This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things,

conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

shop.lww.com

To our fellow nurses who provide comfort and care,
and who instill hope for a healthier world . . .

To our nursing faculty colleagues who nurture,
guide, and steer the future of our profession . . .

To nursing students who challenge themselves with
courage and conviction . . .

You inspire us!

Contributors to the 15th Edition

Marianne T. Adam, PhD, RN, FNP, CNE
Associate Teaching Professor of Nursing
Campus Coordinator, Nursing
Pennsylvania State University Schuylkill
Schuylkill Haven, Pennsylvania

Chapter 38: Assessment of Digestive and Gastrointestinal Function

Rachel Barish, RN, MSN, ANP-BC, AACC
Nurse Practitioner, Division of Cardiology
MedStar Georgetown University Hospital Physicians Group
Washington, District of Columbia

Chapter 24: Management of Patients with Structural, Infectious, and Inflammatory Cardiac Disorders

Jennifer L. Bartlett, PhD, RN-BC, CNE, CHSE
Associate Professor
Georgia Baptist College of Nursing of Mercer University
Atlanta, Georgia

Chapter 39: Management of Patients with Oral and Esophageal Disorders

Susan Bartos, PhD, RN, CCRN
Adjunct Professor
Egan School of Nursing & Health Sciences
Fairfield University
Fairfield, Connecticut

Chapter 25: Management of Patients with Complications from Heart Disease

Cynthia Bautista, PhD, APRN, FNCS, FCNS
Associate Professor
Egan School of Nursing and Health Studies
Fairfield University

Fairfield, Connecticut

Chapter 63: Management of Patients with Neurologic Trauma

Tricia Bernecker, PhD, RN

Associate Professor
DeSales University
Center Valley, Pennsylvania

Chapter 22: Management of Patients with Arrhythmias and Conduction Problems

Lisa Bowman, RN, MSN, CRNP, CNRN

Nurse Practitioner
Jefferson Hospital for Neuroscience
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Chapter 62: Management of Patients with Cerebrovascular Disorders

Carolyn Bradley, MSN, RN, CCRN

Heart & Vascular Center Nursing Professional Development Specialist
Yale New Haven Hospital
New Haven, Connecticut

Chapter 21: Assessment of Cardiovascular Function

Sherry Burrell, PhD, RN, CNE

Assistant Professor
Villanova University M. Louise Fitzpatrick College of Nursing
Villanova, Pennsylvania

Chapter 12: Oncologic Management

Theresa Capriotti, DO, CRNP, MSN, RN

Clinical Professor
Villanova University M. Louise Fitzpatrick College of Nursing
Villanova, Pennsylvania

Chapter 10: Fluid and Electrolytes
Chapter 33: Assessment and Management of Patients with Allergic Disorders

Jean Colaneri, ACNP-BC, CNN

Acute Care Nurse Practitioner
Albany Medical Center Hospital

Albany, New York

Chapter 48: Management of Patients with Kidney Disorders

Linda Carman Copel, PhD, RN, PMHCNS, BC, CNE, ANEF, NCC, FAPA

Professor
Villanova University M. Louise Fitzpatrick College of Nursing
Villanova, Pennsylvania

Chapter 3: Health Education and Health Promotion
Chapter 5: Stress and Inflammatory Responses
Chapter 53: Assessment and Management of Patients with Male Reproductive Disorders

Patricia Dillon, PhD, RN

Chair of Graduate, RN to BSN, and RN to MSN Programs, & Professor
School of Nursing and Health Sciences
La Salle University
Philadelphia, Pennsylvania

Chapter 56: Management of Patients with Dermatologic Disorders

Nancy Donegan, MPH, RN

Independent Consultant
Washington, District of Columbia

Chapter 66: Management of Patients with Infectious Diseases

Paulette Dorney, PhD, RN, CCRN-K

Associate Professor & Director, Accelerated BSN Program
Helen S. Breidegam School of Nursing
Moravian University
Bethlehem, Pennsylvania

Chapter 19: Management of Patients with Chest and Lower Respiratory Tract Disorders

Phyllis Dubendorf, MSN, RN, CCNS, CNRN, ACNP-BC

Clinical Nurse Specialist
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Chapter 61: Management of Patients with Neurologic Dysfunction

Kimberly Silver Dunker, DNP, MSN, RN, CNE, CNEcl

Dean of Nursing
Fortis Institute
Nashville, Tennessee

Unit-opening case studies

Elizabeth C. Evans, CNP, DNP

Nephrology Nurse Practitioner
Renal Medicine Associates
Albuquerque, New Mexico

Chapter 27: Assessment and Management of Patients with Hypertension

Janice Farber, PhD, RN, CNOR

Associate Professor
Helen S. Breidegam School of Nursing
Moravian University
Bethlehem, Pennsylvania

Chapter 4: Adult Health and Physical, Nutritional, and Cultural Assessment

Eleanor Fitzpatrick, DNP, RN, CCRN, AGCNS-BC, ACNP-BC

Clinical Nurse Specialist
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Chapter 43: Assessment and Management of Patients with Hepatic Disorders

Chapter 44: Management of Patients with Biliary Disorders

Anessa M. Foxwell, MSN, CRNP, ACHPN

Predoctoral Fellow, NewCourtland Center for Transitions & Health
University of Pennsylvania School of Nursing
Nurse Practitioner, Clinical Practices of the University of Pennsylvania
Philadelphia, Pennsylvania

Chapter 13: Palliative and End-of-Life Care

Stacy M. Fusner, DNP, APRN, CNP

Assistant Professor of Clinical Practice
The Ohio State University College of Nursing
Columbus, Ohio

Chapter 58: Assessment and Management of Patients with Eye and Vision Disorders

Trudy Gaillard, PhD, RN, CDCES, FAHA
Associate Professor
Nicole Wertheim College of Nursing and Health Sciences
Florida International University
Miami, Florida

Chapter 46: Management of Patients with Diabetes

Dawn M. Goodolf, PhD, RN
Associate Professor and Chairperson
Helen S. Breidegam School of Nursing
Moravian University
Bethlehem, Pennsylvania

Chapter 35: Assessment of Musculoskeletal Function
Chapter 67: Emergency Nursing
Chapter 68: Disaster Nursing

Beth Gotwals, PhD, RN
Associate Professor
Helen S. Breidegam School of Nursing
Moravian University
Bethlehem, Pennsylvania

Chapter 2: Medical-Surgical Nursing

Karen D. Groller, PhD, RN, CV-BC, CMSRN
Assistant Professor
Helen S. Breidegam School of Nursing
Moravian University
Bethlehem, Pennsylvania

Chapter 42: Assessment and Management of Patients with Obesity

Debbie A. Gunter, APRN, FNP-BC, ACHPN
Family & Palliative Care Nurse Practitioner
Emory Healthcare Cognitive Neurology Clinic
Nursing Instructor
Emory University School of Nursing
Atlanta, Georgia

Chapter 18: Management of Patients with Upper Respiratory Tract Disorders

Jamie Heffernan, MSN, RN, CCRN-K, NE-BC

Burn Program Manager
New York-Presbyterian Weill Cornell Medicine
New York, New York

Chapter 57: Management of Patients with Burn Injury

Kristina Hidalgo, ACNP-BC
Nurse Practitioner, Division of Cardiology/Electrophysiology
MedStar Washington Hospital Center
Washington, District of Columbia

Chapter 24: Management of Patients with Structural, Infectious, and Inflammatory Cardiac Disorders

Janice L. Hinkle, PhD, RN, CNRN
Fellow
Villanova University M. Louise Fitzpatrick College of Nursing
Villanova, Pennsylvania

Chapter 34: Assessment and Management of Patients with Inflammatory Rheumatic Disorders

Michael Johnson, PhD, RN, PMH-BC, CNE
Assistant Professor
Director of Clinical Partnerships
School of Nursing
Nevada State College
Henderson, Nevada

Chapter 54: Assessment and Management of Patients Who Are LGBTQ

Debra P. Kantor, PhD, RN, CNE
Associate Professor of Nursing
Molloy College
The Barbara H. Hagan School of Nursing and Health Sciences
Rockville Centre, New York

Chapter 45: Assessment and Management of Patients with Endocrine Disorders

Sarah Kweeder, MSN, RN-BC, CNOR
Lead Clinical Nurse Educator, Surgical Services
Main Line Health
Bryn Mawr, Pennsylvania

Chapter 14: Preoperative Nursing Management

Chapter 15: Intraoperative Nursing Management
Chapter 16: Postoperative Nursing Management

Audra Lewis, PhD, RN, CHSE
Director, Highland Campus Regional Simulation Center
Austin Community College
Austin, Texas

Chapter 59: Assessment and Management of Patients with Hearing and Balance Disorders

Mary Beth Flynn Makic, PhD, CCNS, CCRN-K, FAAN, FNAP, FCNS
Professor
University of Colorado College of Nursing
Aurora, Colorado

Chapter 11: Shock, Sepsis, and Multiple Organ Dysfunction Syndrome

Jane F. Marek, DNP, MSN, RN
Assistant Professor
Frances Payne Bolton School of Nursing
Case Western Reserve University
Cleveland, Ohio

Chapter 41: Management of Patients with Intestinal and Rectal Disorders

Katrina Nice Masterson, DNP, RN, FNP-BC, DCNP
Educational Coordinator
Randall Dermatology
West Lafayette, Indiana

Chapter 55: Assessment of Integumentary Function

Jennifer McCaughey, MSN, BS, RNC-MNN, CCE
Clinical Educator
Women and Children's Services
Inova Fair Oaks Hospital
Fairfax, Virginia

Chapter 50: Assessment and Management of Patients with Female Physiologic Processes
Chapter 51: Management of Patients with Female Reproductive Disorders

Salimah H. Meghani, PhD, MBE, RN, FAAN
Professor & Term Chair of Palliative Care

University of Pennsylvania School of Nursing
Philadelphia, Pennsylvania

Chapter 13: Palliative and End-of-Life Care

Carin Molfetta, MSN, CRNP, BC
Nurse Practitioner
Penn Medicine Lancaster General Health
Lancaster, Pennsylvania

Chapter 52: Assessment and Management of Patients with Breast Disorders

Sue Monaro, PhD, MN, RN
Vascular Clinical Nurse Consultant
Concord Repatriation General Hospital
Concord
Senior Clinical Lecturer
Susan Wakil School of Nursing and Midwifery
University of Sydney
New South Wales, Australia

Chapter 26: Assessment and Management of Patients with Vascular Disorders and Problems of Peripheral Circulation

Melissa V. Moreda, MSN, APRN, ACCNS-AG, CCRN, CNRN, SCRN
Diabetes Educator Clinical Nurse Specialist
Duke Raleigh Hospital
Raleigh, North Carolina

Chapter 65: Management of Patients with Oncologic or Degenerative Neurologic Disorders

Kathleen Nokes, PhD, RN, FAAN
Professor *Emerita*
Hunter College and Graduate Center, CUNY
New York, New York

Chapter 32: Management of Patients with Immune Deficiency Disorders

Geraldine M. O'Leary, MSN, RN, FNP-BC
Clinical Instructor
School of Nursing and Health Sciences
La Salle University
Philadelphia, Pennsylvania

Chapter 23: Management of Patients with Coronary Vascular Disorders

Mae Ann Pasquale, PhD, RN
Associate Professor
School of Nursing
Cedar Crest College
Allentown, Pennsylvania

Chapter 37: Management of Patients with Musculoskeletal Trauma

Sue Pugh, MSN, RN, CNRN, CRRN, CNS-BC, FAHA
Neuro Clinical Nurse Specialist/Stroke Coordinator
Sinai Hospital of Baltimore
Baltimore, Maryland

Chapter 64: Management of Patients with Neurologic Infections, Autoimmune Disorders, and Neuropathies

Katrina A. Pyo, PhD, RN, CCRN
Associate Professor
Robert Morris University
Moon Township, Pennsylvania

Chapter 17: Assessment of Respiratory Function

Ann Quinlan-Colwell, PhD, RN-BC, AHN-BC
Pain Management Clinical Nurse Specialist
Educator and Consultant
Wilmington, North Carolina

Chapter 9: Pain Management

Rebecca Wildman Repetti, RN, ANP-BC
Nurse Practitioner, Thoracic Oncology Service
Memorial Sloan Kettering Cancer Center
New York, New York

Chapter 31: Assessment of Immune Function

Denise Rhew, PhD, RN, CNS, CEN
Clinical Nurse Specialist – Emergency Services
Director, Neuro-Progressive Care
Cone Health
Greensboro, North Carolina

Chapter 8: Management of the Older Adult Patient

Marylou V. Robinson, PhD, FNP-C
Olympia, Washington

Chapter 36: Management of Patients with Musculoskeletal Disorders

Tami J. Rogers, PhD, DVM, RN, CNE
Professor of Nursing, Curriculum QA/Course Development
Rasmussen University
Bloomington, Minnesota

Chapter 28: Assessment of Hematologic Function and Treatment Modalities

Sally Russel, MN, CMSRN, CNE
Director, Education Services
American Nephrology Nurses Association
Pitman, New Jersey

Chapter 49: Management of Patients with Urinary Disorders

Catherine Sargent, PhD, RN, BC, AOCNS
Assistant Professor
Gwynedd Mercy University
Gwynedd Valley, Pennsylvania

Chapter 30: Management of Patients with Hematologic Neoplasms

Susan Parnell Scholtz, PhD, RN
Associate Professor

Jamaica, New York

Preface

Since 1964, when Lillian Sholtis Brunner and Doris Smith Suddarth introduced the first edition of the *Textbook of Medical-Surgical Nursing*, the practice of nursing has flexed, changed, evolved, and advanced to meet changing health needs and expectations for health care. With each subsequent edition of this textbook, Lillian and Doris, and their successors, Suzanne Smeltzer and Brenda Bare (and eventually we, the current authors), admirably updated and revised content to reflect changes and challenges that shaped the practice of nursing, considering complex and interconnected influences and maintaining a focus upon salient social, cultural, economic, and environmental factors. Never have we, nor our distinguished and capable predecessors, had to revise and update seminal medical-surgical nursing concepts, principles, and practices during a global pandemic—until now. Most assuredly, this has been a daunting task. Yet, compared to what many of our phenomenally creative, determined, and resilient professional colleagues have had to confront and contend with as a result of this pandemic, our work was much less onerous. We would also like to recognize the long overdue and growing awareness of structural racism within healthcare and the impact of systemic racism on perpetuating stereotypes and health disparities. We encourage nurse educators and students to thoughtfully consider and discuss these issues when exploring epidemiological factors of specific disorders and nursing care throughout the textbook. Now that we have sent this edition to print and have time to reflect upon our work, we find ourselves humbled to call ourselves your peers and so proud of the important and sacred work that you do today and every day. We have decided to break with a long tradition in this textbook that tends to not provide dedications. To YOU our fellow nurses, nursing faculty, and nursing students, we dedicate this book.

Organization

Brunner & Suddarth's Textbook of Medical-Surgical Nursing, 15th Edition, is organized into 16 units. These units mirror those found in previous editions with the incorporation of some changes. Content was

updated throughout all units, with cross-references to specific chapters included as appropriate. Units 1 through 3 cover foundational principles and core concepts related to medical-surgical nursing practice. Units 4 through 15 discuss adult health conditions that are treated medically or surgically. Unit 16 describes community-based challenges that affect medical-surgical nursing practice.

Units 4 through 15 are structured in the following way to better facilitate comprehension:

- The first chapter in the unit covers assessment and includes a review of normal anatomy and physiology of the body system being discussed.
- Subsequent chapters in the unit cover management of specific disorders. Pathophysiology, clinical manifestations, assessment and diagnostic findings, medical management, and nursing management are presented. Nursing Process sections, provided for select conditions, clarify and expand on the nurse's role in caring for patients with these conditions.

There are fewer chapters in this edition than in the past several editions; however, the seminal content within the deleted chapters remains, and is updated and revised. Notably, core content in previous-edition chapters that focused exclusively on *therapeutic modalities* has now been incorporated into chapters focused on health conditions and disorders, where its application dovetails seamlessly into nursing management and the nursing process. Thus, the application of these modalities to medical-surgical nursing practice is readily apparent.

Special Features

When caring for patients, nurses assume many different roles, including practitioner, educator, advocate, and researcher. Many of the features in this textbook have been developed to help nurses fulfill these varied responsibilities. Key updates to practice-oriented features in the 15th edition include new unit-opening Case Studies with QSEN Competency Focus—a feature that highlights a competency from the Quality and Safety Education for Nurses (QSEN) Institute that is applicable to the case study and poses questions for students to consider about relevant knowledge, skills, and attitudes (KSAs). Quality and Safety Nursing Alerts, Genetics in Nursing Practice charts, Ethical Dilemma charts, and Home Care Checklist charts offer updated information.

Plans of Nursing Care, provided for select disorders, illustrate how the nursing process is applied to meet the patient's health care and nursing needs. New to the 15th edition, nursing diagnoses used in the Plans of Nursing Care and throughout the textbook are those devised and validated by the International Council of Nurses in the *International Classification for Nursing Practice (ICNP) Catalogue*. (Please note that because of the global foci of these nursing diagnoses, select terms in these diagnoses are spelled in the British manner.)

A new addition to the textbook this cycle is a chapter focused exclusively on the unique health care needs of persons who identify as lesbian, gay, bisexual, transgender, and/or queer (LGBTQ). As is the case with other chapters of this textbook, the roles of the professional nurse as a practitioner, educator, advocate, and researcher when providing care for persons who are LGBTQ provide the framework for this new chapter.

In addition, two new features in this edition highlight content related to COVID-19 and care of veterans. *COVID-19 Considerations* sections identify evidence-based information at the time this material was written related to the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) or the nursing care of patients with coronavirus disease 2019 (COVID-19). *Veterans Considerations* sections include information applicable to the special care needs of military veterans. Veterans—who may include persons from all age groups, genders, races, and socioeconomic strata—may have unique health risks based upon dates of service and assignment locale.

The textbook also provides pedagogical features developed to help readers engage and learn critical content. Concept Mastery Alerts continue to clarify fundamental nursing concepts to improve the reader's understanding of potentially confusing topics, as identified by Misconception Alerts in Lippincott's Adaptive Learning Powered by PrepU. An enhanced suite of online, interactive multimedia resources is also highlighted with icons placed in text near relevant topics. Unfolding Patient Stories (case study vignettes) based on vSim for Nursing patients are part of this suite of resources.

Read the User's Guide that follows the Preface for a full explanation and visual representation of all special features. See also the "Special Charts in This Book" and "Case Studies in This Book" sections of this front matter for the location of these items in the text.

A Comprehensive Package for Teaching and Learning

To further facilitate teaching and learning, a carefully designed ancillary package has been developed to assist faculty and students.

Instructor Resources

Tools to assist you with teaching your course are available upon adoption of this text on thePoint at http://thepoint.lww.com/Brunner15e.

- An **e-Book** on thePoint gives you access to the book's full text and images online.
- A thoroughly revised and augmented **Test Generator** contains more than 2900 NCLEX-style questions mapped to chapter learning outcomes.
- An extensive collection of materials is provided for each book chapter:
  - **Lesson Plans** outline learning outcomes and identify relevant resources from the robust instructor and student resource packages to help you prepare for your class.
  - **Pre-Lecture Quizzes** (and answers) allow you to check students' reading.
  - **PowerPoint Presentations** provide an easy way to integrate the textbook with your students' classroom experience; multiple-choice and true/false questions are included to promote class participation.
  - **Guided Lecture Notes** are organized by outcome and provide corresponding PowerPoint slide numbers to simplify preparation for lecture.
  - **Discussion Topics** (and suggested answers) can be used in the classroom or in online discussion boards to facilitate interaction with your students.
  - **Assignments** (and suggested answers) include group, written, clinical, and Web assignments to engage students in varied activities and assess their learning.
  - **Case Studies** with related questions (and suggested answers) give students an opportunity to apply their knowledge to a client case similar to one they might encounter in practice.

- Sample **Syllabi** are provided for one- and two-semester courses.
- A **QSEN Competency Map** identifies content and special features in the book related to competencies identified by the QSEN Institute.
- An **Image Bank** lets you use the photographs and illustrations from this textbook in your course materials.
- Access to all **Student Resources** is provided so that you can understand the student experience and use these resources in your course as well.

Student Resources

An exciting set of free learning resources is available on thePoint to help students review and apply vital concepts in medical-surgical nursing. Multimedia engines have been optimized so that students can access many of these resources on mobile devices. Students can access all these resources at http://thepoint.lww.com/Brunner15e using the codes printed in the front of their textbooks.

- **NCLEX-Style Review Questions** for each chapter, totaling more than 1800 questions, help students review important concepts and practice for NCLEX.
- Interactive learning resources appeal to a variety of learning styles. Icons in the text direct readers to relevant resources:
  - **Concepts in Action Animations** bring physiologic and pathophysiologic concepts to life.
  - **Practice & Learn Case Studies** present case scenarios and offer interactive exercises and questions to help students apply what they have learned.
  - **Watch & Learn Video Clips** reinforce skills from the textbook and appeal to visual and auditory learners.
- **Procedural Guidelines charts** review key nursing interventions and rationales for specific patient care situations.
- **Appendix A, Diagnostic Studies and Interpretation**, provides reference ranges and lab values for common laboratory tests.

- **Journal Articles** offer access to current articles relevant to each chapter and available in Wolters Kluwer journals to familiarize students with nursing literature.

Study Guide

A comprehensive study aid for reviewing key concepts, ***Study Guide for Brunner & Suddarth's Textbook of Medical-Surgical Nursing*, 15th Edition**, has been thoroughly revised and presents a variety of exercises, including case studies and practice NCLEX-style questions, to reinforce textbook content and enhance learning.

vSim for Nursing

Available for separate purchase, vSim for Nursing, jointly developed by Laerdal Medical and Wolters Kluwer, offers innovative scenario-based learning modules consisting of Web-based virtual simulations, course learning materials, and curriculum tools designed to develop critical thinking skills and promote clinical confidence and competence. vSim for Nursing | Medical-Surgical includes 10 virtual simulations based on the National League for Nursing Volume I Complex patient scenarios. Students can progress through suggested readings, pre- and postsimulation assessments, documentation assignments, and guided reflection questions, and will receive an individualized feedback log immediately upon completion of the simulation. Throughout the student learning experience, the product offers remediation back to trusted Lippincott resources, including *Brunner & Suddarth's Textbook of Medical-Surgical Nursing,* as well as Lippincott Nursing Advisor and Lippincott Nursing Procedures—two online, evidence-based, clinical information solutions used in health care facilities throughout the United States. This innovative product provides a comprehensive patient-focused solution for learning and integrating simulation into the classroom.

Contact your Wolters Kluwer sales representative or visit http://thepoint.lww.com/vsim for options to enhance your medical-surgical nursing course with vSim for Nursing.

Lippincott DocuCare

Available for separate purchase, Lippincott DocuCare combines Web-based academic EHR simulation software with clinical case scenarios, allowing students to learn how to use an EHR in a safe, true-to-life

setting, while enabling instructors to measure their progress. Lippincott DocuCare's nonlinear solution works well in the classroom, simulation lab, and clinical practice.

Contact your Wolters Kluwer sales representative or visit http://thepoint.lww.com/DocuCare for options to enhance your medical-surgical nursing course with DocuCare.

A Comprehensive, Digital, Integrated Course Solution

Lippincott® CoursePoint+ is an integrated, digital curriculum solution for nursing education that provides a completely interactive experience geared to help students understand, retain, and apply their course knowledge and be prepared for practice. The time-tested, easy-to-use, and trusted solution includes engaging learning tools, evidence-based practice, case studies, and in-depth reporting to meet students where they are in their learning, combined with the most trusted nursing education content on the market to help prepare students for practice. This easy-to-use digital learning solution of *Lippincott® CoursePoint+,* combined with unmatched support, gives instructors and students everything they need for course and curriculum success!

Lippincott® CoursePoint+ includes:

- Leading content provides a variety of learning tools to engage students of all learning styles.
- A personalized learning approach gives students the content and tools they need at the moment they need it, giving them data for more focused remediation and helping to boost their confidence and competence.
- Powerful tools, including varying levels of case studies, interactive learning activities, and adaptive learning powered by PrepU, help students learn the critical thinking and clinical judgment skills to help them become practice-ready nurses.
- Preparation for Practice tools improve student competence, confidence, and success in transitioning to practice.
    - vSim for Nursing: Co-developed by Laerdal Medical and Wolters Kluwer, vSim for Nursing simulates real nursing scenarios and allows students to interact with virtual patients in a safe, online environment.

    - Lippincott Advisor for Education: With over 8500 entries covering the latest evidence-based content and drug information, Lippincott Advisor for Education provides students with the most up-to-date information possible, while giving them valuable experience with the same point-of-care content they will encounter in practice.
- Unparalleled reporting provides in-depth dashboards with several data points to track student progress and help identify strengths and weaknesses.
- Unmatched support includes training coaches, product trainers, and nursing education consultants to help educators and students implement CoursePoint+ with ease.

Janice L. Hinkle, PhD, RN, CNRN
Kerry H. Cheever, PhD, RN
Kristen J. Overbaugh, PhD, RN, ACNS-BC, CHPN

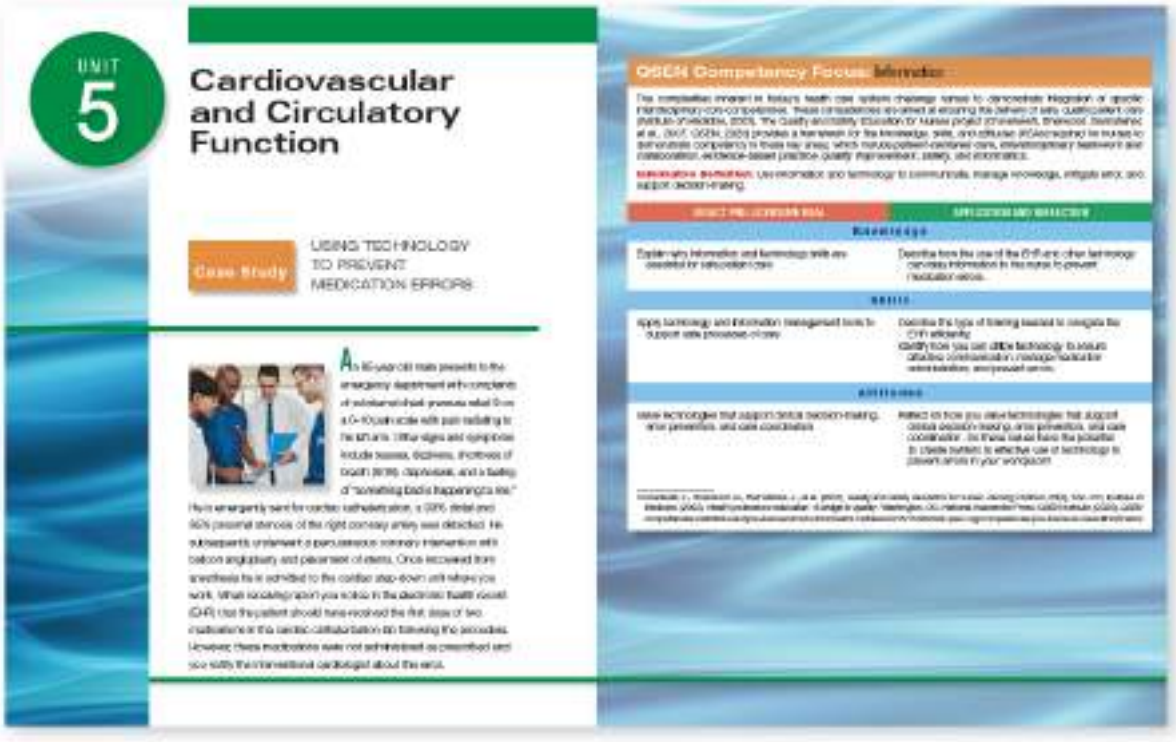
User's Guide

Brunner & Suddarth's Textbook of Medical-Surgical Nursing, 15th Edition, has been revised and updated to reflect the complex nature of nursing practice today. This textbook includes many features to help you gain and apply the knowledge that you need to pass NCLEX and successfully meet the challenges and opportunities of clinical practice. In addition, features have been developed specifically to help you fulfill the varied roles that nurses assume in practice.

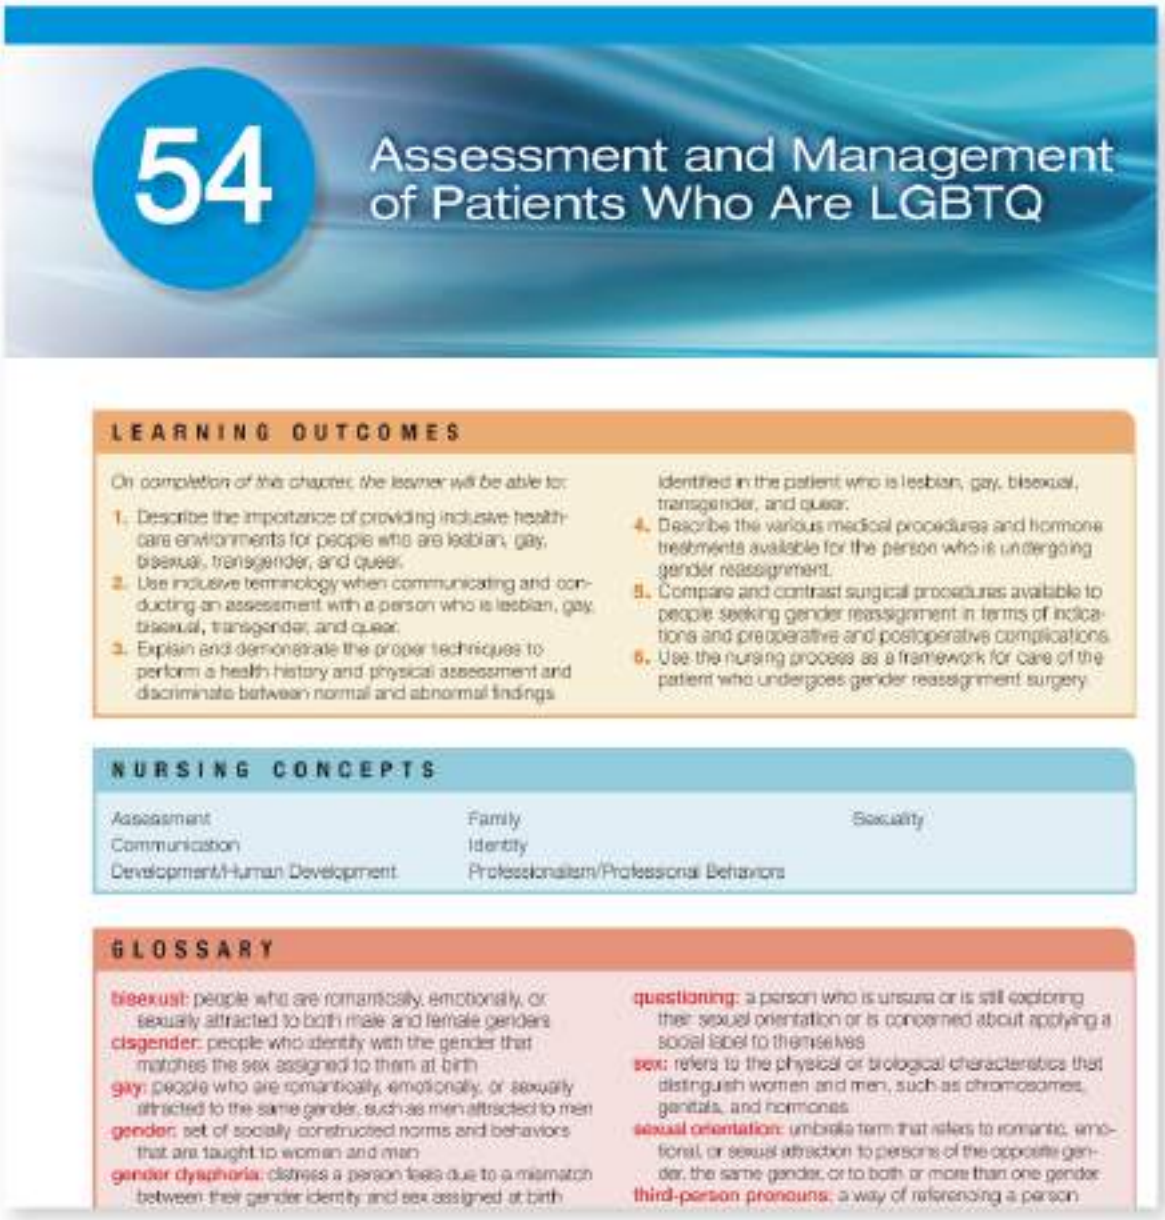
Opening Features That Start with the End in Mind

Unit-opening features put the patient first and highlight competent nursing as well as application of the nursing process.

- **All new! A Case Study with QSEN Competency Focus** opens each unit and provides discussion points focusing on one competency from the QSEN Institute: patient-centered care, interdisciplinary teamwork and collaboration, evidence-based practice, quality improvement, safety, or informatics. This feature helps you consider the KSAs required for the delivery of safe, quality patient care. For your convenience, a list of these case studies, along with their location in the book, appears in the "Case Studies in This Book" section later in this front matter.



- **Learning Outcomes**, succinctly focused and condensed in this edition, provide an overview of each chapter and identify what you will be able to do after completing the material, to help focus reading and studying.
- **NEW! Nursing Concepts** listed at the beginning of each chapter make clear how content applies to Concepts-based curricula.
- A **Glossary** provides a list of key terms and definitions at the beginning of each chapter, providing a review of vocabulary words before reading the material and a useful reference and study tool.



54 Assessment and Management of Patients Who Are LGBTQ

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the importance of providing inclusive health-care environments for people who are lesbian, gay, bisexual, transgender, and queer.
2. Use inclusive terminology when communicating and conducting an assessment with a person who is lesbian, gay, bisexual, transgender, and queer.
3. Explain and demonstrate the proper techniques to perform a health history and physical assessment and discriminate between normal and abnormal findings identified in the patient who is lesbian, gay, bisexual, transgender, and queer.
4. Describe the various medical procedures and hormone treatments available for the person who is undergoing gender reassignment.
5. Compare and contrast surgical procedures available to people seeking gender reassignment in terms of indications and preoperative and postoperative complications.
6. Use the nursing process as a framework for care of the patient who undergoes gender reassignment surgery.

NURSING CONCEPTS

Assessment	Family	Sexuality
Communication	Identity	
Development/Human Development	Professionalism/Professional Behaviors	

GLOSSARY

bisexual: people who are romantically, emotionally, or sexually attracted to both male and female genders
cisgender: people who identify with the gender that matches the sex assigned to them at birth
gay: people who are romantically, emotionally, or sexually attracted to the same gender, such as men attracted to men
gender: set of socially constructed norms and behaviors that are taught to women and men
gender dysphoria: distress a person feels due to a mismatch between their gender identity and sex assigned at birth
questioning: a person who is unsure or is still exploring their sexual orientation or is concerned about applying a social label to themselves
sex: refers to the physical or biological characteristics that distinguish women and men, such as chromosomes, genitals, and hormones
sexual orientation: umbrella term that refers to romantic, emotional, or sexual attraction to persons of the opposite gender, the same gender, or to both or more than one gender
third-person pronouns: a way of referencing a person

Features to Develop the Nurse as Practitioner

One of the central roles of the nurse is to provide holistic care to patients and their families, both independently and through collaboration with other health care professionals. Special features throughout chapters are designed to assist readers with clinical practice.

- **Nursing Process sections** are organized according to the nursing process framework—the basis for all nursing practice—and help clarify the nurse's responsibilities in caring for patients with select disorders.

NURSING PROCESS

The Patient with an Arrhythmia

Assessment

Major areas of assessment include possible causes of the arrhythmia, contributing factors, and the arrhythmia's effect on the heart's ability to pump an adequate blood volume. When cardiac output is reduced, the amount of oxygen reaching the tissues and vital organs is diminished. This diminished oxygenation produces the signs and symptoms associated with arrhythmias. If these signs and symptoms are severe or if they occur frequently, the patient may experience significant distress and disruption of daily life.

- **Plans of Nursing Care**, provided for select disorders, illustrate how the nursing process is applied to meet the patient's health care and nursing needs.

Chart 45-4 **PLAN OF NURSING CARE**

Care of the Patient with Hypothyroidism

NURSING DIAGNOSIS: Impaired breathing associated with depressed ventilation
GOAL: Improved respiratory status and maintenance of normal breathing pattern

Nursing Interventions	Rationale	Expected Outcomes
1. Assess respiratory rate, depth, pattern, pulse oximetry, and arterial blood gases.	1. Identifies patient's baseline to monitor further changes and evaluate effectiveness of interventions.	• Shows improved respiratory status and normal respiratory rate, depth, and pattern • Takes deep breaths, coughs and uses incentive spirometry • Explains rationale for cautious use of medications • Maintains adequate oxygenation
2. Encourage deep breathing, coughing, and the use of incentive spirometry.	2. Prevents atelectasis and promotes adequate ventilation.	
3. Verify with the provider orders to administer any hypnotic and sedative until euthyroid state achieved. If these medications are needed, monitor for adverse side effects.	3. Patients with hypothyroidism are susceptible to respiratory depression with the use of hypnotics and sedatives.	
4. Maintain patient airway through suction and ventilator support if needed (see Chapter 19 for care of patients requiring mechanical ventilation).	4. The use of artificial airway and ventilator support may be necessary.	

- **Assessment charts** focus on data that should be collected as part of the assessment step of the nursing process.

Chart 35-3

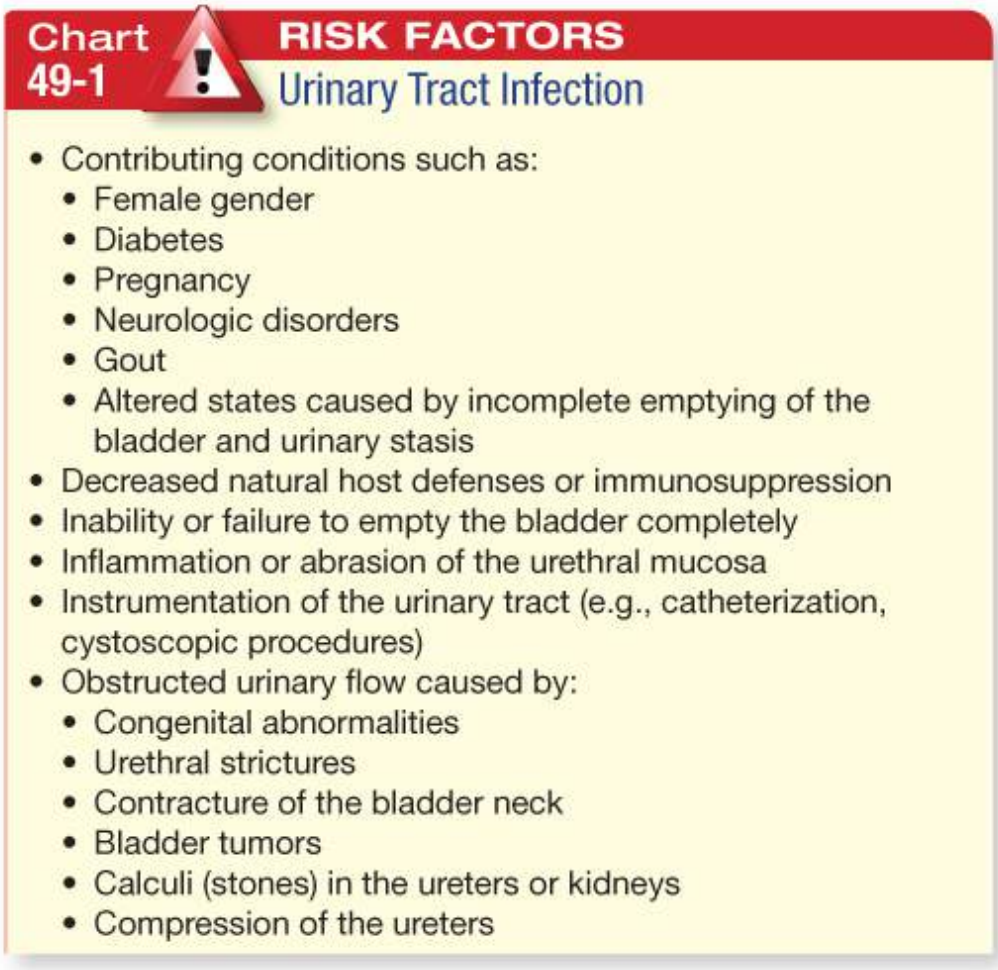
ASSESSMENT

Assessing for Peripheral Nerve Function

Assessment of peripheral nerve function has two key elements: evaluation of sensation and evaluation of motion. The nurse may perform one or all of the following during a musculoskeletal assessment.

Nerve	Test of Sensation	Test of Movement
Peroneal	Prick the skin midway between the great and second toe.	Ask the patient to dorsiflex the foot and extend the toes.

- **Risk Factors charts** outline factors that can impair health and should be considered in the context of social determinants of health and systemic racism.



- **Genetics in Nursing Practice charts** summarize and highlight nursing assessments and management issues related to the role of genetics in select disorders.

Chart 8-1 GENETICS IN NURSING PRACTICE

Genetics Concepts and the Older Adult

Genetic conditions in the older adult may occur from a specific gene mutation or arise as a result of a genetic predisposition combined with other factors (multifactorial). The following are examples of some adult-onset genetic conditions:

- Colon cancer
- Hemochromatosis
- Huntington disease
- Polycystic kidney disease
- Alzheimer's disease

The following are some examples of diseases with multifactorial components, which may include a genetic predisposition, in the older adult:

- Diabetes
- Emphysema
- Heart disease

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to the Older Adult

- Collect and assess family history on both maternal and paternal sides of the family for three generations.
- Determine whether genetic testing has occurred with other family members.
- Assess for individual and family perceptions and beliefs around topics related to genetics.

Patient Assessment Specific to the Older Adult and Genetic Illness

- Assess older adult patient's knowledge and understanding of genetics, genetic testing, and gene-based therapies.
- Assess the patient's understanding of genetic information and decipher health literacy needs.
- Perform cultural, social, and spiritual assessment.
- Assess patient's communication capacities so that communication strategies about genetics are tailored to their needs and abilities.
- Identify patient's support system.

Management Issues Specific to Genetics and the Older Adult

- Refer for further genetic counseling and evaluation as warranted so that family members can discuss inheritance risk to other family members, and availability of genetic testing and gene-based interventions.
- Offer appropriate genetic information and resources that take into consideration older patient's literacy needs.
- Evaluate older patient's understanding before, during, and after the introduction of genetic information and services.
- Take the time to clearly explain the concepts of genetic testing to older patients and provide written information that reinforces the topic of discussion.
- Participate in the management and coordination of care of older patients with genetic conditions and individuals predisposed to develop or pass on a genetic condition.

Genetics Resources

See Chapter 6, Chart 6-7: Components of Genetic Counseling for additional resources.

- **Pharmacology charts and tables** display important considerations related to administering medications and monitoring drug therapy.

