds found in high concentrations in meat products. Urate levels are affected by diet, medications, overproduction in the body, and inadequate excretion by the kidneys. Hyperuricemia (serum concentration greater than 6.8 mg/dL) can, but does not always, cause urate crystal deposition. However, as uric acid levels increase, the risk becomes greater. The initial cause for the gout attack occurs when macrophages in the joint space phagocytize urate crystals. Through a series of immunologic steps, interleukin-1β is secreted, increasing the inflammation. This process is exacerbated by the presence of free fatty acids. Both alcohol and consumption of a large meal, especially with red meat, can lead to increases in free fatty acid concentrations; they also are implicated as triggers to acute gout attacks (Norris, 2019).

With repeated attacks, accumulations of sodium urate crystals, called tophi, are deposited in peripheral areas of the body, such as the great toe, the hands, and the ear. Renal uratelithiasis (kidney stones), with chronic kidney disease secondary to urate deposition, may develop.

Primary hyperuricemia may be caused by severe dieting or starvation, excessive intake of foods that are high in purines (shellfish, organ meats), or heredity. In secondary hyperuricemia, gout is a clinical feature secondary to any of a number of genetic or acquired processes, including conditions in which there is an increase in cell turnover (leukemia, multiple myeloma, some types of anemias, psoriasis) and an increase in cell breakdown. Altered renal tubular function, either as a major action or as an unintended side effect of certain pharmacologic agents (e.g., diuretics such as thiazides and furosemide), low-dose salicylates, or ethanol can contribute to uric acid underexcretion (Klippel et al., 2008). The finding of urate crystals in the synovial fluid of asymptomatic joints suggests that factors other than crystals may be related to the inflammatory reaction. Recovered monosodium urate crystals are coated with immunoglobulins that are mainly IgG. IgG enhances crystal phagocytosis, thereby demonstrating immunologic activity (Klippel et al., 2008).

Clinical Manifestations

Manifestations of the gout syndrome include acute gouty arthritis (recurrent attacks of severe articular and periarticular inflammation), **tophi** (crystalline deposits accumulating in articular tissue, osseous tissue, soft tissue, and cartilage), gouty nephropathy (renal impairment), and uric acid urinary calculi. Four stages of gout can be identified: asymptomatic hyperuricemia, acute gouty arthritis, intercritical gout, and chronic tophaceous gout (Neoai, Jansen, Dalbeth, et al., 2015). The subsequent development of gout is directly related to the duration and magnitude of the hyperuricemia. Therefore, the commitment to lifelong pharmacologic treatment of hyperuricemia is deferred until there is an initial attack of gout.

Acute arthritis is the most common early clinical manifestation. The metatarsophalangeal joint of the big toe is a commonly affected joint. The tarsal area, ankle, or knee may also be affected. Less commonly, the wrists, fingers, and elbows may be affected. Trauma, alcohol ingestion, dieting, medications, surgical stress, or illness may trigger the acute attack. The abrupt onset often occurs at night, awakening the patient with severe pain, redness, swelling, and warmth of the affected joint. Early attacks tend to subside spontaneously over 3 to 10 days without treatment. The attack is followed by a symptom-free period (the intercritical stage) until the next attack, which may not come for months or years. However, with time, attacks tend to occur more frequently, involve more joints, and last longer (Becker & Gaffo, 2019).

Tophi (seen in chronic tophaceous gout) are generally associated with more frequent and severe inflammatory episodes. Higher serum concentrations of uric acid are also associated with more extensive tophus formation. Tophi most commonly occur in the synovium, olecranon bursa, **subchondral bone** (bony plate that supports the articular cartilage), infrapatellar and Achilles tendons, and subcutaneous tissue on the extensor surface of the forearms and overlying joints. They have also been found in the aortic walls, heart valves, nasal and ear cartilage, eyelids, cornea, and sclera. Joint enlargement may cause a loss of joint motion. Uric acid deposits may cause renal stones and kidney damage.

Medical Management

Given that the incidence of gout increases with age, its management can be complicated by other medical conditions, medications, and age-related changes. A definitive diagnosis of gouty arthritis is established by polarized light microscopy of the synovial fluid of the involved joint. Uric acid crystals are seen within the polymorphonuclear leukocytes in the fluid during a disease flare up (CDC, 2019).