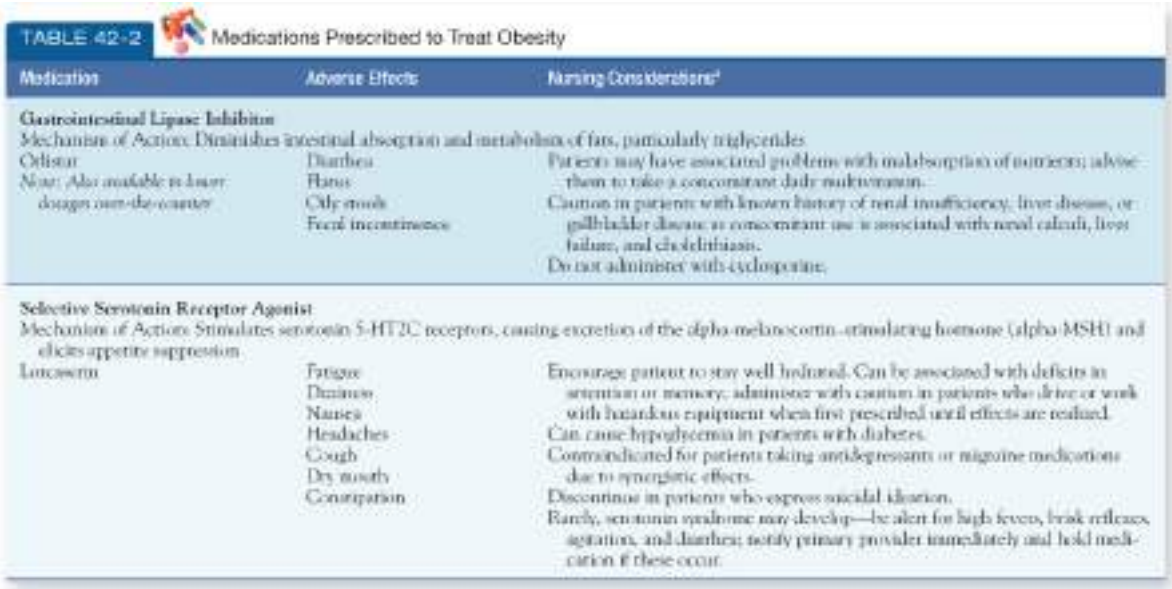


TABLE 42-2 Medications Prescribed to Treat Obesity

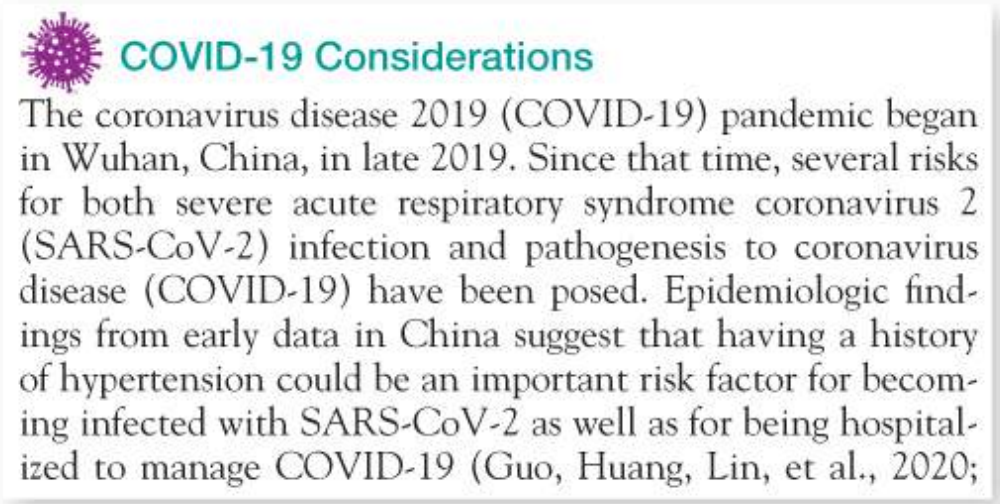
Medication	Adverse Effects	Nursing Considerations[a]
Gastrointestinal Lipase Inhibitor		
Mechanism of Action: Diminishes intestinal absorption and metabolism of fats, particularly triglycerides		
Orlistat *Note: Also available in lower dosages over-the-counter*	Diarrhea Flatus Oily stools Fecal incontinence	Patients may have associated problems with malabsorption of nutrients; advise them to take a concomitant daily multivitamin. Caution in patients with known history of renal insufficiency, liver disease, or gallbladder disease as concomitant use is associated with renal calculi, liver failure, and cholelithiasis. Do not administer with cyclosporine.
Selective Serotonin Receptor Agonist		
Mechanism of Action: Stimulates serotonin 5-HT2C receptors, causing excretion of the alpha-melanocortin–stimulating hormone (alpha-MSH) and elicits appetite suppression		
Lorcaserin	Fatigue Dizziness Nausea Headaches Cough Dry mouth Constipation	Encourage patient to stay well hydrated. Can be associated with deficits in attention or memory; administer with caution in patients who drive or work with hazardous equipment when first prescribed until effects are realized. Can cause hypoglycemia in patients with diabetes. Contraindicated for patients taking antidepressants or migraine medications due to synergistic effects. Discontinue in patients who express suicidal ideation. Rarely, serotonin syndrome may develop—be alert for high fevers, brisk reflexes, agitation, and diarrhea; notify primary provider immediately and hold medication if these occur.

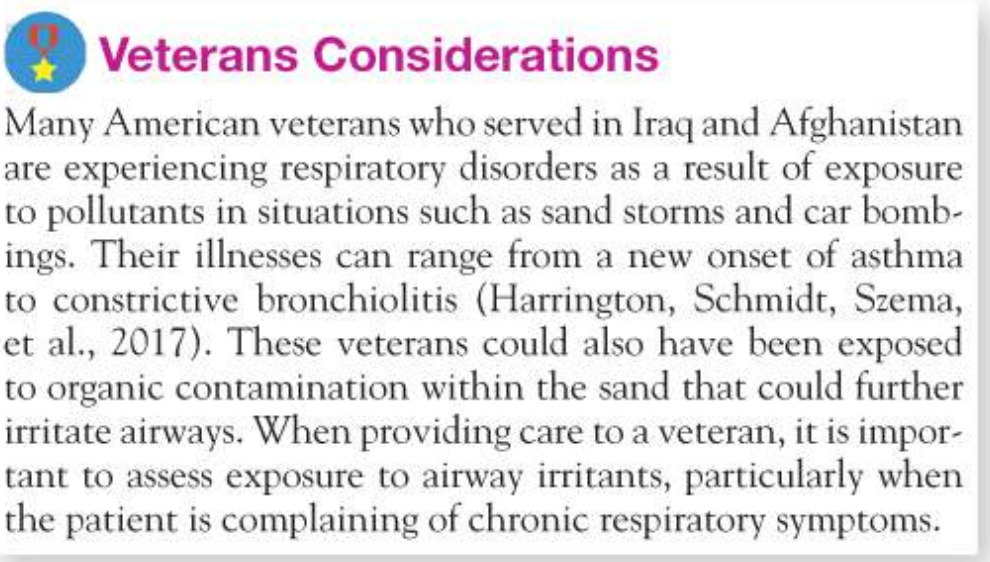
- **Updated! Quality and Safety Nursing Alerts** offer tips for best clinical practice and red-flag safety warnings to help avoid

common mistakes.

- **NEW! COVID-19 Considerations sections** identify evidence-based information at the time this material was written related to the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) or the nursing care of patients with coronavirus disease 2019 (COVID-19).



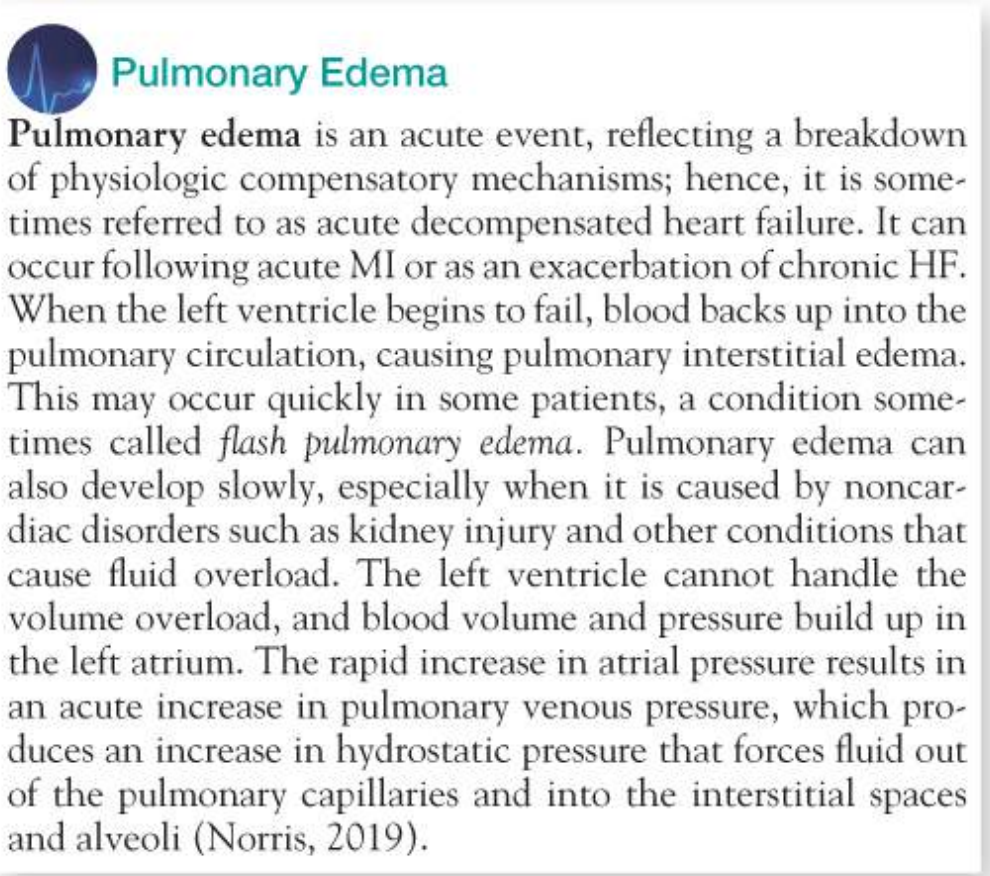
- **NEW! Veterans Considerations sections** highlight information applicable to the special care needs of veterans of the military. Veterans—who may include persons from all age groups, genders, races, and socioeconomic strata—may have unique health risks, based upon dates of service and assignment locale.



Veterans Considerations

Many American veterans who served in Iraq and Afghanistan are experiencing respiratory disorders as a result of exposure to pollutants in situations such as sand storms and car bombings. Their illnesses can range from a new onset of asthma to constrictive bronchiolitis (Harrington, Schmidt, Szema, et al., 2017). These veterans could also have been exposed to organic contamination within the sand that could further irritate airways. When providing care to a veteran, it is important to assess exposure to airway irritants, particularly when the patient is complaining of chronic respiratory symptoms.

- **Critical Care icons** identify nursing considerations for the patient who is critically ill.



Pulmonary Edema

Pulmonary edema is an acute event, reflecting a breakdown of physiologic compensatory mechanisms; hence, it is sometimes referred to as acute decompensated heart failure. It can occur following acute MI or as an exacerbation of chronic HF. When the left ventricle begins to fail, blood backs up into the pulmonary circulation, causing pulmonary interstitial edema. This may occur quickly in some patients, a condition sometimes called *flash pulmonary edema*. Pulmonary edema can also develop slowly, especially when it is caused by noncardiac disorders such as kidney injury and other conditions that cause fluid overload. The left ventricle cannot handle the volume overload, and blood volume and pressure build up in the left atrium. The rapid increase in atrial pressure results in an acute increase in pulmonary venous pressure, which produces an increase in hydrostatic pressure that forces fluid out of the pulmonary capillaries and into the interstitial spaces and alveoli (Norris, 2019).

- **Obesity Considerations icons** identify content related to obesity or to the nursing care of patients with obesity.

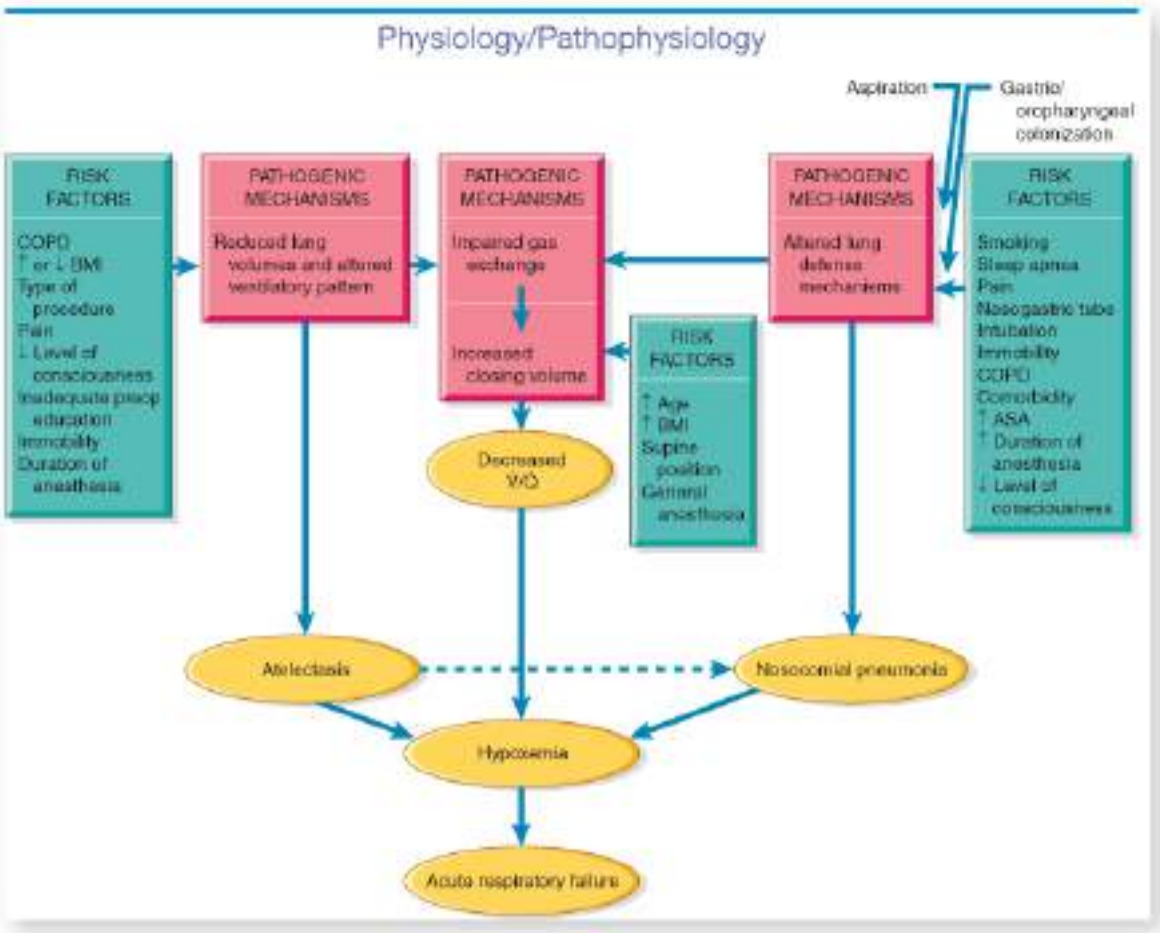
Obesity contributes to back strain by overtaxing the relatively weak back muscles in the absence of abdominal muscle support. Exercises are less effective and more difficult to perform when the patient is overweight. Weight reduction through diet modification is important to minimize recurrence of back pain. A sound nutritional plan that includes a change in eating habits and low-impact activities is vital. Noting achievement of weight reduction and providing positive reinforcement facilitate adherence. Back

- **Gerontologic Considerations icons** highlight information that pertains specifically to the care of the older adult patient. In the United States, older adults comprise the fastest-growing segment of the population.

Gerontologic Considerations

During the normal aging process, the nervous system undergoes many changes and is more vulnerable to illness. Age-related changes in the nervous system vary in degree and must be distinguished from those due to disease. It is important for clinicians not to attribute abnormality or dysfunction to aging without appropriate investigation. For example, although diminished strength and agility are a normal part of aging, localized weakness can only be attributed to disease.

- **Physiology/Pathophysiology figures** include illustrations and algorithms describing normal physiologic and pathophysiologic processes.



Features to Develop the Nurse as Educator

Health education is a primary responsibility of the nursing profession. Nursing care is directed toward promoting, maintaining, and restoring health; preventing illness; and helping patients and families adapt to the residual effects of illness. Patient education and health promotion are central to all of these nursing activities.

- **Patient Education charts and sections** help the nurse prepare the patient and family for procedures, assist them in understanding the patient's condition, and explain to them how to provide self-care.

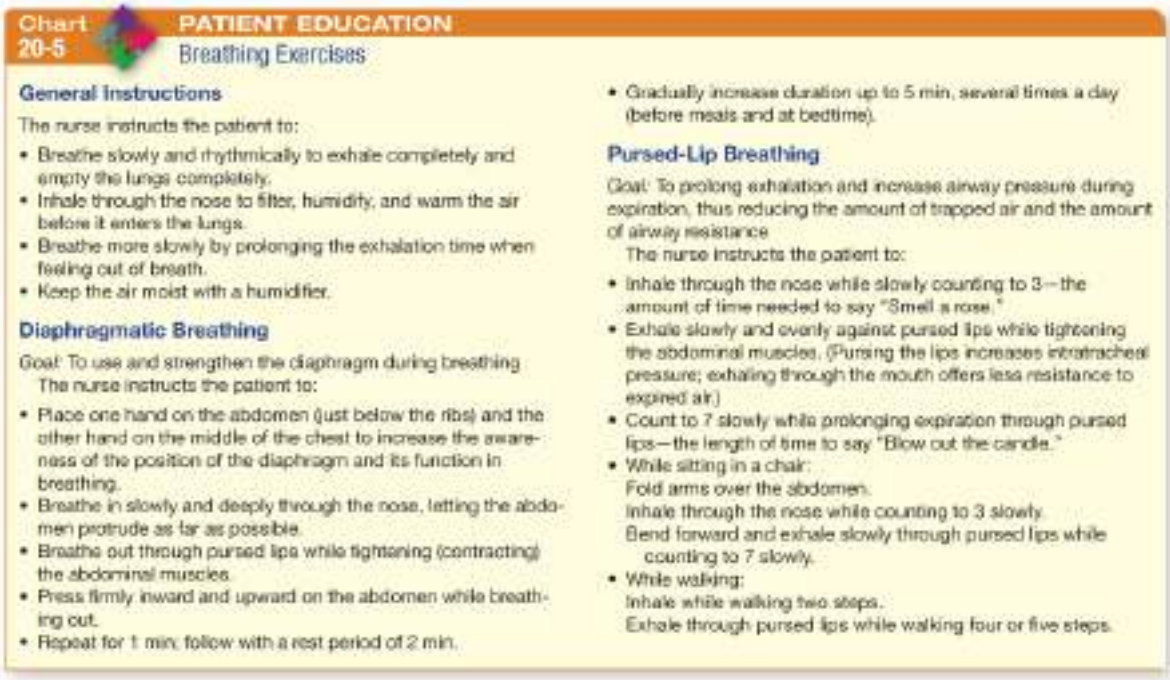


Chart 20-5 PATIENT EDUCATION
Breathing Exercises

General Instructions

The nurse instructs the patient to:

- Breathe slowly and rhythmically to exhale completely and empty the lungs completely.
- Inhale through the nose to filter, humidify, and warm the air before it enters the lungs.
- Breathe more slowly by prolonging the exhalation time when feeling out of breath.
- Keep the air moist with a humidifier.

Diaphragmatic Breathing

Goal: To use and strengthen the diaphragm during breathing
The nurse instructs the patient to:

- Place one hand on the abdomen (just below the ribs) and the other hand on the middle of the chest to increase the awareness of the position of the diaphragm and its function in breathing.
- Breathe in slowly and deeply through the nose, letting the abdomen protrude as far as possible.
- Breathe out through pursed lips while tightening (contracting) the abdominal muscles.
- Press firmly inward and upward on the abdomen while breathing out.
- Repeat for 1 min; follow with a rest period of 2 min.
- Gradually increase duration up to 5 min, several times a day (before meals and at bedtime).

Pursed-Lip Breathing

Goal: To prolong exhalation and increase airway pressure during expiration, thus reducing the amount of trapped air and the amount of airway resistance
The nurse instructs the patient to:

- Inhale through the nose while slowly counting to 3—the amount of time needed to say "Smell a rose."
- Exhale slowly and evenly against pursed lips while tightening the abdominal muscles. (Pursing the lips increases intratracheal pressure; exhaling through the mouth offers less resistance to expired air.)
- Count to 7 slowly while prolonging expiration through pursed lips—the length of time to say "Blow out the candle."
- While sitting in a chair:
  Fold arms over the abdomen.
  Inhale through the nose while counting to 3 slowly.
  Bend forward and exhale slowly through pursed lips while counting to 7 slowly.
- While walking:
  Inhale while walking two steps.
  Exhale through pursed lips while walking four or five steps.

- **Health Promotion charts** review important points that the nurse should discuss with the patient to prevent common health problems from developing.

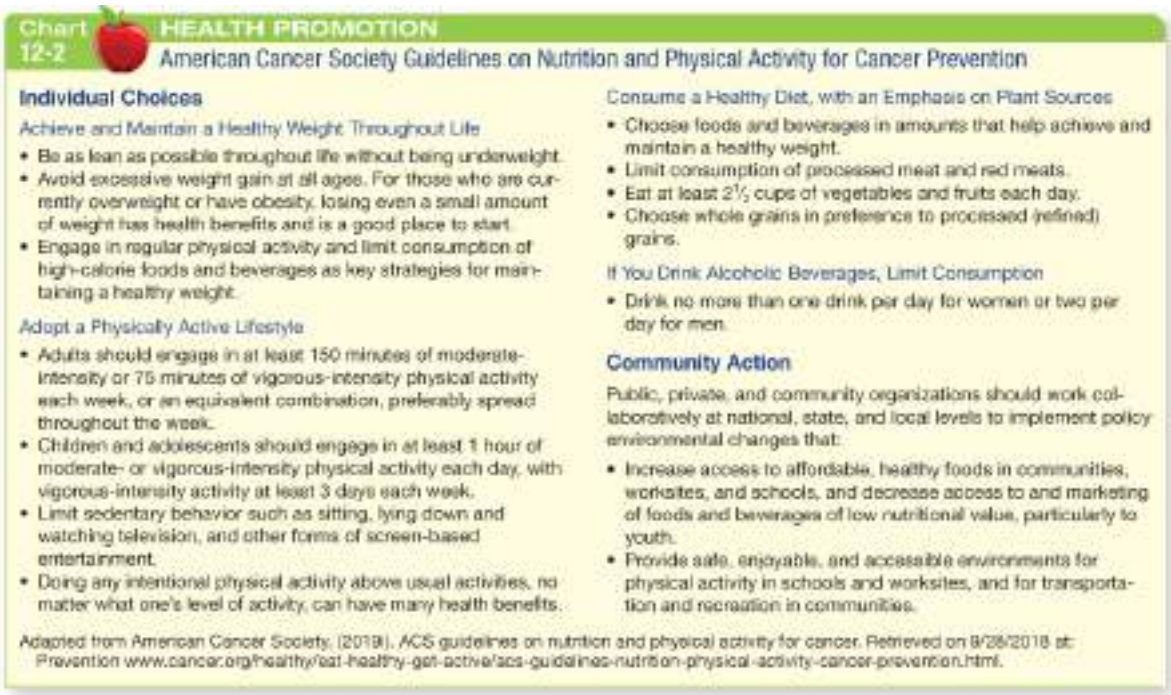

Chart 12-2 HEALTH PROMOTION
American Cancer Society Guidelines on Nutrition and Physical Activity for Cancer Prevention

Individual Choices

Achieve and Maintain a Healthy Weight Throughout Life

- Be as lean as possible throughout life without being underweight.
- Avoid excessive weight gain at all ages. For those who are currently overweight or have obesity, losing even a small amount of weight has health benefits and is a good place to start.
- Engage in regular physical activity and limit consumption of high-calorie foods and beverages as key strategies for maintaining a healthy weight.

Adopt a Physically Active Lifestyle

- Adults should engage in at least 150 minutes of moderate-intensity or 75 minutes of vigorous-intensity physical activity each week, or an equivalent combination, preferably spread throughout the week.
- Children and adolescents should engage in at least 1 hour of moderate- or vigorous-intensity physical activity each day, with vigorous-intensity activity at least 3 days each week.
- Limit sedentary behavior such as sitting, lying down and watching television, and other forms of screen-based entertainment.
- Doing any intentional physical activity above usual activities, no matter what one's level of activity, can have many health benefits.

Consume a Healthy Diet, with an Emphasis on Plant Sources

- Choose foods and beverages in amounts that help achieve and maintain a healthy weight.
- Limit consumption of processed meat and red meats.
- Eat at least 2½ cups of vegetables and fruits each day.
- Choose whole grains in preference to processed (refined) grains.

If You Drink Alcoholic Beverages, Limit Consumption

- Drink no more than one drink per day for women or two per day for men.

Community Action

Public, private, and community organizations should work collaboratively at national, state, and local levels to implement policy environmental changes that:

- Increase access to affordable, healthy foods in communities, worksites, and schools, and decrease access to and marketing of foods and beverages of low nutritional value, particularly to youth.
- Provide safe, enjoyable, and accessible environments for physical activity in schools and worksites, and for transportation and recreation in communities.

Adapted from American Cancer Society. (2019). ACS guidelines on nutrition and physical activity for cancer. Retrieved on 9/28/2018 at: Prevention www.cancer.org/healthy/eat-healthy-get-active/acs-guidelines-nutrition-physical-activity-cancer-prevention.html.

- **Home Care Checklists** review points that should be covered as part of home care education prior to discharge from the health care facility.

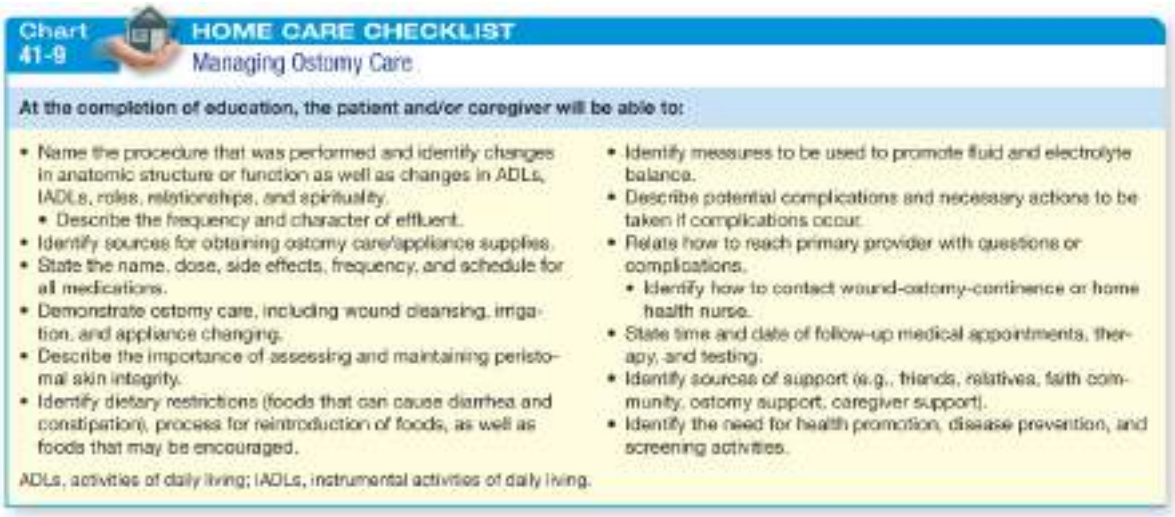

Chart 41-9 HOME CARE CHECKLIST

Managing Ostomy Care

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
  - Describe the frequency and character of effluent.
- Identify sources for obtaining ostomy care/appliance supplies.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Demonstrate ostomy care, including wound cleansing, irrigation, and appliance changing.
- Describe the importance of assessing and maintaining peristomal skin integrity.
- Identify dietary restrictions (foods that can cause diarrhea and constipation), process for reintroduction of foods, as well as foods that may be encouraged.
- Identify measures to be used to promote fluid and electrolyte balance.
- Describe potential complications and necessary actions to be taken if complications occur.
- Relate how to reach primary provider with questions or complications.
  - Identify how to contact wound-ostomy-continence or home health nurse.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community, ostomy support, caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Features to Develop the Nurse as Patient Advocate

Nurses advocate for patients by protecting their rights (including the right to health care) and assisting patients and their families in making informed decisions about health care.

- **All new! Ethical Dilemma charts** provide a clinical scenario, discussion points, and questions to help analyze fundamental ethical principles related to the dilemma.

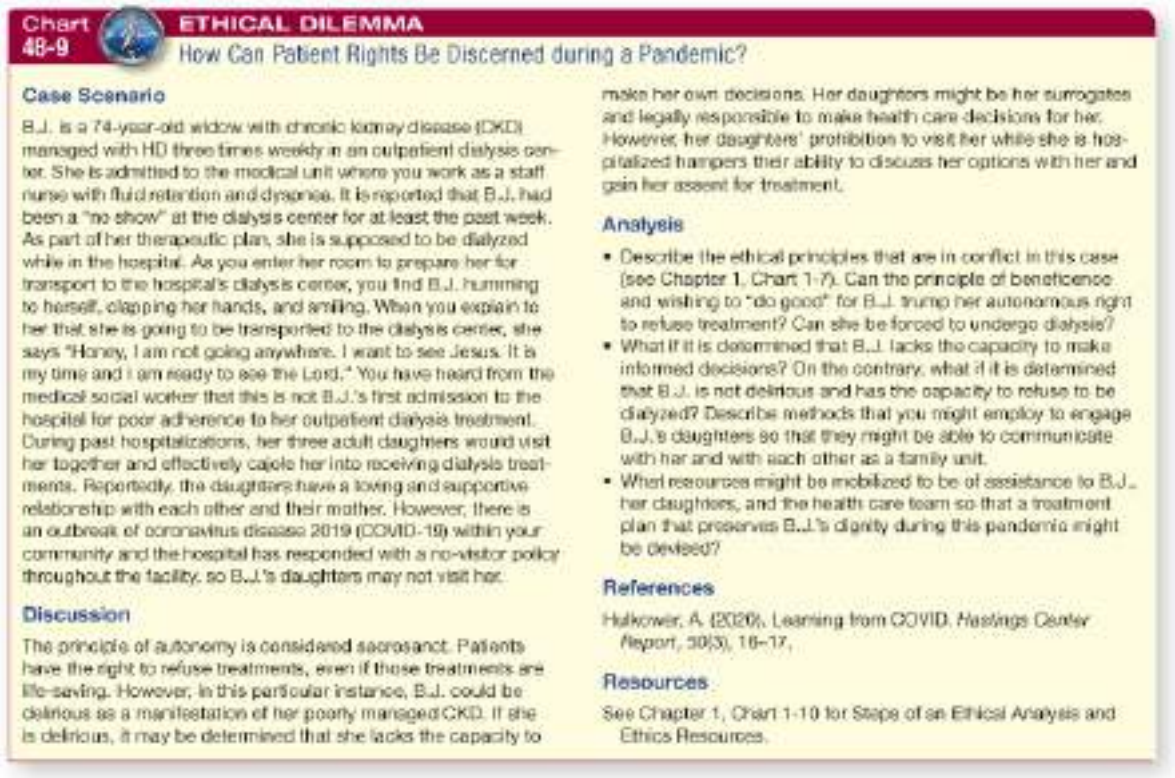

Chart 48-9 ETHICAL DILEMMA

How Can Patient Rights Be Discerned during a Pandemic?

Case Scenario

B.J. is a 74-year-old widow with chronic kidney disease (CKD) managed with HD three times weekly in an outpatient dialysis center. She is admitted to the medical unit where you work as a staff nurse with fluid retention and dyspnea. It is reported that B.J. had been a "no show" at the dialysis center for at least the past week. As part of her therapeutic plan, she is supposed to be dialyzed while in the hospital. As you enter her room to prepare her for transport to the hospital's dialysis center, you find B.J. humming to herself, clapping her hands, and smiling. When you explain to her that she is going to be transported to the dialysis center, she says "Honey, I am not going anywhere. I want to see Jesus. It is my time and I am ready to see the Lord." You have heard from the medical social worker that this is not B.J.'s first admission to the hospital for poor adherence to her outpatient dialysis treatment. During past hospitalizations, her three adult daughters would visit her together and effectively cajole her into receiving dialysis treatments. Reportedly, the daughters have a loving and supportive relationship with each other and their mother. However, there is an outbreak of coronavirus disease 2019 (COVID-19) within your community and the hospital has responded with a no-visitor policy throughout the facility, so B.J.'s daughters may not visit her.

Discussion

The principle of autonomy is considered sacrosanct. Patients have the right to refuse treatments, even if those treatments are life-saving. However, in this particular instance, B.J. could be delirious as a manifestation of her poorly managed CKD. If she is delirious, it may be determined that she lacks the capacity to make her own decisions. Her daughters might be her surrogates and legally responsible to make health care decisions for her. However, her daughters' prohibition to visit her while she is hospitalized hampers their ability to discuss her options with her and gain her assent for treatment.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Can the principle of beneficence and wishing to "do good" for B.J. trump her autonomous right to refuse treatment? Can she be forced to undergo dialysis?
- What if it is determined that B.J. lacks the capacity to make informed decisions? On the contrary, what if it is determined that B.J. is not delirious and has the capacity to refuse to be dialyzed? Describe methods that you might employ to engage B.J.'s daughters so that they might be able to communicate with her and with each other as a family unit.
- What resources might be mobilized to be of assistance to B.J., her daughters, and the health care team so that a treatment plan that preserves B.J.'s dignity during this pandemic might be devised?

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

Features to Develop the Nurse as Researcher

Nurses identify potential research problems and questions to increase nursing knowledge and improve patient care. The use and evaluation of research findings in nursing practice are essential to further the science of nursing.

- **All new and in every chapter! Nursing Research Profiles** identify the implications and applications of nursing research findings for evidence-based nursing practice.

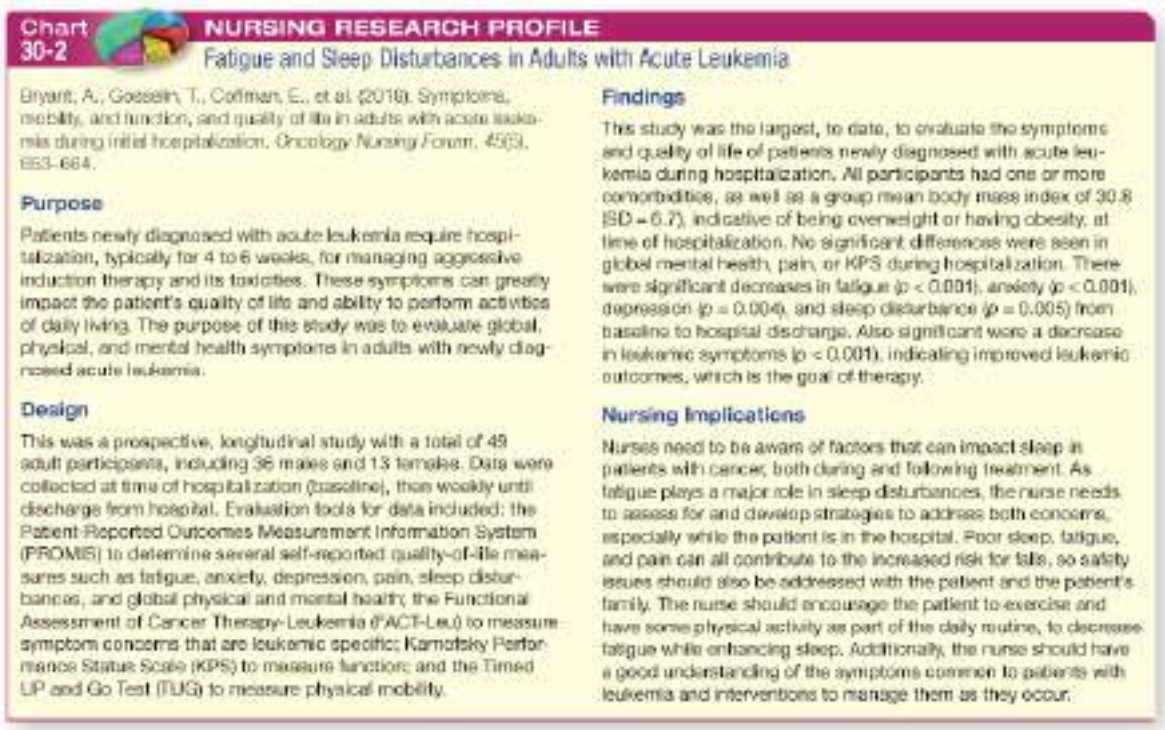

Chart 30-2 NURSING RESEARCH PROFILE

Fatigue and Sleep Disturbances in Adults with Acute Leukemia

Bryant, A., Gosselin, T., Coffman, E., et al. (2016). Symptoms, mobility, and function, and quality of life in adults with acute leukemia during initial hospitalization. *Oncology Nursing Forum, 45*(5), 653-664.

Purpose

Patients newly diagnosed with acute leukemia require hospitalization, typically for 4 to 6 weeks, for managing aggressive induction therapy and its toxicities. These symptoms can greatly impact the patient's quality of life and ability to perform activities of daily living. The purpose of this study was to evaluate global, physical, and mental health symptoms in adults with newly diagnosed acute leukemia.

Design

This was a prospective, longitudinal study with a total of 49 adult participants, including 36 males and 13 females. Data were collected at time of hospitalization (baseline), then weekly until discharge from hospital. Evaluation tools for data included: the Patient-Reported Outcomes Measurement Information System (PROMIS) to determine several self-reported quality-of-life measures such as fatigue, anxiety, depression, pain, sleep disturbances, and global physical and mental health; the Functional Assessment of Cancer Therapy-Leukemia (FACT-Leu) to measure symptom concerns that are leukemic specific; Karnofsky Performance Status Scale (KPS) to measure function; and the Timed UP and Go Test (TUG) to measure physical mobility.

Findings

This study was the largest, to date, to evaluate the symptoms and quality of life of patients newly diagnosed with acute leukemia during hospitalization. All participants had one or more comorbidities, as well as a group mean body mass index of 30.8 (SD = 6.7), indicative of being overweight or having obesity, at time of hospitalization. No significant differences were seen in global mental health, pain, or KPS during hospitalization. There were significant decreases in fatigue ($p < 0.001$), anxiety ($p < 0.001$), depression ($p = 0.004$), and sleep disturbance ($p = 0.005$) from baseline to hospital discharge. Also significant were a decrease in leukemic symptoms ($p < 0.001$), indicating improved leukemic outcomes, which is the goal of therapy.

Nursing Implications

Nurses need to be aware of factors that can impact sleep in patients with cancer, both during and following treatment. As fatigue plays a major role in sleep disturbances, the nurse needs to assess for and develop strategies to address both concerns, especially while the patient is in the hospital. Poor sleep, fatigue, and pain can all contribute to the increased risk for falls, so safety issues should also be addressed with the patient and the patient's family. The nurse should encourage the patient to exercise and have some physical activity as part of the daily routine, to decrease fatigue while enhancing sleep. Additionally, the nurse should have a good understanding of the symptoms common to patients with leukemia and interventions to manage them as they occur.

Features to Facilitate Learning

In addition to practice-oriented features, special features have been developed to help readers learn key information.

- **Concept Mastery Alerts** highlight and clarify fundamental nursing concepts to improve understanding of difficult topics, as identified by Misconception Alerts in Lippincott's Adaptive Learning Powered by PrepU, an adaptive quizzing platform.

Concept Mastery Alert

It is important to remember the different types of cholesterol and the role of each as a risk factor for heart disease. HDL is the "good cholesterol," and higher levels are better; LDL is the "bad cholesterol," and lower levels are better.

- **Unfolding Patient Stories**, written by the National League for Nursing, are an engaging way to begin meaningful conversations in the classroom. These vignettes, which appear throughout the text near related content, feature patients from Wolters Kluwer's vSim for Nursing | Medical-Surgical (co-developed by Laerdal Medical) and DocuCare products; however, each Unfolding Patient Story in the book stands alone, not requiring purchase of these products. For your convenience, a list of these case studies, along with their location in the book, appears in the "Case Studies in This Book" section later in this front matter.

Unfolding Patient Stories: Doris Bowman • Part 2

Recall from Chapter 12 **Doris Bowman**, who is undergoing a total abdominal hysterectomy with bilateral salpingo-oophorectomy. What are potential postoperative complications that the nurse should consider? What assessments and interventions are done by the nurse to monitor for early detection or to prevent these complications? Describe the discharge education provided by the nurse on self-care monitoring required of the patient at home and what should be reported to the health care provider.

Care for Doris and other patients in a realistic virtual environment: ***vSim** for Nursing* (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

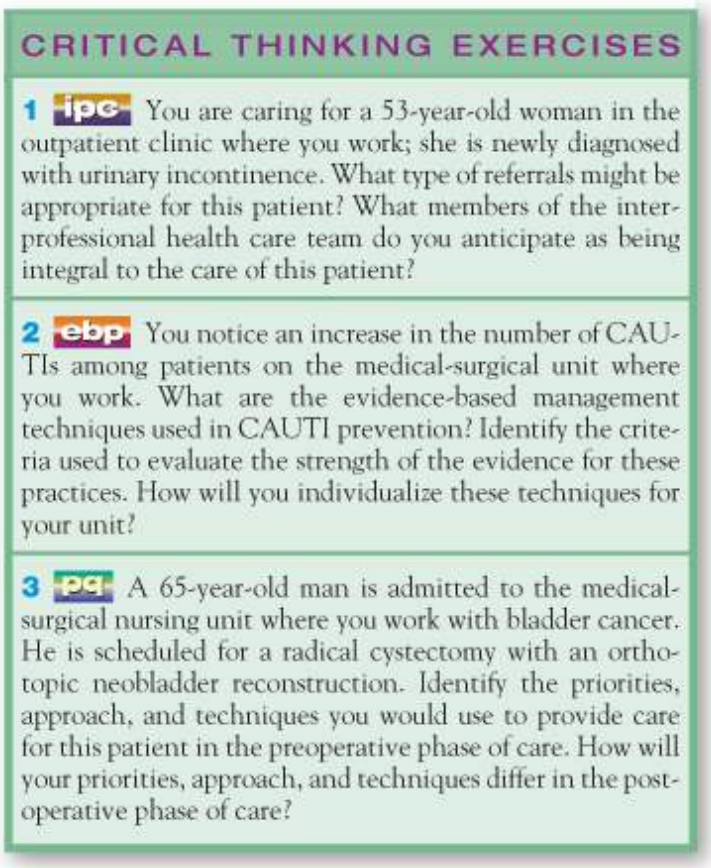
- Interactive learning tools available online enrich learning and are identified with icons in the text:

Concepts in Action Animations bring physiologic and pathophysiologic concepts to life.

Practice & Learn Case Studies present case scenarios and offer interactive exercises and questions to help you apply what you have learned.

Watch & Learn Video Clips reinforce skills from the textbook and appeal to visual and auditory learners.

- **All new! Critical Thinking Exercises** foster critical thinking and challenge you to apply textbook knowledge to clinical scenarios. Evidence-based practice (EBP) questions encourage you to apply best evidence from research findings to nursing interventions. Prioritization (PQ) questions ask you to consider the priorities for nursing care for specific patients and conditions. Interprofessional collaboration (IPC) exercises challenge you to identify the roles and responsibilities of the professional nurse and of interprofessional colleagues in collaboratively delivering quality patient-centered care.



CRITICAL THINKING EXERCISES

1 ipc You are caring for a 53-year-old woman in the outpatient clinic where you work; she is newly diagnosed with urinary incontinence. What type of referrals might be appropriate for this patient? What members of the interprofessional health care team do you anticipate as being integral to the care of this patient?

2 ebp You notice an increase in the number of CAUTIs among patients on the medical-surgical unit where you work. What are the evidence-based management techniques used in CAUTI prevention? Identify the criteria used to evaluate the strength of the evidence for these practices. How will you individualize these techniques for your unit?

3 pq A 65-year-old man is admitted to the medical-surgical nursing unit where you work with bladder cancer. He is scheduled for a radical cystectomy with an orthotopic neobladder reconstruction. Identify the priorities, approach, and techniques you would use to provide care for this patient in the preoperative phase of care. How will your priorities, approach, and techniques differ in the postoperative phase of care?

- **References** cited are listed at the end of each chapter and include updated, current sources.
- **Resources** lists at the end of each chapter include sources of additional information, Web sites, agencies, and patient education materials.

Nursing Management
• *Nursing Process:* The Patient with Pericarditis

25 Management of Patients with Complications from Heart Disease

Heart Failure
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Gerontologic Considerations
• *Nursing Process:* The Patient with Heart Failure

Complications from Heart Disease
Cardiogenic Shock
Thromboembolism
Pericardial Effusion and Cardiac Tamponade
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Cardiac Arrest
Clinical Manifestations
Emergency Assessment and Management: Cardiopulmonary Resuscitation

26 Assessment and Management of Patients with Vascular Disorders and Problems of Peripheral Circulation

Anatomic and Physiologic Overview
Anatomy of the Vascular System
Function of the Vascular System
Pathophysiology of the Vascular System
Gerontologic Considerations
Assessment of the Vascular System
Health History
Physical Assessment
Diagnostic Evaluation
Doppler Ultrasound Flow Studies
Exercise Testing

Duplex Ultrasonography
Computed Tomography Scanning
Angiography
Magnetic Resonance Angiography
Contrast Phlebography (Venography)
Lymphoscintigraphy
Arterial Disorders
Arteriosclerosis and Atherosclerosis
Pathophysiology
Risk Factors
Prevention
Clinical Manifestations
Medical Management
Nursing Management
Peripheral Artery Disease
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Nursing Care of the Postoperative Patient
Upper Extremity Arterial Disease

Medical Management
Nursing Management

27 Assessment and Management of Patients with Hypertension
Hypertension
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* The Patient with Hypertension
Hypertensive Crises
Hypertensive Emergency
Hypertensive Urgency

UNIT 6 Hematologic Function

28 Assessment of Hematologic Function and Treatment Modalities
Anatomic and Physiologic Overview
Bone Marrow
Blood
Reticuloendothelial System (RES)
Hemostasis
Gerontologic Considerations
Assessment
Health History
Physical Assessment

Diagnostic Evaluation
Hematologic Studies
Bone Marrow Aspiration and Biopsy
Therapeutic Approaches to Hematologic Disorders
Splenectomy
Therapeutic Apheresis
Hematopoietic Stem Cell Transplantation
Therapeutic Phlebotomy
Blood Component Therapy
Procuring Blood and Blood Products
Blood Donation
Directed Donation
Standard Donation
Autologous Donation
Intraoperative Blood Salvage
Hemodilution
Complications of Blood Donation
Blood Processing
Transfusion
Pretransfusion Assessment
Patient Education
Transfusion Procedures
Complications
Nursing Management of Transfusion Reactions
Pharmacologic Alternatives to Blood Transfusions

29 Management of Patients with Nonmalignant Hematologic Disorders

Anemia
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Gerontologic Considerations
• *Nursing Process:* The Patient with Anemia
Hypoproliferative Anemias
Iron Deficiency Anemia
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Anemias in Renal Disease

Anemia of Inflammation
Aplastic Anemia
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Megaloblastic Anemias
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Hemolytic Anemias
Sickle Cell Disease
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* The Patient with Sickle Cell Crisis
Thalassemias
Glucose-6-Phosphate Dehydrogenase Deficiency
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Immune Hemolytic Anemias
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Hereditary Hemochromatosis
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Polycythemia
Secondary Polycythemia

Non-Hodgkin Lymphomas
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
MULTIPLE MYELOMA
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Complications
Gerontologic Considerations
Nursing Management

UNIT 7 Immunologic Function

31 Assessment of Immune Function
Anatomic and Physiologic Overview
Anatomy of the Immune System
Function of the Immune System
Advances in Immunology
Genetic Engineering

Stem Cells
Cancer and Immunotherapy
Assessment of the Immune System
Health History
Physical Assessment
Diagnostic Evaluation
Nursing Management

32 Management of Patients with Immune Deficiency Disorders
PRIMARY IMMUNE DEFICIENCIES DISEASES
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Prevention
Medical Management
Nursing Management
Acquired Immune Deficiency
HIV Infection and AIDS
Epidemiology
HIV Transmission
Gerontologic Considerations
Prevention of HIV Infection
Reducing the Risk of Transmission to Health Care Providers
Pathophysiology
Stages of HIV Infection
Assessment and Diagnostic Findings in HIV Infection
Treatment of HIV Infection
Clinical Manifestations
Medical Management
Complementary, Alternative, and Integrative Health Therapies
Supportive Care
• *Nursing Process:* The Patient with HIV Infection
Emotional and Ethical Concerns

33 Assessment and Management of Patients with Allergic Disorders
Physiologic Overview
Function of Immunoglobulins
Function of Antigens
Function of Chemical Mediators
Hypersensitivity
Assessment

Diagnostic Evaluation
Complete Blood Count with Differential
Eosinophil Count
Total Serum Immunoglobulin E Levels
Skin Tests
Provocative Testing
Serum-Specific IgE Test
Allergic Disorders
Anaphylaxis
Pathophysiology
Clinical Manifestations
Prevention
Medical Management
Nursing Management
Allergic Rhinitis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* The Patient with Allergic Rhinitis
Contact Dermatitis
Clinical Manifestations
Assessment and Diagnostic Findings
Atopic Dermatitis
Medical Management
Nursing Management
Drug Hypersensitivity
Pseudoallergic Drug Reactions
Urticaria and Angioedema
Hereditary Angioedema
Clinical Manifestations
Medical Management
Cold Urticaria
Clinical Manifestations
Medical Management
Nursing Management
Food Allergy
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management

Latex Allergy
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management

34 Assessment and Management of Patients with Inflammatory Rheumatic Disorders

Rheumatic Diseases
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Gerontologic Considerations

Diffuse Connective Tissue Diseases
Rheumatoid Arthritis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Systemic Lupus Erythematosus
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Primary Sjögren's Syndrome
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Scleroderma
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Polymyositis
Pathophysiology
Clinical Manifestations

Assessment and Diagnostic Findings
Medical Management
Nursing Management
Polymyalgia Rheumatica and Giant Cell Arteritis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Spondyloarthropathies
Ankylosing Spondylitis
Reactive Arthritis (Reiter's Syndrome)
Psoriatic Arthritis
Medical Management
Nursing Management
Metabolic and Endocrine Diseases Associated with Rheumatic Disorders
Gout
Pathophysiology
Clinical Manifestations
Medical Management
Nursing Management
Fibromyalgia
Pathophysiology
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Miscellaneous Disorders

UNIT 8 Musculoskeletal Function

35 Assessment of Musculoskeletal Function
Anatomic and Physiologic Overview
Structure and Function of the Skeletal System
Structure and Function of the Articular System
Structure and Function of the Skeletal Muscle System
Gerontologic Considerations
Assessment
Health History
Physical Assessment
Diagnostic Evaluation
X-Ray Studies

Computed Tomography
Magnetic Resonance Imaging
Arthrography
Bone Densitometry
Bone Scan
Arthroscopy
Arthrocentesis
Electromyography
Biopsy
Laboratory Studies

36 Management of Patients with Musculoskeletal Disorders

Low Back Pain
Gerontologic Considerations
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Common Upper Extremity Disorders
Bursitis and Tendonitis
Loose Bodies
Impingement Syndrome
Carpal Tunnel Syndrome
Ganglion
Dupuytren Disease
Nursing Management of the Patient Undergoing Surgery of the Hand or Wrist
Common Foot Problems
Callus
Corn
Hammer Toe
Onychocryptosis
Pes Cavus
Hallux Valgus
Morton Neuroma
Pes Planus
Plantar Fasciitis
Nursing Management of the Patient Undergoing Foot Surgery
Osteoarthritis (Degenerative Joint Disease)
Pathophysiology
Clinical Manifestations

Assessment and Diagnostic Findings
Medical Management
Nursing Management
The Patient Undergoing Arthroplasty
Preoperative and Intraoperative Nursing Management
Total Hip Arthroplasty
Nursing Management
Total Knee Arthroplasty
Nursing Management
Metabolic Bone Disorders
Osteoporosis
Prevention
COVID-19 Considerations
Gerontologic Considerations
Pathophysiology
Risk Factors
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* The Patient with a Spontaneous Vertebral Fracture Related to Osteoporosis
Osteomalacia
Pathophysiology
Gerontologic Considerations
Assessment and Diagnostic Findings
Medical Management
Paget Disease of the Bone
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Gerontologic Considerations
Musculoskeletal Infections
Osteomyelitis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Prevention
Medical Management
• *Nursing Process:* The Patient with Osteomyelitis
Septic (Infectious) Arthritis
Clinical Manifestations
Assessment and Diagnostic Findings

Medical Management
Nursing Management
Bone Tumors
Benign Bone Tumors
Malignant Bone Tumors
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
37 Management of Patients with Musculoskeletal Trauma
Contusions, Strains, and Sprains
Management
Joint Dislocations
Medical Management
Nursing Management
Injuries to the Tendons, Ligaments, and Menisci
Rotator Cuff Tears
Lateral and Medial Epicondylitis
Lateral and Medial Collateral Ligament Injury
Medical Management
Nursing Management
Cruciate Ligament Injury
Meniscal Injuries
Rupture of the Achilles Tendon
Fractures
Types of Fractures
Clinical Manifestations
Emergency Management
Medical Management
Nursing Management
Fracture Healing and Complications
The Patient with a Cast, Splint, or Brace
Casts
Splints and Braces
Nursing Management
Nursing Management of the Patient with an Immobilized Upper Extremity
Nursing Management of the Patient with an Immobilized Lower Extremity
Nursing Management of the Patient with a Body or Spica Cast

The Patient with an External Fixator
Management
The Patient in Traction
Principles of Effective Traction
Types of Traction
Skin Traction
Skeletal Traction
Nursing Management of the Patient in Traction
Fractures of Specific Sites
Clavicle
Humeral Neck
Humeral Shaft
Elbow
Proximal Radius
Radial and Ulnar Shafts
Wrist
Hand
Pelvis
Acetabulum
Hip
Clinical Manifestations
Gerontologic Considerations
Medical Management
Nursing Management
Femoral Shaft
Assessment and Diagnostic Findings
Management
Tibia and Fibula
Assessment and Diagnostic Findings
Management
Rib
Gerontologic Considerations
Thoracolumbar Spine
Sports-Related Musculoskeletal Injuries
Management
Occupation-Related Musculoskeletal Disorders
Occupation-Related Musculoskeletal Disorders in Nursing Personnel
Amputation
Level of Amputation
Complications
Medical Management
Rehabilitation

• *Nursing Process:* The Patient Undergoing an Amputation

UNIT 9 Digestive and Gastrointestinal Function

38 Assessment of Digestive and Gastrointestinal Function

Anatomic and Physiologic Overview
Function of the Digestive System
Gerontologic Considerations
Assessment of the Gastrointestinal System
Health History
Physical Assessment
Diagnostic Evaluation
Serum Laboratory Studies
Stool Tests
Breath Tests
Abdominal Ultrasonography
Genetic Testing
Imaging Studies
Endoscopic Procedures
Manometry and Electrophysiologic Studies
Gastric Analysis, Gastric Acid Stimulation Test, and pH Monitoring
Laparoscopy (Peritoneoscopy)

39 Management of Patients with Oral and Esophageal Disorders

Disorders of the Oral Cavity
Dental Plaque and Caries
Prevention
Dental Health and Disease
Periapical Abscess
Clinical Manifestations
Medical Management
Nursing Management
Disorders of the Jaw
Temporomandibular Disorders
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Jaw Disorders Requiring Surgical Management
Nursing Management
Disorders of the Salivary Glands
Parotitis

Sialadenitis
Salivary Calculus (Sialolithiasis)
Neoplasms
Cancer of the Oral Cavity and Pharynx
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Human Papillomavirus Prevention
Medical Management
Nursing Management
Nursing Management of the Patient With Disorders of the Oral Cavity
Promoting Mouth Care
Ensuring Adequate Food and Fluid Intake
Supporting a Positive Self-Image
Minimizing Pain and Discomfort
Preventing Infection
Promoting Home, Community-Based, and Transitional Care
Neck Dissection
• *Nursing Process:* The Patient Undergoing a Neck Dissection
Delivering Nutrition Enterally
Nursing Management
Gastrostomy and Jejunostomy
• *Nursing Process:* The Patient with a Gastrostomy or Jejunostomy
Disorders of the Esophagus
Achalasia
Clinical Manifestations
Assessment and Diagnostic Findings
Management
Esophageal Spasm
Clinical Manifestations
Assessment and Diagnostic Findings
Management
Hiatal Hernia
Clinical Manifestations
Assessment and Diagnostic Findings
Management
Diverticulum
Clinical Manifestations
Assessment and Diagnostic Findings
Management
Perforation

Clinical Manifestations
Assessment and Diagnostic Findings
Management
Foreign Bodies
Chemical Burns
Gastroesophageal Reflux Disease
Clinical Manifestations
Assessment and Diagnostic Findings
Management
Barrett Esophagus
Clinical Manifestations
Assessment and Diagnostic Findings
Management
Benign Tumors of the Esophagus
• *Nursing Process:* The Patient with a Noncancerous Disorder of the Esophagus
Cancer of the Esophagus
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management

40 Management of Patients with Gastric and Duodenal Disorders

Gastritis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Peptic Ulcer Disease
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* The Patient with Peptic Ulcer Disease
Gastric Cancer
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management

Gerontologic Considerations
• *Nursing Process:* The Patient with Gastric Cancer
Tumors of the Small Intestine
Clinical Manifestations
Assessment and Diagnostic Findings
Management

41 **Management of Patients with Intestinal and Rectal Disorders**

Abnormalities of Fecal Elimination
Constipation
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Complications
Gerontologic Considerations
Medical Management
Nursing Management
Diarrhea
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Complications

Intestinal Obstruction
Small Bowel Obstruction
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Large Bowel Obstruction
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Inflammatory Bowel Disease
Crohn's Disease (Regional Enteritis)
Pathophysiology
Clinical Manifestations

Assessment and Diagnostic Findings
Complications
Ulcerative Colitis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Complications
Management of Inflammatory Bowel Disease
Medical Management
• *Nursing Process:* Management of the Patient with Inflammatory Bowel Disease
Delivering Nutrition Parenterally
Nursing Management
• *Nursing Process:* The Patient Receiving Parenteral Nutrition
Management of the Patient Requiring an Ostomy
Preoperative Nursing Management
Postoperative Nursing Management
Colorectal Neoplasms
Colorectal Cancer
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Complications
Gerontologic Considerations
Prevention
Medical Management
• *Nursing Process:* The Patient Having Surgery for Colorectal Cancer
Polyps of the Colon and Rectum
Disorders of the Anorectum
Proctitis
Anorectal Abscess
Anal Fistula
Anal Fissure
Hemorrhoids
Pilonidal Sinus or Cyst
Nursing Management of Patients with Anorectal Disorders

UNIT 10 Metabolic and Endocrine Function

42 Assessment and Management of Patients with Obesity
Obesity
Epidemiology of Obesity

Obesity Risks
Pathophysiology
Assessment of Obesity
Diagnostic Evaluation
Medical Management
Gerontologic Considerations
Veterans Considerations
COVID-19 Considerations
Nursing Management
The Patient Undergoing Bariatric Surgery
Surgical Procedures
• *Nursing Process:* The Patient Undergoing Bariatric Surgery

43 Assessment and Management of Patients with Hepatic Disorders

Assessment of the Liver
Anatomic and Physiologic Overview
Anatomy of the Liver
Functions of the Liver
Gerontologic Considerations
Assessment
Health History
Physical Assessment
Diagnostic Evaluation
Liver Function Tests
Liver Biopsy
Other Diagnostic Tests

Manifestations of Hepatic Dysfunction
Jaundice
Hemolytic Jaundice
Hepatocellular Jaundice
Obstructive Jaundice
Hereditary Hyperbilirubinemia
Portal Hypertension
Ascites
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Esophageal Varices
Pathophysiology

Clinical Manifestations
Assessment and Diagnostic Findings

Surgical Management
Nursing Management
Hepatic Encephalopathy and Coma
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Other Manifestations of Hepatic Dysfunction
Edema and Bleeding
Vitamin Deficiency
Metabolic Abnormalities
Pruritus and Other Skin Changes
Viral Hepatitis
Hepatitis A Virus
Clinical Manifestations
Assessment and Diagnostic Findings
Prevention
Medical Management
Nursing Management
Hepatitis B Virus
Gerontologic Considerations
Clinical Manifestations
Assessment and Diagnostic Findings
Prevention
Medical Management
Nursing Management
Hepatitis C Virus
Hepatitis D Virus
Hepatitis E Virus
Hepatitis G Virus and GB Virus-C
Nonviral Hepatitis
Toxic Hepatitis
Drug-Induced Hepatitis
Acute Liver Failure
Hepatic Cirrhosis
Pathophysiology
Clinical Manifestations

Assessment and Diagnostic Findings
Medical Management
Nursing Management
Cancer of the Liver
Primary Liver Tumors
Liver Metastases
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Surgical Management
Nursing Management
Liver Transplantation
Surgical Procedure
Complications
Nursing Management
Liver Abscesses
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
44 Management of Patients with Biliary Disorders
Anatomic and Physiologic Overview
The Gallbladder
The Pancreas
The Exocrine Pancreas
The Endocrine Pancreas
Endocrine Control of Carbohydrate Metabolism
Gerontologic Considerations
Disorders of the Gallbladder
Cholecystitis
Cholelithiasis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* The Patient Undergoing Surgery for Gallbladder Disease
Disorders of the Pancreas
Acute Pancreatitis
Gerontologic Considerations

Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Chronic Pancreatitis
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Pancreatic Cysts
Cancer of the Pancreas
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Tumors of the Head of the Pancreas
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Pancreatic Islet Tumors
Surgical Management
Nursing Management
Hyperinsulinism
Ulcerogenic Tumors

45 Assessment and Management of Patients with Endocrine Disorders

Assessment of the Endocrine System

Anatomic and Physiologic Overview
Glands of the Endocrine System
Function and Regulation of Hormones
Classification and Action of Hormones
Assessment
Health History
Physical Assessment
Diagnostic Evaluation
Blood Tests
Urine Tests
Additional Diagnostic Studies

The Pituitary Gland

Anatomic and Physiologic Overview

Anterior Pituitary
Posterior Pituitary
Pathophysiology
Anterior Pituitary
Posterior Pituitary
Pituitary Tumors
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Diabetes Insipidus
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Syndrome of Inappropriate Antidiuretic Hormone Secretion
Medical Management
Nursing Management
The Thyroid Gland
Anatomic and Physiologic Overview
Thyroid Hormone
Calcitonin
Pathophysiology
Assessment
Physical Examination
Diagnostic Evaluation
Thyroid Tests
Nursing Implications
Hypothyroidism
Clinical Manifestations
Medical Management
Nursing Management
Gerontologic Considerations
Hyperthyroidism
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Gerontologic Considerations
• *Nursing Process:* The Patient with Hyperthyroidism
Thyroid Tumors
Endemic (Iodine-Deficient) Goiter
Nodular Goiter

Thyroid Cancer
Assessment and Diagnostic Findings
Medical Management
Nursing Management
The Parathyroid Glands
Anatomic and Physiologic Overview
Pathophysiology
Hyperparathyroidism
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Complications: Hypercalcemic Crisis
Hypoparathyroidism
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
The Adrenal Glands
Anatomic and Physiologic Overview
Adrenal Medulla
Adrenal Cortex
Pheochromocytoma
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Adrenocortical Insufficiency (Addison's Disease)
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Cushing's Syndrome
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* The Patient with Cushing's Syndrome
Primary Aldosteronism
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management

Nursing Management
Corticosteroid Therapy
Side Effects
Therapeutic Uses of Corticosteroids
Dosage
Tapering
Nursing Management

46 Management of Patients with Diabetes
Diabetes
Epidemiology
Classification
COVID-19 Considerations
Pathophysiology
Prevention
Clinical Manifestations
Assessment and Diagnostic Findings
Gerontologic Considerations
Medical Management
Nursing Management
Acute Complications of Diabetes
Hypoglycemia (Insulin Reactions)
Gerontologic Considerations
Clinical Manifestations
Assessment and Diagnostic Findings
Management
Diabetic Ketoacidosis
Pathophysiology
Prevention
Clinical Manifestations
Assessment and Diagnostic Findings
Management
Hyperglycemic Hyperosmolar Syndrome
Clinical Manifestations
Assessment and Diagnostic Findings
Management
• *Nursing Process:* The Patient with Diabetic Ketoacidosis or Hyperglycemic Hyperosmolar Syndrome
Long-Term Complications of Diabetes
Macrovascular Complications
Role of Diabetes in Macrovascular Diseases
Management

Microvascular Complications
Diabetic Retinopathy
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Nephropathy
Clinical Manifestations
Assessment and Diagnostic Findings
Management
Diabetic Neuropathies
Peripheral Neuropathy
Clinical Manifestations
Management
Autonomic Neuropathies
Clinical Manifestations
Management
Foot and Leg Problems
Medical Management
Nursing Management
Special Issues in Diabetes Care
Patients with Diabetes Who Are Undergoing Surgery
Management of Patients with Diabetes Who Are Hospitalized
Self-Care Issues
Hyperglycemia During Hospitalization
Hypoglycemia During Hospitalization
Common Alterations in Diet
Hygiene
Stress
Gerontologic Considerations
Nursing Management

UNIT 11 Kidney and Urinary Tract Function

47 Assessment of Kidney and Urinary Function
Anatomic and Physiologic Overview
Anatomy of the Kidney and Urinary Systems
Physiology of the Kidney and Urinary Systems
Gerontologic Considerations
Assessment of the Kidney and Urinary Systems
Health History
Physical Assessment

Diagnostic Evaluation
Urinalysis and Urine Culture
Specific Gravity
Osmolality
Renal Function Tests
Diagnostic Imaging
Urologic Endoscopic Procedures
Biopsy

48 Management of Patients with Kidney Disorders
Fluid and Electrolyte Imbalances in Kidney Disorders
Clinical Manifestations
Gerontologic Considerations
Kidney Disorders
Chronic Kidney Disease
Pathophysiology
Stages of Chronic Kidney Disease
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Gerontologic Considerations
Nephrosclerosis
Pathophysiology
Assessment and Diagnostic Findings
Medical Management
Primary Glomerular Diseases
Acute Nephritic Syndrome
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Complications
Medical Management
Nursing Management
Chronic Glomerulonephritis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Nephrotic Syndrome
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings

Assessment and Diagnostic Findings
Complications
Medical Management
Urinary Catheters
Indwelling Catheters
Suprapubic Catheters
Nursing Management
Urolithiasis and Nephrolithiasis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* The Patient with Renal Calculi
Genitourinary Trauma
Specific Injuries
Ureteral Trauma
Bladder Trauma
Urethral Trauma
Medical Management
Nursing Management
Urinary Tract Cancers
Cancer of the Bladder
Clinical Manifestations

Assessment and Diagnostic Findings
Medical Management
Urinary Diversions
Ileal Conduit
Complications
Nursing Management
Orthotopic Neobladder
Surgical Management
Complications
Nursing Management
Other Continent Urinary Diversion Procedures
• *Nursing Process:* The Patient Undergoing Urinary Diversion Surgery

UNIT 12 Reproductive Function

50 Assessment and Management of Patients with Female Physiologic Processes
CHALLENGES in Women's Health
Assessment of the Female Reproductive System
Anatomic and Physiologic Overview
Anatomy of the Female Reproductive System
Function of the Female Reproductive System
Assessment
Health History
Physical Assessment
Diagnostic Evaluation
Cytologic Test for Cancer (Pap Smear)
Colposcopy and Cervical Biopsy
Cryotherapy and Laser Therapy
Cone Biopsy and Loop Electrosurgical Excision Procedure
Endometrial (Aspiration) Biopsy
Dilation and Curettage
Endoscopic Examinations
Other Diagnostic Procedures
Management of Female Physiologic Processes
Menstruation
Psychosocial Considerations
Cultural Considerations
Menstrual Disorders
Premenstrual Syndrome
Clinical Manifestations
Medical Management

Nursing Management
Dysmenorrhea
Assessment and Diagnostic Findings
Management
Amenorrhea
Abnormal Uterine Bleeding
Dyspareunia
Contraception
Contraindications
Abstinence
Long-Acting Reversible Contraceptive (LARC) Methods
Sterilization
Hormonal Contraception
Mechanical Barriers
Coitus Interruptus or Withdrawal
Fertility Awareness–Based Methods
Emergency Contraception
Nursing Management
Abortion
Spontaneous Abortion
Habitual Abortion
Medical Management
Nursing Management
Induced Abortion
Medical Management
Nursing Management
Infertility
Diagnostic Findings
Medical Management
Nursing Management
Preconception/Periconception Health Care
Ectopic Pregnancy
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* The Patient with an Ectopic Pregnancy
Perimenopause
Nursing Management
Menopause
Postmenopausal Bleeding
Clinical Manifestations
Psychological Considerations

Medical Management
Nursing Management

51 Management of Patients with Female Reproductive Disorders

Vulvovaginal Infections

Candidiasis
Clinical Manifestations
Medical Management

Bacterial Vaginosis
Clinical Manifestations
Medical Management

Trichomoniasis
Clinical Manifestations
Medical Management

Gerontologic Considerations

• *Nursing Process:* The Patient with a Vulvovaginal Infection

Human Papillomavirus
Pathophysiology
Medical Management
Prevention

Herpes Virus Type 2 Infection (Herpes Genitalis, Herpes Simplex Virus)
Pathophysiology
Clinical Manifestations
Medical Management

• *Nursing Process:* The Patient with a Genital Herpes Infection

Endocervicitis and Cervicitis
Chlamydia and Gonorrhea
Medical Management
Nursing Management

Pelvic Inflammatory Disease
Pathophysiology
Clinical Manifestations
Complications
Medical Management
Nursing Management

Human Immune Deficiency Virus Infection and Acquired Immune Deficiency Syndrome

Structural Disorders

Fistulas of the Vagina
Clinical Manifestations

Assessment and Diagnostic Findings
Medical Management
Pelvic Organ Prolapse: Cystocele, Rectocele, Enterocele
Clinical Manifestations
Medical Management
Uterine Prolapse
Medical Management
Nursing Management
Benign Disorders
Vulvitis and Vulvodynia
Medical Management
Vulvar Cysts
Medical Management
Vulvar Dystrophy
Medical Management
Nursing Management
Ovarian Cysts
Medical Management
Benign Tumors of the Uterus: Fibroids (Leiomyomas, Myomas)
Clinical Manifestations
Medical Management
Endometriosis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Chronic Pelvic Pain
Adenomyosis
Endometrial Hyperplasia
Malignant Conditions
Cancer of the Cervix
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Cancer of the Uterus (Endometrium)
Pathophysiology
Assessment and Diagnostic Findings
Medical Management
Cancer of the Vulva
Clinical Manifestations

Medical Management
Nursing Management
Cancer of the Vagina
Medical Management
Cancer of the Fallopian Tubes
Cancer of the Ovary
Epidemiology
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Hysterectomy
Preoperative Management
Postoperative Management
• *Nursing Process:* The Patient Undergoing a Hysterectomy
Radiation Therapy
Methods of Radiation Therapy
Nursing Considerations for Radiation Safety

52 **Assessment and Management of Patients with Breast Disorders**

Breast Assessment
Anatomic and Physiologic Overview
Assessment
Health History
Physical Assessment: Female Breast
Physical Assessment: Male Breast
Diagnostic Evaluation
Breast Self-Examination
Mammography
Contrast Mammography
Ultrasonography
Magnetic Resonance Imaging
Procedures for Tissue Analysis
Conditions Affecting the Nipple
Nipple Discharge
Fissure
Breast Infections
Mastitis
Lactational Abscess
Benign Conditions of the Breast

Breast Pain
Nursing Management
Cysts
Fibroadenomas
Benign Proliferative Breast Disease
Atypical Hyperplasia
Lobular Carcinoma In Situ
Other Benign Conditions
Malignant Conditions of the Breast
Types of Breast Cancer
Ductal Carcinoma In Situ
Medical Management
Invasive Cancer
Risk Factors
Protective Factors
Breast Cancer Prevention Strategies in the Patient Who Is at High Risk
Clinical Manifestations
Assessment and Diagnostic Findings
Staging
Prognosis
Surgical Management
Nursing Management
• *Nursing Process:* The Patient Undergoing Surgery for Breast Cancer
Radiation Therapy
Side Effects
Nursing Management
Systemic Treatments
Chemotherapy
Side Effects
Nursing Management
Hormonal Therapy
Targeted Therapy
Treatment of Recurrent and Metastatic Breast Cancer
Nursing Management
Reconstructive Procedures After Mastectomy
Tissue Expander Followed by Permanent Implant
Tissue Transfer Procedures
Nipple–Areola Reconstruction
Prosthetics
Special Issues in Breast Cancer Management
Implications of Genetic Testing

Pregnancy and Breast Cancer
Quality of Life and Survivorship
Gerontologic Considerations
Breast Health of Women with Disability
Reconstructive Breast Surgery
Reduction Mammoplasty
Augmentation Mammoplasty
Mastopexy
Diseases of the Male Breast
Gynecomastia
Male Breast Cancer

53 Assessment and Management of Patients with Male Reproductive Disorders
Assessment of the Male Reproductive System
Anatomic and Physiologic Overview
Gerontologic Considerations
Assessment
Health History
Physical Assessment
Diagnostic Evaluation
Prostate-Specific Antigen Test
Ultrasonography
Prostate Fluid or Tissue Analysis
Tests of Male Sexual Function
Disorders of Male Sexual Function
Erectile Dysfunction
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Disorders of Ejaculation
Infections of the Male Genitourinary Tract
Prostatic Disorders
Prostatitis
Clinical Manifestations
Medical Management
Nursing Management
Benign Prostatic Hyperplasia (Enlarged Prostate)
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management

Cancer of the Prostate
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
The Patient Undergoing Prostate Surgery
Surgical Procedures
Complications
• *Nursing Process:* Patient Undergoing Prostatectomy
Disorders Affecting the Testes and Adjacent Structures
Orchitis
Epididymitis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Testicular Torsion
Testicular Cancer
Classification of Testicular Tumors
Risk Factors
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Hydrocele
Varicocele
Vasectomy
Nursing Management
Vasovasostomy (Sterilization Reversal)
Semen Cryopreservation (Sperm Banking)
Disorders Affecting the Penis
Phimosis
Cancer of the Penis
Clinical Manifestations
Assessment and Diagnostic Findings
Prevention
Medical Management
Priapism
Peyronie Disease
Urethral Stricture
Circumcision

54 Assessment and Management of Patients Who Are LGBTQ
Sexuality and Gender Identity
Sexuality
Gender Identity
Statistics on LGBTQ Populations
Health Risks
Assessment
Gerontologic Considerations
Assessment and Management of Patients Seeking Gender Reassignment
Medical Management
• *Nursing Process:* The Patient Undergoing Gender Reassignment Surgery

UNIT 13 Integumentary Function

55 Assessment of Integumentary Function
Anatomic and Physiologic Overview
Anatomy of the Skin, Hair, Nails, and Glands of the Skin
Functions of the Skin
Gerontologic Considerations
Assessment
Health History
Physical Assessment
Skin Consequences of Select Systemic Diseases
Diagnostic Evaluation
Skin Biopsy
Patch Testing
Skin Scrapings
Tzanck Smear
Wood Light Examination
Clinical Photographs
Nursing Implications

56 Management of Patients with Dermatologic Disorders
Skin Care
Protecting the Skin
Preventing Secondary Infection
Wound Dressing Care
Autolytic Débridement
Categories of Dressings

Medical Management
Nursing Management
Pressure Injury
• *Nursing Process:* The Patient with Pressure Injury
Pruritus
General Pruritus
Gerontologic Considerations
Pathophysiology
Medical Management
Nursing Management
Perineal and Perianal Pruritus
Management
Secretory Disorders
Hidradenitis Suppurativa
Pathophysiology
Clinical Manifestations
Management
Seborrheic Dermatitis
Clinical Manifestations
Medical Management
Nursing Management
Acne Vulgaris
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Infectious Dermatoses
Bacterial Skin Infections
Impetigo
Clinical Manifestations
Medical Management
Nursing Management
Folliculitis, Furuncles, and Carbuncles
Medical Management
Nursing Management
Viral Skin Infections
Herpes Zoster
Clinical Manifestations
Medical Management
Nursing Management
Herpes Simplex

COVID-19 Considerations
Fungal (Mycotic) Skin Infections
Parasitic Skin Infestations
Pediculosis: Lice Infestation
Clinical Manifestations
Medical Management
Nursing Management
Scabies
Clinical Manifestations
Gerontologic Considerations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Noninfectious Inflammatory Dermatoses
Irritant Contact Dermatitis
Clinical Manifestations
Management
COVID-19 Considerations
Psoriasis
Pathophysiology
Clinical Manifestations
Complications
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Generalized Exfoliative Dermatitis
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Blistering Diseases
Pemphigus Vulgaris
Assessment and Diagnostic Findings
Management
Bullous Pemphigoid
Assessment and Diagnostic Findings
Management
Dermatitis Herpetiformis
Assessment and Diagnostic Findings
Management
• *Nursing Process:* Care of the Patient with a Blistering Disease
Toxic Epidermal Necrolysis and Stevens–Johnson Syndrome

Clinical Manifestations
Complications
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* Care of the Patient with Toxic Epidermal Necrolysis or Stevens–Johnson Syndrome
Skin Tumors
Benign Skin Tumors
Cysts
Seborrheic and Actinic Keratoses
Verrucae: Warts
Angiomas
Pigmented Nevi: Moles
Keloids
Dermatofibroma
Neurofibromatosis: Von Recklinghausen Disease
Malignant Skin Tumors
Basal Cell Carcinoma and Squamous Cell Carcinoma
Clinical Manifestations
Medical Management
Nursing Management
Melanoma
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Metastatic Skin Tumors
Kaposi Sarcoma
Plastic, Reconstructive, and Cosmetic Procedures
Wound Coverage: Grafts and Flaps
Skin Grafts
Flaps
Cosmetic Procedures
Chemical Face Peeling
Dermabrasion
Facial Reconstructive Surgery
Rhytidectomy
Laser Treatment of Cutaneous Lesions
Nursing Management
57 Management of Patients with Burn Injury
Overview of Burn Injury

Incidence
Gerontologic Considerations
Prevention
Outlook for Survival and Recovery
Severity
Pathophysiology
Management of Burn Injury
Emergent/Resuscitative Phase
On-the-Scene Care
Medical Management
Nursing Management
Acute/Intermediate Phase
Medical Management
Nursing Management
Rehabilitation Phase
Psychological Support
Abnormal Wound Healing
• *Nursing Process:* Care of the Patient during the Rehabilitation Phase
Outpatient Burn Care

UNIT 14 Sensory Function

58 Assessment and Management of Patients with Eye and Vision Disorders
Assessment of the Eye
Anatomic and Physiologic Overview
Assessment
Ocular History
Visual Acuity
External Eye Examination
Diagnostic Evaluation
Direct Ophthalmoscopy
Indirect Ophthalmoscopy
Slit-Lamp Examination
Tonometry
Color Vision Testing
Amsler Grid
Ultrasonography
Optical Coherence Tomography
Fundus Photography
Laser Scanning
Angiography

Perimetry Testing
Impaired Vision
Refractive Errors
Vision Impairment and Blindness
Assessment and Diagnostic Testing
Gerontologic Considerations
Medical Management
Nursing Management
Ocular Medication Administration
Common Ocular Medications
Topical Anesthetic Agents
Mydriatic and Cycloplegic Agents
Medications Used to Treat Glaucoma
Anti-Infective Medications
Corticosteroids and Nonsteroidal Anti-Inflammatory Drugs
Antiallergy Medications
Ocular Irrigants and Lubricants
Nursing Management
Glaucoma
Physiology
Pathophysiology
Classification of Glaucoma
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Cataracts
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Corneal Disorders
Corneal Dystrophies
Keratoconus
Fuchs Endothelial Dystrophy
Corneal Surgeries
Phototherapeutic Keratectomy
Penetrating Keratoplasty
Additional Keratoplasty Surgeries
Keratoprosthesis
Nursing Management

Refractive Surgeries
Laser Vision Correction Photorefractive Keratectomy
Phakic Intraocular Lenses
Conductive Keratoplasty
Retinal Disorders
Retinal Detachment
Clinical Manifestations
Assessment and Diagnostic Findings
Surgical Management
Nursing Management
Retinal Vascular Disorders
Central Retinal Vein Occlusion
Branch Retinal Vein Occlusion
Central Retinal Artery Occlusion
Age-Related Macular Degeneration
Medical Management
Nursing Management
Orbital and Ocular Trauma
Orbital Trauma
Soft Tissue Injury and Hemorrhage
Orbital Fractures
Foreign Bodies
Ocular Trauma
Assessment and Diagnostic Findings
Medical Management
Infectious and Inflammatory Conditions
Dry Eyes
Clinical Manifestations
Assessment and Diagnostic Findings
Management
Conjunctivitis
Clinical Manifestations
Assessment and Diagnostic Findings
Types of Conjunctivitis
Medical Management
Uveitis
Medical Management
Orbital Cellulitis
Medical Management
Orbital and Ocular Tumors
Benign Tumors of the Orbit

Benign Tumors of the Eyelids
Benign Tumors of the Conjunctiva
Malignant Tumors of the Orbit
Malignant Tumors of the Eyelid
Malignant Tumors of the Conjunctiva
Malignant Tumors of the Globe
Surgical Procedures and Enucleation
Orbital Surgeries
Enucleation
Ocular Prostheses
Medical Management
Nursing Management
Ocular Consequences of Systemic Disease
Diabetic Retinopathy
Cytomegalovirus Retinitis
Medical Management
Hypertension-Related Eye Changes
59 Assessment and Management of Patients with Hearing and Balance Disorders
Assessment of the Ear
Anatomic and Physiologic Overview
Anatomy of the External Ear
Anatomy of the Middle Ear
Anatomy of the Inner Ear
Function of the Ears
Assessment
Inspection of the External Ear
Otoscopic Examination
Evaluation of Gross Auditory Acuity
Cultural Considerations
Diagnostic Evaluation
Audiometry
Tympanogram
Auditory Brain Stem Response Audiometry
Electronystagmography
Platform Posturography
Sinusoidal Harmonic Acceleration
Middle Ear Endoscopy
Hearing Loss
Clinical Manifestations

Prevention
Gerontologic Considerations
Medical Management
Nursing Management
Conditions of the External Ear
Cerumen Impaction
Management
Foreign Bodies
Management
External Otitis (Otitis Externa)
Clinical Manifestations
Medical Management
Nursing Management
Malignant External Otitis
Masses of the External Ear
Conditions of the Middle Ear
Tympanic Membrane Perforation
Medical Management
Acute Otitis Media
Clinical Manifestations
Medical Management
Serous Otitis Media
Clinical Manifestations
Management
Chronic Otitis Media
Clinical Manifestations
Medical Management
• *Nursing Process:* The Patient Undergoing Mastoid Surgery
Otosclerosis
Clinical Manifestations
Medical Management
Middle Ear Masses
Conditions of the Inner Ear
Motion Sickness
Clinical Manifestations
Management
Ménière's Disease
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Benign Paroxysmal Positional Vertigo

Tinnitus
Labyrinthitis
Clinical Manifestations
Management
Ototoxicity
Acoustic Neuroma
Assessment and Diagnostic Findings
Management
Aural Rehabilitation
Hearing Aids
Implanted Hearing Devices
Hearing Guide Dogs

UNIT 15 Neurologic Function

60 Assessment of Neurologic Function
Anatomic and Physiologic Overview
Cells of the Nervous System
Neurotransmitters
The Central Nervous System
The Peripheral Nervous System
Motor and Sensory Pathways of the Nervous System
Assessment of the Nervous System
Health History
Physical Assessment
Gerontologic Considerations
Diagnostic Evaluation
Computed Tomography Scanning
Magnetic Resonance Imaging
Positron Emission Tomography
Single-Photon Emission Computed Tomography
Cerebral Angiography
Myelography
Noninvasive Carotid Flow Studies
Transcranial Doppler
Electroencephalography
Electromyography
Nerve Conduction Studies
Evoked Potential Studies
Lumbar Puncture and Examination of Cerebrospinal Fluid
Promoting Home, Community-Based, and Transitional Care

61 Management of Patients with Neurologic Dysfunction
Altered Level of Consciousness
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* The Patient with an Altered Level of Consciousness
Increased Intracranial Pressure
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Complications
Medical Management
• *Nursing Process:* The Patient with Increased Intracranial Pressure
Intracranial Surgery
Supratentorial and Infratentorial Approaches
Preoperative Management
Medical Management
Nursing Management
Postoperative Management
Reducing Cerebral Edema
Relieving Pain and Preventing Seizures
Monitoring Intracranial Pressure
• *Nursing Process:* The Patient Who Has Undergone Intracranial Surgery
Transsphenoidal Approach
Complications
Preoperative Management
Medical Management
Nursing Management
Postoperative Management
Medical Management
Nursing Management
Other Neurologic Dysfunctions
Delirium
Dementia
Pseudobulbar Affect
Seizure Disorders
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings

Nursing Management
The Epilepsies
Pathophysiology
Epilepsy in Women
Gerontologic Considerations
Prevention
Medical Management
• *Nursing Process:* The Patient with Epilepsy
Status Epilepticus
Medical Management
Nursing Management
Headache
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Prevention
Medical Management
Nursing Management
62 Management of Patients with Cerebrovascular Disorders
Ischemic Stroke
COVID-19 Considerations
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Prevention
Medical Management
• *Nursing Process:* The Patient Recovering from an Ischemic Stroke
Hemorrhagic Stroke
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Prevention
Complications
Medical Management
• *Nursing Process:* The Patient with a Hemorrhagic Stroke
63 Management of Patients with Neurologic Trauma
Head Injuries
Pathophysiology
Clinical Manifestations
Veterans Considerations

Assessment and Diagnostic Findings
Gerontologic Considerations
Medical Management
Brain Injury
Types of Brain Injury
Medical Management
• *Nursing Process:* The Patient with a Traumatic Brain Injury
Spinal Cord Injury (SCI)
Pathophysiology
Veterans Considerations
Clinical Manifestations
Assessment and Diagnostic Findings
Emergency Management
Medical Management (Acute Phase)
Management of Acute Complications of Spinal Cord Injury
• *Nursing Process:* The Patient with Acute Spinal Cord Injury
Medical Management of Long-Term Complications of SCI
• *Nursing Process:* The Patient with Tetraplegia or Paraplegia

64 Management of Patients with Neurologic Infections, Autoimmune Disorders, and Neuropathies

Infectious Neurologic Disorders

Meningitis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Prevention
Medical Management
Nursing Management
Brain Abscess
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Herpes Simplex Encephalitis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Arthropod-Borne Virus Encephalitis

Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Creutzfeldt–Jakob and Variant Creutzfeldt–Jakob Diseases
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Autoimmune Processes
Multiple Sclerosis
Pathophysiology
Clinical Manifestations
Gerontologic Considerations
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* The Patient with MS
Myasthenia Gravis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Complications
Nursing Management
Guillain–Barré Syndrome
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
• *Nursing Process:* The Patient with GBS
Cranial Nerve Disorders
Trigeminal Neuralgia
Medical Management
Nursing Management
Bell's Palsy
Medical Management
Nursing Management
Disorders of the Peripheral Nervous System
Peripheral Neuropathies
Mononeuropathy

65 Management of Patients with Oncologic or Degenerative Neurologic Disorders

Oncologic Disorders of the Brain and Spinal Cord

Brain Tumors
- Types of Primary Brain Tumors
- Gerontologic Considerations
- Clinical Manifestations
- Assessment and Diagnostic Findings
- Medical Management
- Nursing Management

Cerebral Metastases
- Medical Management

• *Nursing Process:* The Patient with Nervous System Metastases or Primary Brain Tumor

Spinal Cord Tumors
- Assessment and Diagnostic Findings
- Medical Management
- Nursing Management

Degenerative Disorders

Parkinson's Disease
- Pathophysiology
- Clinical Manifestations
- Assessment and Diagnostic Findings
- Medical Management

• *Nursing Process:* The Patient with Parkinson's Disease

Huntington Disease
- Pathophysiology
- Clinical Manifestations
- Assessment and Diagnostic Findings
- Medical Management

Amyotrophic Lateral Sclerosis
- Clinical Manifestations
- Assessment and Diagnostic Findings
- Management

Muscular Dystrophies
- Medical Management
- Nursing Management

Degenerative Disc Disease
- Pathophysiology
- Gerontologic Considerations
- Clinical Manifestations
- Assessment and Diagnostic Findings

Medical Management
Herniation of a Cervical Intervertebral Disc
Clinical Manifestations
Medical Management
• *Nursing Process:* The Patient Undergoing a Cervical Discectomy
Herniation of a Lumbar Disc
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Post-Polio Syndrome
Pathophysiology
Assessment and Diagnostic Findings
Management