Acute attacks are managed with colchicine (oral or parenteral), an NSAID such as indomethacin, or a corticosteroid. Management of hyperuricemia,

tophi, joint destruction, and renal disorders is usually initiated after the acute inflammatory process has subsided. Once the acute attack has subsided, uric acid lowering therapy should be considered. Xanthine oxidase inhibitors, such as allopurinol and febuxostat, are the agents of choice. Given the role of IL-1 in the pathogenesis of gout, some experts suggest that there may be a role for anakinra, an IL-1 receptor antagonist in the management of acute gout (Becker & Perez-Ruiz, 2019).

Management between gout attacks needs to include lifestyle changes such as avoiding purine-rich foods, weight loss, decreasing alcohol consumption, and avoiding certain medications. Uricosuric agents, such as probenecid, may be indicated in patients with frequent acute attacks. Uricosuric medications correct hyperuricemia and dissolve deposited urate. Corticosteroids may also be used in patients who have no response to other therapy. In patients with refractory chronic gout who are not controlled with the regimens mentioned earlier, pegloticase, a newer agent, has been shown to be effective in lowering uric acid levels (Becker & Perez-Ruiz, 2019). Specific treatment is based on the serum uric acid level, 24-hour urinary uric acid excretion, and renal function (see Table 34-4).

TABLE 34-4 Common Medications Used to Treat Gout

Medication	Actions and Use	Nursing Implications
colchicine	Lowers the deposition of uric acid and interferes with leukocyte infiltration, thus reducing inflammation; does not alter serum or urine levels of uric acid; used in acute and chronic management	*Acute management:* Administer when attack begins; dosage increased until pain is relieved or diarrhea develops, then stop medication *Chronic management:* Causes gastrointestinal upset in most patients.
probenecid	Uricosuric agent; inhibits renal reabsorption of urates and increases the urinary excretion of uric acid; prevents tophi formation	Be alert for nausea and rash.
allopurinol, febuxostat	Xanthine oxidase inhibitors; interrupt the breakdown of purines before uric acid is formed; inhibit xanthinoxidase because uric acid formation is blocked	Monitor for side effects, including bone marrow depression, nausea, vomiting, diarrhea, abdominal pain, or rash. Avoid starting medication or increasing dose if active flare present.

Nursing Management

Research indicates that providers overestimate patient knowledge of gout and that patients prefer the use of both written and verbal materials (Abhishek & Doherty, 2018). Therefore, the nurse takes every opportunity to educate and reinforce knowledge of gout verbally and in writing. Severe dietary restriction is not necessary; however, the nurse encourages the patient to restrict consumption of foods high in purines, especially organ meats, and to limit alcohol intake. Maintenance of normal body weight should be encouraged. In an acute episode of gouty arthritis, pain management with prescribed medications is essential, along with avoidance of factors that increase pain and inflammation, such as trauma, stress, and alcohol. Medication adherence is critical but poor among patients prescribed urate lowering therapies (Scheepers, van Onna, Stehouwer, et al., 2018). The nurse reinforces the importance of taking prescribed medications. Between acute episodes, the patient feels well and may abandon medications and preventive behaviors, which may result in an acute attack. Acute attacks are most effectively treated if therapy begins early.

Fibromyalgia

Fibromyalgia is a chronic pain syndrome that involves chronic fatigue, generalized muscle aching, stiffness, sleep disturbances, and functional impairment. It is estimated to affect more than 5 million Americans, representing 2% to 5% of the general population, with women affected more than men. Between 25% and 65% of patients with fibromyalgia have other rheumatic conditions such as RA, SLE, and AS (CDC, 2017).

Pathophysiology

The amplified pain experienced by patients with fibromyalgia is thought to be neurogenic in origin. The central nervous system's ascending and descending pathways that regulate and moderate pain processing function abnormally, causing amplification of pain signals. Some describe this as if the "volume control setting" for pain were abnormally high. Therefore, stimulation that may not normally elicit pain, such as touch, may do so. In addition, there are a number of predisposing factors to pain, including anxiety, depression, physical trauma, emotional stress, sleep disorder, and viral infection (CDC, 2017; Melin, Svensson, & Thulesius, 2018).