UNIT 16 Acute Community-Based Challenges

66 Management of Patients with Infectious Diseases
The Infectious Process
The Chain of Infection
Colonization, Infection, and Infectious Disease
Infection Control and Prevention
Preventing Infection in Health Care Settings
Preventing Infection in the Community
Home-Based Care of the Patient with an Infectious Disease
Reducing Risk to the Patient
Reducing Risk to Household Members
Nursing Management
Diarrheal Diseases
Transmission
Causes
• *Nursing Process:* The Patient with Infectious Diarrhea
Sexually Transmitted Infections
Syphilis
Stages of Syphilis
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Chlamydia trachomatis and *Neisseria gonorrhoeae* Infections
Clinical Manifestations
Complications
Assessment and Diagnostic Findings

Medical Management
Nursing Management
• *Nursing Process:* The Patient with a Sexually Transmitted Infection
Emerging Infectious Diseases
COVID-19
Pathophysiology
Risk Factors
Clinical Manifestations
Medical Management
Nursing Management
Zika Virus
West Nile Virus
Ebola Virus Disease
Pathophysiology
Clinical Manifestations
Medical Management
Nursing Management
Legionnaires Disease
Pathophysiology
Risk Factors
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Pertussis
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Medical Management
Nursing Management
Travel and Immigration
Immigration and Acquired Immune Deficiency Syndrome
Immigration and Tuberculosis
Immigration and Vector-Borne Diseases

67 Emergency Nursing

Issues in Emergency Nursing Care

Documentation of Consent and Privacy
Limiting Exposure to Health Risks
COVID-19 Considerations
Violence in the Emergency Department
Providing Holistic Care

Patient-Focused Interventions
Family-Focused Interventions
Caring for Emergency Personnel
COVID-19 Considerations
Emergency Nursing and the Continuum of Care
Discharge Planning
Community and Transitional Services
Gerontologic Considerations
Obesity Considerations
Principles of Emergency Care
Triage
COVID-19 Considerations
Assess and Intervene
Airway Obstruction
Pathophysiology
Clinical Manifestations
Assessment and Diagnostic Findings
Management
Hemorrhage
Management
Hypovolemic Shock
Wounds
Management
Trauma
Collection of Forensic Evidence
Injury Prevention
Multiple Trauma
Assessment and Diagnostic Findings
Management
Intra-Abdominal Injuries
Assessment and Diagnostic Findings
Management
Crush Injuries
Assessment and Diagnostic Findings
Management
Fractures
Management
Environmental Emergencies
Heat-Induced Illnesses
Gerontologic Considerations
Assessment and Diagnostic Findings

Management
Frostbite
Assessment and Diagnostic Findings
Management
Hypothermia
Assessment and Diagnostic Findings
Management
Nonfatal Drowning
Management
Decompression Sickness
Assessment and Diagnostic Findings
Management
Animal and Human Bites
Snakebites
Clinical Manifestations
Management
Spider Bites
Tick Bites
Poisoning
Ingested (Swallowed) Poisons
Carbon Monoxide Poisoning
Clinical Manifestations
Management
Skin Contamination Poisoning (Chemical Burns)
Food Poisoning
Substance Use Disorder (SUD)
Acute Alcohol Intoxication
Alcohol Withdrawal Syndrome
Violence, Abuse, and Neglect
Family Violence, Abuse, and Neglect
Gerontologic Considerations
Clinical Manifestations
Assessment and Diagnostic Findings
Management
Sexual Assault
Assessment and Diagnostic Findings
Management
Human Trafficking
Psychiatric Emergencies
Patients Who Are Overactive
Patients with Posttraumatic Stress Disorder (PTSD)

Veterans Considerations
Patients Who Are Underactive or Depressed
Patients Who Are Suicidal

68 Disaster Nursing
Disaster Planning
Federal, State, and Local Responses to Disasters
Federal Agencies
State and Local Agencies
The Incident Command System
Hospital Emergency Preparedness Plans
COVID-19 Considerations
Components of the Emergency Operations Plan
Initiating the Emergency Operations Plan
Preparedness and Response
Recognition and Awareness
Personal Protective Equipment (PPE)
Decontamination
Natural Disasters
Outbreaks, Epidemics, and Pandemics
Weapons of Terror
Blast Injury
Biologic Weapons
Chemical Weapons
Nuclear Radiation Exposure

Appendix A: Diagnostic Studies and Interpretation
Available on thePoint

Index

Case Studies in This Book

QSEN Cases That Open Each Unit

UNIT 1 Principles of Nursing Practice
Educating Older Adults to Navigate Their Electronic Health Records

UNIT 2 Concepts and Principles of Patient Management
Promoting Teamwork and Collaboration in Palliative Care

UNIT 3 Perioperative Concepts and Nursing Management
Maintaining a Culture of Safety Using the Surgical Safety Checklist

UNIT 4 Gas Exchange and Respiratory Function
Providing Evidence-Based Care for a Patient with COVID-19

UNIT 5 Cardiovascular and Circulatory Function
Using Technology to Prevent Medication Errors

UNIT 6 Hematologic Function
Evaluating Complications of Chemotherapy

UNIT 7 Immunologic Function
Utilizing a Team Approach to Care for the Patient with HIV

UNIT 8 Musculoskeletal Function
Implementing Evidence-Based Practice in Pain Management

UNIT 9 Digestive and Gastrointestinal Function
Improving Nutrition Utilizing Quality Indicators

UNIT 10 Metabolic and Endocrine Function
Applying Patient-Centered Care for the Patient with Diabetes

UNIT 11 Kidney and Urinary Tract Function
Avoiding Falls for the Patient at Risk

UNIT 12 Reproductive Function
Implementing Alternative, Complementary, and Spiritual Practices

UNIT 13 Integumentary Function
Managing and Preventing Skin Cancer

UNIT 14 Sensory Function
Making a Rapid Change to Telehealth

UNIT 15 Neurologic Function
Developing a Team-Based Plan of Care

UNIT 16 Acute Community-Based Challenges
Using Evidence-Based Practices for Effective Care during a Novel Virus Outbreak

Cases That Unfold Across Chapters

Unfolding Patient Stories: Vincent Brody
Part 1: Chapter 3
Part 2: Chapter 55

Unfolding Patient Stories: Skyler Hansen
Part 1: Chapter 5
Part 2: Chapter 46

Unfolding Patient Stories: Stan Checketts
Part 1: Chapter 9
Part 2: Chapter 41

Unfolding Patient Stories: Doris Bowman
Part 1: Chapter 12
Part 2: Chapter 51

Unfolding Patient Stories: Vernon Watkins
Part 1: Chapter 14
Part 2: Chapter 58

Unfolding Patient Stories: Kenneth Bronson
Part 1: Chapter 19

Part 2: Chapter 22

Unfolding Patient Stories: Jennifer Hoffman
Part 1: Chapter 20
Part 2: Chapter 33

Unfolding Patient Stories: Carl Shapiro
Part 1: Chapter 23
Part 2: Chapter 67

Unfolding Patient Stories: Lloyd Bennett
Part 1: Chapter 28
Part 2: Chapter 47

Unfolding Patient Stories: Marilyn Hughes
Part 1: Chapter 37
Part 2: Chapter 60

Special Charts in This Book

Assessment

Chart 2-2, Assessing Potential Struggles in Function or Movement
Chart 2-8, Assessing the Home Environment
Chart 2-9, Assessing the Need for Home Visits
Chart 4-3, Patient Profile
Chart 4-4, Assessing the Health of People with Disability
Chart 4-7, Assessing for Patients' Cultural Beliefs
Chart 5-1, Assessing for Stress
Chart 6-6, Assessing Psychosocial Genetic Health
Chart 8-3, Assessing Mental Status: Mini-Mental State Examination Sample Items
Chart 8-7, Confusion Assessment Method (CAM)
Chart 10-3, Assessing Arterial Blood Gases
Chart 10-5, Assessing for Phlebitis
Chart 10-6, Assessing for Infiltration
Chart 13-3, Preferred Language for Assessing Goals of Care
Chart 13-8, Cultural and Spiritual Issues at the End-of-Life
Chart 17-6, Assessing Psychosocial Factors Related to Respiratory Function and Disease
Chart 18-4, Assessing for Obstructive Sleep Apnea
Chart 20-2, Assessing Patients with Chronic Obstructive Pulmonary Disease
Chart 21-3, Assessing Patients for Orthostatic Hypotension
Chart 23-4, Assessing Angina
Chart 23-6, Assessing for Acute Coronary Syndrome or Acute Myocardial Infarction
Chart 25-1, Heart Failure
Chart 29-10, Assessing for Thrombosis and Bleeding in Disseminated Intravascular Coagulation
Chart 31-3, Assessing for Immune Dysfunction
Chart 33-1, Allergy Assessment Form
Chart 34-1, Assessing for Rheumatic Disorders
Chart 35-3, Assessing for Peripheral Nerve Function
Chart 39-5, Assessing Patients Receiving Tube Feedings
Chart 41-1, Rome IV Diagnostic Criteria for Functional Constipation
Chart 41-6, Assessing for Home Nutrition Support

Chart 43-9, Assessing for Cirrhosis
Chart 46-3, Assessing the Patient with Diabetes
Chart 48-6, Assessing for End-Stage Kidney Disease
Chart 50-4, Assessing a Woman with a Disability
Chart 52-1, Abnormal Assessment Findings during Inspection of the Breasts
Chart 54-1, Personal Information
Chart 55-2, Assessing for Skin Disorders
Chart 56-8, Assessing the ABCDEs of Moles
Chart 58-1, Taking a History of Patients with Eye and Vision Disorders
Chart 59-3, Assessing for Hearing Loss
Chart 63-4, Glasgow Coma Scale
Chart 64-1, Assessing for Brain Abscesses
Chart 66-5, Assessing for Infectious Disease
Chart 67-7, Food Poisoning
Chart 67-8, Assessing for Abuse, Maltreatment, and Neglect

Ethical Dilemma

Chart 1-7, Common Ethical Principles
Chart 1-10, Steps of an Ethical Analysis
Chart 6-2, Can Predictive Genetic Testing Threaten Patient Autonomy?
Chart 8-8, Does Stopping of Eating and Drinking Violate the Principle of Nonmaleficence?
Chart 13-9, Does Intent Matter When Palliative Care Leads to Death?

UNIT 1 Principles of Nursing Practice

Case Study

EDUCATING OLDER ADULTS TO NAVIGATE THEIR ELECTRONIC HEALTH RECORDS

You are a nurse working in a community health center that provides services for older adults. A recent needs assessment indicates that patrons of the health center are underutilizing electronic resources available to them. Furthermore, these

individuals need education about resources such as their electronic health records (EHRs) including how to access, maintain, and utilize this tool. EHRs enable patients to be more aware and have better control over their health management. You implement a plan for educating older adults in the community on this technology. The main goal of this project is to empower older adults to easily access their own EHRs and manage their appointments, medications, and follow-up visits. An additional goal is that use of this technology will enable patients, families, and communities to have up-to-date information and increased access to health-related resources.

QSEN Competency Focus: **Patient-Centered Care**

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety,*** and ***informatics.***

Patient-Centered Care Definition: Recognize the patient or designee as the source of control and full partner in providing compassionate and coordinated care based on respect for patient's preferences, values, and needs.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Describe strategies to empower patients or families in all aspects of the health care process	How does providing access to patient information empower patients, families, and communities to manage their health? What are the advantages to having immediate access to patient information?
Skills	
Engage patients or designated surrogates in active partnerships that promote health, safety and well-being, and self-care management	What is the responsibility of the nurse in helping patients navigate their EHR? Discuss how you would advocate for patients so they have the resources to access, understand, and utilize their EHR.
Attitudes	
Seek learning opportunities with patients who represent all aspects of human diversity	Think about your own experience and training with patients, families, and communities that have technology barriers. Why is it important for nurses to provide opportunities to patients, families, and communities of diverse backgrounds about the use of technology to access information?

Cronenwett, L., Sherwood, G., Barnsteiner, J., et al. (2007). Quality and safety education for nurses. *Nursing Outlook*, *55*(3), 122–131; Institute of Medicine. (2003). *Health professions education: A bridge to quality*. Washington, DC: National Academies Press; QSEN Institute. (2020). *QSEN competencies: Definitions and pre-licensure KSAs; Patient-centered care*. Retrieved on 8/15/2020 at: qsen.org/competencies/pre-licensure-ksas/#patient-centered_care

1 Professional Nursing Practice

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Define nursing, patient, health, wellness, health promotion, and health care.
2. Describe salient influences on the delivery of health care.
3. Discuss practices that improve quality and safety and ensure the use of evidence-based practices within the health care system.
4. Discuss behavioral competencies and characteristics of professional nursing practice and the nurse's role as a collaborative member of the interprofessional health care team.
5. Define the characteristics of critical thinking, the critical thinking process, and clinical decision making.
6. Describe the components of the nursing process.
7. Identify strategies that can be implemented in ethical decision making.

NURSING CONCEPTS

Accountability

Safety

GLOSSARY

assessment: the systematic collection of data, through interview, observation, and examination, to determine the patient's health status and any actual or potential problems

bundle: a set of three to five evidence-based practices that, when implemented appropriately, can measurably improve patient outcomes

critical thinking: a cognitive process that utilizes thinking that is purposeful, insightful, reflective, and goal directed to develop conclusions, solutions, and alternatives that are appropriate to the given solution

ethics: the formal, systematic process used to understand, analyze, and evaluate decisions regarding matters of right and wrong as they apply to well-being

evaluation: determination of the patient's response to nursing interventions and the extent to which the outcomes have been achieved

evidence-based practice (EBP): a best practice derived from valid and reliable research studies that also considers the health care setting, patient preferences and values, and clinical judgment

health: according to the World Health Organization (2006), a "state of complete physical, mental, and social well-being and not merely the absence of disease and infirmity" (p. 1)

health informatics: the use of health information technology to improve the quality, efficiency, or delivery of health care

health promotion: focuses on the potential for wellness and targets appropriate alterations in personal habits, lifestyle, and environment in ways that reduce risks and enhance health and well-being

implementation: actualization or carrying out of the nursing plan of care through nursing interventions

interprofessional collaborative practice: employing multiple health professionals to work together with patients, families, and communities to deliver best practices, thus ensuring best patient outcomes

morality: specific beliefs or actions whose outcomes are often examined utilizing the principles of autonomy, beneficence, nonmaleficence, double effect, and distributive justice

moral dilemma: situation in which two or more ethically plausible principles are in opposition to each other and only one may be chosen

moral distress: internal response that occurs when a health care provider believes they inherently know the correct ethical action that is needed but cannot act on that knowledge

moral integrity: virtue composed of veracity, fidelity, benevolence, wisdom, and moral courage

moral problem: competing moral claim or principle; one principle is clearly dominant

moral uncertainty: internal conflict that arises when the person cannot define what the moral situation is or what moral principles apply but has a strong feeling that something is not right

nursing: according to the American Nurses Association (2015b), "the protection, promotion, and optimization of health and abilities, prevention of illness and injury, facilitation of healing, alleviation of suffering through the diagnosis and treatment of human response, and advocacy in the care of individuals, families, groups, communities, and populations" (p. 1)

nursing diagnosis: a clinical judgment concerning a person's, family's, or community's actual or potential health problems, state of health promotion, or potential risk that can be managed by independent nursing interventions

nursing process: a systematic, problem-solving approach for meeting people's health care and nursing needs; components involve assessment, diagnosis, planning, implementation, and evaluation

patient: a traditional term used to identify someone who is a recipient of health care

planning: development of measurable goals and outcomes as well as a plan of care designed to assist the patient in resolving the diagnosed problems and achieving the identified goals and outcomes

precision medicine: using advances in research, technology, and policies to develop individualized plans of care to prevent and treat disease

Quality and Safety Education for Nurses (QSEN): a project whose aim is to develop curricula that prepare future nurses with the knowledge, skills, and attitudes (KSA) required to continuously improve the quality and safety of the health care system through demonstrating competency in patient-centered care, teamwork and collaboration, evidence-based practice, quality improvement, safety, and informatics

telehealth: the use of technology to deliver health care, health information, or health education at a distance

The Joint Commission: a nonprofit organization that accredits hospitals and health care organizations

wellness: the ability to perform well, adjust and adapt to varying situations, and report feeling well and harmoniousa

As American society has undergone changes, so has the nation's health care system. Nursing, as the health care profession with the greatest number of employees and a major contributor to the health care delivery system, has been significantly affected by these changes. Nursing has played an important role in the health care system and will continue to do so. This chapter provides an overview of the practice of nursing in the United States today, as well important factors and issues that will continue to affect its practice into the future.

Nursing

Since the time of Florence Nightingale, who wrote in 1858 that the goal of nursing was "to put the patient in the best condition foar nature to act upon him," nursing scholars and leaders have described nursing as both an art and a science. However, the definition of nursing has evolved over time. In the American Nurses Association (ANA) Scope and Standards of Practice (ANA, 2015b, p. 1), **nursing** is defined as "the protection, promotion, and optimization of health and abilities, prevention of illness and injury, facilitation of healing, alleviation of suffering through the diagnosis and treatment of human response, and advocacy in the care of individuals, families, groups, communities, and populations." Nurses have a responsibility to carry out their role as described in Nursing's Social Policy Statement (ANA, 2010; Fowler, 2015), to comply with the nurse practice act of the state in which they practice, and to comply with the Code of Ethics for Nurses as spelled out by the ANA (2015a) and the International Council of Nurses (ICN, 2012). Advocacy, promotion of a safe environment, research, education, and participation in patient and health systems management as well as shaping health policy are also key nursing roles (ICN, 2012).

The Patient: Consumer of Nursing and Health Care

The term **patient**, derived from a Latin verb meaning "to suffer," has traditionally been used to describe a person who is a recipient of care. The connotation commonly attached to the word is one of dependence. For this reason, many nurses prefer to use the term *client,* which is derived from a Latin verb meaning "to lean," connoting alliance and interdependence. The term *patient* is used purposely throughout this book; it is most commonly used by clinicians, as evidenced by its usage by the Interprofessional Education Collaborative (IPEC, 2016a), whose members include 15 national associations of schools of the health professions, including nursing, allopathic medicine, osteopathic medicine, pharmacy, dentistry, and public health, to name a few (see later discussion of IPEC).

The patient who seeks care for a health problem or problems (increasing numbers of people have multiple health problems or comorbidities) is also an individual person, a member of a family, a member of various social groups, and a citizen of the community. Patients' needs vary depending on problems, associated circumstances, and past experiences. Many patients, who as consumers of health care have become more knowledgeable about health care options, expect a collaborative approach with the nurse in the quest for optimal health (Majid & Gagliardi, 2019). Among the nurse's important functions in health care delivery are identifying the patient's immediate, ongoing, and long-term needs and working together with the patient to address them.

The Patient's Basic Needs: Maslow Hierarchy of Needs

Certain needs are basic to all people. Some of these needs are more important than others. Once an essential need is met, people often experience a need on a higher level of priority. Addressing needs by priority reflects Maslow's Hierarchy of Needs (Fig. 1-1).

Maslow ranked human needs to include physiologic needs, safety and security, sense of belonging and affection, esteem and self-respect, and self-actualization. Self-actualization includes self-fulfillment, desire to know and understand, and aesthetic needs. Lower-level needs always remain; however, a person's ability to pursue higher-level needs indicates movement toward psychological health and well-being (Maslow, 1954). Such a hierarchy of needs is a useful framework that can be applied to many nursing models for assessment of a patient's strengths, limitations, and need for nursing interventions.

Health

How health is perceived depends on how health is defined. The World Health Organization (WHO, 2006) defines **health** in the preamble to its constitution as a "state of complete physical, mental, and social well-being and not merely the absence of disease and infirmity" (p. 1). This definition implies that health and illness are not polar opposites. Theoretically, therefore, it is possible for a patient to have a physical illness and yet strive for and perhaps attain health in another domain (e.g., mental, social). Although commonly cited worldwide, this definition has been criticized for being too utopian—after all, it is not possible for anyone to achieve *complete* physical, mental, and social well-being (Murdaugh, Parsons, & Pender, 2019).

Figure 1-1 • This scheme of Maslow's hierarchy of needs shows how a person moves from fulfillment of basic needs to higher levels of needs, with the ultimate goal being integrated human functioning and health.

Wellness

Wellness has been defined as being equivalent to health. Wellness involves being proactive and being involved in self-care activities aimed toward a state of physical, psychological, social, and spiritual well-being. Wellness is conceptualized as having four components: (1) the capacity to perform to the best of one's ability, (2) the ability to adjust and adapt to varying situations, (3) a reported feeling of well-being, and (4) a feeling that "everything is together" and harmonious (Hood, 2018). With this in mind, nurses must aim to promote positive changes that are directed toward health and well-being. The sense of wellness has a subjective aspect that addresses the importance of recognizing and responding to patient individuality and diversity in health care and nursing.

Health Promotion

Today, increasing emphasis is placed on health, wellness, health promotion, and self-care. Health is seen as resulting from a lifestyle oriented toward wellness. **Health promotion** focuses on the potential for wellness and targets appropriate alterations in personal habits, lifestyle, and environment in ways that reduce risks and enhance health and well-being (see Chapter 3).

People are increasingly knowledgeable about health and take more interest in and responsibility for health and well-being. Organized self-care wellness education programs emphasize health promotion, disease prevention, management of illness, self-care, and collaborative use of the professional health care system. Web sites, chat groups, open forums, and social media support groups promote sharing of experiences and information about self-care with others who have similar conditions, chronic diseases, or disabling conditions. The advent of mobile wireless computer technologies (e.g., Fitbit™) and novel informatics tools (e.g., Carb Manager) have had the effect of tailoring health promotion activities to meet individual preferences (Murdaugh et al., 2019). Researchers have begun to take advantage of these popular technologic advancements by developing population-based registries. The use of mobile health apps has demonstrated a positive impact on health-related behaviors, specifically, physical activity, dietary management, adherence to medication or therapy, and knowledge related to medications and diagnostic testing. Moreover, most mobile health apps seem to promote better clinical health outcomes (Han & Lee, 2018). According to the WHO (2019), "primary health care ensures people receive comprehensive care—ranging from promotion and prevention to treatment, rehabilitation and palliative care—as close as feasible to people's everyday environment" (p. 1). Primary health care includes a lifelong commitment to meeting individuals' health needs across the lifespan; empowerment of individuals to assume accountability for their own health care; and attention to societal needs for health care through social policy and action.

Health Care

Health care describes services that are offered to individuals, families, and communities to help them maintain health and wellness, prevent and manage illness and complications, and provide support through rehabilitation, recovery, and transitions to palliative care. Health care can be provided in inpatient, outpatient, and community settings by a variety of health professionals, including but not limited to nurses, primary providers, pharmacists, dieticians, social workers, psychologists, and physical, occupational, speech and respiratory therapists.

Influences on Health Care Delivery

The health care delivery system is constantly adapting to changes in health care needs and expectations. Shifting population demographics; changing patterns of disease and wellness; advances in technology and genetics; and greater emphasis on health care quality, costs, reform efforts, and interprofessional collaborative practices have impacted health care delivery and the practice of nursing.

Population Demographics

Changes in the population in general are affecting the need for and the delivery of health care. According to the United States (U.S.) Census Bureau (2020), over 329 million people reside in the country. Not only is the population increasing, but its composition is also changing. The decline in birth rate and the increase in lifespan have resulted in proportionately fewer school-age children and more senior citizens, many of whom are women. Much of the population resides in highly congested urban areas, with a steady migration of members of ethnic minorities to urban settings. Poverty is a growing concern. According to the U.S. Department of Housing and Urban Development's (HUD's) 2019 Annual Homeless Assessment Report, on a given night, approximately 568,000 individuals were documented as homeless in the United States. Homelessness increased by 3% from 2018 to 2019, with almost 40% of this population staying on the streets or other unsheltered locations; in addition, a higher percentage of minority populations compared to the total U.S. population are impacted by homelessness today (U.S. Department of Housing and Urban Development, 2020).

Gerontologic Considerations

Both the number and proportion of Americans 65 years of age and older have grown substantially in the past century. In 2017, an estimated 47.8 million older adults resided in the United States; this number continues to climb, with the greatest growth in the Hispanic population (U.S. Census Bureau, 2017).

The health care needs of older adults are complex and demand significant investments, both professional and financial (see Chapter 8 for further discussion). Many older adults suffer from multiple chronic conditions that are exacerbated by acute episodes. In particular, older women are frequently underdiagnosed and undertreated. According to the United Nations' (2017) report on world population aging, globally, the number of people 80 years of age or older is projected to increase more than threefold between 2017 and 2050, rising from 137 to 425 million.

Veterans Considerations

Veterans of the U.S. armed services comprise a unique population with health care needs that vary dependent upon branch of military service, whether service occurred during wartime eras, time and place of service, and individual experiences (Olenick, Flowers, & Diaz, 2015). According to the U.S. Census Bureau (2019), there are currently 18 million veterans, 1.8 million of whom are female. Substance use disorders (SUDs), posttraumatic stress disorder (PTSD), traumatic brain injury (TBI), suicide, depression, hazardous substance exposure, and amputations are common health care problems found among veterans (Olenick et al., 2015) (see Chapter 4). According to a Pew Research Center

(2017) report, the proportion of Americans who served in the U.S. military has been steadily declining since 1980, when 18% of American adults were veterans. In 2016, 7% of Americans were veterans. That proportion is projected to continue to decline, and by 2045 the U.S. Department of Veteran Affairs estimates that there will be approximately 12 million veterans, roughly a 40% decrease from 2016 (Pew Research Center, 2017).

Cultural Diversity

An appreciation for the diverse characteristics and needs of people from varied ethnic and cultural backgrounds is important in health care and nursing. Some projections indicate that by 2030, racial and ethnic minority populations in the United States will triple. The latest U.S. census classified five distinct races as White, Black or African American, Asian, Native American or Alaska Native, and Native Hawaiian/Pacific Islander. The Asian race had the largest growth rate among these five racial groups. The Hispanic population, classified primarily under the White race, was noted to account for more than half of the increased population growth. The non-Hispanic Caucasian population will proportionally decrease so that they will no longer comprise the majority population, and other ethnic and racial minority populations will collectively comprise the majority of all Americans by approximately 2044 (Colby & Ortman, 2015). As the cultural composition of the population changes, it is increasingly important to address cultural considerations in the delivery of health care. Patients from diverse sociocultural groups not only bring various health care beliefs, values, and practices to the health care setting but also have unique risk factors for some disease conditions and unique reactions to treatment. These factors significantly affect a person's responses to health care problems or illnesses, to caregivers, and to the care itself. Unless these factors are assessed, understood, and respected by nurses, the care delivered may be ineffective, and health care outcomes may be negatively affected (see Chapter 4 for additional information on cultural assessment).

Changing Patterns of Disease and Wellness

During the past several decades, the health problems of Americans have changed significantly. Chronic diseases, including cardiovascular disease, cancers, diabetes, and chronic lung diseases account for 7 out of the 10 leading causes of death (Centers for Disease Control and Prevention [CDC], 2019). Nearly half of all adults live with one diagnosed chronic condition; 60 million live with two or more (CDC, 2019). Tobacco use, SUD (e.g., alcohol, illicit drugs), poor physical activity and nutrition habits, and obesity have become major health concerns (CDC, 2019).

As the prevalence of chronic conditions increases, health care broadens from a focus on cure and eradication of disease to include health promotion and the prevention or rapid treatment of exacerbations of chronic conditions. Nursing,

which has always encouraged patients to take control of health and wellness, has a prominent role in the current focus on management of chronic illness and disability (see Chapter 7).

Healthy People 2030

The *Healthy People* initiatives identify important periodic goals that, if reached, could have major impacts on the health and overall well-being of people in the United States (U.S. Department of Health and Human Services [HHS], 2020a). Since their inception over four decades ago, these initiatives have contributed to substantial decreases in cancer and cardiovascular deaths, infant and maternal mortality, and improvements in vaccinations (HHS, 2020a). Leading health indicators (LHIs) or goals outlined in the *Healthy People 2020* initiative aimed to improve access to health services, environmental quality, use of preventive services, nutrition and physical activity, and to address social determinants of health, while decreasing rates of injury and violence, obesity, tobacco use, and substance abuse, among others (HHS, 2020b). This initiative considered social influences that shape health, such as poverty and social injustices, rather than simply focusing on disease states. To date, significant progress has been made in decreasing the number of adults who are smoking and in improving physical activity of adults (HHS, 2020b). The *Healthy People 2030* framework, guided the development of the *Healthy People 2030* initiative and identified the need to collaborate more effectively with a variety of stakeholders across diverse agencies to accomplish its vision of helping all people in the United States optimize their health and well-being across developmental life stages, with a continued emphasis on reducing health disparities and improving health equity and health literacy (HHS, 2020a). The development of *Healthy People 2030* is in progress, data-driven national objectives have been established, and updates can be found by visiting its website. Enacting the goals set by the LHIs and other health care reforms have contributed to continuous change in health care organizations and delivery in the United States.

Advances in Technology and Genetics

Advances in technology and genetics have occurred rapidly during the past several decades. Sophisticated techniques and devices, such as robot assisted technology, have revolutionized treatments making it possible to perform many procedures and tests on an outpatient basis. Increased knowledge and understanding of genetics and genomics have resulted in expanded screening, diagnostic testing, and treatments for a variety of conditions (see Chapter 6 for information on genetics and genomics and nursing practice implications; in addition, note that there are charts that focus upon *Genetics in Nursing Practice* throughout the book, which highlight various relevant genetic disorders).

In January 2015, President Obama announced the launching of the *Precision Medicine Initiative (PMI),* which aimed to leverage advances in research,

technology, and policies to develop individualized plans of care to prevent and treat disease (Genetics Home Reference, 2020). **Precision medicine** is possible because of the recent development of biologic databases (e.g., human genome sequencing), technologic advances that can identify unique characteristics of individual people (e.g., genomics, cellular assay tests), and computer-driven systems that can mine and analyze data sets. The immediate goal of the PMI is to focus on preventing and curing cancers; however, there are long-term implications that hold promise for preventing and treating many other conditions and diseases (Ciupka, 2018).

Health Informatics

The sophisticated communication systems that connect most parts of the world, with the capability of rapid storage, retrieval, and dissemination of information, have stimulated advances in health information technology (HIT). Using HIT to improve the quality, efficiency, or delivery of health care is an interdisciplinary field of study called **health informatics.** Key examples of recent advances in HIT include artificial intelligence, blockchain, cloud technology, disease management technology, and improved operability of electronic health records (EHRs). The *Technology Informatics Guiding Education Reform (TIGER)* initiative, now a subsidiary of the Healthcare Information Management Systems Society (HIMSS), provides expert panel reports and guidelines for incorporating HIT into nursing practice (HIMSS, 2020).

The *International Classification of Diseases (ICD)* (WHO) launched its 10th iteration for use in the United States in 2015. The ICD-10 classifies diseases and conditions into nearly 70,000 codes. In June 2018, WHO released a version of ICD-11, which was presented to the World Health Assembly in 2019 for adoption by countries (WHO, 2018). Currently, the Centers for Medicare & Medicaid Services (CMS, 2015) and most other major health insurance programs require utilization of ICD-10 codes when treatment is rendered for providers to claim reimbursement. This system provides for common nomenclature and tracking of the incidence and prevalence of various diseases and conditions globally. CMS (2020) also requires that clinicians and health care systems use EHRs; its final rule for stage 3 of the *EHR Incentive Program,* now known as the *Promoting Interoperability Program,* required that by 2018 providers use EHRs or face reductions in reimbursement.

In addition to these HIT advancements, **telehealth,** which uses technology to deliver health care, health information, or health education at a distance, is being utilized by both individual clinicians and health care systems more and more frequently. In particular, home health services use telehealth to develop more individualized care plans for patients. One type of telehealth application uses *real-time communication,* characterized by an exchange of information between people at one point in time. For instance, a nurse practitioner in a rural clinic may consult with a specialist on a webcam about a patient's condition. Another type of telehealth application uses *store-and-forward,* characterized by transmission of

digital images that may be retrieved and reviewed at later points in time (HealthIT.gov, 2018).

Quality, Safety, and Evidence-Based Practice

At the turn of the millennium, the Institute of Medicine (IOM, 2000) reported an alarming breakdown in quality control in the American health care system. The IOM report *To Err Is Human: Building a Safer Health System* (2000) noted that nearly 100,000 Americans died annually from preventable errors in hospitals, and many more suffered nonfatal injuries from errors. A subsequent IOM report, *Crossing the Quality Chasm: A New Health System for the 21st Century* (2001), described an inefficient, fragmented, health care system fraught with inequities and inaccessibility. It envisioned a reformed health care system that is evidence-based and systems oriented. Its proposed six aims for improvement included ensuring that patient care is safe, effective, patient centered, timely, efficient, and equitable (IOM, 2001). The following sections describe a series of key practices that are aimed at improving quality and safety and ensuring use of evidence-based practices (EBPs) within the U.S. health care system.

Principles of Evidence-Based Nursing Practice

An **evidence-based practice (EBP)** is a best practice derived from valid and reliable research studies that also considers the health care setting, patient preferences and values, and clinical judgment. The facilitation of EBP involves identifying and evaluating current literature and research findings, and then incorporating these findings into patient care as a means of ensuring quality care (Melnyk & Fineout-Overholt, 2018).

Evidence-Based Practice Bundles

The Institute for Healthcare Improvement (IHI) has developed numerous sets of readily implemented EBP sets for use by hospitals (IHI, 2020). These **bundles** include a set of three to five EBPs that, when implemented appropriately, can measurably improve patients' outcomes. Many of these practices are within the scope of independent nursing practice. For instance, the IHI Ventilator Bundle advocates that the head of the bed should be elevated, and that oral care should be provided using chlorhexidine for all patients on ventilators (IHI, 2012; see Chapter 19).

EBP tools used for planning patient care may include not only bundles but also clinical guidelines, algorithms, care mapping, multidisciplinary action plans (MAPs), and clinical pathways. These tools are used to move patients toward predetermined, measurable outcomes. Algorithms are used more often in acute situations to determine a particular treatment based on patient information or response. Care maps, clinical guidelines, and MAPs (the most detailed of these tools) help to facilitate coordination of care and education throughout hospitalization and after discharge. Nurses who provide direct care have an

important role in the development and use of these tools through participation in researching the literature and then developing, piloting, implementing, and revising the tools as needed.

Quality and Safety Education for Nurses

The **Quality and Safety Education for Nurses (QSEN)** project was initially funded by the nonprofit Robert Wood Johnson Foundation (RWJF) to develop curricula that prepare future nurses with the knowledge, skills, and attitudes (KSA) required to continuously improve the quality and safety of the health care system. In particular, nurses educated under QSEN concepts demonstrate the KSA consonant with competency in patient-centered care, teamwork and collaboration, EBP, quality improvement, safety, and informatics (QSEN, 2020). Each of the Unit Openers in this book highlights a case study that demonstrates the application of QSEN competencies germane to pre-licensure nursing practice. Table 1-1 highlights the QSEN definition of teamwork and collaboration and its associated KSA.

Interprofessional Collaborative Practice

The IOM report, *Health Professions Education: A Bridge to Quality* (IOM, 2003), challenged health professions education programs to integrate interdisciplinary core competencies into respective curricula to include patient-centered care, interdisciplinary teamwork and collaboration, EBP, quality improvement, safety, and informatics. In response to this report, the Interprofessional Education Collaborative Expert Panel (IPEC) published *Core Competencies for Interprofessional Collaborative Practice* (IPEC, 2011) with the goal to "prepare all health professions students for deliberately working together with the common goal of building a safer and better patient-centered and community/population-oriented US health care system" (p. 3). **Interprofessional collaborative practice** involves employing multiple health professionals to work together with patients, families, and communities to deliver best practices, thus assuring best patient outcomes. In 2016, the IPEC updated this document by organizing the four original competencies under the essential domain of interprofessional collaboration; topics within this central domain, as displayed in Figure 1-2**,** include values/ethics for interprofessional practice, roles and responsibilities for collaborative practice, interprofessional communication practices, and interprofessional teamwork and team-based practice (IPEC, 2016b). In addition, updates aimed to standardize language used among health care professionals to better facilitate interprofessional education, improve assessment and evaluation of outcomes, and more effectively meet contemporary health care goals, with a greater focus on population health. However, the updated guidelines maintain the IPEC's original vision "that interprofessional collaborative practice is key to the safe, high-quality, patient-centered care desired by all" (IPEC, 2016b, p. 4). Many of the end-of-chapter Critical Thinking

Exercises that are presented throughout this book highlight the role of the nurse as a member of the interprofessional collaborative team.

TABLE 1-1 Quality and Safety Education for Nurses (QSEN) Definition of Safety and Knowledge, Skills, and Attitudes (KSA) for Pre-Licensure Nursing Students

Teamwork and Collaboration

Definition: Function effectively within nursing and inter-professional teams, fostering open communication, mutual respect, and shared decision making to achieve quality patient care.

Knowledge	Skills	Attitudes
Describe own strengths, limitations, and values in functioning as a member of a team	Demonstrate awareness of own strengths and limitations as a team member Initiate plan for self-development as a team member Act with integrity, consistency and respect for differing views	Acknowledge own potential to contribute to effective team functioning Appreciate importance of intra- and inter-professional collaboration
Describe scopes of practice and roles of health care team members Describe strategies for identifying and managing overlaps in team member roles and accountabilities Recognize contributions of other individuals and groups in helping patient/family achieve health goals	Function competently within own scope of practice as a member of the health care team Assume role of team member or leader based on the situation Initiate requests for help when appropriate to situation Clarify roles and accountabilities under conditions of potential overlap in team member functioning Integrate the contributions of others who play a role in helping patient/family achieve health goals	Value the perspectives and expertise of all health team members Respect the centrality of the patient/family as core members of any health care team Respect the unique attributes that members bring to a team, including variations in professional orientations and accountabilities
Analyze differences in communication style preferences among patients and families, nurses and other members of the health team Describe impact of own communication style on others Discuss effective strategies for communicating and resolving conflict	Communicate with team members, adapting own style of communicating to needs of the team and situation Demonstrate commitment to team goals Solicit input from other team members to improve individual, as well as team, performance Initiate actions to resolve conflict	Value teamwork and the relationships upon which it is based Value different styles of communication used by patients, families and health care providers Contribute to resolution of conflict and disagreement
Describe examples of the impact of team functioning on safety and quality of care	Follow communication practices that minimize risks associated with	Appreciate the risks associated with handoffs

Explain how authority gradients influence teamwork and patient safety	handoffs among providers and across transitions in care Assert own position/perspective in discussions about patient care Choose communication styles that diminish the risks associated with authority gradients among team members	among providers and across transitions in care
Identify system barriers and facilitators of effective team functioning	Participate in designing systems that support effective teamwork	Value the influence of system solutions in achieving effective team functioning

The Practice of Nursing

As scientific advances in health care technology continue to evolve, nurses face increasingly complex issues and situations. Greater acuity of patients in both hospital and community settings, an aging population, complex disease processes, and end-of-life concerns, as well as ethical issues and cultural factors must be considered. The decision making component of nurses' problem-solving activities has become increasingly multifaceted and requires critical thinking based upon sound ethical principles.

Critical Thinking

Critical thinking is a cognitive process that utilizes thinking that is purposeful, insightful, reflective, and goal directed in order to develop conclusions, solutions, and alternatives that are appropriate for the given situation. Critical thinking, which includes reasoning and judgment, is based upon a body of knowledge and includes analysis of all information and ideas. Critical thinking leads to the formulation of conclusions and alternatives that are the most appropriate for the situation and is used to plan patient-centered care. Critical thinking has been identified as an essential core competency for nurses by the National League for Nursing (NLN) and the American Association of Colleges of Nursing (AACN, 2008; NLN, 2012). This cognitive process is critical to effective use of the nursing process and clinical reasoning (Flanders, Gunn, Wheeler, et al., 2017).

Critical thinking includes metacognition—the examination of one's own reasoning or thought processes—to help refine thinking skills. Independent

nursing judgments and decisions evolve from a sound knowledge base and the ability to synthesize information within the context in which it is presented. Nursing practice in today's society requires the use of high-level critical thinking skills. Critical thinking enhances clinical decision making, helping to identify patient needs and the best nursing actions that will assist patients in meeting those needs. Because critical thinking is a deliberate, outcome-oriented activity, it is logical, organized, and iterative. "In nursing, critical thinking is the ability to think systematically and reflect on the reasoning process used to ensure safe nursing practice" (Zarifsanaiey, Amini, & Saadat, 2016, p. 2). The process of critical thinking gives nurses the tools to make sound decisions and implement quality nursing care.

Critical thinkers are inquisitive truth seekers who are open to the alternative solutions that might surface. Critical thinking is influenced by "habits of the mind including: confidence, perseverance, inquisitiveness, intuition, flexibility, creativity, intellectual integrity, contextual perspective, open-mindedness and reflection" (Griffits, Hines, Maloney, et al., 2017, p. 2832). Clinical reasoning is a thought process that is a specific method of critical thinking. The process of clinical reasoning results in clinical judgment, which is nursing actions. Clinical reasoning is the core of the nursing process (see later discussion) (Alfaro-LeFevre, 2017).

The following factors are identified as critical components of clinical reasoning: communication and relationships, educational level, knowledge and ability to use critical thinking, familiarity with the environment and the context of care, experience and exposure to a variety of situations, as well as professionalism (Griffits et al., 2017). The skills involved in critical thinking are developed over time through effort, practice, and experience.

Rationality and Insight

Skills needed in critical thinking include interpretation, analysis, inference, explanation, evaluation, self-reflection, and self-regulation. Critical thinking requires strong background knowledge and knowledge of key concepts as well as logical thinking. Nurses use this disciplined process to validate the accuracy of data and the reliability of any assumptions they have made, and they then carefully evaluate the effectiveness of what they have identified as the necessary actions to take. Nurses also evaluate the reliability of sources, being mindful of and questioning inconsistencies. Nurses use interpretation to determine the significance of data that are gathered, analysis to identify patient problems suggested by the data, and inference to draw conclusions. Explanation is the justification of actions or interventions used to address patient problems and to help patients move toward desired outcomes. Evaluation is the process of determining whether outcomes have been or are being met. Self-regulation is the process of examining the care provided and adjusting the interventions as needed. All processes are iterative.

Critical thinking is also reflective, involving metacognition, active evaluation, and refinement of the thinking process. Metacognition involves reflective thinking as well as awareness of the nursing skills needed for patient-centered care (Alfaro-LeFevre, 2017). Nurses engaged in critical thinking consider the possibility of cultural differences and personal bias when interpreting data and determining appropriate actions (see Chapter 4 for further discussion). Critical thinkers must be insightful and have a sense of fairness and integrity; the courage to question personal ethics; and the perseverance to strive continuously to minimize the effects of egocentricity, ethnocentricity, and other biases on the decision making process (Alfaro-LeFevre, 2017).

Components of Critical Thinking

Certain cognitive or mental activities are key components of critical thinking as it relates to nurses. Critical thinkers (Alfaro-LeFevre, 2017):

- Identify the priorities that will determine the nurse's plan of patient-centered care.
- Gather pertinent data from the patient's chart and assessments to determine why certain developments have occurred and to determine if additional data are needed to address the situation accurately.
- Validate the information presented to make sure that it is accurate and compare it with any preexisting data. Information should be evidence based.
- Analyze the information to determine its significance and to identify the formation of clusters or patterns that point to certain conclusions.
- Utilize logical thinking, past clinical experiences, theoretical knowledge, and intuitive thinking to assess the status of the patient's condition. Anticipate the patient's needs and outcomes while acknowledging personal bias and cultural influences.
- Maintain a flexible attitude that facilitates thinking and inquiry and consider all possibilities.
- Utilize inductive and deductive reasoning to identify available options and analyze each in terms of its advantages and disadvantages.
- Formulate decisions that reflect creativity and independent decision making.
- Demonstrate personal humility in terms of one's knowledge deficits and willingly seek additional information to assist with decision making.
- Exhibit the courage to seek new, innovative approaches to patient-centered care. Detach their personal viewpoints from situations and look at things objectively, a process called *bracketing*.

Critical thinking requires going beyond basic problem solving into a realm of inquisitive exploration, looking for all relevant factors that affect the issue, and being an "out-of-the-box" thinker. Nurses' ongoing quest for "best practice" clearly demonstrates intellectual integrity, a component of critical thinking.