Assessment and Diagnostic Findings

Since fibromyalgia is a diffuse syndrome, standard diagnostic testing is often not useful except to rule out other conditions that may be causing the pain.

One study reported that two items, pain upon pinching the Achilles tendon using 4 kg of pressure for 4 seconds and an affirmative answer to the statement "I have a persistent deep aching all over my body," were the most useful in recognizing fibromyalgia (Jones, Aebischer, St John, et al., 2017). Positive responses to these screening items need to be followed by a comprehensive examination for confirmation of a diagnosis (Jones et al., 2017).

Medical Management

Treatment consists of attention to the specific symptoms reported by the patient. NSAIDs may be used to treat the diffuse muscle aching and stiffness. Tricyclic antidepressants such as amitriptyline and nortriptyline as well as sleep hygiene measures are used to improve or restore normal sleep patterns (CDC, 2017). Muscle relaxants such as cyclobenzaprine may also be used to help with relaxation and pain. Cognitive behavioral therapy is also useful in improving sleep and attentional dysfunction. In addition, serotonin norepinephrine reuptake inhibitors, such as duloxetine, venlafaxine, and milnacipran; selective serotonin reuptake inhibitors, including fluoxetine, paroxetine, and sertraline; as well as anticonvulsants such as gabapentin and pregabalin may be effective. Individualized programs of exercise are used to decrease muscle weakness and discomfort and to improve the general deconditioning that occurs in affected patients. There has been some promising research in complementary, alternative, and integrative health therapies, such as acupuncture (Kim, Kim, Lee, et al., 2019).

Nursing Management

Typically, patients with fibromyalgia have endured their symptoms for a long period of time. They may feel as if their symptoms have not been taken seriously. Nurses need to pay special attention to supporting these patients and providing encouragement as they begin their program of therapy. Patient support groups may be helpful (Melin et al., 2018). Careful listening to patients' descriptions of their concerns and symptoms is essential to help them make the changes that are necessary to improve their quality of life.

Miscellaneous Disorders

The last category in the classification of the rheumatic diseases is aptly labeled miscellaneous disorders because it contains a mix of disorders that are frequently associated with arthritis and other conditions. These include the direct consequences of trauma (including internal derangement and loose bodies of joints), pancreatic disease (related to avascular necrosis or

osteonecrosis), sarcoidosis (a multisystem disorder particularly of the lymph nodes and lungs), and palindromic rheumatism (an uncommon variety of recurring and acute arthritis and periarthritis that in some may progress to RA but is characterized by symptom-free periods of days to months). Other conditions include villonodular synovitis, chronic active hepatitis, and drug-related rheumatic syndromes. The nursing interventions related to these varied conditions are specific to the multisystemic problems experienced by the patient. However, the musculoskeletal components should not be neglected or overlooked. Further information about these rare disorders can be found in specialty references.

CRITICAL THINKING EXERCISES

1 pq Your patient, a 52-year-old male with RA, is being discharged from the medical surgical unit where you work. He smokes 1 pack of cigarettes a day and drinks alcohol on occasion. He is 6′0″ and weighs 240 lb. Identify the priorities, approach, and techniques you would use to provide discharge education to this patient. What lifestyle modifications are a priority for this patient?

2 ipc A 28-year-old patient who was recently diagnosed with SLE comes to the clinic where you work for a follow-up appointment. She tells you that she is planning to become pregnant soon. What additional members of the health care team should be included in the care of this patient given her childbearing plans?

3 ebp You are the nurse taking care of a woman newly diagnosed with fibromyalgia. What is the evidence for symptom management for this patient? What criteria would you use to assess the strength of the evidence? What is the evidence for complementary therapy options to improve her symptoms?

UNIT 8 Musculoskeletal Function

Case Study

IMPLEMENTING EVIDENCE-BASED PRACTICE IN PAIN MANAGEMENT

You are a nurse working on an orthopedic unit caring for a 76-year-old female with osteoporosis who had fallen at home and underwent a right hip replacement. She is 2 days postoperative,

recovering from her surgery without complications, and you are discussing plans for her transition to a skilled rehabilitation unit. However, the patient does not want to get out of bed and participate in physical or occupational therapy because she is in pain. Despite having spoken with the pain team, she states she does not want to take any medications that may cause her to become addicted. You need to develop an evidence-based plan of care that implements pharmacologic and nonpharmacologic strategies for pain management so the patient is able to participate in her physical and occupational therapies and thus help facilitate her recovery.

QSEN Competency Focus: **Evidence-Based Practice (EBP)**

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Evidence-Based Practice Definition: Integrate best current evidence with clinical expertise and patient/family preferences and values for delivery of optimal health care.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Explain the role of evidence in determining best clinical practice	Differentiate between evidence-based guidelines in managing acute postoperative pain verses chronic osteoporosis pain. Evidence-based practice guidelines include adherence to pharmacologic and nonpharmacologic interventions to promote recovery after surgery. How does managing the patient's pain reduce postoperative complications, including risk for blood clot, pneumonia, and gastric complications?
Skills	
Locate evidence reports related to clinical practice topics and guidelines	What additional strategies might you use to educate this patient on controlling acute postoperative pain? Differentiate between the various types of pain medications, including opioid and nonopioid analgesics, that are used to decrease pain. Evidence-based pain management includes the use of pain scales. Which scale would be the best to evaluate this patient's pain?
Attitudes	
Value the need for continuous improvement in clinical practice based on new knowledge	Reflect on your attitudes toward patients who are prescribed opioid medications postoperatively for pain control. Because this patient may have chronic pain due to her osteoporosis, how can your approach regarding acute and chronic pain management reflect evidence-based practice guidelines?

35 Assessment of Musculoskeletal Function

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the basic structure and function of the musculoskeletal system.
2. Discuss the significance of the health history to the assessment of musculoskeletal health.
3. Recognize and evaluate the major manifestations of musculoskeletal dysfunction by applying concepts from the patient's health history and physical assessment findings.
4. Explain clinical indications, patient preparation, and other related nursing implications for common tests and procedures used to assess musculoskeletal function.

NURSING CONCEPTS

Assessment
Mobility

GLOSSARY

atonic: without tone; denervated muscle that atrophies

atrophy: decrease in the size of a muscle

bursa: fluid-filled sac found in connective tissue, usually in the area of joints

callus: cartilaginous/fibrous tissue at fracture site

cancellous bone: latticelike bone structure; trabecular bone

cartilage: tough, elastic, avascular tissue at ends of bone

clonus: rhythmic contractions of a muscle

contracture: abnormal shortening of muscle, joint, or both; fibrosis

cortical bone: compact bone

crepitus: grating or crackling sound or sensation; may occur with movement of ends of a broken bone or irregular joint surface

diaphysis: shaft of long bone

effusion: excess fluid in joint

endosteum: a thin, vascular membrane covering the marrow cavity of long bones and the spaces in cancellous bone

epiphysis: end of long bone

fascia: fibrous tissue that covers, supports, and separates muscles (*synonym:* epimysium)

fasciculation: involuntary twitch of muscle fibers

flaccid: limp; without muscle tone

hypertrophy: enlargement; increase in the size of a muscle

isometric contraction: muscle tension is increased without changing its length; there is no associated joint motion

isotonic contraction: muscle is shortened without a change in its tension; a joint is moved as a result

joint: area where bone ends meet; provides for motion and flexibility

joint capsule: fibrous tissue that encloses bone ends and other joint surfaces

kyphosis: increase in the convex curvature of the thoracic spine

lamellae: mature compact bone structures that form concentric rings of bone matrix; lamellar bone

ligament: ropelike bundles of collagen fibrils connecting bones

lordosis: increase in concave curvature of the lumbar spine

ossification: process in which minerals (calcium) are deposited in bone matrix

osteoblast: bone-forming cell

osteoclast: bone resorption cell

osteocyte: mature bone cell

osteogenesis: bone formation
osteon: microscopic functional bone unit
osteopenic: refers to a reduction in bone mass to below-normal levels
paresthesia: abnormal sensation (e.g., burning, tingling, numbness)
periosteum: fibrous connective tissue covering bone
remodeling: process that ensures bone maintenance through simultaneous bone resorption and formation
resorption: removal/destruction of tissue, such as bone
scoliosis: lateral curving of the spine
spastic: having greater-than-normal muscle tone
synovium: membrane in joint that secretes lubricating fluid
tendon: cord of fibrous tissue connecting muscle to bone
tone: normal tension (resistance to stretch) in resting muscle (*synonym:* tonus)
trabeculae: latticelike bone structure; cancellous bone