Critical Thinking and Clinical Reasoning in Nursing Practice

Critical thinking and decision making are thought to be associated with improved clinical expertise. Critical thinking is the foundation of the process of clinical reasoning and clinical judgment (Alfaro-LeFevre, 2017). Using critical thinking to develop a plan of nursing care requires considering the human factors that might influence the plan. Nurses interact with patients, families, and other health care providers in the process of providing appropriate, individualized nursing care.

Nurses must use critical thinking skills in all practice settings—acute care, ambulatory care, extended care, and the home and community—and must view each patient situation as unique and dynamic. The unique factors that patients and nurses bring to the health care situation are considered, studied, analyzed, interpreted, and evaluated. Interpretation of the information then allows nurses to focus on those factors that are most relevant and most significant to the clinical situation. Decisions about a nursing plan, priority of actions, and measurable outcomes are developed into an action plan.

In decision making related to the nursing process, nurses use cognitive and metacognitive skills as well as logical reasoning to set priorities. These skills include systematic and comprehensive assessment, recognition of assumptions, inconsistencies and biases, verification of reliability and accuracy, identification of missing information, distinguishing relevant from irrelevant information, support of the evidence with facts and conclusions, priority setting with timely decision making, determination of patient-specific outcomes, and reassessment of responses and outcomes (Alfaro-LeFevre, 2017). All of these data are examined within the context of a solid knowledge base. For example, Goodrich, Wagner-Johnston, and Delibovi (2017) describe how oncology nurses use critical thinking, clinical reasoning, and decision making skills in identifying and managing complications of novel and complex therapies for cancer treatment when they:

- Develop greater knowledge of potential adverse events by examining evidence-based guidelines.
- Partner with the patient and family to better understand how treatments impact activities of daily living, quality of life, and overall symptom burden.
- Distinguish potential complications from expected manifestations associated with the underlying cancer diagnosis.
- Collaborate with interprofessional team members to modify treatment plans based on assessment data.

Because developing the skill of critical thinking involves experiential learning and practice, critical thinking exercises are offered at the end of each chapter as a means of honing the reader's ability to think critically. Some exercises include questions that stimulate the reader to seek information about EBP relative to the clinical situation described, others challenge the reader to identify priority assessments and interventions, while others challenge the reader to describe the

role of the nurse as a member of the interprofessional collaborative team, as noted previously. Additional exercises may be found in the study guide that accompanies the text. The questions listed in Chart 1-1 can serve as a guide in working through the exercises. It is important to remember that each clinical situation is unique and calls for an individualized approach that fits its unique set of circumstances. As critical thinking may require consideration of ethical principles and cultural contexts, these concepts are discussed in this chapter and in Chapter 4.

The Nursing Process

The **nursing process** is a deliberate problem-solving approach for meeting people's health care and nursing needs. Although the steps of the nursing process have been stated in various ways by different writers, the common components cited are assessment, diagnosis, planning, implementation, and evaluation (Carpenito, 2017). The ANA's *Scope and Standards of Practice* (ANA, 2015b) includes an additional component entitled outcome identification, defined as identification of expected outcomes for a plan that is tailored to the patient's needs. The sequence of steps in this process is assessment, diagnosis, outcome identification, planning, implementation, and evaluation. For the purposes of this text, the nursing process is based on the traditional five steps and delineates two components in the diagnosis step: nursing diagnoses and collaborative problems. After the diagnoses or problems have been determined, the desired outcomes are often evident. The traditional steps are defined as follows:

1. ***Assessment:*** The systematic collection of data through interview, observation, and examination to determine the patient's health status as well as any actual or potential health problems. (Analysis of data is included as part of the assessment. Analysis may also be identified as a separate step of the nursing process.)
2. ***Diagnosis:*** Identification of the following two types of patient problems:
   - ***Nursing diagnoses:*** According to Carpenito (2017), "Are clinical judgments about individual, family, or community responses to actual or potential health problems/life processes" that can be managed by independent nursing interventions (p. 9).
   - ***Collaborative problems:*** According to Carpenito (2017), "Certain physiologic complications that nurses monitor to detect onset or changes in status. Nurses manage collaborative problems using physician- and nurse-prescribed interventions to minimize the complications of the events" (p. 9).
3. ***Planning:*** Development of measurable goals and outcomes as well as a plan of care designed to assist the patient in resolving the diagnosed problems and achieving the identified goals and desired outcomes.

Chart 1-1

The Inquiring Mind: Critical Thinking in Action

Throughout the critical thinking process, a continuous flow of questions evolves in the thinker's mind. It is not sufficient to rely solely on the acquisition of knowledge or a set of problem-solving skills; rather, it is the combination of one's application of knowledge, analysis of the situation, synthesis, and evaluation that promotes effective critical thinking inquiry. Although posing questions will vary according to the particular clinical situation, certain general inquiries can serve as a basis for reaching conclusions and determining a course of action.

When faced with a patient situation, seeking answers to some or all of the following questions may help to determine those actions that are most appropriate:

- What relevant assessment information do I need, and how do I interpret this information? What is the most effective way to gather this information? What does this information tell me? What contextual factors must be considered when gathering this information? What are the priority assessments?
- Have I identified the most important assessments and findings? Does the information I have gathered point to any other problems that I should consider?
- Have I gathered all of the necessary information (signs and symptoms, laboratory values, medication history, emotional factors, mental status)? Is anything missing?
- Is there anything that needs to be reported immediately? Do I need to seek additional assistance?
- What risks factors are specific to this patient? Which risk factors are of the highest priority? What must I do to minimize these risks?
- What possible complications must I anticipate?
- What are the most important problems in this situation? Do the patient and the patient's family recognize the same problems?
- What are the desired outcomes for this patient? Which have the highest priority? Do the patient and I agree on these points?
- What is going to be my first action in this situation? Why is this action a priority?
- How can I construct a plan of care to achieve the goals?
- Are there any age-related factors involved, and will they require some special approach? Will I need to make some change in the plan of care to take these factors into account?
- How do the family dynamics affect this situation, and will they affect my actions or the plan of care?
- Are there cultural factors that I must address and consider?
- Am I dealing with an ethical issue here? If so, how am I going to resolve it?
- Has any nursing research been conducted on this subject? What are the nursing implications of this research for care of this patient? What is the strength of the evidence found from research?

Adapted from Alfaro-LeFevre, R. (2017). *Critical thinking and clinical judgment: A practical approach* (6th ed.). Philadelphia, PA: Elsevier; Alfaro-LeFevre, R. (2019). Promoting critical thinking in frontline nurses. Retrieved on 2/29/2020 at: www.alfaroteachsmart.com

4. ***Implementation:*** Actualization or carrying out of the plan of care through nursing interventions.
5. ***Evaluation:*** Determination of the patient's responses to the nursing interventions and the extent to which the outcomes have been achieved.

Dividing the nursing process into distinct steps serves to emphasize the essential nursing actions that must be taken to address the patient's nursing diagnoses and manage any collaborative problems or complications. However, dividing the process into separate steps is artificial: The process functions as an integrated whole, with the steps being interrelated, interdependent, and recurrent (Fig. 1-3). Chart 1-2 presents an overview of the nursing activities involved in applying the nursing process. Note that the use of the nursing process requires critical thinking and consideration of common ethical principles to ensure that a truly comprehensive plan of care is developed.

Assessment

According to Carpenito (2017), the initial or baseline assessment is a systematic process of collecting predetermined data during the first contact with the patient. Data are gathered through the health history and the physical assessment. In addition, ongoing assessment and monitoring are crucial to remain aware of changing patient needs and the effectiveness of nursing care.

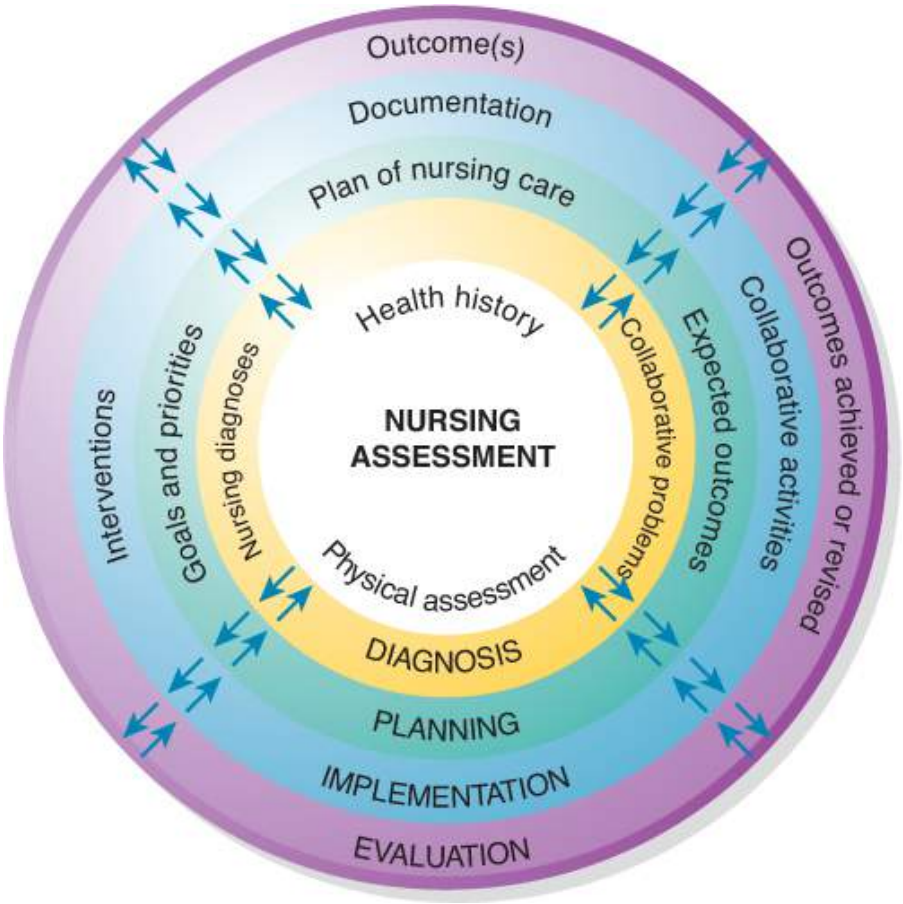

Figure 1-3 • The nursing process is depicted schematically in this circle. Starting from the innermost circle, nursing assessment, the process moves outward through the formulation of nursing diagnoses and collaborative problems; planning, with setting of goals and priorities in the nursing plan of care; implementation and documentation; and, finally, the ongoing process of evaluation and outcomes.

Chart 1-2

Steps of the Nursing Process

Assessment

1. Conduct the health history.
2. Perform the physical assessment.
3. Interview the patient's family or significant others.
4. Study the health record.
5. Organize, analyze, synthesize, and summarize the collected data.

Diagnosis

Nursing Diagnoses

1. Identify the patient's nursing problems or potential problems.
2. Identify the defining characteristics of the nursing problems.
3. Identify the etiology of the nursing problems.
4. State nursing diagnoses concisely and precisely.

Collaborative Problems

1. Identify potential problems or complications that require collaborative interventions.
2. Identify health care members with whom collaboration is essential.

Planning

1. Assign priority to the nursing diagnoses.
2. Specify the goals.
   a. Develop immediate, intermediate, and long-term goals.
   b. State the goals in realistic and measurable terms.
3. Identify nursing interventions appropriate for goal attainment.
4. Establish expected outcomes.
   a. Make sure that the outcomes are realistic and measurable.
   b. Identify critical times for the attainment of outcomes.
5. Develop the written plan of nursing care.
   a. Include nursing diagnoses, goals, nursing interventions, expected outcomes, and critical times.
   b. Write all entries precisely, concisely, and systematically.
   c. Keep the plan current and flexible to meet the patient's changing problems and needs.
6. Involve the patient, family or significant others, nursing team members, and other health care team members in all aspects of planning.

Implementation

Put the plan of nursing care into action.

1. Coordinate the activities of the patient, family or significant others, nursing team members, and other health care team members.
2. Record the patient's responses to the nursing actions.

Evaluation

1. Collect data.
2. Compare the patient's actual outcomes with the expected outcomes. Determine the extent to which the expected outcomes were achieved.
3. Include the patient, family or significant others, nursing team members, and other health care team members in the evaluation.
4. Identify alterations that need to be made in the nursing diagnoses, collaborative problems, goals, nursing interventions, and expected outcomes.
5. Continue all steps of the nursing process: assessment, diagnosis, planning, implementation, and evaluation.

Health History

The health history is conducted to determine a person's state of wellness or illness and is best accomplished as part of a planned interview. The interview is a personal dialogue between a patient and a nurse that is conducted to obtain information. The nurse's approach to the patient largely determines the amount and quality of the information received. To achieve a relationship of mutual trust and respect, the nurse must communicate a sincere interest in the patient. Examples of therapeutic communication techniques are found in Table 1-2**.**

A health history guide may help in obtaining pertinent information and directing the course of the interview. Various health history formats designed to guide the interview are available; however, they must be adapted to the responses, health problems, and needs of the person (see Chapter 4 for more information about the health history).

Physical Assessment

A physical assessment may be carried out before, during, or after the health history, depending on a patient's physical and emotional status and the immediate priorities of the situation. The purpose of the physical assessment is to identify those aspects of a patient's physical, psychological, and emotional state that indicate a need for nursing care. It requires the use of sight, hearing, touch, and smell as well as appropriate interview skills and techniques. Physical examination techniques, as well as techniques and strategies for assessing behaviors and role changes, are presented in Chapter 4 and in the first chapter of each unit of this book, beginning with Unit 4 and continuing through Unit 15.

Other Components of the Assessment

Additional relevant information should be obtained from the patient's family or significant others, from other members of the health care team, and from the patient's EHR. Depending on the patient's immediate needs, this information may have been completed before the health history and the physical assessment were obtained. A review of a past medical history or records from previous admissions may provide important information for consideration. Whatever the sequence of

events, the nurse should use all available sources of pertinent data to complete the nursing assessment.

Recording the Data

After the health history and physical assessment are completed, the information obtained is recorded in the patient's permanent record. These records are more commonly becoming electronic (i.e., EHRs). The ANA (2009) advocates that when EHRs are used, "patients should receive written, easily understood notification of how their health records are used and when their individually identifiable health information is disclosed to third parties" (p. 1). It is imperative that the patient's right to privacy and confidentiality are not violated through the use of EHRs. Regardless of whether the record is in a traditional paper format or an EHR, it must provide a means of communication among members of the health care team and facilitate coordinated planning and continuity of care (Räsänen & Günther, 2019). The record fulfills other functions as well:

TABLE 1-2 Select Therapeutic Communication Techniques

Technique	Definition	Therapeutic Value
Listening	Active process of receiving information and examining one's reactions to the messages received	Nonverbally communicates nurse's interest in the patient
Silence	Periods of no verbal communication among participants for therapeutic reasons	Gives patient time to think and gain insights, slows the pace of the interaction, and encourages the patient to initiate conversation while conveying the nurse's support, understanding, and acceptance
Restating	Repeating to the patient what the nurse believes is the main thought or idea expressed	Demonstrates that the nurse is listening and validates, reinforces, or calls attention to something important that has been said
Reflection	Directing back to the patient their feelings, ideas, questions, or content	Validates the nurse's understanding of what the patient is saying and signifies empathy, interest, and respect for the patient
Clarification	Asking the patient to explain what they mean or attempting to verbalize vague ideas or unclear thoughts of the patient to enhance the nurse's understanding	Helps to clarify the patient's feelings, ideas, and perceptions and to provide an explicit correlation between them and the patient's actions
Focusing	Questions or statements to help the patient develop, explore, or expand an idea or verbalize feelings	Allows the patient to discuss central issues and keeps communication goal directed
Broad openings	Encouraging the patient to select topics for discussion	Indicates acceptance by the nurse and the value of the patient's initiative
Humor	Discharge of energy through the comic enjoyment of the imperfect	Promotes insight by bringing repressed material to consciousness, resolving paradoxes, tempering aggression, and revealing new options; a socially acceptable form of sublimation
Informing	Providing information	Helpful in health teaching or patient education about relevant aspects of the patient's well-being and self-care
Sharing perceptions	Asking the patient to verify the nurse's understanding of what the patient is thinking or feeling	Conveys the nurse's understanding to the patient and has the potential to clarify confusing communication; may promote additional reflection
Theme identification	Underlying issues or problems experienced by the patient that emerge repeatedly during	Allows the nurse to best promote the patient's exploration and understanding of important problems

	the course of the nurse–patient relationship	
Suggesting	Presentation of alternative ideas for the patient's consideration relative to problem solving	Increases the patient's perceived options or choices

Adapted from Stuart, G. W. (2012). *Principles and practice of psychiatric nursing* (10th ed.). St. Louis, MO: CV Mosby.

- Serves as the legal and business record for a health care agency and for the professional staff members who are responsible for the patient's care. Various systems are used for documenting patient care, and each health care agency selects the system that best meets its needs.
- Serves as a basis for evaluating the quality and appropriateness of care and for reviewing the effective use of patient care services.
- Provides data that are useful in research, education, and short- and long-range planning.

Diagnosis

The assessment component of the nursing process serves as the basis for identifying nursing diagnoses and collaborative problems. Soon after the completion of the health history and the physical assessment, nurses organize, analyze, synthesize, and summarize the data collected and determine the patient's need for nursing care.

Nursing Diagnoses

Nursing diagnoses, the first taxonomy created in nursing, have fostered autonomy and accountability in nursing and have helped to delineate the scope of practice. Many state nurse practice acts include nursing diagnosis as a nursing function, and nursing diagnosis is included in the ANA's *Scope and Standards of Practice* (2015b) and the standards of nursing specialty organizations. Nursing diagnoses are routinely validated, refined, and updated to reflect current clinical practice and research.

NANDA International (NANDA-I; formerly known as the North American Nursing Diagnosis Association) was the first official organization responsible for developing the taxonomy of nursing diagnoses. In 2000, the International Classification for Nursing Practice (ICNP®) was established as an alternative system to support nursing care and standardization in documentation for practicing nurses at the point of care and across specialties (Coenen, 2003; International Council of Nurses [ICN], 2019). ICNP offers nursing diagnoses, intervention statements, and outcome statements designed to assist nurses within each step of the nursing process and all phases of care and was most recently updated in 2019. The nursing diagnoses used throughout this book are ICNP diagnoses. Because ICNP is proprietary to ICN, which has a global health focus, ICNP terms are spelled using the British method.

Choosing a Nursing Diagnosis

When identifying a nursing diagnosis for a particular patient, nurses must first identify the commonalities among the assessment data collected. These common features lead to the categorization of related data that reveal the existence of a problem and the need for nursing intervention. The identified problems are then defined as specific nursing diagnoses. Nursing diagnoses represent actual or potential health problems, state of health promotion, or potential risks that can be managed by independent nursing actions.

It is important to remember that nursing diagnoses are not medical diagnoses; they are not medical treatments prescribed by the primary provider, and they are not diagnostic studies. Rather, they are succinct statements of specific patient problems that guide nurses in the development of the plan of nursing care.

To give additional meaning to the nursing diagnosis, the characteristics and etiology of the problem are identified and included as part of the diagnosis. For example, the nursing diagnoses and their defining characteristics and etiology for a patient who has anemia may include the following:

- Activity intolerance associated with imbalance between supply and demand of oxygen
- Impaired peripheral tissue perfusion associated with decreased hemoglobin
- Impaired nutritional status associated with fatigue and inadequate intake of essential nutrients

Collaborative Problems

In addition to nursing diagnoses and their related nursing interventions, nursing practice involves certain situations and interventions that do not fall within the definition of nursing diagnoses. These activities pertain to potential problems or complications that are medical in origin and require collaborative interventions with the primary provider and other members of the health care team. The term *collaborative problem* is used to identify these situations.

Collaborative problems are certain physiologic complications that nurses monitor to detect changes in the status or onset of complications. Nurses manage collaborative problems using primary provider- and nurse-prescribed interventions to minimize complications (Carpenito, 2017). When treating collaborative problems, the primary nursing focus is monitoring patients for the onset of complications or changes in the status of existing complications. The complications are usually related to the disease process, treatments, medications, or diagnostic studies. The nurse recommends nursing interventions that are appropriate for managing the complications and implements the treatments prescribed by the patient's primary provider. According to Carpenito (2017), collaborative problems do not have patient goals; therefore, the approach to evaluation is different from a nursing diagnosis. The algorithm in Figure 1-4 depicts the differences between nursing diagnoses and collaborative problems.

After the nursing diagnoses and collaborative problems have been identified, they are recorded on the plan of nursing care.

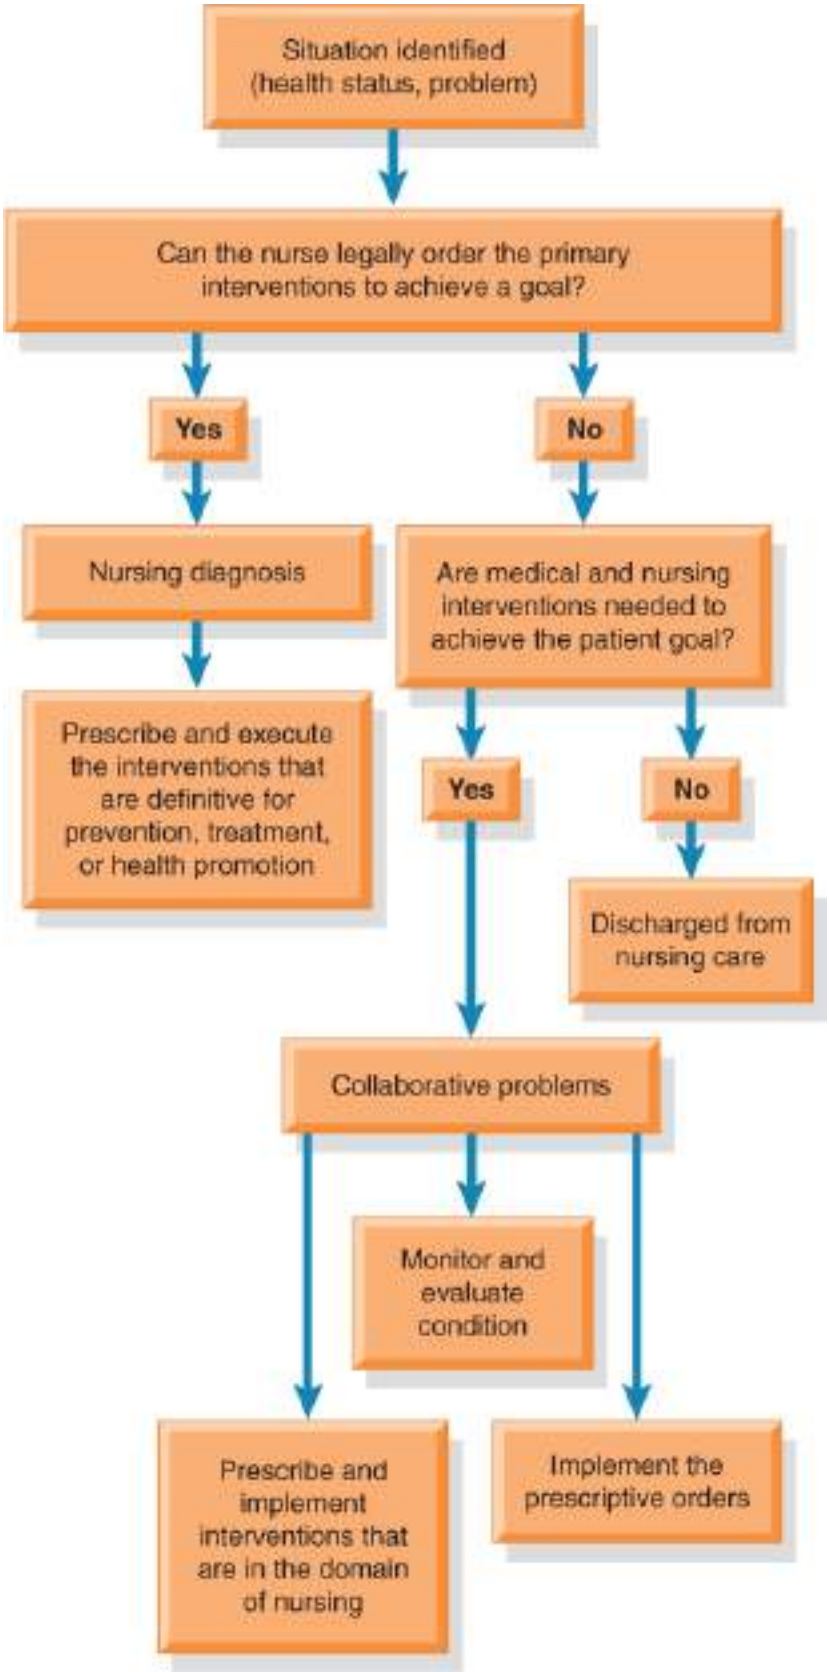

Figure 1-4 • Differentiating nursing diagnoses and collaborative problems. Redrawn with permission from Carpenito, L. J. (2017). *Nursing diagnosis: Application to clinical practice* (15th ed., p. 25). Philadelphia, PA: Lippincott Williams & Wilkins.

Planning

Once the nursing diagnoses have been identified, the planning component of the nursing process begins. This phase involves the following steps:

1. Assigning priorities to the nursing diagnoses and collaborative problems
2. Specifying realistic and measurable expected outcomes
3. Specifying the immediate, intermediate, and long-term goals of nursing action
4. Identifying specific nursing interventions appropriate for attaining the outcomes
5. Identifying interdependent interventions
6. Documenting the nursing diagnoses, collaborative problems, expected outcomes, nursing goals, and nursing interventions on the plan of nursing care
7. Communicating to appropriate personnel any assessment data that point to health care needs that can best be met by other members of the health care team

Setting Priorities

Assigning priorities to the nursing diagnoses and collaborative problems is a joint effort by the nurse and the patient or family members. Any disagreement about priorities is resolved in a way that is mutually acceptable. Consideration must be given to the urgency of the problems, with the most critical problems receiving the highest priority. Maslow Hierarchy of Needs provides one framework to prioritize problems (see previous discussion).

Establishing Expected Outcomes

Expected outcomes of the nursing interventions, identified either as long term or short term, are written in terms of the patient's behaviors and the time period in which the outcomes are to be met. The outcomes must be attainable and quantifiable (Carpenito, 2017). Resources for identifying appropriate expected outcomes include the ICNP and the standard outcome criteria developed by the Nursing Outcomes Classification (NOC) (Moorhead, Swanson, Johnson, et al., 2018) (Chart 1-3) and by health care agencies for people with specific health problems. These outcomes can be associated with nursing diagnoses and interventions and can be used when appropriate. However, the NOC may need to be adapted to establish realistic criteria for the specific patient involved.

The expected outcomes that define the patient's desired behavior are used to measure the progress made toward resolving the problem. The expected outcomes also serve as the basis for evaluating the effectiveness of the nursing interventions and for deciding whether additional nursing care is needed or whether the plan of care needs to be revised.

Establishing Goals

After the priorities of the nursing diagnoses and expected outcomes have been established, goals (immediate, intermediate, and long term) and the nursing actions appropriate for attaining the goals are identified. The patient and family are included in establishing goals for the nursing actions. Immediate goals are those that can be attained within a short time frame. Intermediate and long-term goals require a longer time frame to be achieved and usually involve preventing complications and other health problems and promoting self-care and rehabilitation. For example, goals for a patient with a nursing diagnosis of impaired mobility associated with pain and edema following total knee replacement may be stated as follows:

- Immediate goal: Stands at bedside for 5 minutes 6 to 12 hours after surgery
- Intermediate goal: Ambulates 15 to 20 minutes with walker or crutches in hospital and home
- Long-term goal: Ambulates independently 1 to 2 miles each day

Determining Nursing Actions

In planning appropriate nursing actions to achieve the desired goals and outcomes, the nurse, with input from the patient and significant others, identifies individualized interventions based on the patient's circumstances and preferences that address each outcome. Interventions should identify the activities needed, who will implement them, as well as the frequency. Determination of interdisciplinary activities is made in collaboration with other health care providers as needed. The patient's medications and other prescribed treatments should be integrated into the plan of care to assist the nurse in determining how all interventions contribute to resolution of the identified problems.

The nurse identifies and plans patient education as needed to assist the patient in learning certain self-care activities. Planned interventions should be ethical and appropriate to the patient's culture, age, developmental level, and gender. Standardized interventions, such as those found on standardized care plans, the ICNP, or in the Nursing Interventions Classification (NIC) (Butcher, Bulechek, Dochterman, et al., 2018) can be used. Chart 1-4 describes the NIC system and provides an example of an NIC system intervention. It is important to individualize prewritten interventions to promote optimal effectiveness for each patient. Actions of nurses should be based on established standards.

Implementation

The implementation phase of the nursing process involves carrying out the proposed plan of nursing care. The nurse assumes responsibility for implementation and coordinates the activities of all those involved in implementation, including the patient and family, and other members of the health care team so that the schedule of activities facilitates the patient's recovery. The plan of nursing care serves as the basis for implementation as such:

- The immediate, intermediate, and long-term goals are used as a focus for the implementation of the designated nursing interventions.
- While implementing nursing care, the nurse continually assesses the patient and the patient's individual response to the nursing care.
- Revisions are made in the plan of care as the patient's condition, problems, and responses change and when reordering of priorities is required.

Implementation includes direct or indirect execution of the planned interventions. It is focused on resolving the patient's nursing diagnoses and collaborative problems and achieving expected outcomes, thus meeting the patient's health needs. The following are examples of nursing interventions:

- Supervise the patient performing active range-of-motion exercises three times a day.

Chart 1-3

Nursing Outcomes Classification

The Nursing Outcomes Classification (NOC) is a classification of patient outcomes that are sensitive to nursing interventions. Each outcome is a neutral statement about a variable patient condition, behavior, or perception, coupled with a rating scale. The outcome statement and scale can be used to identify baseline functioning, expected outcomes, and actual outcomes for individual patients. The following table is an example of a nursing-sensitive outcome.

Cardiac Pump Effectiveness (0400)

Definition: Adequacy of blood volume ejected from the left ventricle to support systemic perfusion pressure.

Outcome Target Rating ***Maintain at*** _____ ***Increase to*** _____

Cardiac Pump Effectiveness Overall Rating		Severe Deviation From Normal Range 1	Substantial Deviation From Normal Range 2	Moderate Deviation From Normal Range 3	Mild Deviation From Normal Range 4	No Deviation From Normal Range 5	
Indicators							
040001	Systolic blood pressure	1	2	3	4	5	NA
040019	Diastolic blood pressure	1	2	3	4	5	NA
040002	Apical heart rate	1	2	3	4	5	NA
040003	Cardiac index	1	2	3	4	5	NA
040004	Ejection fraction	1	2	3	4	5	NA
040006	Peripheral pulses	1	2	3	4	5	NA
040007	Heart size	1	2	3	4	5	NA
040020	Urine output	1	2	3	4	5	NA
040022	24-hour intake and output balance	1	2	3	4	5	NA
040025	Central venous pressure	1	2	3	4	5	NA

- Teach the patient who is postoperative to use an incentive spirometer 10 times every hour while awake.
- Monitor the patient for adverse effects of opioid analgesic medications, including sedation and respiratory depression.
- Assist the patient in developing a plan to reduce dietary sodium and increase daily activity.
- Administer sublingual nitroglycerin as prescribed to the patient who complains of angina.

- Assess electrolyte levels prior to administering scheduled intravenous diuretics.

Chart 1-4

Nursing Interventions Classification

The Nursing Interventions Classification (NIC) is an in-depth, evidence-based taxonomy of interventions that includes independent and collaborative interventions. These interventions are performed in a variety of health care settings. Intervention labels are terms such as *bleeding precautions, medication administration,* or *pain management: acute.* Listed under each intervention are multiple discrete nursing actions that together constitute a comprehensive approach to the treatment of a particular condition. Not all actions are applicable to every patient; nursing judgment and critical thinking will determine which actions to implement. The following is an example of a nursing intervention:

Fluid Resuscitation

Definition

Administering prescribed intravenous (IV) fluids rapidly

Activities

Obtain and maintain a large-bore IV.
Collaborate with primary providers to ensure administration of both crystalloids (e.g., normal saline and lactated Ringer's) and colloids (e.g., Hesban, and Plasmanate), as appropriate.
Administer IV fluids, as prescribed.
Obtain blood specimens for crossmatching, as appropriate.
Administer blood products, as prescribed.
Monitor hemodynamic response.
Monitor oxygen status.
Monitor for fluid overload.
Monitor output of various body fluids (e.g., urine, nasogastric drainage, and chest tube).
Monitor BUN, creatinine, total protein, and albumin levels.
Monitor for pulmonary edema and third spacing.

Used with permission from Butcher, H. K., Bulecheck, G. M., Dochterman, J. M., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis, MO: Elsevier.

- Check gastric residuals in the patient receiving tube feedings before each feeding.

Clinical judgment, critical thinking, and good decision-making skills are essential in the selection of appropriate evidence-based and ethical nursing interventions. All nursing interventions are patient centered and outcome directed

and are implemented with compassion, skill, confidence, and a willingness to accept and understand the patient's responses.

Concept Mastery Alert

Implementation is nursing action. Therefore, statements involving implementation always start with a verb.

Although many nursing actions are independent, others are interdependent, such as carrying out prescribed treatments, administering medications and therapies, and collaborating with other health care team members to accomplish specific expected outcomes and to monitor and manage potential complications. Such interdependent functioning is just that—interdependent. Requests or prescriptions from other health care team members should not be followed blindly but must be assessed critically and questioned when necessary. The implementation phase of the nursing process ends when the nursing interventions have been completed.

Evaluation

Evaluation, the final step of the nursing process, allows the nurse to determine the patient's response to the nursing interventions and the extent to which the objectives have been achieved. The plan of nursing care is the basis for evaluation. The nursing diagnoses, collaborative problems, priorities, nursing interventions, and expected outcomes provide the specific guidelines that dictate the focus of the evaluation. Through evaluation, the nurse can answer the following questions:

- Were the nursing diagnoses and collaborative problems accurate?
- Did the patient achieve the expected outcomes within the critical time periods?
- Have the patient's nursing diagnoses been resolved?
- Have the collaborative problems been resolved?
- Do priorities need to be reordered?
- Have the patient's nursing needs been met?
- Should the nursing interventions be continued, revised, or discontinued?
- Have new problems evolved for which nursing interventions have not been planned or implemented?
- What factors influenced the achievement or lack of achievement of the objectives?
- Should changes be made to the expected outcomes and outcome criteria?

Objective data that provide answers to these questions are collected from all available sources (e.g., patients, families, significant others, health care team

members). These data are included in patients' records and must be substantiated by direct patient observation before the outcomes are documented.

Documentation of Outcomes and Revision of the Plan

Outcomes are documented concisely and objectively. Documentation should relate outcomes to the nursing diagnoses and collaborative problems, describe the patient's responses to the interventions, indicate whether the outcomes were met, and include any additional pertinent data. As noted previously, the nurse individualizes a plan of care for each patient's particular circumstances. Chart 1-5 gives an example of a plan of nursing care that has been developed for a 22-year-old woman admitted to a postoperative surgical unit after having an emergent laparoscopic appendectomy.

The plan of care is subject to change as a patient's needs change, as the priorities of needs shift, as needs are resolved, and as additional information about a patient's state of health is collected. As the nursing interventions are implemented, the patient's responses are evaluated and documented, and the plan of care is revised accordingly. A well-developed, continuously updated plan of care is the greatest assurance that the patient's nursing diagnoses, and collaborative problems are addressed, and their basic needs are met.

Chart 1-5 **PLAN OF NURSING CARE**

Example of a Plan of Nursing Care for a Patient Post Laparoscopic Appendectomy

NURSING DIAGNOSIS: Acute pain
GOAL: Relief of pain and discomfort

Nursing Interventions	Rationale	Expected Outcomes
1. When taking vital signs, use pain scale to assess pain and discomfort characteristics: location, quality, frequency, durations, etc., at baseline and on an ongoing basis.	1. Provides baseline data.	• Reports decreased level of pain and discomfort on pain scale.
2. Assure the patient that you know that pain is real and will assist in reducing it.	2. Fear that pain will not be considered real increases anxiety and reduces pain tolerance.	• Reports less disruption in activity and quality of life from pain and discomfort.
3. Assess other factors contributing to patient's pain: fear; fatigue; other symptoms; psychosocial and/or spiritual distress, etc.	3. Provides data about factors that decrease patient's ability to tolerate pain and increase pain level.	• Reports decrease in other symptoms and psychosocial distress.
4. Administer prescribed analgesic regimen, and provide education to patient and family regarding regimen.	4. Analgesics tend to be more effective when given early in pain cycle, around the clock at regular intervals, or when given in long-acting forms; breaks the pain cycle; premedication with analgesics is used for activities that cause increased pain or breakthrough pain.	• Adheres to analgesic regimen as prescribed. • Barriers to adequately addressing pain do not interfere with strategies for managing pain.
5. Address myths or misconceptions and lack of knowledge about use of opioid analgesics.	5. Barriers to adequate pain management involve patients' fear of side effects, fatalism about the possibility of achieving pain control, fear of distracting providers from treating the postoperative pain, belief that pain is	• Takes an active role in administration of analgesia. • Identifies additional effective pain relief strategies. • Uses previously employed successful pain relief strategies appropriately.
6. Collaborate with patient, primary provider/surgeon, and other health care team members when changes in pain management are necessary.		• Reports effective use of nonpharmacologic pain relief

7. Encourage strategies of pain relief that patient has used successfully in previous pain experience. 8. Offer nonpharmacologic strategies to relieve pain and discomfort: distraction, guided imagery, relaxation, cutaneous stimulation, therapeutic touch, Reiki, etc.	indicative of progressive disease, and fears about addiction. Professional health providers also have demonstrated limited knowledge about pain management, potential analgesic side effects, and management and risk of addiction. 6. New methods of administering analgesia must be acceptable to the patient, primary provider/surgeon, and health care team to be effective; patient's participation decreases sense of powerlessness. 7. Encourages success of pain relief strategies accepted by patient and family. 8. Increases options and strategies available to patient that serve as adjuncts to pharmacologic interventions.	strategies and a decrease in pain. • Reports that decreased level of pain permits early ambulation postoperatively.

NURSING DIAGNOSIS: Risk for infection (i.e., wound infection, pneumonia, urinary tract infection [UTI])
GOAL: No evidence of infection

Nursing Interventions	Rationale	Expected Outcomes
1. Assess wound site for signs of infection	1. Some manifestations of	• No drainage, increased

or increased inflammation:

a. If there is a dressing or bandage present, verify whether and when it will be changed by the primary provider/surgeon.
b. Note the color, consistency, and amount of drainage, if present; if so, also note if any odor is present; notify the primary provider/surgeon as indicated.
c. Note any changes in appearance of wound over time, particularly if it becomes increasingly edematous or erythematous.

2. Monitor vital signs, temperature, and laboratory results (if available) for signs of infection.

3. Monitor for manifestations of atelectasis or pneumonia.

a. Assess for adventitious lung sounds (e.g., rales, wheezes) or for decreased air movement.

inflammation are to be expected (e.g., wound tenderness, slight erythema, and edema); however, this should decrease over time and there should be no evidence of an infection at the wound site.

a. The primary provider/surgeon may wish to remove the first dressing or bandage, to assess the status of the wound and presence of drainage firsthand.
b. Drainage may indicate an infectious process, particularly if it is malodorous.
c. Increased wound edema or erythema may indicate an infection.

2. Changes in vital signs, particularly temperature, may suggest an infection; if these changes are marked, they may suggest sepsis (see Chapter 11 for further discussion of the clinical manifestations of

erythema, or edema at the laparoscopic wound site.
- Temperature within normal limits (i.e., between 36.1°C [97°F] and 38.0°C [100.4°F]).
- Lung sounds clear to auscultation; no cough.
- Voids clear yellow urine without complaints of burning on micturition or feelings of bladder fullness.
- Laboratory results, if assessed, are within normal limits.

b. Encourage early movement (e.g., demonstrate and encourage use of incentive spirometer, encourage early ambulation).

c. Preemptively treat postoperative pain, as described above.

4. Monitor micturition status; note when patient first voids, the amount, and if there are any complaints of burning or bladder fullness; notify the primary provider/surgeon as indicated; monitor laboratory results, including the CBC and urinalysis as indicated.

sepsis); laboratory results, particularly the presence of leukocytosis with a shift to the left on the differential of the white blood cell count (WBC) on the complete blood count (CBC), may suggest an infection is present. Postoperatively, most patients will have a slightly elevated temperature (up to 38.0°C [100.4°F]), which is consistent with the inflammatory process. A temperature higher than this in a previously healthy adult suggests some type of underlying infectious process.

3. Atelectasis and pneumonia are prevalent postoperative pulmonary complications (see Chapter 16, Table 16-4).

a. Lung sounds should be clear to auscultation bilaterally; the presence of adventitious sounds may suggest the development of atelectasis or pneumonia; diminished lung

sounds may suggest poor air movement from splinting respirations, which can lead to respiratory compromise.

b. Movement mobilizes respiratory secretions and respiratory effort.

c. Pain interferes with the ability to move; pain results in splinting of respiratory effort.

4. Urinary retention and urinary tract infections are prevalent postoperative complications (see Chapter 16, Table 16-4); CBC results may reveal leukocytosis with a shift to the left on the WBC differential; urinalysis results may reveal the presence of blood cells (e.g., red blood cells [RBCs], WBCs) that may suggest a urinary tract infection.

NURSING DIAGNOSIS: Impaired nutritional status associated with perioperative *nil per os* (NPO) status
GOAL: Will consume typical diet by discharge

Nursing Interventions	Rationale	Expected Outcomes
1. Assess for return of gastrointestinal function postoperatively. a. Auscultate for the presence of bowel sounds. b. Ask the patient if they have passed flatus. c. Encourage early ambulation as this will assist with return of gastrointestinal function.	1. Gastrointestinal motility is diminished post surgery; peristalsis should return within hours and is evidenced by return of bowel sounds and passing of flatus.	• Will advance diet, as tolerated. • No complaints of nausea.
2. Advance diet as tolerated and prescribed by primary provider/surgeon. a. Assess for complaints of nausea. If present, may give antiemetic medications as prescribed (e.g., ondansetron) and delay advancement of diet.	2. Patient will need to demonstrate ability to tolerate fluids and food prior to discharge. a. Complaints of nausea are prevalent post laparoscopic surgery; if patient vomits, that may delay recovery (e.g., disrupt wound, delay intake of nutrients); administering antiemetic medications may preempt complications.	

NURSING DIAGNOSIS: Activity intolerance associated with fatigue post surgery
GOAL: Participation in activities of daily living within tolerance

Nursing Interventions	Rationale	Expected Outcomes
1. Assess factors contributing to activity intolerance and fatigue. 2. Promote atmosphere conducive to physical and mental rest: a. Encourage alternation of rest and activity. b. Encourage limitation of visitors and stress-producing interactions.	1. Indicates factors contributing to severity of fatigue 2. Promotes rest, activity tolerance, and decreased overall stress	• Identifies factors contributing to fatigue • Alternates periods of rest and activity • Limits visitors to ensure adequate rest periods
NURSING DIAGNOSIS: Lack of knowledge regarding methods to ensure postoperative recovery **GOAL:** Increased knowledge about expected postoperative recovery and transition back to preoperative baseline functional status		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Educate patient on expectations for recovery, discharge, and transition to home. a. Demonstrate wound care to patient, as prescribed by primary provider/surgeon; ask patient to return demonstrate wound care. b. Educate patient on use of prescribed analgesic medications	1. Inpatient recovery time after a laparoscopic appendectomy is short (e.g., 1 day, assuming there are no complications [see Chapter 16, Table 16-4]); therefore, preparing patient for discharge must commence expeditiously.	• Demonstrates appropriate care of wound. • Verbalizes understanding of continued analgesic regimen, including when to take prescriptive analgesic medications (e.g., oxycodone), and whether there are any activity restrictions associated with their use (e.g., no driving).

(e.g., oxycodone), including actions, indications, side effects, and when to take them (e.g., prior to ambulation). c. Educate patient on activity restrictions (e.g., bathing, lifting, return to work or school) as prescribed by primary provider/surgeon. d. Educate patient on when to follow up with primary provider/surgeon postoperatively, for scheduled postoperative appointment and as needed.	• Verbalizes understanding of activity restrictions, including bathing, lifting, return to work/school, as prescribed by primary provider/surgeon. • Verbalizes adherence to scheduled postoperative appointment.

Frameworks for a Common Approach to Nursing

Various frameworks or taxonomies can be used for determining nursing diagnoses, establishing outcomes, designing interventions, and guiding clinical decision making. Ultimately, a framework that uses a language common to all aspects of nursing, regardless of the classification system, is desirable. In 2001, a taxonomy of nursing practice was developed for the harmonization of NANDA-I, NIC, and NOC. This three-part combination links nursing diagnoses, accompanying interventions, and outcomes, organizing them in the same way. Similarly, the ICNP has developed catalogues that align nursing diagnoses, outcome statements, and intervention statements. Such organization of concepts in a common language or taxonomy may facilitate the process of clinical judgment and critical thinking, because interventions and outcomes are more accurately matched with appropriately developed nursing diagnoses (Carpenito, 2017). More recently, the National Council of State Boards of Nursing (NCSBN®) developed the NCSBN Clinical Judgment Measurement Model, which offers a framework to measure clinical decision making and clinical judgment in the context of the National Council Licensure Examination (NCLEX-RN® examination; see Chart 1-6). Figure 1-5 illustrates the application of this model to the nursing process.

Ethical Nursing Care

In the complex health care world, nurses are faced with numerous ethical issues. Consequently, there has been a heightened interest in the field of ethics in an attempt to gain a better understanding of how these issues can be addressed. Specifically, the focus on ethics in health care has intensified in response to controversial developments, including advanced technology, genomics, medical futility, scarcity of resources, and end-of-life issues, to name a few.

Today, sophisticated technology can prolong life well beyond the time when death would have occurred in the past. Expensive experimental procedures, clinical trials, complex equipment and treatments are available to prolong life, even when such attempts may not provide quality of life. The development of technologic support has influenced the quality and delivery of nursing care at all stages of life and also has contributed to an increase in average life expectancy. For example, robotic technology is helping older adults living in the community to better manage chronic health problems (Bakas, Sampsel, Israel, et al., 2018). Adults with end-stage heart failure who are not candidates for cardiac transplantation can live longer with the support of newer generation left ventricular assist devices (LVADs), which require less invasive surgery and are associated with less complications than older model LVADs (Kubrusly, 2019). Advances in immunotherapy have increased life expectancies for patients diagnosed with advanced stage melanomas and nonsquamous cell lung cancers

(Munro, 2019). Patients who would have died of organ failure are living longer because of organ transplantation and stem cell transplant.

These advances in technology have been a mixed blessing. Questions have been raised about whether it is appropriate to use such technology and, if so, under what circumstances. Although many patients do achieve a good quality of life, others face extended suffering as a result of efforts to prolong life, usually at great expense both emotionally and financially. Ethical issues also surround those practices or policies that seem to allocate health care resources unjustly on the basis of age, race, gender, disability, or social mores. Older adults may be at risk for being denied health care because of their advanced age and the bias known as ageism (see Chapter 8 for a further discussion of ageism).

Ethical dilemmas that nurses may encounter in the medical-surgical nursing arena are diverse and occur in all settings. An awareness of underlying concepts helps nurses use reason to work through these dilemmas. Basic concepts related to moral philosophy, such as ethics and its principles, theories, and approaches, are included in this chapter. Understanding the role of the professional nurse in ethical decision making not only helps nurses articulate their ethical positions and develop the skills needed to make ethical decisions, but also helps them use the nursing process to develop plans of care from an ethical perspective.

Ethics versus Morals

The terms *ethics* and *morality* are used to describe beliefs about right and wrong and to suggest appropriate guidelines for action. In essence, **ethics** is the formal, systematic study of moral beliefs to understand, analyze, and evaluate matters of right and wrong; whereas, **morality** includes specific values, characters, or actions whose outcomes are often examined through systematic ethical analysis. Because the distinction between ethics and morality is slight, the terms are often used interchangeably.

Ethics Theories

One classic theory in ethics is teleologic theory or consequentialism, which focuses on the ends or consequences of actions. The best-known form of this theory, utilitarianism, is based on the concept of "the greatest good for the greatest number." The choice of action is clear under this theory, because the action that maximizes good over bad is the correct one. The theory poses difficulty when one must judge intrinsic values and determine whose good is the greatest. In addition, it is important to ask whether good consequences can justify any amoral actions that might be used to achieve them.

Chart 1-7 **ETHICAL DILEMMA**

Common Ethical Principles

The following common ethical principles may be used to validate moral claims.

Autonomy

This word *autonomy* is derived from the Greek words *autos* ("self") and *nomos* ("rule" or "law") and therefore refers to self-determination. The principle of autonomy entails the right of patients to receive adequate and accurate information so that they have the ability to make a choice free from external constraints. It is synonymous with self-determination.

Beneficence and Nonmaleficence

Beneficence is the duty to perform acts that can be of benefit others. It also entails taking positive action to prevent patients from harming themselves or others, including society as a whole. There is also an implied commitment to help people with disability.

Nonmaleficence is the duty to not inflict harm. The only time when it is considered morally permissible to exercise power over a competent person against their will is when by doing so, harm to others is prevented.

Double Effect

The double effect is a principle that may morally justify some actions that produce both good and evil effects.

All four of the following criteria must be fulfilled:

1. The action itself is good or morally neutral.
2. The agent sincerely intends the good and not the evil effect (the evil effect may be foreseen but is not intended).
3. The good effect is not achieved by means of the evil effect.
4. There is proportionate or favorable balance of good over evil.

Distributive Justice

From a broad perspective, justice states that like cases should be treated alike. More specifically, distributive justice is an ethical principle commonly applicable to clinical situations. This principle is upheld when benefits and burdens are distributed equitably and fairly without consideration of age, gender, socioeconomic status, religion, ethnicity, or sexual orientation. Simply stated, there is an ethical obligation to distribute or allocate resources fairly.

Adapted from Beauchamp, T. L., & Childress, J. F. (2019). *Principles of biomedical ethics* (8th ed.). New York: Oxford University Press.

Another theory in ethics is the deontologic or formalist theory, which argues that ethical standards or principles exist independently of the ends or consequences. In a given situation, nurses have a "sense of duty" to act based on the one relevant principle, or the most relevant of several ethical principles. Their actions must be independent of the ends or consequences. Problems arise with

this theory when personal and cultural biases influence the choice of the most primary ethical principle.

Approaches to Ethics

Two approaches to ethics are meta-ethics and applied ethics. An example of meta-ethics (understanding the concepts and linguistic terminology used in ethics) in the health care environment is analysis of the concept of informed consent. Nurses are aware that patients must give consent before surgery; however, sometimes a question arises as to whether a patient is truly informed and mentally competent. Delving more deeply into the concept of informed consent would be a meta-ethical inquiry (see Chapter 14 for more information about informed consent before surgery).

Applied ethics refers to identification of ethical problems relevant to a specific discipline and that discipline's practice. It addresses the implications of actions or practices in terms of their moral permissibility. Various disciplines use the frameworks of general ethical theories and principles and apply them to specific problems within their domain. Nursing ethics may be considered a form of applied ethics because it addresses moral situations that are specific to the nursing profession and patient care. Common ethical principles that can be used to validate moral claims in clinical practice include autonomy, beneficence and nonmaleficence, double effect, and distributive justice. Brief definitions of these important principles can be found in Chart 1-7**.**

Moral Situations

Many situations exist in which ethical analysis is needed. Some are **moral dilemmas,** or situations in which a clear conflict exists between two or more moral principles or competing moral claims, and nurses must choose the lesser of two evils. Other situations represent **moral problems,** in which there may be competing moral claims or principles, although one claim or principle is clearly dominant. Some situations result in **moral uncertainty,** when one cannot accurately define what the moral situation is or what moral principles apply but has a strong feeling that something is not right. Still other situations may result in **moral distress,** in which one is aware of the correct course of action, but institutional constraints stand in the way of pursuing the correct action. Altaker, Howie-Esquivel, and Cataldo (2018) found that moral distress in critical-care nurses was related to perceptions of a poor ethical climate and poor personal empowerment (see Nursing Research Profile in Chart 1-8).

Many scenarios may occur in clinical practice that require an ethical analysis. For example, an older adult patient with a history of advanced dementia and heart failure is admitted to the hospital with shortness of breath and diagnosed with aspiration pneumonia. This is the patient's third hospitalization in the last year for aspiration pneumonia. The patient fails a swallow evaluation and the speech-language pathologist recommends that the patient remain NPO (nothing by mouth). The primary provider coordinates a family meeting to discuss options for

nutrition which include inserting a percutaneous feeding tube or carefully hand feeding the patient to promote comfort. The team learns that the patient never completed a living will or assigned a health care representative. The patient's son recalls his mother telling him once on a trip to Italy that "eating was one of her greatest pleasures." However, the patient's daughter is adamant that her mother receives a feeding tube, despite learning that feeding tubes do not increase survival and are associated with complications in patients with significant cognitive deficits. Both the son and daughter have a close relationship with their mother, but neither have had a formal discussion with her about her end-of-life wishes. They do not have any other siblings and their father died several years ago suddenly from a cerebral aneurysm. The son is reluctant to go against his sister's wishes. The nurse has worked with other patients and families in similar situations and knows that his role is to advocate for his patient. He is familiar with current literature which suggests enteral feedings do not improve nutritional or functional status in this population and feels strongly that a feeding tube will not enhance the patient's quality of life. The primary provider is concerned that the daughter will create "problems" for the hospital if a feeding tube is not inserted and states that "he does not have time to deal with her" so schedules the patient for the procedure. The nurse feels strongly that this is the wrong decision and that the daughter would benefit from more education and time to process this complex decision. However, the nurse does not feel empowered to voice his concerns to the primary provider and is left feeling a sense of moral distress; he knows the right course of action, but institutional factors, including existing power hierarchies among nurses and primary providers and lack of time and additional supportive services, prevent him from acting. The nurse wishes that he had had more time to discuss this case with his charge nurse or nurse manager, or to consult the palliative care team which is not in the hospital on the weekends, and today is a Saturday.

Chart 1-8 NURSING RESEARCH PROFILE

Moral Distress in Critical-Care Nurses

Altaker, K. W., Howie-Esquivel, J., & Cataldo, J. K. (2018). Relationships among palliative care, ethical climate, empowerment, and moral distress in intensive care unit nurses. *American Journal of Critical Care*, *27*(4), 295–302.

Purpose

Between 10% and 29% of patients admitted to intensive care units (ICUs) die. Difficulty delivering adequate end-of-life comfort care can cause moral distress among nurses who work in ICUs. Delivering quality comfort care can be predicated upon the ability of the critical-care nurses to appropriately access palliative care services. Moral distress may also be affected by the overall ethical climate in the ICU, as well as by the personal sense of empowerment by the individual critical-care nurse. Therefore, the purpose of this study was to evaluate relationships between critical-care nurses' moral distress, palliative care service access, ICU ethical climate, and personal empowerment.

Design

A Web-based survey was sent to a nationally representative sample of critical-care nurses who belonged to the American Association of Critical-Care Nurses. In order to be eligible for the study, participants had to be currently working as a direct provider of nursing care in an adult ICU and had to have provided care to at least one dying patient within the past 6 months. Of those who agreed to participate, 235 completed all survey items. Items included in the survey were derived from psychometrically validated instruments including the Moral Distress Scale-Revised, the Hospital Ethical Climate Survey, and the Psychological Empowerment Instrument. In addition, survey items that assessed participants' perceptions of access to, use of, and barriers to palliative care in the ICU were developed and included in the survey.

Findings

Moral distress was negatively associated with feelings of empowerment ($r = -0.145$; $p = 0.02$) and with the ICU ethical climate ($r = -0.354$; $p < 0.001$). Multiple regression analysis found that the factors that contributed to variance in moral distress included the ICU ethical climate, access to palliative care services, size of the ICU, and personal characteristics of the nurse, such as ethnicity and educational level. The factor that contributed the most to moral distress was the ICU ethical climate, with a positive ICU ethical climate correlating with lower levels of moral distress.

Nursing Implications

Findings from this study suggest that critical-care nurses who feel less empowered also feel greater moral distress; however, this relationship was not clear when the variable of ICU ethical climate was analyzed. It seems that personal characteristics of the critical-care nurse, including feelings of empowerment, as well as the ethical climate within the ICU, have roles in determining whether the critical-care nurse experiences moral distress. An unexpected finding was that critical-care nurses who reported access to

palliative care services reported greater moral distress. The quality of the interprofessional relationships between critical-care nurses and interdisciplinary members of palliative care teams must be explored. Further studies must be conducted to better discern the causes of moral distress among critical-care nurses so that appropriate interventions may be targeted to mitigate moral distress, which can cause nurse burnout and patient care avoidance.

It is essential that nurses freely engage in dialogue concerning moral situations, even though such dialogue is difficult for everyone involved. Improved interdisciplinary collaboration is supported when all members of the health care team can voice their concerns and come to an understanding of the moral situation. Consultation with an ethics committee could be helpful to assist the health care team, patient, and family to identify the moral dilemma and possible approaches to the dilemma (see the Ethics Committees section). Nurses should be familiar with agency policy supporting patient self-determination and resolution of ethical issues.

Types of Ethical Problems in Nursing

As a profession, nursing is accountable to society. Nursing has identified its standards of accountability through formal codes of ethics that explicitly state the profession's values and goals. The ICN has endorsed a globally applicable *Code of Ethics for Nurses* (ICN, 2012). Likewise, the ANA established a *Code of Ethics for Nurses* that includes ethical standards, each with its own interpretive statements (ANA, 2015a). The interpretive statements provide guidance to address and resolve ethical dilemmas by incorporating universal moral principles. In addition, the ANA sponsors a Center for Ethics and Human Rights that contains a repository of position statements that can be used to guide nursing practice (Chart 1-9).

Ethical issues have always affected the role of professional nurses. The accepted definition of professional nursing not only supports the advocacy role for nurses, but also the claim that nurses must be actively involved in the decision making process regarding ethical concerns surrounding health care and human responses. Nurses are morally obligated to present ethical conflicts within a logical, systematic framework. Health care settings in which nurses are valued members of the team promote interdisciplinary communication and may enhance patient care. The nurse presented in the case study in the previous section is morally obligated to address his concerns constructively. He should carve out the time to discuss his concerns within his chain of command, through notifying his charge nurse of his concerns for the patient. To practice effectively in these settings, nurses must be aware of ethical issues and serve as patient advocates to assist patients in asserting their autonomy in decision making.

Chart 1-9

Position Statements from the American Nurses Association Center for Ethics and Human Rights

Position Statement	Latest Approval/Revision Date
Addressing Nurse Fatigue to Promote Safety and Health	Revised 9/10/14
Capital Punishment and Nurses' Participation in Capital Punishment	Revised 2016
Euthanasia, Assisted Suicide, and Aid in Dying	Revised 4/24/19
Nurse's Role in Providing Ethically and Developmentally Appropriate Care to People with Intellectual and Developmental Disabilities	Approved 10/10/19
Nursing Advocacy for LGBTQ+ Populations	Approved 4/19/18
Nursing Care and Do Not Resuscitate (DNR) and Allow Natural Death (AND)	Approved 3/12/12
Nutrition and Hydration at the End of Life	Revised 6/7/17
Privacy and Confidentiality	Revised 6/2015
Reduction of Patient Restraint and Seclusion in Health Care Settings	Approved 3/12/12
Registered Nurses' Role and Responsibilities in Providing Expert Care and Counseling at End of Life	Revised 2016
Risk and Responsibility in Providing Nursing Care	Approved 6/2015
Stem Cell Research	Approved 1/10/07
The Nurses' Role in Ethics and Human Rights: Protecting and Promoting Individual Worth, Dignity, and Human Rights in Practice Setting	Approved 2/2016
Therapeutic Use of Marijuana and Related Cannabinoids	Revised 2016

Nursing theories that incorporate the biopsychosocial–spiritual dimensions emphasize a holistic viewpoint, with humanism or caring at the core. Caring and compassion are often cited as virtues inherent within the moral foundation for professional nursing practice. For nurses to embrace this professional ethos, they must be aware not only of major ethical dilemmas but also of those daily interactions with health care consumers that frequently give rise to less easily identifiable ethical challenges. Although technologic advances and diminished resources have been instrumental in raising numerous ethical questions and controversies, including life-and-death issues, nurses should not ignore the many routine situations that involve ethical considerations. Some of the most common issues faced by nurses today include confidentiality, the use of restraints, truth-telling, refusing to provide care, and end-of-life decisions and palliative care.

Confidentiality

All nurses should be aware of the confidential nature of information obtained in daily practice. Confidentiality acknowledges and respects each person's privacy. If information is not pertinent, nurses should question whether it is prudent to document it in a patient's record. In the practice setting, discussion of patients

with other members of the health care team is often necessary. However, these discussions should occur in a private area where it is unlikely that the conversation will be overheard. Nurses should also be aware that the use of family members or hospital ancillary personnel as interpreters for patients who are not fluent in English language or who are deaf violates patients' rights of confidentiality. Translation services should be provided for non–English-speaking patients, and interpreters should be provided for those who use sign language by the hospital or institution.

Another threat to confidentiality is the widespread use of computer-based technologies, particularly EHRs, and people's easy access to them. The growing demand for telehealth innovations and the increasing use of this method can result in unchecked access to health information. In addition, personal and health information is often made available to numerous individuals and corporate stakeholders, which may increase the potential for misuse of health care information. Because of these possibilities of maleficence, sensitivity to the principle of confidentiality is essential. The ANA (2015) published a position statement that addresses patients' rights to privacy and confidentiality of their health information.

Federal legislation has been developed to protect the right of confidentiality. According to the Health Insurance Portability and Accountability Act (HIPAA) (HHS, 2003), efforts must be made to protect each patient's private health information (PHI), whether it is transmitted by verbal, written, or electronic means of communication. Communication should be confined to the appropriate settings and with appropriate individuals and should occur for the appropriate purposes of facilitating patient care. Violations of protection of any patient's privacy could result in criminal or civil litigation (HHS, 2003).

Restraints

The use of restraints (including physical and pharmacologic measures) and patient seclusion are additional issues with ethical overtones because of the limits on a person's autonomy and human dignity when these measures are used. Nurses must weigh carefully the risks of limiting autonomy and increasing the risks of injury by using restraints against the risks of injury if not using restraints, which have been documented as resulting in physical harm and death. The ANA (2012) advocates that in situations where restraints and seclusion must be used, all staff must be educated on safety measures. In addition, there must be adequate staff that are vigilant in monitoring their use. These interventions may be utilized only when there is no other viable option available. **The Joint Commission,** a nonprofit organization that accredits hospitals and health care organizations, and CMS have designated standards for the use of restraints (see The Joint Commission and CMS Web sites listed in the Resources section).

Trust Issues

Truth-telling or veracity is one of the basic principles in the nurse–patient relationship. Truth-telling is based upon the principle of autonomy; it requires that the nurse understands and supports patient self-determination (Beauchamp & Childress, 2019). For example, failure to disclose a diagnosis to a patient deprives the person of the right to make informed decisions. Three ethical dilemmas in clinical practice that can directly conflict with this principle are the use of placebos (nonactive substances used for treatment), not revealing a diagnosis to a patient, and revealing a diagnosis to people other than the patient with the diagnosis. All involve the issue of trust, which is an essential element in the nurse–patient relationship.

Placebos may be used in experimental research, in which a patient is involved in the decision making process and is aware that placebos are being used in the treatment regimen. However, the use of a placebo as a substitute for an active drug to show that a patient does not have actual symptoms of a disease is deceptive, has both ethical and legal implications, and severely undermines the nurse–patient relationship.

Informing a patient of his or her diagnosis when the family and primary provider have chosen to delay full disclosure of pertinent information is an ethical dilemma that can occur in nursing practice. The nurse may experience moral distress when asked by the patient for a truthful diagnosis. The nurse may use evasive comments with the patient in these situations. This area is indeed complex, because it challenges a nurse's **moral integrity.** Nurses could consider the following strategies:

- Avoid lying to the patient.
- Provide all information related to nursing procedures and diagnoses.
- Act as a patient advocate and communicate the patient's requests for information to the family and primary provider. The family is often unaware of the patient's repeated questions to the nurse. With a better understanding of the situation, the family members may change their perspective.
- Make a referral to the institution's ethics committee.

Although providing the information may be the morally appropriate behavior, the manner in which the patient is told is important. Nurses must be compassionate and caring when informing patients; disclosure of information merely for the sake of patient autonomy does not convey respect for others and in some circumstances may result in emotional distress. Family support or the support of a spiritual advisor (e.g., chaplain) may be needed to reduce the impact of distressing information or a poor prognosis.

Disclosing the patient's diagnosis to others without the patient's consent is a HIPAA violation and therefore is not only unethical but also illegal. Failure to protect the patient's right to privacy and a breach of confidentiality is unethical.

Refusing to Provide Care

Any nurse who feels morally obliged to refuse to provide care for a particular type of patient faces an ethical dilemma. Reasons for refusal range from a conflict of personal values to a fear that the nurse would place either the patient or self in jeopardy. Feelings related to care of people of different ethnicities or sexual orientation also surface as societal changes emerge. The ethical obligation to care for all patients is clearly identified in the *Code of Ethics for Nurses* (ANA, 2015a). Accordingly, the nurse must give patient-centered care to all patients, regardless of their socioeconomic status, sexual orientation, gender expression, ethnicity, or proximity to death. In particular, patients facing end-of-life decisions must receive supportive care, which must be extended to their family and surrogate decision makers (ANA, 2015a).

End-of-Life Issues

Dilemmas that center on death and dying are prevalent in medical-surgical nursing practice. With the availability of increasingly sophisticated and advanced technology, it may be difficult to accept that nothing more can be done to prolong life or that technology may prolong life but at the expense of the patient's comfort and quality of life. When providing end-of-life care, nurses serve as the patient's advocate and manage pain and suffering. Nurses have the moral obligation to facilitate a patient's right to self-determination. Furthermore, nurses should facilitate end-of-life discussions between the patient and the family in order to prevent suffering and preserve the patient's dignity (ANA, 2015a).

Many people who are terminally ill seek legal options for a peaceful and dignified death. Nurses who deliver palliative care must understand that their actions are targeted at relieving pain and suffering and not hastening death. According to Provision 1.4 of the *Code of Ethics for Nurses,* "The nurse should provide interventions to relieve pain and other symptoms in the dying patient consistent with palliative care practice standards and may not act with the sole intent to end life (2015a, p. 3)," even if the intent to end life is motivated by compassion or respect for patient autonomy.

End-of-life issues shift the focus from curative care to palliative and end-of-life care. Focusing on the caring as well as the curing role may help nurses deal with these difficult moral situations. Needs of patients and families require holistic and interdisciplinary approaches. End-of-life issues that often involve ethical dilemmas include pain control, "do not resuscitate" (DNR) orders, life support measures, and administration of food and fluids. These issues are discussed in detail in Chapter 13.

Preventive Ethics

When a nurse is faced with two conflicting alternatives, it is the nurse's moral responsibility to choose the lesser of the two evils. These situations often result in feelings of moral distress in the nurse who is obliged to make a choice.

Patient Self-Determination

Frequently, dilemmas occur when health care practitioners are unsure of the patient's wishes because the patient is unconscious or mentally incompetent and cannot communicate. The Patient Self-Determination Act, enacted in December 1991, encourages people to prepare advance directives in which they indicate their wishes concerning the degree of supportive care they wish if they become incapacitated. This legislation requires that patients be informed about advance directives by the staff of the health care facility.

Advance directives are legal documents that specify a person's wishes before hospitalization and provide valuable information that may assist health care providers in decision making. A living will is one type of advance directive. Typically, living wills are limited to situations in which the patient's medical condition is deemed terminal. Because it is difficult to define *terminal* accurately, living wills are not always honored. Another potential drawback is that living wills are frequently written while people are in good health. It is not unusual for people to change their minds as an illness progresses; therefore, patients retain the option to nullify these documents.

Identifying a health care representative, in which one person identifies another person to make health care decisions on his or her behalf, is another type of advance directive. It is the responsibility of the health care representative to act as the patient stated in the advance directive. For example, patients may have clarified their wishes concerning various medical situations. If there is no advance directive, the health care representative must act in good faith and make decisions that they believe the patient would make if mentally competent. Laws concerning advance directives vary among state jurisdictions. However, even in states where these documents are not legally binding, they provide helpful information to determine the patient's prior expressed wishes in situations in which this information can no longer be obtained.

Advance directives are limited in scope to hospital and long-term care facility environments. Emergency medical system (EMS) personnel (e.g., paramedics) therefore cannot legally follow advance directives. Yet, there are many patients with debilitating long-term chronic and eventually fatal illnesses who reside at home. Some of these patients may not wish to have invasive, life-sustaining emergency interventions should their status rapidly deteriorate. To protect the wishes of these patients to forego life-sustaining treatments, a document titled Physician Orders for Life-Sustaining Treatment (POLST) has been legally endorsed by many states. POLST gives EMS personnel the ability to rapidly determine whether a patient wishes to have cardiopulmonary resuscitation (CPR) or receive any type of emergency interventions that may sustain life in the event when the patient suddenly becomes incapacitated (National POLST Paradigm, 2019).

Ethics Committees

Institutional ethics committees exist in many hospitals to assist clinicians with ethical dilemmas. The purpose of these multidisciplinary committees varies among institutions. In some hospitals, the committees exist solely for the purpose

of developing policies; whereas in others, they may have a strong educational or consultation focus. Consultations can be conducted on the nursing unit, at the patient's bedside, or in a designated conference room. These committees usually are composed of people with some advanced training in ethics and are important resources for the health care team, patient, and family. Nurses with a particular interest or expertise in the area of ethics can serve as members of these committees, which are valuable resources for staff nurses. In addition, primary providers, social workers, and hospital chaplains are often members of the team.

Ethical Decision Making

Ethical dilemmas are common and diverse in nursing practice. Situations vary, and experience indicates that there are no clear solutions to these dilemmas (Beauchamp & Childress, 2019). However, the fundamental philosophical principles are the same, and the process of moral reflection helps nurses justify their actions. The systematic approach to ethical decision making can follow the steps of the nursing process. Ethics charts contained in all units within this text present case scenarios that challenge the reader to identify the ethical principles involved that may or may not be in conflict (Chart 1-10). Chart 1-10 outlines the steps of an ethical analysis that may be used to resolve the moral dilemmas presented in these charts.

Chart 1-10 ETHICAL DILEMMA

Steps of an Ethical Analysis

The following guidelines reflect an active process in decision making, similar to the nursing process detailed in this chapter. Nurses can use these guidelines to engage in ethical decision making. Key resources that may assist in ethical decision making are also included.

Assessment

1. Once the ethical issue has been identified, assess the ethical/moral situations of the problem. This step entails recognition of the ethical, legal, and professional dimensions involved.
   - **a.** Does the situation entail substantive moral problems (conflicts among ethical principles or professional obligations)? Examine the ethical issue using the principles of autonomy, beneficence, justice, and nonmaleficence.
   - **b.** Are there procedural conflicts? (e.g., Who should make the decisions? Any conflicts among the patient, health care providers, family, and guardians?)
   - **c.** Identify the significant people involved and those affected by the decision.
   - **d.** Identify agency or hospital policy or protocol to use when a conflict exists. Is there an ethics committee or council? How is an ethics consult made, and who may request this consultation? What other resources are available to help resolve this conflict?

Planning

2. Collect information.
   - **a.** Include the following information: the medical facts, treatment options, nursing diagnoses, legal data, and the values, beliefs, cultures, and religious components.
   - **b.** Make a distinction between the factual information and the values/beliefs.
   - **c.** Validate the patient's capacity, or lack of capacity, to make decisions.
   - **d.** Identify any other relevant information that should be elicited.
   - **e.** Identify the ethical/moral issues and the competing claims.
   - **f.** If it is an end-of-life issue, determine whether an advance directive exists and whether a medical power of attorney or a heath care representative has been identified.

Implementation

3. List the alternatives. Compare alternatives with applicable ethical principles and the 2015 ANA *Code of Ethics for Nurses.* Choose either of the frameworks that follow, or other frameworks, and compare outcomes.
   - **a.** *Utilitarian approach:* Predict the consequences of the alternatives; assign a positive or negative value to each consequence; choose the consequence that predicts the highest positive value or "the greatest good for the greatest number."
   - **b.** *Deontologic approach:* Identify the relevant moral principles; compare alternatives with moral principles; appeal to the "higher-level" moral principle if there is a conflict.

Evaluation

4. Decide and evaluate the decision.
   - **a.** What is the best or morally correct action?
   - **b.** Give the ethical reasons for your decision.
   - **c.** What are the ethical reasons against your decision or your biases?
   - **d.** How do you respond to the reasons against your decision?

CRITICAL THINKING EXERCISES

1 ebp Recently a team of staff nurses working on a pulmonary step-down unit was asked to examine the incidence of tracheotomy-related skin breakdown and found a 30% increase over the last year. The team reported these findings to the evidence-based practice council who determined the need to examine nursing interventions to improve skin integrity. As part of this team, what steps will you take to identify best practices? Based on this review, how will you determine which nursing practices would be most effective in helping to reduce the incidence of tracheotomy-related skin breakdown on your unit?

2 ipc You are part of an interprofessional team discussing the plan of care for a patient who experienced an ischemic stroke. After the meeting, the physical therapist asks you to explain how you formulate a nursing diagnosis and prioritize goals and interventions for your patients. How do you respond? The physical therapist also asks you for suggestions on ways the team could improve communication and teamwork to better address collaborative problems. Using professional practice guidelines, what recommendations do you share with the physical therapist?

2 Medical-Surgical Nursing

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Discuss principles of medical-surgical nursing practice as well as characteristics and settings of select nursing practice specialties in today's health care delivery system.
2. Describe the significance of the nurse as coordinator of care transitions.
3. Specify the components of a comprehensive assessment of functional capacity.
4. Use the nursing process as a framework for care of the patient with self-care deficits or with impaired physical mobility.
5. Describe the role and practice settings of home health nursing and the significance of continuity of care in transition into community or home settings.

NURSING CONCEPTS

Accountability
Collaboration
Evidence-Based Practice
Functional Ability
Mobility
Safety

GLOSSARY

activities of daily living (ADLs): personal care activities, such as bathing, dressing, grooming, eating, toileting, and transferring

adaptive device: a type of assistive technology that is used to change the environment or help the person modify the environment

assistive device: a type of assistive technology that helps people with disability perform a given task

assistive technology: any item, piece of equipment, or product system that is used to improve the functional capabilities of individuals with disability; this term encompasses both assistive devices and adaptive devices

critical-care nursing: a specialty area of practice that provides nursing services to critically ill patients across the lifespan in acute care settings such as the hospital intensive unit; current practice settings have expanded to include virtual care and community settings

home health nursing: a specialty area of practice that provides nursing services to patients across the lifespan in a home setting; practice roles include holistic care planning which incorporates resource and service coordination as part of an interdisciplinary team

impairment: loss or abnormality of psychological, physiologic, or anatomic structure or function at the organ level (e.g., dysphagia, hemiparesis); an abnormality of body structure, appearance, an organ, or system function resulting from any cause

instrumental activities of daily living (IADLs): complex skills needed for independent living, such as shopping, cooking, housework, using the telephone, managing medications and finances, and being able to travel by car or public transportation

medical-surgical nursing: a specialty area of practice that provides nursing services to patients from adolescence through the end of life in hospital-based and community-based settings

orthosis: an external appliance that provides support, prevents or corrects joint deformities, and improves function

prosthesis: a device used to replace a body part

rehabilitation: making able again; learning or relearning skills or abilities or adjusting existing functions to meet maximum potential

rehabilitation nursing: a specialty area of evidence-based practice that provides holistically-focused nursing services to patients who have been incapacitated by illness or injury or are facing potentially life-altering health conditions throughout their lifespan

rehospitalization: admission to the hospital within 30 days of a prior discharge from a hospitalization

telehealth: the use of technology to provide health care services

third-party payer: an organization or insurance company that provides reimbursement for services covered by a health plan

transfer: movement of a patient from one place to another, such as a bed to chair, chair to commode, or wheelchair to tub

transitional care: a process of ensuring consistency and coordination of care as patients move within and between health care settings

The profession of nursing is ever expanding to meet the health needs of patients, families, and communities. The practice of medical-surgical nursing continues to evolve, too, and is no longer restricted to the traditional environment of the inpatient hospital-based medical-surgical unit. The shift in delivery of medical-surgical nursing from only inpatient settings to also include outpatient settings is a result of multiple factors, including population trends (the growing number of older adults), changes in federal legislation, tighter insurance regulations, and decreasing hospital revenues. Transitions in the health care industry, the nursing profession, and changing patterns of disease and wellness have also affected the shift in care delivery settings. On an increasing basis, hospitals, health care organizations, and providers are held accountable for providing health care using best practices, as evidenced by meeting performance benchmarks for quality and efficiency; this system is known as pay for performance or value-based purchasing. Under this system, hospitals, health care organizations, and providers can reduce costs and earn additional income by carefully monitoring the types of services they provide, discharging patients as soon as possible, and keeping patients who are discharged from the hospital from being readmitted. Consequently, patients who transition from the hospital to the home or to residential or long-term care facilities are in the early stages of recovery. With these changes in health care delivery and accountability, specialty practices under the scope of medical-surgical nursing practice have arisen to further identify evidence-based nursing care and interventions. This chapter provides an overview of medical-surgical nursing and other associated nursing specialty practices.

The Practice of Nursing in Today's Health Care Delivery System

Novice, entry-level registered nurses, as well as those with advanced degrees who work in highly specialized settings, all engage in the practice of nursing. The American Nurses Association (ANA, 2015b) notes that the profession of nursing's scope of practice encompasses the full range of nursing practice, pertinent to general and specialty practice. "The depth and breadth in which individual registered nurses and advanced practice registered nurses engage in the total scope of nursing practice is dependent on education, experience, role, and the population served" (p. 2). The ANA (2015b, pp. 7–9) also identifies the following tenets characteristic of all nursing practice:

- Caring and health are central to the practice of the registered nurse.
- Nursing practice is individualized.

- Registered nurses use the nursing process to plan and provide individualized care for health care consumers (see Chapter 1).
- Nurses coordinate care by establishing partnerships.
- A strong link exists between the professional work environment and the registered nurse's ability to provide quality health care and achieve optimal outcomes.

The profession of nursing has a distinct disciplinary body of knowledge, education, and specialty standards of practice (ANA, 2015b); social contract (ANA, 2010; Fowler, 2015); and code of ethics (ANA, 2015a). Nursing's Standards of Practice describe basic competencies in delivering nursing care using the nursing process, whereas the Standards of Professional Performance describe expectations for behavioral competencies (ANA, 2015b, pp. 5–6), which include that the registered nurse:

- Practices ethically
- Practices in a manner that is congruent with cultural diversity and inclusion principles
- Communicates effectively in all areas of practice
- Collaborates with the health care consumer and other key stakeholders in the conduct of nursing practice
- Leads within the professional practice setting and the profession
- Seeks knowledge and competence that reflect current nursing practice and promote futuristic thinking
- Integrates evidence and research findings into practice
- Contributes to quality nursing practice
- Evaluates one's own and others' nursing practice
- Utilizes appropriate resources to plan, provide, and sustain evidence-based nursing services that are safe, effective, and fiscally responsible
- Practices in an environmentally safe and healthy manner

Medical-Surgical Nursing

Medical-surgical nursing is a specialty area of practice that provides nursing services to patients from adolescence through the end of life in a variety of inpatient and outpatient clinical settings. These settings may include traditional hospital medical-surgical units as well as intensive care units (ICUs), acute and subacute care rehabilitation units, clinics, ambulatory care units, urgent care centers, home health care agencies, and long-term care facilities (Academy of Medical-Surgical Nurses [AMSN], 2018; AMSN 2019). The *Scope and Standards of Medical-Surgical Nursing Practice* (AMSN, 2018) mirror the scope of practice and standards for practice set by the ANA (2015b) for professional nursing practice; the AMSN (2018) further delineates specific role expectations for the medical-surgical nurse. Medical-surgical nurses can demonstrate proficiency in

their role by completing certification requirements. They may also enhance practice by completing graduate degree programs in nursing (AMSN, 2018).

The Nurse as Coordinator of Care Transitions

Nearly one third of the $3.5 trillion spent on health care in the United States is spent on hospitalizations, including hospital readmissions within 30 days of a prior hospital discharge, called **rehospitalizations** (Centers for Medicare & Medicaid Services [CMS], 2018a). Rehospitalizations raise concerns not only about costs, but also about health care quality (Bailey, Weiss, Barrett, et al., 2019). Approximately 20% of patients insured by Medicare experience rehospitalization. Rehospitalizations in those over 65 years of age are not only costly; these patients may experience weakness and stress which can make them vulnerable to falls and other adverse events (Agency for Healthcare Research and Quality [AHRQ], 2019). Medicare is one example of a health insurance plan holding hospitals accountable for readmissions within 30 days of hospital discharge through a reduction in reimbursement for costs associated with these readmissions (Bailey et al., 2019). Rehospitalizations can result from breakdowns in care transitions including during the discharge planning processes, as evidenced by patients' inability to manage their own care; and, as a result of poor communication between the hospital and the next level of care (e.g., home health agency, primary care office) regarding patients' needs and resources (AHRQ, 2019). Altogether, these factors have led to an increasing focus on **transitional care,** a process of ensuring consistency and coordination of care as patients move within and between care settings (Carr, 2019). For example, transitional care takes place as a patient is transferred from intensive care to a medical-surgical unit within an acute care setting. Another important time of transitional care occurs with patient discharge from the acute care setting to continued care out in the community. See Chart 2-1 for a Nursing Research Profile on transitional care and the important components needed to assure positive outcomes during this transition process. A number of models and programs of transitional care describe the process as an interdisciplinary team approach in which team members include both the patient and the caregivers. Nurses in a variety of settings are important transitional care team members, managing many aspects of the transition process (Carr, 2019).

Chart 2-1 **NURSING RESEARCH PROFILE**

Important Components of Transitional Care

Naylor, M. D., Shaid, E. C., Carpenter, D., et al. (2017). Components of comprehensive and effective transitional care. *Journal of the American Geriatrics Society*, *65*(6), 1119–1125.

Purpose

Transitional care is recognized as important in assuring improved health care outcomes and health care quality while decreasing costs associated with unnecessary hospital readmissions. A national study called Project ACHIEVE that focused on Medicare beneficiaries was conducted to identify key aspects of transitional care that lead to positive patient and caregiver outcomes.

Design

Project ACHIEVE included experts, patients, and caregivers in a multimethod approach that included interviews, focus groups, and review of literature, which led to the identification and definition of critical components of transitional care. The working group collected case studies to evaluate how these components connect to the real experience of transitional care, selecting one case study for concept mapping of the components, all leading to further refinement of the critical components.

Findings

Eight core components were identified and visualized on a transitional care model: patient engagement, caregiver engagement, complexity management, patient education, caregiver education, patient and caregiver well-being, care continuity, and accountability. Each of the eight components was defined with examples of the issues as they related to patients and caregivers. Additional information provided suggestions for interdisciplinary interventions from the reviewed evidence.

Nursing Implications

Transitional care is a team approach that includes the patient and caregiver, and so research into transitional care should include these important stakeholders. The model and definitions for transitional care yielded from Project ACHIEVE provide a common framework for interdisciplinary health care team members who can then focus on providing optimal patient outcomes. Nurses who work in transitional care can utilize these core components in assessment of individual patients, and then tailor interventions to needed components. The model also provides a framework for program development, evaluation, and future refinement through additional investigation of transitional care.

Patient care must be coordinated seamlessly from the inpatient hospital environment through transitions into the community setting. Various nursing roles have evolved to provide improved care coordination and care transitions, including the nurse navigator, case manager, and the clinical nurse leader (CNL). Nurse navigators are registered nurses employed by hospitals and health networks

who work with a given population of patients with a common diagnosis or disease (e.g., cancer). Their role involves helping the patient and the patient's family transition through different levels of care (e.g., from hospital to a skilled nursing facility, from home care to assisted care). One example of an essential role function for the oncology nurse navigator (ONN) is education. In this role, the ONN assesses patients, families, and caregivers for their educational needs and recognizes barriers to education, which can impact health in areas such as diagnosis, treatment, and management of treatment associated side effects (Baileys, McMullen, Lubejko, et al., 2018).

Case management is a system of coordinating health care services to ensure cost-effectiveness, accountability, and quality care. Case managers may be nurses or may have backgrounds in other health professions, such as social work. The case manager coordinates the care of a caseload of patients through facilitating communication between nurses, other health care personnel who provide care, and insurance companies. In some settings, particularly the community setting, the case manager focuses on coordinating the treatment plan of the patient with complex conditions. The case manager may follow the patient throughout hospitalization and at home after discharge in an effort to coordinate health care services that will avert or delay rehospitalization. The caseload is usually limited in scope to patients with similar diagnoses, needs, and therapies (Case Management Society of America [CMSA], 2019).

A CNL is a certified nurse generalist with a master's degree in nursing educated to help patients navigate the complex health care system (American Association of Colleges of Nursing [AACN], 2019a). The CNL coordinates care for a distinct group of patients, may provide direct care as the situation warrants, and assumes a leadership role among members of the health care team. The CNL integrates evidence-based practices with advocacy, care coordination, outcomes measurement, risk assessment, quality improvement, and interprofessional communication skills (AACN, 2019a). Currently, CNLs are being utilized in hospital-based environments as well as in community settings.

Critical-Care Nursing

Critical-care nursing is a specialty area of practice that provides nursing services to critically ill patients across the lifespan, traditionally delivered in acute care settings such as the hospital ICU. Current practice settings for critical-care nursing have now expanded to include virtual care and a variety of community settings, including the home (American Association of Critical-Care Nurses [AACN], 2019b). When patients face actual or potential life-threatening illness, critical-care nurses provide holistic nursing interventions individualized to each patient.

The *Scope and Standards for Progressive and Critical-Care Nursing* (AACN, 2019b) mirror the scope and standards set by the ANA (2015b) for professional nursing practice; these are revised as needed based on health care trends and technologic advances in the care of patients facing critical illness. The AACN

(2019b) further delineates specific role expectations with the nursing process as the foundation and guide. For example, the standard of assessment includes competencies in holistic data collection based on current evidence and the recognition of assessment priorities for each individual patient. The current *Scope and Standards* (AACN, 2019b) recognize two types of nursing care provided by the progressive care nurse and the critical-care nurse. The progressive care nurse provides care for the acutely ill patient who is moving toward physiologic stability yet still at risk for life-threatening illness. The critical-care nurse provides care for those acute care patients with an actual or at high risk of life-threatening illness. The AACN also sets the standards for proficiency in progressive and critical-care nursing that may lead to specialty certification. In addition to specialty certification, there are opportunities for nurses to enhance critical-care nursing practice by completing graduate nursing programs leading to advanced practice as a critical-care clinical nurse specialist or acute care nurse practitioner.

The AACN recognizes the role of the critical-care nurse in care transitions and the need to begin discharge planning early, even during the critical or acute phase of hospitalization (Alspach, 2018). With caregiver tasks ranging from activities of daily living (ADLs) and instrumental activities of daily living (IADLs) (see later discussion) to advocacy and coordination, the critical-care nurse can involve family members or significant others of the patient who is critically ill in rounds and patient care planning, begin to assess their capabilities, and start the education needed so that family members or significant others can manage the role of caregiver.

Rehabilitation Nursing

Rehabilitation means to make able again; it involves learning or relearning skills or abilities or adjusting existing functions to meet maximum potential. Thus, rehabilitation is a goal-oriented process of caring for people with disability or chronic disorders. This philosophy of practice works to restore or optimize abilities rather than focus on disability (Association of Rehabilitation Nursing [ARN], 2013). Rehabilitation is an integral part of nursing because every major illness or injury carries the threat of disability or **impairment**, which involves a loss of function or an abnormality in body structure or function. **Rehabilitation nursing** is a specialty area of practice that focuses on returning patients to optimal functionality through a holistic approach to care that is based on scientific evidence (ARN, 2019a). The ARN has developed an *ARN Competency Model for Professional Rehabilitation Nurses* with resources. The domains in the model (nurse-led interventions, promotion of successful living, leadership and interprofessional care) encompass all competencies needed to promote rehabilitation nursing of people with disability and/or chronic illness (ARN, 2019b). The ARN further describes the roles of the rehabilitation nurse as teacher, caregiver, collaborator, and patient advocate working in a variety of inpatient and outpatient settings (ARN, 2019a).