The musculoskeletal system is composed of the bones, joints, muscles, tendons, ligaments, and bursae of the body. The major functions of this system are to support and protect the body and foster movement of the extremities. The components of this system are highly integrated; therefore, disease in or injury to one component adversely affects the others. For instance, an infection in a joint (e.g., septic arthritis) causes degeneration of the articular surfaces of the bones within the joint and local muscle atrophy.

Musculoskeletal disorders and injuries directly affect the quality of life of individuals and are a leading cause of disability in the United States. The annual cost to treat these conditions is estimated to be over $980 billion for direct costs as well as indirect costs, such as lost wages from loss of work time (United States Bone and Joint Initiative [USBJI], 2018). Arthritis is the chief cause of musculoskeletal-related disability in the United States, with an estimated 54.4 million adults diagnosed with this disorder. Because the incidence of arthritis increases with age, the number of adults with arthritis is expected to increase to 78 million by 2040 (Centers for Disease Control and Prevention [CDC], 2019). Nurses in all practice areas may encounter patients with complaints about or impairment of the musculoskeletal system.

Anatomic and Physiologic Overview

The musculoskeletal system provides protection for vital organs, including the brain, heart, and lungs; serves as a framework to support body structures; and makes mobility possible. Muscles and tendons hold the bones together, and joints allow the body to move. They also move to produce heat that helps

maintain body temperature. Movement facilitates the return of deoxygenated blood to the right side of the heart by massaging the venous vasculature. The musculoskeletal system serves as a reservoir for immature blood cells and essential minerals, including calcium, phosphorus, magnesium, and fluoride (Norris, 2019). More than 98% of total-body calcium is present in bone (National Institutes of Health [NIH], 2019a).

Structure and Function of the Skeletal System

There are 206 bones in the human body, divided into four categories classified by their shape: long, short, flat, and irregular. The long bones are found in the upper and lower extremities (e.g., the femur). Long bones are shaped like rods or shafts with rounded ends (Fig. 35-1). The shaft, known as the **diaphysis**, is primarily **cortical bone** (compact bone). The ends of the long bones, called **epiphyses**, are primarily **cancellous bone** (trabecular bone). During childhood and adolescence, there is a layer of cartilage known as the epiphyseal plate, or growth plate, that separates the epiphysis from the diaphysis. The epiphyseal plate nurtures and facilitates longitudinal growth. The epiphyseal plate is calcified in adults. The ends of long bones are covered at the joints by articular **cartilage**, which is tough, elastic, and avascular tissue (Norris, 2019).

The short bones are the irregularly shaped bones located in the ankle and hand (e.g., metacarpals). The flat bones are located where extensive protection of underlying structures is needed (e.g., the sternum or skull). Finally, because of their shape, the irregular bones cannot be categorized in any other group and include bones such as the vertebrae and bones of the jaw.

The shape and construction of a specific bone are determined by its function and the forces exerted on it. Bones are constructed of cortical or cancellous bone tissue. Cortical bone exists in areas where support is needed, and cancellous bone is found where hematopoiesis and bone formation occur. For example, long bones are designed for weight bearing and movement and tend to be composed primarily of cortical bone, whereas flat bones, which are important sites of hematopoiesis and frequently protect vital organs, are made of cancellous bone layered between compact bone. Short bones consist of cancellous bone covered by a layer of cortical bone. Irregular bones have unique shapes related to their function. Generally, irregular bone structure is similar to that of flat bones (Norris, 2019).