Rehabilitation services are required by more people than ever before because of advances in technology that save or prolong the lives of seriously ill and injured patients and patients with disability. Increasing numbers of patients who are recovering from serious illnesses or injuries are returning to their homes and communities with ongoing needs. Significant disability caused by war and terrorism also increases the demand for rehabilitation services. All patients, regardless of age, gender, ethnic group, socioeconomic status, or diagnosis, have a right to rehabilitation services.

A person is considered to have a disability, such as a restriction in performance or function in everyday activities, if they have difficulty talking, hearing, seeing, walking, climbing stairs, lifting or carrying objects, performing ADLs, doing schoolwork, or working at a job. The disability is considered severe if the person cannot perform one or more activities, receives federal benefits because of an inability to work, uses an assistive device for mobility, or needs help from another person to accomplish basic activities. The purpose of **assistive technology** is to incorporate devices to improve the functional capabilities of people with disability; these may include any item, piece of equipment, or product system that may be acquired commercially, off the shelf, modified, or customized. Types of assistive technology may include **adaptive devices**, which help a person with a disability to either modify or change the environment (e.g., an access ramp used in place of steps for a person who uses a wheelchair), and **assistive devices,** which help a person with a disability perform a given task (e.g., a lap board with pictures used to assist a person who cannot talk to communicate) (see Chapter 7 for further discussion on disability).

Assessment of Functional Ability

Comprehensive assessment of functional capacity is the basis for developing a rehabilitation program. Functional capacity is a person's ability to perform ADLs and IADLs. **Activities of daily living (ADLs)** are those self-care activities that the patient must accomplish each day to meet personal needs; they include personal hygiene/bathing, dressing/grooming, feeding, toileting, and transferring. Many patients cannot perform such activities easily. **Instrumental activities of daily living (IADLs)** include those complex skills needed for independent living, such as meal preparation, grocery shopping, household and financial management, medication management, telephone usage, and transportation.

The nurse observes the patient performing specific activities (e.g., eating, dressing) and notes the degree of independence; the time taken; the patient's mobility, coordination, and endurance; and the amount of assistance required. The nurse also carefully assesses joint motion, muscle strength, cardiovascular reserve, and neurologic function, because functional ability depends on these factors as well. Observations are recorded on a functional assessment tool. These tools provide a way to standardize assessment parameters and include a scale or score against which improvements may be measured. They also clearly communicate the patient's level of functioning to all members of the rehabilitation team. Rehabilitation staff members use these tools to provide an initial assessment

of the patient's abilities and to monitor the patient's progress in achieving independence.

One of the most frequently used tools to assess the patient's level of independence is the Functional Independence Measure (FIM™) (Keith, Granger, Hamilton, et al., 1987). The FIM is a minimum data set, measuring 18 self-care items including eating, bathing, grooming, dressing upper body, dressing lower body, toileting, bladder management, and bowel management. The FIM addresses transfers and the ability to ambulate and climb stairs and also includes communication and social cognition items. Scoring is based on a seven-point scale, with items used to assess the patient's level of independence. The Alpha FIM, a short version of the FIM, is used frequently within 72 hours of admission in acute care settings to measure functional independence and the amount of assistance the patient needs to perform ADLs.

Although there are many disease-specific tools used to assess the patient's functional ability, some frequently used generic measures include the following (Fidecki, Wysokiński, Wrońska, et al., 2017):

- The Katz Index of Independence in Activities of Daily Living (Katz Index) (Katz, Downs, Cash, et al., 1970) is used to assess six areas of ADLs (i.e., bathing, dressing, toileting, transferring, continence, feeding) and rate them as done independently or done with assistance.
- The Barthel Index (Mahoney & Barthel, 1965) is used to measure the patient's level of independence in ADLs, continence, toileting, transfers, and ambulation (or wheelchair mobility). This scale does not address communicative or cognitive abilities.

A detailed functional evaluation of secondary conditions related to the patient's disability, such as muscle atrophy and deconditioning, skin integrity, bowel and bladder control, and sexual function, together with residual strengths unaffected by disease or disability, is necessary. In addition, the nurse assesses the patient's physical, mental, emotional, spiritual, social, and economic status, as well as cultural and familial environment. These elements may provide a context to the functional findings and influence the rehabilitation plan. For example, the patient's perception of what it means to have a disability and the implications that this might have on familial and social roles can influence the rehabilitation process.

NURSING PROCESS

The Patient with Self-Care Deficits in Activities of Daily Living

An ADL program is started as soon as the rehabilitation process begins, because the ability to perform ADLs is frequently the key to independence, return to the home, and transition into the community.

Assessment

The nurse must observe and assess the patient's ability to perform ADLs to determine the level of independence in self-care and the need for nursing intervention. Chart 2-2 depicts behaviors that may indicate struggles with function or movement and thus should be assessed. For example, bathing requires obtaining bath water and items used for bathing (e.g., soap, washcloth), washing, and drying the body after bathing. Dressing requires getting clothes from the closet, putting on and taking off clothing, and fastening the clothing. Self-feeding requires using utensils to bring food to the mouth and chewing and swallowing the food. Toileting includes removing clothing to use the toilet, cleansing oneself, and readjusting clothing. Grooming activities include combing hair, brushing one's teeth, shaving or applying makeup, and handwashing. Patients who can sit up and raise their hands to their head can begin self-care activities. Assistive devices are often essential in achieving some level of independence in ADLs.

Additional assessment should include gaining an understanding of the patient's and family members' perspectives on the patient's condition and how it affects functional ability. The nurse should also be aware of the patient's medical conditions or other health problems, the effect that they have on the ability to perform ADLs, and the family's involvement in the patient's ADLs. This information is valuable in setting goals and developing the plan of care to maximize self-care.

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired ability to perform hygiene
- Impaired ability to dress
- Impaired self feeding
- Impaired self toileting
- Impaired health maintenance

Chart 2-2 **ASSESSMENT**

Assessing Potential Struggles in Function or Movement

Be alert for the following behaviors:

- Holding onto a hand rail to pull the body while going up stairs
- Holding onto a bedside rail or bedcovers to pull to a sitting position in bed
- Leaning to one side and using both hands on the hand rail while going down the stairs or a ramp
- Holding onto furniture or doorways and watching the feet while walking in the house
- Lifting a leg (or arm) by using the other leg (or arm) as support or by lifting with the pants leg (or sleeve)
- Tilting the head to reach the back or side of the hair while grooming
- Pushing up, rocking forward and back, and/or leaning the body over for momentum ("nose over toes") when rising to stand from a chair
- Leaning over from the waist without bending the knees and then placing one hand on the thigh, as if it were a prop, and pushing against the thigh to assist in moving to the upright position
- Turning to reach for an object and then using the other arm or an object to support the reaching arm at the elbow or wrist
- Positioning a chair before sitting down by using the front or back of the knees and then using the back of the knees to guide sitting down; using the torso and hips to lean against a table or chair
- Reaching and leaning with the body rather than with an arm
- Walking with a lean to one side, a limp, a waddle, or other variation of a gait
- Scanning (i.e., observing or being aware of surroundings) ineffectively while eating or grooming
- Rolling or scooting the body, sliding forward in a seat, or other maneuvers to move off a bed or out of a chair

Adapted from Weber, J. R., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Planning and Goals

Major goals for the patient include performing the following activities independently or with assistance, using adaptive or assistive devices as appropriate: bathing/hygiene, dressing/grooming, feeding, and toileting. A related goal is patient expression of satisfaction with the extent of independence achieved in self-care activities. Another major goal is that the patient acknowledges adjustments in new lifestyle and ADLs and can identify resources to facilitate optimal functioning (Carpenito, 2017).

Nursing Interventions

Repetition, practice, and demonstrations help patients achieve maximum independence in personal care activities. The nurse's role is to provide an

optimal learning environment that minimizes distractions. The nurse can identify the patient's optimal time to work on activities, encourage concentration, identify endurance issues that may affect safety, and provide cues and reminders to patients with specific disability, such as alteration in or loss of sensation that may occur with stroke (Gregory & Galloway, 2017). Patients with impaired mobility, sensation, strength, or dexterity may need to use assistive devices to accomplish self-care.

Fostering Self-Care Abilities

A patient's approach to self-care may be affected by altered or impaired mobility and influenced by family or cultural expectations. The inability to perform self-care as carried out previously may lead to ineffective coping behaviors, such as social isolation, dependency on caregivers, or depression. The nurse must motivate the patient to learn and accept responsibility for self-care. It helps to encourage an "I'd rather do it myself" attitude. The nurse must also help the patient identify the safe limits of independent activity; knowing when to ask for assistance is particularly important.

The nurse educates, guides, and supports the patient who is learning or relearning how to perform self-care activities while maintaining a focus on patient strengths and optimal level of function. Consistency in instructions and assistance given by health care providers, including rehabilitation therapists (e.g., physiotherapists, occupational therapists, recreation therapists, speech-language pathologists, primary providers) facilitates the learning process. Recording the patient's performance provides data for evaluating progress and may be used as a source for motivation and morale building. Guidelines for educating patients and families about ADLs are presented in Chart 2-3.

Often, performing a simple maneuver requires the patient with a disability to concentrate intensely and exert considerable effort; therefore, self-care techniques need to be adapted to accommodate the individual patient's lifestyle. Because a self-care activity usually can be accomplished in several ways, common sense and a little ingenuity may promote increased independence. For example, a person who cannot quite reach his or her head may be able to do so by leaning forward. Encouraging the patient to participate in a support group may also help the patient discover creative solutions to self-care problems.

Chart 2-3 PATIENT EDUCATION

Educating Patients About Activities of Daily Living

The nurse instructs the patient to:

1. Be realistic about the goal of the activity and set short-term goals that can be accomplished in the near future.
2. Identify several approaches to accomplish the task (e.g., there are several ways to put on a given garment).
3. Select the approach most likely to succeed.
4. Identify the motions necessary to accomplish the activity (e.g., to pick up a glass, extend arm with hand open; place open hand next to glass; flex fingers around glass; move arm and hand holding glass vertically; flex arm toward body).
5. Focus on gross functional movements initially, and gradually include activities that use finer motions (e.g., buttoning clothes, eating with a fork).

The nurse should also be sure to:

1. Specify the approach selected to accomplish the task on the patient's plan of care and the patient's level of accomplishment on the progress notes.
2. Encourage the patient to perform the activity up to maximal capacity within the limitations of the disability.
3. Monitor the patient's tolerance.
4. Minimize frustration and fatigue.
5. Support the patient by giving appropriate praise for effort put forth and for acts accomplished.
6. Assist the patient to perform and practice the activity in real-life situations and in a safe environment.

Preexisting cultural norms may influence the degree of self-care the patient is willing to consider. Cultural and ethnic beliefs about hygiene can vary among individuals and families. The nurse must recognize these beliefs, work through any issues with the patient and family, and communicate pertinent findings to the rehabilitation team.

Recommending Adaptive and Assistive Devices

If the patient has difficulty performing an ADL, an adaptive or assistive device (self-help device) may be useful. Such devices may be obtained commercially or can be constructed by the nurse, occupational therapist, patient, or family. The devices may include built-up handles on toothbrushes or razors; long, curved handles on mirrors or shoe horns; suction cups to hold items in place; shower chairs; raised toilet seats; and universal cuffs to grip self-care items. Some of these are shown in Figure 2-1. To assist premenopausal women with managing menstruation, clothing adaptations (e.g., Velcro crotch flaps for ease of access), mirrors, self-sticking sanitary pads, packaged wipes, and loose underwear may be used.

Quality and Safety Nursing Alert

To avoid injury or bleeding, people who take anticoagulant medication should be encouraged to use an electric razor. Women may wish to consider depilatory creams or electrolysis.

A wide selection of computerized devices is available, or devices can be designed to help individual patients with severe disability to function more independently. The AbleData project (see Resources list at the end of this chapter) offers a computerized listing of commercially available aids and equipment for patients with disability.

The nurse should be alert to "gadgets" coming on the market and evaluate their potential usefulness. The nurse must exercise professional judgment and caution in recommending devices, because in the past, unscrupulous vendors have marketed unnecessary, overly expensive, or useless items to patients.

Helping Patients Accept Limitations

If the patient has a severe disability, independent self-care may be an unrealistic goal. In this situation, the nurse educates the patient how to take charge by directing their care. The patient may require a personal caregiver to perform ADLs. Family members may not be appropriate for providing bathing/hygiene, dressing/grooming, feeding, and toileting assistance, and spouses may have difficulty providing bowel and bladder care for patients and maintaining the role of sexual partners. If a personal caregiver is necessary, the patient and family members must learn how to manage an employee effectively. The nurse helps the patient accept self-care dependency. Independence in other areas, such as social interaction, should be emphasized to promote a positive self-concept.

Ensuring Effective Health Management

The nurse ensures effective health management by educating the patient and caregiver in appropriate language so that they understand the nature of the health condition or disorder and the resulting changes in ADLs. This understanding facilitates transition to a new way of life upon discharge. Barriers that may impede successful health maintenance are identified and strategies employed to mitigate them. The transition team, under the guidance of the nurse, collaborates on identifying and securing resources that are needed to make the transition successful and prevent complications (Carpenito, 2017).

Evaluation

Expected patient outcomes may include:

1. Demonstrates independent self-care in bathing/hygiene or with assistance, using adaptive devices as appropriate
   a. Bathes self at maximal level of independence
   b. Uses adaptive and assistive devices effectively

c. Reports satisfaction with level of independence in bathing/hygiene

Figure 2-1 • Adaptive and assistive devices. **A.** Raised toilet seat. **B.** Shower chair.

2. Demonstrates independent self-care in dressing/grooming or with assistance, using adaptive devices as appropriate
   a. Dresses/grooms self at maximal level of independence
   b. Uses adaptive devices effectively
   c. Reports satisfaction with level of independence in dressing/grooming
   d. Demonstrates increased interest in appearance
3. Demonstrates independent self-care in feeding or with assistance, using adaptive and assistive devices as appropriate
   a. Feeds self at maximal level of independence
   b. Uses adaptive and assistive devices effectively
   c. Demonstrates increased interest in eating
   d. Maintains adequate nutritional intake
4. Demonstrates independent self-care in toileting or with assistance, using adaptive and assistive devices as appropriate
   a. Toilets self at maximal level of independence
   b. Uses adaptive and assistive devices effectively
   c. Indicates positive feelings regarding level of toileting independence
   d. Experiences adequate frequency of bowel and bladder elimination
   e. Does not experience incontinence, constipation, urinary tract infection, or other complications
5. Demonstrates knowledge about effective health maintenance

a. Verbalizes knowledge of health problem/disorder and resulting changes in functional abilities and lifestyle
b. Identifies and secures resources needed to maintain health upon discharge

NURSING PROCESS

The Patient with Impaired Physical Mobility

Problems commonly associated with immobility include weakened muscles, joint contracture, and deformity. Each joint of the body has a normal range of motion; if the range is limited, the functions of the joint and the muscles that move the joint are impaired, and painful deformities may develop. The nurse must identify patients at risk for such complications. The nurse needs to assess, plan, and intervene to prevent complications of immobility.

Another problem frequently seen in rehabilitation nursing is an altered ambulatory/mobility pattern. Patients with disability may be either temporarily or permanently unable to walk independently and unaided. The nurse assesses the mobility of the patient and designs care that promotes independent mobility within the prescribed therapeutic limits. If a patient cannot exercise and move his or her joints through their full range of motion, contractures may develop. A contracture is a shortening of the muscle and tendon that leads to deformity and limits joint mobility. When the contracted joint is moved, the patient experiences pain; in addition, more energy is required to move when joints are contracted.

Disability brings change to the patient and family unit as well as adjustments in lifestyle, mobility, and interactions as members of a community. Whether temporary or permanent, patients can grieve the loss of health and will need to process the loss as part of the adaptation process and plan of care (Carpenito, 2017).

Assessment

Mobility may be restricted owing to pain, paralysis, loss of muscle strength, systemic disease, an immobilizing device (e.g., cast, brace), or prescribed limits to promote healing. Assessment of mobility includes positioning, ability to move, muscle strength and tone, joint function, and the prescribed mobility limits. The nurse must collaborate with physical therapists or other team members to assess mobility.

During position change, transfer, and ambulation activities, the nurse assesses the patient's abilities, the extent of disability, and residual capacity for physiologic adaptation. The nurse observes for orthostatic hypotension, pallor, diaphoresis, nausea, tachycardia, and fatigue.

In addition, the nurse assesses the patient's ability to use various assistive devices that promote mobility. If the patient cannot ambulate without assistance, the nurse assesses the patient's ability to balance, transfer, and use assistive devices (e.g., crutches, walker). Crutch walking requires high energy expenditure and produces considerable cardiovascular stress; therefore, people with reduced exercise capacity, decreased arm strength, and problems with balance because of aging or multiple diseases may be unable to use crutches. A walker is more stable and may be a better choice for such patients. If the

patient uses an orthosis, the nurse monitors the patient for effective use and potential problems associated with its use.

The assessment process includes gaining an understanding of the meaning of illness or disability for the patient and family, whether it be a temporary or permanent loss of normal functioning or lifestyle. Signs and symptoms evidenced by the patient or family members such as disbelief, crying, expressions of emotions such as sorrow and anger can be part of the grieving process. The nurse collaborates with the interdisciplinary team to develop a holistic plan of care that addresses relevant actual or potential nursing diagnoses (Carpenito, 2017).

Nursing Diagnosis

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired mobility
- Activity intolerance or risk for activity intolerance
- Risk for injury
- Risk for disuse
- Impaired walking
- Impaired wheelchair mobility
- Impaired mobility in bed
- Grief

Planning and Goals

Major goals for the patient may include absence of contracture and deformity, maintenance of muscle strength and joint mobility, independent mobility, increased activity tolerance, and prevention of further disability. A major goal for the patient and family may include that they express an understanding of the meaning of the illness or disability and its associated losses.

Nursing Interventions

Positioning to Prevent Musculoskeletal Complications

Deformities and contractures can often be prevented by proper positioning. Maintaining correct body alignment when the patient is in bed is essential regardless of the position selected. During each patient contact, the nurse evaluates the patient's position and assists the patient to achieve and maintain proper positioning and alignment. The most common positions that patients assume in bed are supine (dorsal), side-lying (lateral), and prone. The nurse helps the patient assume these positions and uses pillows to support the body in correct alignment. At times, a splint (e.g., wrist or hand splint) may be made by the occupational therapist to support a joint and prevent deformity. The nurse must ensure proper use of the splint and provide skin care.

Preventing External Rotation of the Hip. The patient who is in bed for an extended period of time may develop external rotation deformity of the hip because the ball-and-socket joint of the hip tends to rotate outward when the

patient lies on their back. A trochanter roll (i.e., a flannel sheet or bath towel folded in thirds lengthwise and rolled toward the patient or a commercially manufactured roll) extending from the crest of the ilium to the midthigh prevents this deformity; with correct placement, it serves as a mechanical wedge under the projection of the greater trochanter.

Concept Mastery Alert

Abduction moves the body part away from the body; adduction moves the body part toward the body. External rotation occurs as the leg moves outward. To prevent external rotation deformity, the patient's hip should *not* be abducted or moved away from the body.

Preventing Footdrop. Footdrop is a deformity in which the foot is plantar flexed (the ankle bends in the direction of the sole of the foot). If the condition continues without correction, the patient will not be able to hold the foot in a normal position and will be able to walk only on their toes, without touching the ground with the heel of the foot. The deformity is caused by contracture of both the gastrocnemius and soleus muscles. Damage to the peroneal nerve or loss of flexibility of the Achilles tendon may also result in footdrop. To prevent this disabling deformity, the patient is positioned to sit at a 90-degree angle in a wheelchair with the feet on the footrests or flat on the floor.

When the patient is supine in bed, padded splints or protective boots are used to keep the patient's feet at right angles to the legs. Frequent skin inspection of the feet must also be performed to determine whether positioning devices have created any unwanted pressure areas.

The patient is encouraged to perform the following ankle exercises several times each hour: dorsiflexion and plantar flexion of the feet, flexion and extension (curl and stretch) of the toes, and eversion and inversion of the feet at the ankles. The nurse provides frequent passive range-of-motion exercises if the patient cannot perform active exercises.

Quality and Safety Nursing Alert

Prolonged bed rest, lack of exercise, incorrect positioning in bed, and the weight of bedding that forces the toes into plantar flexion must be avoided to prevent footdrop. Patients should be encouraged to wear shoes for support and protection to prevent footdrop.

Maintaining Muscle Strength and Joint Mobility

Optimal function depends on the strength of the muscles and joint motion, and active participation in ADLs promotes maintenance of muscle strength and joint mobility. Range-of-motion exercises and specific therapeutic exercises may be included in the nursing plan of care.

Performing Range-of-Motion Exercises. Range of motion involves moving a joint through its full range in all appropriate planes (Chart 2-4). To maintain or increase the motion of a joint, range-of-motion exercises are initiated as soon as the patient's condition permits. The exercises are planned for individual patients to accommodate the wide variation in the degrees of motion that people of varying body builds and age groups can attain.

Range-of-motion exercises may be active (performed by the patient under the supervision of the nurse), assisted (with the nurse helping if the patient cannot do the exercise independently), or passive (performed by the nurse). Unless otherwise prescribed, a joint should be moved through its range of motion three times, at least two times a day. The joint to be exercised is supported, the bones above the joint are stabilized, and the body part distal to the joint is moved through the range of motion of the joint. For example, the humerus must be stabilized while the radius and ulna are moved through their range of motion at the elbow joint.

A joint should not be moved beyond its free range of motion; the joint is moved to the point of resistance and stopped at the point of pain. If muscle spasms are present, the joint is moved slowly to the point of resistance. Gentle, steady pressure is then applied until the muscle relaxes, and the motion is continued to the joint's final point of resistance.

Chart 2-4

Range-of-Motion Terminology

Abduction: movement away from the midline of the body
Adduction: movement toward the midline of the body
Flexion: bending of a joint so that the angle of the joint diminishes
Extension: the return movement from flexion; the joint angle is increased
Rotation: turning or movement of a part around its axis
Internal: turning inward, toward the center
External: turning outward, away from the center
Dorsiflexion: movement that flexes or bends the hand back toward the body or the foot toward the leg
Palmar flexion: movement that flexes or bends the hand in the direction of the palm
Plantar flexion: movement that flexes or bends the foot in the direction of the sole
Pronation: rotation of the forearm so that the palm of the hand is down
Supination: rotation of the forearm so that the palm of the hand is up
Opposition: touching the thumb to each fingertip on same hand
Inversion: movement that turns the sole of the foot inward
Eversion: movement that turns the sole of the foot outward

To perform assisted or passive range-of-motion exercises, the patient must be in a comfortable supine position with the arms at the sides and the knees extended. Good body posture is maintained during the exercises. The nurse also uses good body mechanics during the exercise session.

Performing Therapeutic Exercises. Therapeutic exercises are prescribed by the primary provider and performed with the assistance and guidance of the physical therapist or nurse. The patient should have a clear understanding of the goal of the prescribed exercise. Written instructions about the frequency, duration, and number of repetitions, as well as simple line drawings of the exercise, help to ensure adherence to the exercise program. Return demonstration of the exercises also helps the patient and family to follow the instructions correctly.

When performed correctly, exercise assists in maintaining and building muscle strength, maintaining joint function, preventing deformity, stimulating circulation, developing endurance, and promoting relaxation. Exercise is also valuable in helping to restore motivation and the well-being of the patient. Weight-bearing exercises may slow the bone loss that occurs with disability. There are five types of exercise: passive, active-assistive, active, resistive, and isometric. The description, purpose, and action of each of these exercises are summarized in Table 2-1.

Promoting Independent Mobility

When the patient's condition stabilizes, their physical condition permits, and the patient is able to stand, the patient is assisted to sit up on the side of the bed and then to stand. Tolerance of this activity is assessed. Orthostatic (postural) hypotension may develop when the patient assumes a vertical position. Because of inadequate vasomotor reflexes, blood pools in the splanchnic (visceral or intestinal) area and in the legs, resulting in inadequate cerebral circulation. If indicators of orthostatic hypotension (e.g., drop in blood pressure, pallor, diaphoresis, nausea, tachycardia, dizziness) are present, the activity is stopped, and the patient is assisted to a supine position in bed.

Some disabling conditions, such as spinal cord injury (SCI), acute brain injury, and other conditions that require extended periods in the recumbent position, prevent the patient from assuming an upright position at the bedside. Several strategies can be used to help the patient assume a 90-degree sitting position. A reclining wheelchair with elevating leg rests allows a slow and controlled progression from a supine position to a 90-degree sitting position. A tilt table (a board that can be tilted in 10-degree increments from a horizontal to a vertical position) may also be used. The tilt table promotes vasomotor adjustment to positional changes and helps patients with limited standing balance and limited weight-bearing activities avoid the decalcification of bones and low bone mass associated with disuse syndrome and lack of weight-bearing exercise. Physical therapists may use a tilt table for patients who have not been upright owing to illness or disability. Gradual elevation of the head of the bed may help. When getting patients with SCI out of bed, it is important to

gradually raise the head of the bed to a 90-degree angle; this may take approximately 10 to 15 minutes.

Graduated compression stockings are used to prevent venous stasis. For some patients, a compression garment (leotard) or snug-fitting abdominal binder and elastic compression bandaging of the legs are needed to prevent venous stasis and orthostatic hypotension. When the patient is standing, the feet are protected with a pair of properly fitted shoes. Extended periods of standing are avoided because of venous pooling and pressure on the soles of the feet. The nurse monitors the patient's blood pressure and pulse and observes for signs and symptoms of orthostatic hypotension and cerebral insufficiency (e.g., the patient reports feeling faint and weak), which suggest intolerance of the upright position. If the patient does not tolerate the upright position, the nurse should return the patient to the reclining position and elevate their legs.

TABLE 2-1 Therapeutic Exercises

	Description	Purposes	Action
Passive	An exercise carried out by the therapist or the nurse without assistance from the patient	To retain as much joint range of motion as possible; to maintain circulation	Stabilize the proximal joint and support the distal part; move the joint smoothly, slowly, and gently through its full range of motion; avoid producing pain.
Active-assistive	An exercise carried out by the patient with the assistance of the therapist or the nurse	To encourage normal muscle function	Support the distal part, and encourage the patient to take the joint actively through its range of motion; give no more assistance than is necessary to accomplish the action; short periods of activity should be followed by adequate rest periods.
Active	An exercise accomplished by the patient without assistance; activities include turning from side to side and from back to abdomen and moving up and down in bed	To increase muscle strength	When possible, active exercise should be performed against gravity; the joint is moved through full range of motion without assistance; make sure that the patient does not substitute another joint movement for the one intended.
Resistive	An active exercise carried out by the patient working against resistance produced by either manual or mechanical means	To provide resistance to increase muscle power	The patient moves the joint through its range of motion, while the therapist resists slightly at first and then with progressively increasing resistance; sandbags and weights can be used and are applied at the distal point of the involved joint; the movements should be performed smoothly.
Isometric or muscle setting	Alternately contracting and relaxing a muscle while keeping the part in a fixed position; this exercise is performed by the patient	To maintain strength when a joint is immobilized	Contract or tighten the muscle as much as possible without moving the joint, hold for several seconds, then let go and relax; breathe deeply.

Assisting Patients with Transfer. A **transfer** is movement of the patient from one place to another (e.g., bed to chair, chair to commode, wheelchair to tub). As soon as the patient is permitted out of bed, transfer activities are

started. The nurse assesses the patient's ability to participate actively in the transfer and determines, in conjunction with occupational therapists or physical therapists, the adaptive equipment required to promote independence and safety. A lightweight wheelchair with brake extensions, removable and detachable armrests, and leg rests minimize structural obstacles during the transfer. Tub seats or benches make transfers in and out of the tub easier and safer. Raised, padded commode seats may also be warranted for patients who must avoid flexing the hips greater than 90 degrees when transferring to a toilet. It is important that the nurse educate the patient about hip precautions (e.g., no adduction past the midline, no flexion greater than 90 degrees, and no internal rotation); abduction pillows can be used to keep the hip in correct alignment if precautions are warranted.

It is important that the patient maintains muscle strength and, if possible, performs push-up exercises to strengthen the arm and shoulder extensor muscles. The push-up exercises require the patient to sit upright in bed; a book is placed under each of the patient's hands to provide a hard surface, and the patient is instructed to push down on the book, raising the body. The nurse should encourage the patient to raise and move the body in different directions by means of these push-up exercises.

The nurse or physical therapist instructs the patient how to transfer. There are several methods of transferring from the bed to the wheelchair when the patient cannot stand, and the technique chosen should consider the patient's abilities and disability. It is helpful to demonstrate the technique to the patient. If the physical therapist is involved in teaching the patient to transfer, the nurse and physical therapist must collaborate so that consistent instructions are given to the patient. During transfer, the nurse assists and coaches the patient. Figure 2-2 shows weight-bearing and non–weight-bearing transfers. For example, with a weight-bearing transfer from bed to chair, the patient stands up, pivots until his back is opposite the new seat, and sits down. If the patient's muscles are not strong enough to overcome the resistance of body weight, a polished lightweight board (transfer board, sliding board) may be used to bridge the gap between the bed and the chair. The patient slides across on the board with or without assistance from a caregiver. This board may also be used to transfer the patient from the chair to the toilet or bathtub bench. It is important to avoid the effects of shear on the patient's skin while sliding across the board. The nurse should make sure that the patient's fingers do not curl around the edge of the board during the transfer, because the patient's body weight can crush the fingers as they move across the board.

Safety is a primary concern during a transfer, and the following guidelines are recommended:

- Wheelchairs and beds must be locked before transfer begins.
- Detachable arm- and footrests are removed to make getting in and out of the chair easier.
- One end of the transfer board is placed under the buttocks and the other end on the surface to which the transfer is being made (e.g., the chair).

- The patient is instructed to lean forward, push up with his or her hands, and then slide across the board to the other surface.

Nurses frequently assist patients who are weak and incapacitated out of bed. The nurse supports and gently assists the patient during position changes, protecting the patient from injury. The nurse avoids pulling on a weak or paralyzed upper extremity to prevent dislocation of the shoulder. The patient is assisted to move toward the stronger side.

In the home setting, getting in and out of bed and performing chair, toilet, and tub transfers are difficult for patients with weak muscles and loss of hip, knee, and ankle motion. A rope attached to the headboard of the bed enables a patient to move toward the center of the bed, and the use of a rope attached to the footboard facilitates getting in and out of bed. The height of a chair can be raised with cushions on the seat or with hollowed-out blocks placed under the chair legs. Grab bars can be attached to the wall near the toilet and tub to provide leverage and stability.

Preparing for Ambulation. Regaining the ability to walk is a prime morale builder. However, to be prepared for ambulation—whether with a brace, walker, cane, or crutches—the patient must strengthen the muscles required. Therefore, exercise is the foundation of preparation. The nurse and physical therapist instruct and supervise the patient in these exercises.

For ambulation, the quadriceps muscles, which stabilize the knee joint, and the gluteal muscles are strengthened. To perform quadriceps-setting exercises, the patient contracts the quadriceps muscle by attempting to push the popliteal area against the mattress and at the same time raising the heel. The patient maintains the muscle contraction for a count of five and relaxes for a count of five. The exercise is repeated 10 to 15 times hourly. Exercising the quadriceps muscles prevents flexion contractures of the knee. In gluteal setting, the patient contracts or "pinches" the buttocks together for a count of five, relaxes for a count of five; the exercise is repeated 10 to 15 times hourly.

If assistive devices (i.e., walker, cane, crutches) will be used, the muscles of the upper extremities are exercised and strengthened. Push-up exercises are especially useful. While in a sitting position, the patient raises the body by pushing the hands against the chair seat or mattress. The patient should be encouraged to do push-up exercises while in a prone position as well. Pull-up exercises done on a trapeze while lifting the body are also effective for conditioning. The patient is taught to raise the arms above the head and then lower them in a slow, rhythmic manner while holding weights. Gradually, the weight is increased. The hands are strengthened by squeezing a rubber ball.

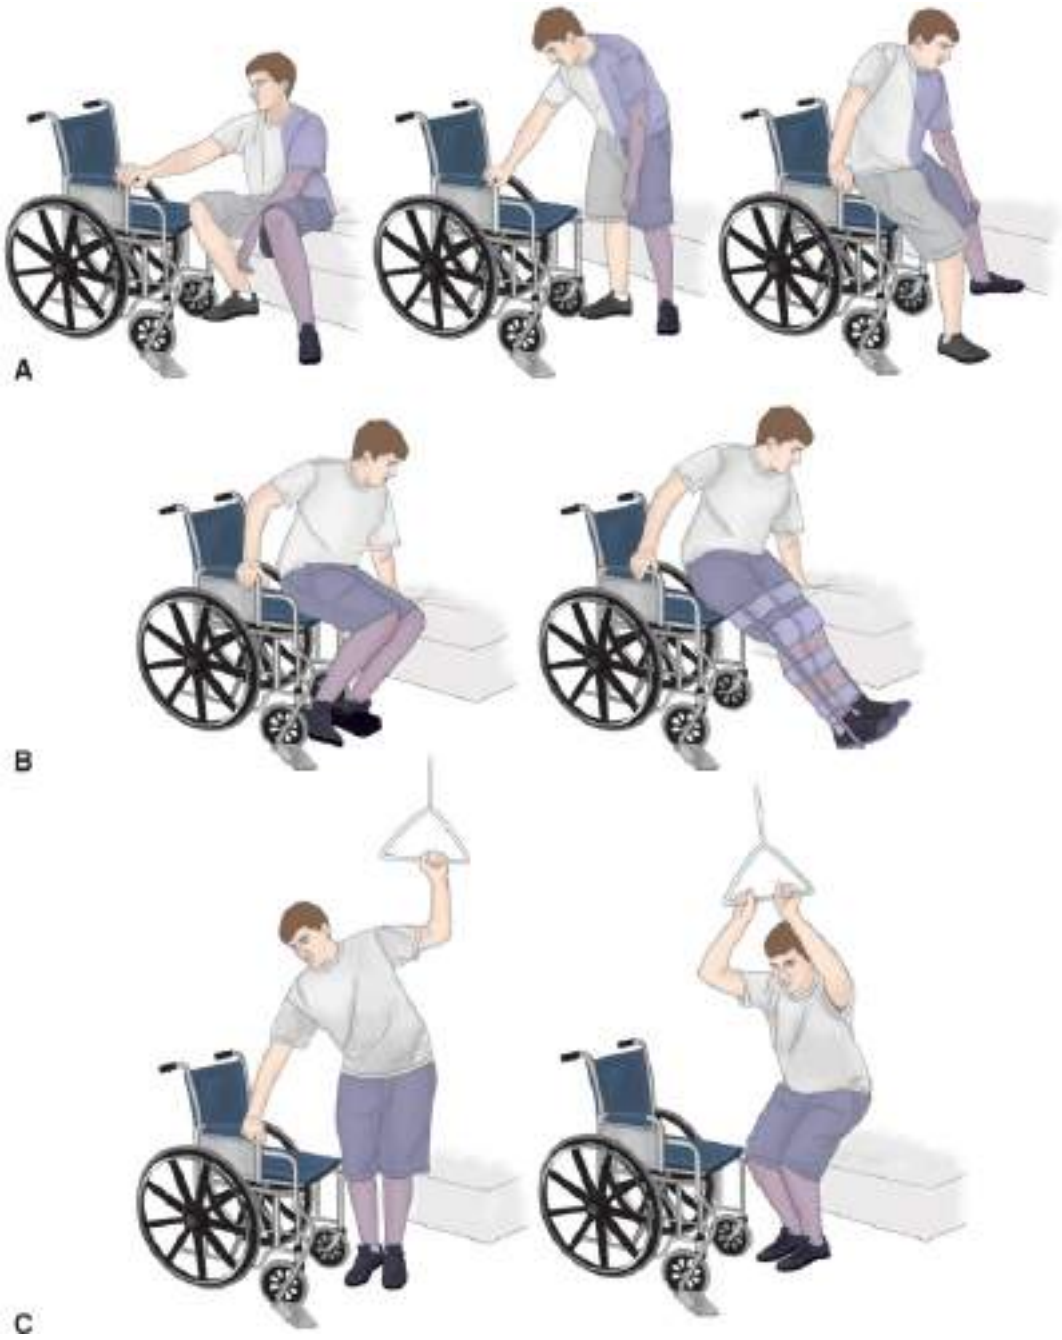

Figure 2-2 • Methods of patient transfer from the bed to a wheelchair. The wheelchair is in a locked position. Colored areas indicate non–weight-bearing body parts. **A.** Weight-bearing transfer from bed to chair. The patient stands up, pivots until his back is opposite the new seat, and sits down. **B.** (**Left**) Non–weight-bearing transfer from chair to bed. (**Right**) With legs braced. **C.** (**Left**) Non–weight-bearing transfer, combined method. (**Right**) Non–weight-bearing transfer, pull-up method. One of the wheelchair arms is removed to make getting in and out of the chair easier.

Typically, the physical therapist designs exercises to help the patient develop sitting and standing balance, stability, and coordination needed for

ambulation. After sitting and standing balance is achieved, the patient is able to use parallel bars. Under the supervision of the physical therapist, the patient practices shifting weight from side to side, lifting one leg while supporting weight on the other, and then walking between the parallel bars.

A patient who is ready to begin ambulation must be fitted with the appropriate assistive device, instructed about the prescribed weight-bearing limits (e.g., non–weight-bearing, partial weight-bearing ambulation), and taught how to use the device safely. Figure 2-3 illustrates some of the more common assistive devices used in rehabilitation settings. The nurse continually assesses the patient for stability and adherence to weight-bearing precautions and protects the patient from falling. The nurse provides contact guarding by holding on to a gait belt that the patient wears around the waist. The patient should wear sturdy, well-fitting shoes and be advised of the dangers of wet or highly polished floors and throw rugs. The patient should also learn how to ambulate on inclines, uneven surfaces, and stairs.

Ambulating with an Assistive Device: Crutches, a Walker, or a Cane

Crutches are for partial weight-bearing or non–weight-bearing ambulation. Good balance, adequate cardiovascular reserve, strong upper extremities, and erect posture are essential for crutch walking. Ambulating a functional distance (at least the length of a room or house) or maneuvering stairs on crutches requires significant arm strength, because the arms must bear the patient's weight (Fig. 2-4). The nurse or physical therapist determines which gait is best (Chart 2-5).

A walker provides more support and stability than a cane or crutches. A pick-up walker is best for patients with poor balance and poor cardiovascular reserve, and a rolling walker, which allows automatic walking, is best for patients who cannot lift. A cane helps the patient walk with balance and support and relieves the pressure on weight-bearing joints by redistributing weight.

Figure 2-3 • Mechanical aids to walking. **A.** Two types of walkers: pick-up and rolling. **B.** Three types of canes: C-cane, functional cane, and quad cane.

Before patients can be considered to be independent in walking with crutches, a walker, or a cane, they should learn to sit, stand from sitting, and go up and down stairs using the device. Table 2-2 describes how patients can ambulate and maneuver using each of the three devices and nursing actions to support using assistive devices.

Assisting Patients with an Orthosis or Prosthesis

Orthoses and prostheses are designed to facilitate mobilization and to maximize the patient's quality of life. An **orthosis** is an external appliance that provides support, prevents or corrects deformities, and improves function. Orthoses include braces, splints, collars, corsets, and supports that are designed and fitted by orthotists or prosthetists. Static orthoses (no moving parts) are used to stabilize joints and prevent contractures. Dynamic orthoses are flexible and are used to improve function by assisting weak muscles. A **prosthesis** is an artificial body part that may be internal, such as an artificial knee or hip joint, or external, such as an artificial leg or arm.

Figure 2-4 • For a person walking with crutches, the tripod stance, with crutches out to the sides and in front of the toes, increases stability.

In addition to learning how to apply and remove the orthosis and maneuver the affected body part correctly, patients must learn how to properly care for the skin that comes in contact with the appliance. Skin problems or pressure injuries may develop if the device is applied too tightly or too loosely, or if it is adjusted improperly. The nurse instructs the patient to clean and inspect the skin daily, to make sure the brace fits snugly without being too tight, to check that the padding distributes pressure evenly, and to wear a cotton garment without seams between the orthosis and the skin.

If the patient has had an amputation, the nurse promotes tissue healing, uses compression dressings to promote residual limb shaping, and minimizes contracture formation. A permanent prosthetic limb cannot be fitted until the tissue has healed completely and the residual limb shape is stable and free from edema. The nurse also helps the patient cope with the emotional issues surrounding loss of a limb and encourages acceptance of the prosthesis. The prosthetist, nurse, and primary provider collaborate to provide instructions related to skin care and care of the prosthesis.

Supporting the Grieving Process

Developing a trusting nurse–patient relationship provides an opportunity to support patients and families as they grieve and process the meaning of the illness or disability, whether it be a temporary or permanent loss of normal functioning and lifestyle. The nurse helps the grieving process by providing clear, simple communications that do not minimize the loss. The nurse also educates the patient and family about the grieving process, normal grief reactions, and signs and symptoms of complicated grieving. Time should be planned to share feelings in a safe setting which provides needed privacy. In many cases, just being present and listening supports the grieving process. Patients and families may benefit from community resources such as support groups as well as connection to their local faith community for spiritual support through the changes associated with disability (Carpenito, 2017).

Chart 2-5

Crutch Gaits

Shaded areas are weight bearing. Arrow indicates advance of foot or crutch. (Read chart from bottom, starting with beginning stance.)