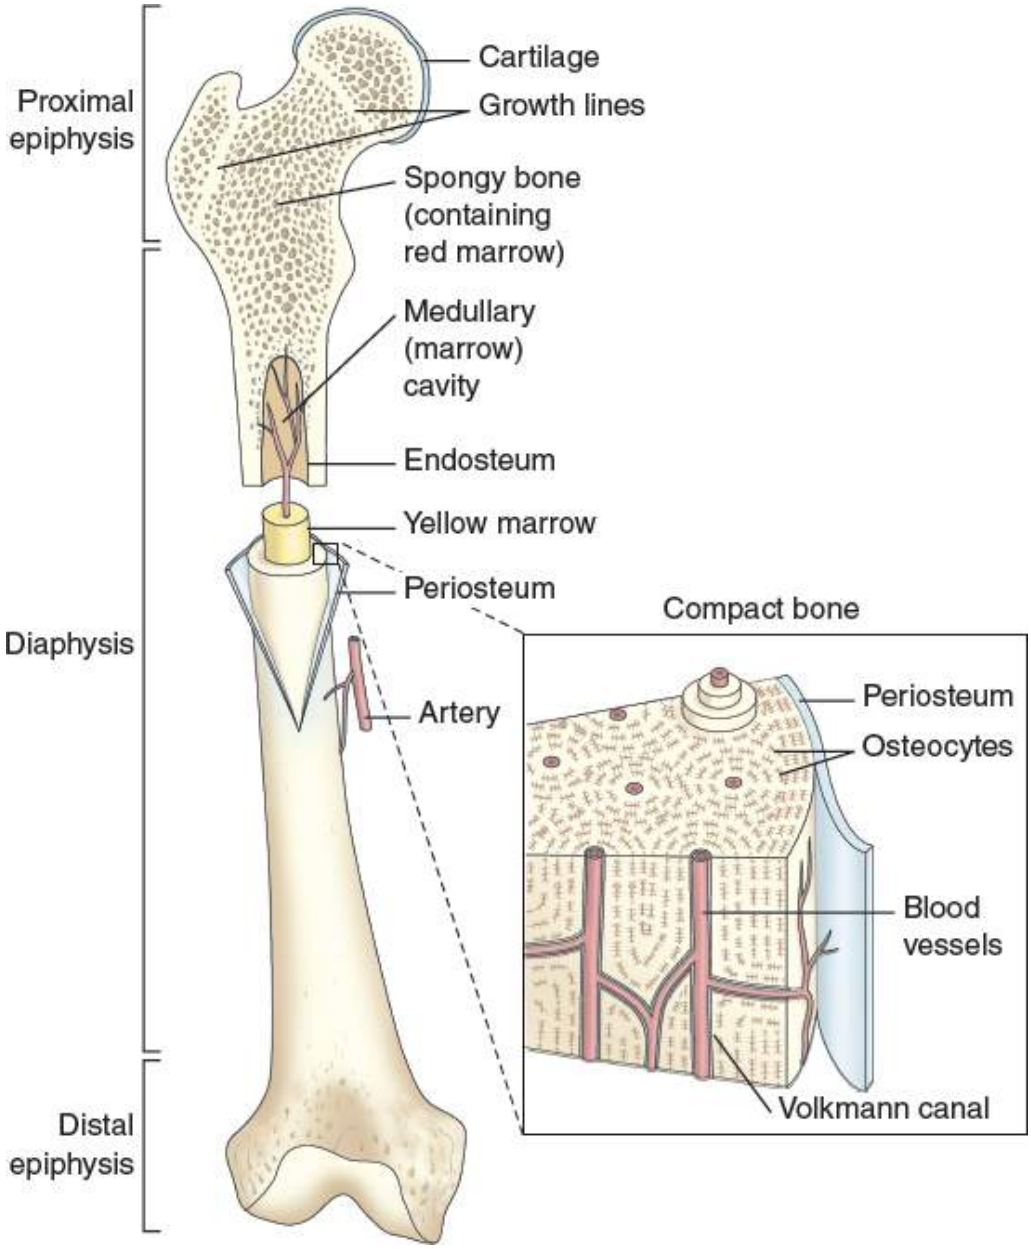

Figure 35-1 • Structure of a long bone; composition of compact bone.

Bone is composed of cells, protein matrix, and mineral deposits. The cells are of three basic types—osteoblasts, osteocytes, and osteoclasts. **Osteoblasts** function in bone formation by secreting bone matrix. The matrix consists of collagen and ground substances (glycoproteins and proteoglycans) that provide a framework in which inorganic mineral salts are deposited. These minerals are primarily composed of calcium and phosphorus. **Osteocytes** are mature bone cells involved in bone maintenance; they are located in lacunae (bone matrix units). **Osteoclasts**, located in shallow Howship's lacunae (small pits in bones), are multinuclear cells involved in dissolving and resorbing bone. The microscopic functioning unit of mature cortical bone is the **osteon**, or

haversian system. The center of the osteon—the haversian canal—contains a capillary. Around the capillary are circles of mineralized bone matrix called **lamellae**. Within the lamellae are lacunae that contain osteocytes. These are nourished through tiny structures called *canaliculi* (canals), which communicate with adjacent blood vessels within the haversian system. Lacunae in cancellous bone are layered in an irregular lattice network known as **trabeculae**. Red bone marrow fills the lattice network. Capillaries nourish the osteocytes located in the lacunae (Norris, 2019).

Covering the bone is a dense, fibrous membrane known as the **periosteum**. This membranous structure nourishes bone and facilitates its growth. The periosteum contains nerves, blood vessels, and lymphatics. It also provides for the attachment of tendons and ligaments (Norris, 2019).

The **endosteum** is a thin, vascular membrane that covers the marrow cavity of long bones and the spaces in cancellous bone. Osteoclasts, which dissolve bone matrix to maintain the marrow cavity, are located near the endosteum in Howship's lacunae (Norris, 2019).

Bone marrow is a vascular tissue located in the medullary cavity (shaft) of long bones and in flat bones. Red bone marrow, located mainly in the sternum, ilium, vertebrae, and ribs in adults, is responsible for producing red blood cells, white blood cells, and platelets through a process called *hematopoiesis.* In adults, the long bone is filled with fatty, yellow marrow (Norris, 2019).

Bone tissue is well vascularized. Cancellous bone receives a rich blood supply through metaphyseal and epiphyseal vessels. Periosteal vessels carry blood to compact bone through minute Volkmann canals. In addition, nutrient arteries penetrate the periosteum and enter the medullary cavity through foramina (small openings). Arteries supply blood to the marrow and bone. The venous system may accompany arteries or may exit independently (Norris, 2019).

Bone Formation

Osteogenesis (bone formation) begins before birth. **Ossification** is the process by which the bone matrix is formed and hard mineral crystals composed of calcium and phosphorus (e.g., hydroxyapatite) are bound to the collagen fibers. These mineral components give bone its characteristic strength, whereas the proteinaceous collagen gives bone its resilience (Norris, 2019).

Bone Maintenance

Bone is a dynamic tissue in a constant state of turnover. Throughout the lifespan, a process known as bone **remodeling** occurs, in which old bone is removed and new bone is added to the skeleton (formation). During childhood and the teenage years, new bone is added faster than old bone is removed; therefore, bones become larger, heavier, and denser. This continues until peak

bone mass is reached, typically by age 20 years. Remodeling maintains bone structure and function through simultaneous resorption and osteogenesis, and as a result, complete skeletal turnover occurs every 10 years (Norris, 2019).

The balance between bone **resorption** (removal or destruction) and formation is influenced by the following factors: physical activity; dietary intake of certain nutrients, especially calcium; and several hormones, including calcitriol (i.e., activated vitamin D), parathyroid hormone (PTH), calcitonin, thyroid hormone, cortisol, growth hormone, and the sex hormones estrogen and testosterone (Norris, 2019).

Physical activity, particularly weight-bearing activity, acts to stimulate bone formation and remodeling. Bones subjected to continued weight bearing tend to be thick and strong. Conversely, people who are unable to engage in regular weight-bearing activities, such as those on prolonged bed rest or those with some physical disabilities, have increased bone resorption from calcium loss, and their bones become **osteopenic** (reduced in terms of mass) and weak. These weakened bones may fracture easily (Meiner & Yeager, 2019).

Good dietary habits are integral to bone health. Daily intake of approximately 1000 to 1200 mg of calcium is essential to maintaining adult bone mass. Quality sources of calcium include low-fat milk, yogurt, and cheese. Foods with added calcium such as orange juice, cereals, and bread are also beneficial (NIH, 2019a). Vitamin D also plays a major role in calcium absorption and bone health. Young adults need a daily vitamin D intake of 600 IU, whereas adults 50 years and older require a daily intake of 800 to 1000 IU to ensure good bone health (NIH, 2019b). Dietary sources of vitamin D include vitamin D–fortified milk and cereals, egg yolks, saltwater fish, and liver.

Several hormones are vital in ensuring that calcium is properly absorbed and available for bone mineralization and matrix formation. Calcitriol functions to increase the amount of calcium in the blood by promoting absorption of calcium from the gastrointestinal tract. It also facilitates mineralization of osteoid tissue. A deficiency of vitamin D results in bone mineralization deficit, deformity, and fracture (Norris, 2019).

PTH and calcitonin are the major hormonal regulators of calcium homeostasis. PTH regulates the concentration of calcium in the blood, in part by promoting movement of calcium from the bone. In response to low calcium levels in the blood, increased levels of PTH prompt the mobilization of calcium, the demineralization of bone, and the formation of bone cysts. Calcitonin, secreted by the thyroid gland in response to elevated blood calcium levels, inhibits bone resorption and increases the deposit of calcium in bone (Norris, 2019).

Both thyroid hormone and cortisol have multiple systemic effects with specific effects on bones. Excessive thyroid hormone production in adults (e.g., Graves' disease) can result in increased bone resorption and decreased

bone formation. Increased levels of cortisol have these same effects. Patients receiving long-term synthetic cortisol or corticosteroids (e.g., prednisone) are at increased risk for steroid-induced osteopenia and fractures.

Growth hormone has direct and indirect effects on skeletal growth and remodeling. It stimulates the liver and, to a lesser degree, the bones to produce insulinlike growth factor 1 (IGF-I), which accelerates bone modeling in children and adolescents. Growth hormone also directly stimulates skeletal growth in children and adolescents. It is believed that the low levels of both growth hormone and IGF-I that occur with aging may be partly responsible for decreased bone formation and resultant osteopenia (Norris, 2019).

The sex hormones testosterone and estrogen have important effects on bone remodeling. Estrogen stimulates osteoblasts and inhibits osteoclasts; therefore, bone formation is enhanced and resorption is inhibited. Testosterone has both direct and indirect effects on bone growth and formation. It directly causes skeletal growth in adolescence and has continued effects on skeletal muscle growth throughout the lifespan. Increased muscle mass results in greater weight-bearing stress on bones, resulting in increased bone formation. In addition, testosterone converts to estrogen in adipose tissue, providing an additional source of bone-preserving estrogen for aging men (Kennedy-Malone, Martin-Plank, & Duffy, 2019).

During the process of bone remodeling, osteoblasts produce a receptor for activated nuclear factor-kappa B ligand (RANKL) that binds to the receptor for activated nuclear factor-kappa B (RANK) present on the cell membranes of osteoclast precursors, causing them to differentiate and mature into osteoclasts, which causes bone resorption. Conversely, osteoblasts may produce osteoprotegerin (OPG), which blocks the effects of RANKL, thereby turning off the process of bone resorption. T cells that may become activated as a result of the inflammatory process may also produce RANKL, overriding the effects of OPG and causing continued bone resorption during times of stress and injury, which can lead to loss of bone matrix and fractures (Takeno, Kanazawa, Notsu, et al., 2018).

Blood supply to the bone also affects bone formation. With diminished blood supply or hyperemia (congestion), osteogenesis, and bone density decrease. Bone necrosis occurs when the bone is deprived of blood (Norris, 2019).

Bone Healing

Most fractures heal through a combination of intramembranous and endochondral ossification processes. When a bone is fractured, the bone begins a healing process to reestablish continuity and strength. The bone fragments are not patched together with scar tissue; instead, the bone regenerates itself.

Fracture healing occurs in the bone marrow, where endothelial cells rapidly differentiate into osteoblasts; in the bone cortex, where new osteons are