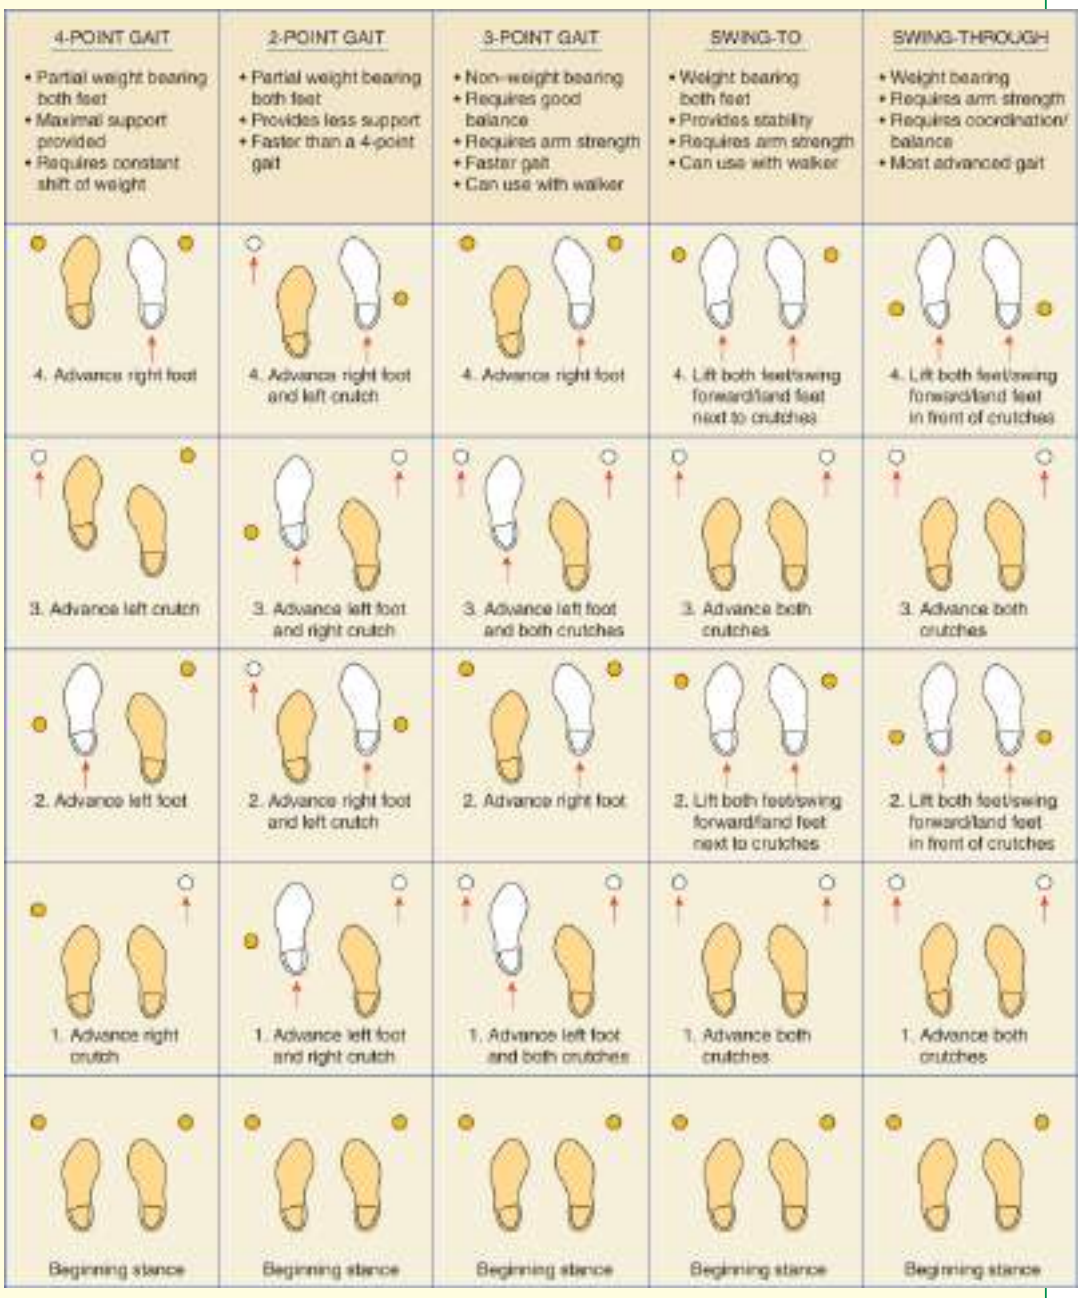

TABLE 2-2 Nursing Actions Involved in Using Assistive Devices

	Crutches	Walker	Cane
Patient Preparation Adjusting device to fit patient	Measure patient standing or lying down: If standing, set crutch length approximately 5 cm (2 inches) below axilla. If lying down, measure from anterior fold of axilla to sole of the foot and add 5 cm. If using patient's height, subtract 40 cm (16 inches) to obtain crutch height. Adjust hand grip to allow 20 to 30 degrees of flexion at elbow. Use foam rubber pad on underarm piece to relieve pressure of crutch.	Adjust height to individual patient. Patient's arms should be in 20 to 30 degrees of flexion at elbows when hands are resting on hand grips.	With patient flexing elbow at 30-degree angle, hold handle of cane level with greater trochanter and place tip of cane 15 cm (6 inches) lateral to base of 5th toe. Fit cane with gently flaring tip that has flexible, concentric rings to provide stability, absorb shock, and enable greater speed and less fatigue with walking.
Assessment	Assess safety. Crutches should have large rubber tips, and patients should wear firm-soled, well-fitting shoes. Assess balance by asking patient to stand on unaffected leg by a chair. Assess stability and stamina (tolerance). Sweating and shortness of breath indicate that rest is necessary.	Assess safety. Patients should wear firm-soled, well-fitting shoes. Assess stability and stamina (tolerance). Sweating and shortness of breath indicate that rest is necessary.	Assess safety. Patients should wear firm-soled, well-fitting shoes. Assess stability and stamina (tolerance). Sweating and shortness of breath indicate that rest is necessary.
Interventions and patient education	Assist with balance by using a transfer belt or holding patient near waist. Have patient practice shifting weight and maintaining balance. Protect patient from falls.	Walk with patient, holding at waist if needed for balance. Instruct patient to never pull self up using walker and to	Walk with patient, holding at waist if needed for balance. Have patient hold cane in hand opposite to affected extremity, if possible, to widen the base of support and reduce stress on involved extremity.

	To maximize stability, encourage patient to use tripod stance, with crutches to the front and sides of toes. Have patient perform prescribed preparatory exercises to strengthen shoulder girdle and upper extremity muscles.[a]	look up when walking. Discuss full, partial, or non–weight bearing as prescribed. Protect patient from falls.	Instruct patient to move opposite arm and leg together. Protect patient from falls.
Ambulation Gait/action used	Determine which gait is best (see Chart 2-5, Tripod Gait)[b] Four-point Three-point Two-point Swing-to Swing-through	Instruct patient to: Pick-up walker: lift device and move it forward with each step. Rolling walker: roll device forward and walk automatically.	Instruct patient to: Advance cane at same time that affected leg is moved forward. Keep cane fairly close to body to prevent leaning. Bear down on cane when unaffected extremity begins swing phase.
Sitting	Instruct patient to: Grasp hand-piece for control. Bend forward slightly while assuming sitting position. Place affected leg forward to prevent weight bearing and flexion while sitting.	Instruct patient to hold walker on hand grips for stability.	
Standing	Instruct patient to: Move forward to edge of chair, and keep unaffected leg slightly under seat. Place both crutches on side of affected extremity. Push down on hand-piece while rising to standing position.	Instruct patient to: Push off chair or bed to come to a standing position. Rolling walker: if walker has a brake, apply it before standing. Lift walker, placing it in front of self while leaning	Instruct patient to: Push off chair or bed to come to a standing position. Hold cane for stability. Step forward on unaffected extremity. Swing cane and affected extremity forward in a normal walking gait.

		slightly forward. Walk into walker, supporting weight on hands when advancing. Balance on feet. Lift walker and place it in front of self again.	
Going down stairs	Instruct patient to: Walk forward as far as possible. Advance crutches to lower step; advance affected leg, then unaffected leg.	Continue pattern.	Instruct patient to: Step down on affected extremity. Place the cane and then unaffected extremity on down step.
Going up stairs	Instruct patient to: Advance unaffected leg first up next step. Advance crutches and affected extremity. Unaffected leg goes up first.	n/a	Instruct patient to: Step up on unaffected extremity. Place cane and affected extremity up on step.

[a]For patients who cannot support their weight through the wrist and hand because of arthritis or fracture, platform crutches that support the forearm and allow the weight to be borne through the elbow are available. If weight is borne on the axilla, the pressure of the crutch can damage the brachial plexus nerves, producing "crutch paralysis."

[b]Teach patients two gaits so that they can change from one to another to avoid fatigue. In addition, a faster gait can be used when walking an uninterrupted distance, and a slower gait can be used for shorter distances or in crowded places.

n/a, not applicable.

Evaluation

Expected patient outcomes may include:

1. Demonstrates improved physical mobility
   a. Maintains muscle strength and joint mobility
   b. Does not develop contractures
   c. Participates in exercise program
2. Transfers safely
   a. Demonstrates assisted transfers
   b. Performs independent transfers
3. Ambulates with maximum independence
   a. Uses ambulatory aid safely
   b. Adheres to weight-bearing prescription
   c. Requests assistance as needed

4. Demonstrates increased activity tolerance
   a. Does not experience episodes of orthostatic hypotension
   b. Reports absence of fatigue with ambulatory efforts
   c. Gradually increases distance and speed of ambulation
5. Patient and family members verbalize loss and express feelings of grief
   a. Describe the meaning of the loss as it relates to function or lifestyle
   b. Share grief with each other and those who are important to well-being
   c. Acquire knowledge of resources for support after discharge

Promoting Home, Community-Based, and Transitional Care

An important goal of rehabilitation is to assist the patient to return to the home environment after learning to manage the disability. A referral system maintains continuity of care when the patient is transferred to the home or to a long-term care facility. The plan for discharge is formulated when the patient is first admitted to the hospital, and discharge plans are made with the patient's functional potential in mind.

Educating Patients About Self-Care

Significant expenditures of time and resources are necessary to ensure that patients gain the skills and confidence to self-manage their health effectively after discharge from the hospital (Naylor, Shaid, Carpenter, et al., 2017). Formal programs provide patients with effective strategies for interpreting and managing disease-specific issues and skills needed for problem solving, as well as building and maintaining self-awareness and self-efficacy. Self-care programs often use multifaceted approaches, including didactic teaching, group sessions, individual learning plans, and Web-based resources. When planning the approach to self-care, the nurse must consider the individual patient's knowledge, experience, social and cultural background, level of formal education, and psychological status. The preparation for self-care must also be spread out over the course of the recovery period, and it must be monitored and updated regularly as the patient masters aspects of self-care. Preparation for self-care is also highly relevant for informal caregivers of patients in rehabilitation.

When a patient is discharged from acute care or a rehabilitation facility, informal caregivers, typically family members, often assume the care and support of the patient. Although the most obvious care tasks involve physical care (e.g., personal hygiene, dressing, meal preparation), other elements of the caregiving role include psychosocial support and a commitment to this supportive role. Thus, the nurse must assess the patient's support system (family, friends) well in advance of discharge. The positive attitudes of family and friends toward the patient, the patient's disability, and the return home are important in making a successful transition to home. Not all families can carry out the arduous programs

of exercise, physical therapy, and personal care that the patient may need. They may not have the resources or stability to care for family members with a severe disability. The physical, emotional, economic, and energy strains of a disabling condition may overwhelm even a stable family. Members of the rehabilitation team must not judge the family but rather should provide supportive interventions that help the family to attain its highest level of function.

The family members need to know as much as possible about the patient's condition and care so that they do not fear the patient's return home. The nurse develops methods to help the patient and family cope with problems that may arise. For example, the nurse may develop an ADLs checklist individualized for the patient and family to ensure that the family is proficient in assisting the patient with certain tasks (Chart 2-6).

Continuing and Transitional Care

A home health or transitional care nurse may visit the patient prior to discharge, interview the patient and the family, and review the ADLs sheet to learn which activities the patient can perform. This helps to ensure that continuity of care is provided and that the patient does not regress yet maintains the independence gained while in the hospital or rehabilitation setting. The family may need to purchase, borrow, or improvise needed equipment, such as safety rails, a raised toilet seat or commode, or a tub bench. Ramps may need to be built or doorways widened to allow full access.

Family members are taught how to use equipment and are given a copy of the equipment manufacturer's instruction booklet, the names of resource people, lists of equipment-related supplies, and locations where they may be obtained. A written summary of the care plan is included in family education. The patient and family members are reminded about the importance of routine health screening and other health promotion strategies.

A network of support services and communication systems may be required to enhance opportunities for independent living. The nurse uses collaborative, administrative skills to coordinate these activities and pull together the network of care. The nurse also provides skilled care, initiates additional referrals when indicated, and serves as a patient advocate and counselor when obstacles are encountered. The nurse continues to reinforce prior patient education and helps the patient to set and achieve attainable goals. The degree to which the patient adapts to the home and community environment depends on the confidence and self-esteem developed during the rehabilitation process and on the acceptance, support, and reactions of family members, employers, and community members.

Chart 2-6 **HOME CARE CHECKLIST**

Managing the Therapeutic Regimen at Home

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of disability on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in lifestyle (e.g., diet, activity) necessary to maintain health.
- State the name, dose, side effects, frequency, and schedule for all medications.
- State how to obtain medical supplies after discharge.
- Identify durable medical equipment needs, proper usage, and maintenance necessary for safe utilization:
  - Wheelchair—manual/power
  - Cushion
  - Grab bars
  - Sliding board
  - Mechanical lift
  - Raised padded commode seat
  - Padded commode wheelchair
  - Bedside commode
  - Crutches
  - Walker
  - Cane
  - Prosthesis
  - Orthosis
  - Shower chair
  - Specialty bed
- Demonstrate usage of adaptive equipment for activities of daily living:
  - Long-handled sponge
  - Reacher
  - Universal cuff
  - Plate mat and guard
  - Rocker knife, spork, weighted utensils
  - Special closures for clothing
  - Other
- Demonstrate mobility skills:
  - Transfers: bed to chair; in and out of toilet and tub; in and out of car
  - Negotiate ramps, curbs, stairs
  - Assume sitting from supine position
  - Turn side to side in bed
  - Maneuver wheelchair; manage armrests and leg rests; lock brakes
  - Ambulate safely using assistive devices
  - Perform range-of-motion exercises
  - Perform muscle-strengthening exercises

- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community)
  - Identify phone numbers of support groups for people with disability and their caregivers/families
  - State meeting locations and times
- Demonstrate how to access transportation:
  - Identify locations of wheelchair accessibility for public buses or trains
  - Identify phone numbers for private wheelchair van
  - Contact Division of Motor Vehicles for handicapped parking permit
  - Contact Division of Motor Vehicles for driving test when appropriate
  - Identify resources for adapting private vehicle with hand controls or wheelchair lift
- Identify vocational rehabilitation resources:
  - State name and phone number of vocational rehabilitation counselor
  - Identify educational opportunities that may lead to future employment
- Identify community resources for recreation:
  - State local recreation centers that offer programs for people with disability
  - Identify leisure activities that can be pursued in the community
  - State how to reach primary provider with questions or if complications arise
  - State time and date of follow-up appointments
  - Identify the need for health promotion, disease prevention, and screening activities

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

There is a growing trend toward independent living by people with severe disability, either alone or in groups that share resources. Preparation for independent living should include training in managing a household and working with personal caregivers as well as training in mobility. The goal is integration into the community—living and working in the community with accessible housing, employment, public buildings, transportation, and recreation.

State rehabilitation administration agencies provide services to assist people with disability in obtaining the help they need to engage in gainful employment. These services include diagnostic, medical, and mental health services. Counseling, training, placement, and follow-up services are available to help people with disability select and obtain jobs.

If the patient is transferred to a long-term care facility, the transition is planned to promote continued progress. Independence gained continues to be supported, and progress is fostered. Adjustment to the facility is promoted through communication. Family members are encouraged to visit, to be involved, and to take the patient home on weekends and holidays if possible.

Home Health Nursing

Home health care is a unique component of posthospital care for patients who return home to complete recuperation following an acute illness episode or exacerbation of chronic illness. Home health agencies can also provide advanced technologies in the home setting. All together, these services provided in the home setting work to maximize the patient's ability to function at his highest level of wellness (Rector, 2018).

The ANA defines **home health nursing** as a specialty area of practice that provides nursing services to patients across the lifespan in a home setting (Wilson, 2019). Home health nursing practice roles include holistic care planning, which incorporates resource and service coordination as part of a collaborative interdisciplinary team. This team includes home health aides; social workers; physical, speech, and occupational therapists; and primary providers. The approach provides health and social services with oversight of the total health care plan by a case manager, clinical nurse specialist, or nurse practitioner. Interdisciplinary collaboration is required if a home health agency is to receive Medicare certification (Rector, 2018).

Most home health agencies are reimbursed by various sources, including Medicare and Medicaid programs, private insurance, and direct patient payment. Older adults are the most frequent users of home care expenditures financed by Medicare, which allows nurses to manage and evaluate care of seriously ill patients who have complex, labile conditions and are at high risk for rehospitalization. Each funding source has its own requirements for services rendered, number of visits allowed, and amount of reimbursement the agency receives. The Omaha System's care documentation, referred to as the Outcome and Assessment Information Set (OASIS), has been a requirement for some time to ensure that outcome-based care is provided for all care reimbursed by Medicare. This system uses sociodemographic, environment, support system, health status, and functional status domains to assess and plan care for adult patients. OASIS is also used to collect data and improve performance or quality outcomes (CMS, 2018b).

Services Provided

Many home care patients are acutely ill or have chronic health problems or disability requiring that nurses provide more education and monitoring to patients and families. Home health nurses make home visits to provide skilled nursing care, follow-up care, and education to promote health and prevent complications. Home health care visits may be intermittent or periodic, and case management via telephone or Internet may be used to promote communication with home care consumers. The nurse instructs the patient and family about skills, self-care strategies, and health maintenance and promotion activities (e.g., nutritional counseling, exercise programs, stress management). Nursing care includes skilled assessment of the patient's physical, psychological, social, and environmental status (Fig. 2-5). Nursing interventions may include intravenous (IV) therapy and injections, parenteral nutrition, venipuncture, catheter insertion, pressure injury treatment, wound care, ostomy care, and patient and family education. Complex

technical equipment such as mechanical ventilation and procedures such as peritoneal dialysis may be involved in home health care. Nurses have a role in evaluating the safety and effectiveness of technology in the home setting. In addition, **telehealth** is useful in home health care in facilitating exchange of information via telephone or computers between patients and nurses regarding health information such as blood glucose readings, vital signs, and cardiac parameters. The use of a broad spectrum of computer and Internet resources, such as webcams, also facilitates exchange of information (Rector, 2018).

Figure 2-5 • Assessment is an important part of any home health visit.

The Home Setting

The home health nurse is a guest in the patient's home and must have permission to visit and give care. The nurse has minimal control over the lifestyle, living situation, and health practices of the visited patients. This lack of full decision making authority can create a conflict for the nurse and lead to problems in the nurse–patient relationship. To work successfully with patients in any setting, the nurse must be nonjudgmental and convey respect for patients' beliefs, even if they differ sharply from those of the nurse. This can be difficult when a patient's lifestyle involves activities that a nurse considers harmful or unacceptable, such as smoking, excessive use of alcohol, use of illicit drugs or misuse of prescription drugs, or overeating (Rector, 2018).

The cleanliness of a patient's home may not meet the standards of a hospital. Although the nurse can provide education points about maintaining clean surroundings, the patient and family decide if they will implement the nurse's

suggestions. The nurse must accept their decisions and deliver the care required regardless of the conditions of the setting. The kind of equipment and the supplies or resources that usually are available in acute care settings are often unavailable in the patient's home. The nurse has to learn to improvise when providing care, such as when changing a dressing or catheterizing a patient in a regular bed that is not adjustable and lacks a bedside table (Rector, 2018).

Infection control is as important in the home as it is in the hospital; however, it can be more challenging in the home and requires creative approaches. As in any situation, it is important to perform hand hygiene before and after giving direct patient care, even in a home that does not have running water. If aseptic technique is required, the nurse must have a plan for implementing this technique before going to the home. This applies to universal precautions, transmission-based precautions, and disposal of bodily secretions and excretions. If injections are given, the nurse must use a closed container to dispose of syringes. Injectable and other medications must be kept out of the reach of children during visits and stored in a safe place if the medications remain in the home.

Quality and Safety Nursing Alert

Friends, neighbors, or family members may ask the nurse about the patient's condition. The patient has a right to confidentiality, and information should be shared only with the patient's permission. The nurse should be mindful of any sensitive information (e.g., electronic health records [EHRs]) taken into the home and prevent it from being misplaced or picked up by others.

Home Health Visits

Most agencies have a policy manual that identifies the agency's philosophy and procedures and defines the services provided. The eligibility of a patient and provision of services may be prescribed by the type of insurance the patient carries. For example, Medicare beneficiaries must meet certain eligibility requirements such as homebound criteria and may be permitted only intermittent skilled services of a registered nurse or licensed therapist (CMS, 2019). Becoming familiar with these policies is essential before initiating a home visit. It is also important to know the state laws regarding what actions to take if the nurse finds a patient dead, suspects abuse, determines that a patient cannot safely remain at home, or observes a situation that possibly indicates harm to the community at large.

Preparing for a Home Visit

Before making a home visit, the nurse should review pertinent data about the patient that is typically provided on a referral form. It may be necessary to contact the referring agency if the purpose for the referral is unclear or important

information is missing. The nurse calls the patient to obtain permission to visit, schedules a time for the visit, and verifies the address. This initial phone conversation provides an opportunity to introduce oneself, identify the agency, and explain the reason for the visit. If the patient does not have a telephone, the nurse should see if the person who made the referral is able to contact the patient regarding the visit. If an unannounced visit to a patient's home must be made, the nurse should ask permission to come in before entering the house. Explaining the purpose of the referral at the outset and setting up the times for future visits before leaving are also recommended.

Conducting a Home Visit

Personal Safety Precautions

Home health nurses must pay attention to personal safety, because they often practice in unknown environments. Based on the principle of due diligence, agencies should investigate at-risk working environments prior to making the assignment and must inform employees accordingly. Agencies have policies and procedures concerning the promotion of safety for clinical staff, and training is provided to facilitate personal safety. The individual nurse and agency must proactively assess environments for safety. Suggested precautions to take when making a home visit are presented in Chart 2-7.

Initial Home Visit

The first visit sets the tone for subsequent visits and is crucial in establishing the nurse–patient relationship. The situations encountered depend on numerous factors. Patients may be in pain and have additional factors that make them unable to care for themselves. Family members may be overwhelmed and doubt their ability to care for loved ones. They may not understand why the patient was sent home from the hospital before being totally rehabilitated. They may not comprehend what home care is or why they cannot have 24-hour nursing services. It is critical that the nurse conveys an understanding of what patients and families are experiencing and how the illness is affecting their lives.

Chart 2-7

Safety Precautions in Home Health Care

- Learn, or preprogram a phone with, the telephone numbers of the agency, police, and emergency services. Most agencies provide phones for nurses so that the agency can contact the nurse and the nurse can easily contact the agency.
- Carry agency identification and a charged phone to make telephone calls if you become lost or have problems; a mobile phone charger provides additional backup.
- Let the agency know your daily schedule and the telephone numbers of your patients (if available) so that you can be located if you do not return when expected.
- Know where the patient lives before leaving to make the visit, and either carry a map or use the navigation system in your car or the GPS software on your smartphone for quick referral.
- Keep your car in good working order, and have sufficient gas in the tank.
- Park the car near the patient's home, and lock the car during the visit.
- Do not drive an expensive car or wear expensive jewelry when making visits.
- Know the regular bus schedule, and know the routes when using public transportation or walking to the patient's house.
- When making visits in high-crime areas, visit with another person rather than alone (if possible).
- Try to schedule visits during daylight hours (when possible).
- Never walk into a patient's home uninvited; be vigilant for unrestrained pets.
- If you do not feel safe entering a patient's home, leave the area.
- Become familiar with the layout of the house, including exits from the house.
- If a patient or family member is visibly intoxicated, under the influence, or hostile, leave and reschedule the visit.
- If a family is having a serious argument or abusing the patient or anyone else in the household, leave, reschedule the visit, contact your supervisor, and report the abuse to the appropriate authorities.

GPS, Global Positioning System.

During the initial home visit, which may take 1 hour or more, the patient is evaluated and a plan of care is established that may be modified on subsequent visits. The nurse informs the patient of the agency's practices, policies, and hours of operation. If the agency is to be reimbursed for the visit, the nurse asks for insurance information, such as a Medicare or Medicaid card. The initial assessment includes evaluating the patient, the home environment (Chart 2-8), the patient's self-care abilities or the family's ability to provide care, and the patient's need for additional resources. After the assessment, necessary skilled interventions are accomplished. Most agencies provide nurses with bags that contain standard supplies and equipment needed during home visits. It is

important to keep the bag properly supplied and to bring any additional items that might be needed for the visit. Depending on insurance coverage, supplies may be delivered to the home or may need to be purchased by the patient. Home health nurses need to be prepared for the inevitability that a patient may not have the medical supplies needed for treatment, and work to procure all needed items.

One important aspect of the transition from hospital to home is self-management of the medication regimen. Older adults may have multiple prescribers, or may use alternative therapies such as herbal remedies as well as vitamins and other over-the-counter medications. While the patient is under the care of the home health agency, the home health nurse promotes medication management through the process of medication reconciliation. The nurse reviews current medication orders and assists with solving problems or medication discrepancies such as wrong dosages, duplicate medications, omissions, or use of a medication for something other than the prescribed reason (Kollerup, Curtis, & Schantz Laursen, 2018). Home health agencies may mandate medication reconciliation at each skilled nursing visit. As patients and families observe medication reconciliation, they begin to understand the importance of medication management. Managing the medication regimen is an important part of a successful transition home; without it, there is risk for readmission to the hospital.

Chart 2-8 **ASSESSMENT**

Assessing the Home Environment

Physical Facilities (check all that apply)

Exterior

- Steps
- Unsafe steps
- Porch
- Litter
- Noise
- Adequate lighting
- Other

Interior

- Accessible bathroom
- Level, safe floor surface
- Number of rooms
- Privacy
- Sleeping arrangements
- Refrigeration
- Trash management
- Animals
- Adequate lighting
- Steps/stairs
- Other

Safety Hazards (check all that apply)

- None
- Inadequate floor, roof, or windows
- Inadequate lighting
- Unsafe gas/electric appliances
- Inadequate heating
- Inadequate cooling
- Lack of fire safety devices
- Unsafe floor coverings
- Inadequate stair rails
- Lead-based paint (particularly for homes built prior to 1978) or lead in drinking water (particularly in homes built prior to 1986)
- Improperly stored hazardous material
- Improper wiring/electrical cords
- Other

Safety Factors (check all that apply)

- Fire/smoke detectors
- Working telephone

- Placement of electrical cords
- Emergency plan
- Emergency phone numbers displayed
- Safe portable heaters
- Oxygen in use
- Obstacle-free paths
- Other

Determining the Need for Future Visits

While assessing a patient's situation, the home health nurse evaluates and clearly documents the need for future visits and the optimal frequency for those visits. To make these judgments, the nurse should consider the questions listed in Chart 2-9. With each subsequent visit, these same factors are evaluated to determine the continuing health needs of the patient. As progress is made and the patient—with or without the help of significant others—becomes more capable of self-care and more independent, the need for home visits may decline.

Ending the Visit

As the visit comes to a close, the nurse summarizes the main points of the visit for the patient and family and identifies expectations for future visits or patient achievements. The following points should be considered at the end of each visit:

- What are the main points the patient or family should remember from the visit?
- What positive attributes have been noted about the patient and the family that will give a sense of accomplishment?
- What were the main points of the education plan or the treatments needed to ensure that the patient and family understand what they must do? A written set of instructions should be left with the patient or family, provided they can read and see (alternative formats include video or audio recordings). Printed material must be in the patient's primary language and in large print when indicated.
- Whom should the patient or family call if someone needs to be contacted immediately? Are current emergency telephone numbers readily available? Is telephone service available, or can an emergency phone service be provided?
- What signs of complications should be reported immediately?
- How frequently will visits be made? How long will they last (approximately)?
- What is the day and time of the next visit? Will a different nurse make the visit?

Documenting the Visit

Documentation considerations for home visits follow fairly specific regulations. The patient's needs and the nursing care provided must be documented to ensure

that the agency qualifies for payment for the visit. Medicare, Medicaid, and other **third-party payers** (i.e., organizations that provide reimbursement for services covered under a health care insurance plan) require documentation of the patient's homebound status and the need for skilled professional nursing care. The medical diagnosis and specific detailed information on the functional limitations of the patient are usually part of the documentation. The goals and the actions appropriate for attaining those goals must be identified. Expected outcomes of the nursing interventions must be stated in terms of patient behaviors and must be realistic and measurable. In addition, the goals must reflect the nursing diagnosis or the patient's problems and must specify those actions that address the patient's problems. Inadequate documentation may result in nonpayment for the visit and care services.

Chart 2-9 **ASSESSMENT**

Assessing the Need for Home Visits

Current Health Status

- How well is the patient progressing?
- How serious are the present signs and symptoms?
- Has the patient shown signs of progressing as expected, or does it seem that recovery will be delayed?

Home Environment

- Are safety concerns apparent?
- Are family or friends available to provide care, or is the patient alone?

Level of Self-Care Ability

- Is the patient capable of self-care?
- What is the patient's level of independence?
- Is the patient ambulatory or bedridden?
- Does the patient have sufficient energy, or are they frail and easily fatigued?
- Does the patient need and use assistive devices?

Level of Nursing Care Needed

- What level of nursing care does the patient require?
- Does the care require basic skills or more complex interventions?

Prognosis

- What is the expectation for recovery in this particular instance?
- What are the chances that complications may develop if nursing care is not provided?

Educational Needs

- How well has the patient or family grasped the education points made?
- Is there a need for further follow-up and retraining?
- What level of proficiency does the patient or family show in carrying out the necessary care?

Mental Status

- How alert is the patient?
- Are there signs of confusion or thinking difficulties?
- Does the patient tend to be forgetful or have a limited attention span?

Level of Adherence

- Is the patient following the instructions provided?
- Does the patient seem capable of following the instructions?

- Are the family members helpful, or are they unwilling or unable to assist in caring for the patient as expected?

Discharge Planning for Transition to the Community or Home Care Setting

Discharge planning is an essential component of facilitating the transition of the patient from the acute care to the community or home care setting, or for facilitating the transfer of the patient from one health care setting to another. A documented discharge plan is mandatory for patients who receive Medicare or Medicaid health insurance benefits. Discharge planning begins with the patient's admission to the hospital or health care setting and must consider the potential for necessary follow-up care in the home or another community setting. Several different personnel (e.g., social workers, home health nurses, case managers) or agencies may be involved in the planning process.

The development of a comprehensive discharge plan requires collaboration between professionals at the referring agency and the home care agency, as well as other community agencies that provide specific resources upon discharge. The process involves identifying the patient's needs and developing a thorough plan to meet them. It is essential to have open lines of communication with family members to ensure understanding and cooperation.

Continuing the Transition through Community Resources and Referrals

Case managers and discharge planners often make referrals to other team members, such as home health aides and social workers. These nurses work collaboratively with the health care team and the referring agency or person. Continuous coordinated care among all health care providers involved in a patient's care is essential to avoid duplication of effort by the various personnel caring for the patient. These nurses must also be knowledgeable about community resources available to patients, as well as services provided by local agencies, eligibility requirements for those services, and any charges for the services (i.e., co-pays). Most communities have directories, which may include online directories or resource booklets, that list local health and social service agencies and their offerings. The Internet is useful in helping patients identify the location and accessibility of grocery and drug stores, banks, health care facilities, ambulances, primary providers, dentists, pharmacists, social service agencies, and senior citizens' programs. In addition, a patient's place of worship or faith community may be an important resource for services. The process includes informing the patient and family about the community resources available to meet their needs. When appropriate, nurses may make the initial contact.

CRITICAL THINKING EXERCISES

1 pq An 80-year-old community-dwelling woman with a new diagnosis of heart failure was transferred to your medical-surgical unit from the intensive care unit (ICU). The transfer report from the ICU nurse included the notation that prior to this admission and diagnosis, the patient lived alone at home. The patient has one son who lives locally. Both the patient and son agree with a plan to transition the patient from living alone to living with her son at his home. She has been prescribed new medications to take at home and will need to see her primary provider in 2 weeks. What are your priorities as you work on discharge planning for this patient? What referrals will you consider to achieve a successful transition from hospital to home?

2 ebp An 82-year-old man newly diagnosed with diabetes is being referred for home care after discharge from the hospital. He needs regular monitoring and diabetes education. He has several family members at home who have assisted with IADLs in the past; however, they all work. You are concerned about his ability to manage his diabetes as his family reports he will be home alone during the day and has decreased activity tolerance related to ADLs since his hospitalization and new diagnosis of diabetes. Identify a specific evidence-based question related to this patient in order to conduct a relevant and focused literature search. What key words would you use in this search, and what sources would be appropriate to search? What resources could you use to assist him to remain in his home for as long as possible? How would you go about obtaining this information? What is the strength of the evidence?

3 ipc You are a home health nurse caring for a 75-year-old man who has transitioned home from inpatient rehabilitation following a fall in which his hip was fractured. He had surgery to reduce the fracture and stabilize the hip. He lives with his wife who is also 75 and who has memory impairment. Both need assistance with IADLs. He needs assistance with ADLs as he continues the rehabilitation process at home. As the home health nurse and case manager, develop a list of resources and interdisciplinary services that will enhance this transition to the home setting.

3 Health Education and Health Promotion

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the purposes and significance of health education.
2. Distinguish between the concepts of adherence to a therapeutic regimen and health literacy.
3. Explain the variables that affect learning and apply them to the teaching—learning process.
4. Describe the components of health promotion and discuss major health promotion models.
5. Specify the variables that affect health promotion activities across the life cycle, and describe the role of the nurse in health promotion.

NURSING CONCEPTS

Community-Based Practice
Family
Health Promotion
Health, Wellness, and Illness
Managing Care
Stress and Coping
Teaching and Learning

GLOSSARY

adherence: the process of faithfully following guidelines or directions

community: an interacting population of individuals living together within a larger society

feedback: the return of information given to a person

health education: various learning experiences designed to promote behaviors that facilitate health

health literacy: the capability of a person to obtain, communicate, process, and understand essential health information for the purpose of securing health care services and for making health care decisions

health promotion: activities that assist people in developing resources to maintain or enhance well-being and improve quality of life

learning: the act of acquiring knowledge, attitudes, or skills

learning readiness: the optimum time for learning to occur; usually corresponds to the learner's perceived need and desire to obtain specific knowledge

nutrition: the science that deals with food and nourishment in humans

physical fitness: the condition of being physically healthy as a result of proper exercise and nutrition

self-responsibility: personal accountability for one's actions or behavior

stress management: behaviors and techniques used to strengthen a person's resources against stress

teaching: helping another person learn

therapeutic regimen: a routine that promotes health and healing

Effective health education lays a solid foundation for individual and **community** (population of individuals living together within a larger society) wellness. All nurses use teaching as a tool to assist patients and families in developing effective health behaviors and altering lifestyle patterns that predispose people to health risks. Health education is an influential factor directly related to positive health outcomes.

Purpose of Health Education

Today's health care environment mandates the use of an organized approach to **health education** (learning experiences designed to promote behaviors that facilitate health) so that patients can meet their specific health care needs. There are many reasons for providing health education.

Meeting Nursing Standards

Teaching, as a function of nursing, is included in all state nurse practice acts and in the American Nurses Association's (ANA's) *Scope and Standards of Practice* (ANA, 2015). Health teaching and health promotion are independent functions of nursing practice and essential nursing responsibilities. All nursing care is directed toward promoting, maintaining, and restoring health; preventing illness; and helping people adapt to the residual effects of illness. Many of these nursing activities are accomplished through patient education. Nurses are challenged to focus on the health education needs of communities and to provide specific patient and family education. Health education is important to nursing care because it affects the abilities of people and families to perform important self-care activities.

Every contact a nurse has with a health care consumer, whether or not that person is ill, should be considered an opportunity for health education. Although people have a right to decide whether to learn, nurses have the responsibility to present information that motivates people to recognize the need to learn. Therefore, nurses must use opportunities in all health care settings to promote wellness. There are many educational environments. Some examples include homes, hospitals, community health centers, schools, places of business, service agencies, shelters, and consumer action or support groups (deChesnay & Anderson, 2020).

Supporting Informed Decision Making and Self-Care

The emphasis on health education stems in part from the public's right to comprehensive health care, which includes up-to-date health information. It also reflects the emergence of an informed public that is asking more questions about health and health care. Because of the importance that American society places on health and the responsibility that all people must maintain and promote their own health, members of

the health care team, specifically nurses, are obligated to make health education available. Significant factors to consider when planning patient education include the availability of health care, the use of diverse health care providers to accomplish care management goals, and the increased use of complementary and alternative strategies rather than traditional approaches to care. Without adequate knowledge and training in self-care skills, consumers cannot make informed decisions about their health. Guidance from nurses may assist consumers to obtain health information from trustworthy, credible, and timely Internet resources, as well as from appropriate health promotion practitioners and researchers (Cohn, Lyman, Broshek, et al., 2018). People with chronic illnesses and disability are among those most in need of health education. As the lifespan of the population increases, the number of people with such illnesses also increases. Health information targeted at identifying and managing the exacerbations or issues commonly associated with having a chronic illness or disability is a major focus of health education. People with chronic illness need health care information to participate actively in and assume responsibility for self-care. Health education can help those with chronic illness adapt to their illness, prevent complications, carry out prescribed therapy, and solve problems when confronted with new situations. It can also help to prevent crisis situations and reduce the potential for rehospitalization resulting from inadequate information about self-care. The goal of health education is to teach people to live a healthy life and strive toward achieving their maximum health potential.

In addition to the public's right to and desire for health education, patient education is also a strategy for promoting self-care at home and in the community, reducing health care costs by preventing illness, effectively managing necessary therapies, avoiding expensive medical interventions, decreasing lengths of hospital stay, and facilitating earlier discharge. For health care agencies, offering community wellness programs is a public relations tool for increasing patient satisfaction and for developing a positive image of the institution. Patient education is also a cost-avoidance strategy in that positive staff–patient relationships may avert malpractice suits. Some insurance companies support health education through reimbursement for programs, such as diabetes management classes and fitness and weight management programs.

Promoting Adherence to the Therapeutic Regimen

One of the goals of patient education is to encourage people to adhere to their **therapeutic regimen** (a routine that promotes health and healing). **Adherence** (the process of faithfully following guidelines or directions) to treatment usually requires that a person make one or more lifestyle changes to carry out specific activities that promote and maintain health. Common examples of behaviors facilitating health include taking prescribed medications, maintaining a healthy diet, increasing daily activities and exercise, self-monitoring for signs and symptoms of illness and changes in baseline health status, practicing specific hygiene measures, seeking recommended health evaluations and screening, and performing other therapeutic and preventive measures.

Factors Affecting Adherence

Many people do not adhere to their prescribed regimens; rates of adherence are generally low, especially when the regimens are complex or of long duration (e.g., therapy for chronic inflammatory rheumatic diseases, hypertension, breast cancer, human immune deficiency virus [HIV] infection, hemodialysis). Nonadherence to prescribed therapy has been the subject of many studies (Al-Noumani, Wu, Barksdale, et al., 2019; Hine, Smith, Eshun-Wilson, et al., 2018; Lambert, Balneaves, Howard, et al., 2018; Lavielle, Puyraimond-Zenmour, Romand, et al., 2018). For the most part, findings have been inconclusive, and no one predominant causative factor has been identified. Instead, a wide range of variables influences the degree of adherence, including the following:

- Demographic variables, such as age, gender, race, socioeconomic status, and level of education
- Illness variables, such as the severity of the illness and the relief of symptoms afforded by the therapy
- Therapeutic regimen variables, such as the complexity of the regimen, treatment fatigue, and uncomfortable side effects
- Psychosocial variables, such as intelligence, motivation, availability of significant and supportive people (especially family members and significant others), competing or conflicting demands, attitudes toward health professionals, acceptance or denial of illness, substance abuse, and religious or cultural beliefs
- Financial variables, especially the direct and indirect costs associated with a prescribed regimen

Another factor to consider when the nurse is developing strategies to promote patient adherence is the concept of **health literacy** or the capability of a person to obtain, communicate, process, and understand essential health information for the purpose of securing health care services and for making health care decisions. A challenge for all health care providers is to improve the health literacy of patients. In establishing suitable health education materials, technologic innovations and services, providers must communicate health information in plain language and work with patients to promote accurate processing and understanding of the health information. Nurses must consider their knowledge of the myriad factors that affect health literacy in any given population. The primary factors influencing health literacy are the effective use of communication and cultural skills, along with the presentation of health care information, and a basic background of mathematical skills. Without such skills, patients are at risk for being unable to share personal health information, perform self-care management for both acute and chronic health conditions, navigate through health systems and complete health forms, and calculate information such as nutritional information on food labels (Carrara & Schulz, 2018; Osborne, 2018).

Health literacy skills are basic to understanding the body and how it functions, assessing lifestyle choices along with the variables that cause and perpetuate disease, as well as making health care decisions. If people have low health literacy, the consequence is poor overall health. Deconstructing this cycle of low health literacy leading to poor health status and higher risk of health problems is essential. To increase health literacy, providers must design and distribute accurate health information and must ensure that these health materials are culturally appropriate for various populations. It is imperative to build community partnerships to support education and public health activities. Nurses can be instrumental in performing evaluation research on the educational undertakings that support individuals, groups, or communities. Furthermore, nurses must be directly involved in facilitating change through the development of health care policies that address the promotion of a health literate society (Patton, Zalon, & Ludwick, 2019).

Nurses' success with health education is determined by both the development of strong health literacy and the ongoing assessment of the variables that affect patients' ability to adopt specific behaviors to obtain resources, and maintain a healthy social environment (Edelman & Kudzma, 2018). Programs are more likely to succeed if patients have

improved health literacy and providers pay careful attention to the variables affecting patient adherence. Both health literacy and the concept of adherence must be considered in the patient's teaching plan. Teaching strategies are discussed later in the chapter.

Motivation

The problem of nonadherence to therapeutic regimens is substantial and must be addressed before patients can achieve their maximum health potential. Patients' need for knowledge has not been found to be a sufficient stimulus for acquiring knowledge and thereby enabling complete adherence to a health regimen. Teaching directed toward stimulating patient motivation results in varying degrees of adherence. Research suggests that factors such as personal relevance of strategies for self-care, perceived control, and type of health problem must also be considered (Seibre, Toumpakari, Turner, et al., 2018; Whiteley, Brown, Lally, et al., 2018). The variables of choice, establishment of mutual goals, and quality of the patient–provider relationship also influence the behavioral changes that can result from patient education. Many factors are linked to motivation for learning.

Using a learning contract or agreement can also be a motivator for learning. Such a contract is based on assessment of patient needs; health care data; and specific, measurable goals (Miller & Stoeckel, 2019). The learning contract is recorded in writing and contains methods for ongoing evaluation. A well-designed learning contract is realistic and positive. In a typical learning contract, a series of measurable goals is established, beginning with small, easily attainable objectives and progressing to more advanced goals. Frequent, positive reinforcement is provided as the person moves from one goal to the next. For example, incremental goals such as weight loss of 1 to 2 pounds per week are more appropriate in a weight reduction program than a general goal such as a 30-pound weight loss.

Gerontologic Considerations

Nonadherence to therapeutic regimens is a significant problem for older adults, leading to increased morbidity, mortality, and cost of treatment (Abada, Clark, Sinha, et al., 2019; Taylor, Coogle, Cotter, et al., 2019). Many admissions to nursing homes and hospitals are associated with nonadherence.

Older adults frequently have one or more chronic illnesses that are managed with numerous medications, and their disease course may be complicated by periodic acute episodes (Miller, 2019). Older adults may have additional issues that affect adherence to therapeutic regimens, such as increased sensitivity to medications and their side effects, difficulty in adjusting to change and stress, financial constraints, forgetfulness, inadequate support systems, lifetime habits of self-treatment with over-the-counter medications, visual and hearing impairments, and mobility limitations. To promote adherence among older adults, all variables that may affect health behavior should be assessed (Fig. 3-1). Nurses must also consider that cognitive impairment may result in the older adult's inability to draw inferences, apply information, or understand the major points (Mauk, 2017; Touhy & Jett, 2018). The person's strengths and limitations must be assessed to encourage the use of existing strengths to compensate for limitations. Above all, health care professionals must work together to provide continuous, coordinated care; otherwise, the efforts of one health care professional may be negated by those of another.

The Nature of Teaching and Learning

Learning can be defined as acquiring knowledge, attitudes, or skills. **Teaching** is defined as helping another person learn. These definitions indicate that the teaching–learning process is an active one, requiring the involvement of both the teacher and the learner in the effort to reach the desired outcome—a change in behavior. The teacher does not simply give knowledge to the learner but instead serves as a facilitator of learning. Although learning can take place without teachers, most people who are attempting to learn new or altered health behaviors benefit from contact with a nurse. The interpersonal interaction between the person and the nurse who is attempting to meet the person's learning needs may be formal or informal, depending on the method and techniques of teaching.

Figure 3-1 • Taking time to teach patients about their medication and treatment program promotes interest and cooperation. Older adults who are actively involved in learning about their medication and treatment program and the expected effects may be more likely to adhere to the therapeutic regimen.

There is no definitive theory about how learning occurs and how it is affected by teaching. However, learning can be affected by factors, such as readiness to learn, the learning environment, and the teaching techniques used (Miller & Stoeckel, 2019).

Learning Readiness

One of the most significant factors influencing learning is a person's **learning readiness** or the optimum time for learning to occur, which usually corresponds to the learner's perceived need and desire to obtain specific knowledge. For adults, readiness is based on culture, personal values, physical and emotional status, and past experiences in learning. The "teachable moment" occurs when the content and skills being taught are congruent with the task to be accomplished (Miller & Stoeckel, 2019).

Culture encompasses values, ideals, and behaviors, and the traditions within each culture provide the framework for solving the issues and concerns of daily living. Because people with different cultural backgrounds have different values and lifestyles, choices about health care vary. Culture is a major variable influencing readiness to learn because it affects how people learn and what information can be learned. Sometimes people do not accept health teaching because it conflicts with culturally mediated values. Before beginning health teaching, nurses must conduct an individual cultural assessment instead of relying only on generalized assumptions about a particular culture. A patient's social and cultural patterns must be appropriately incorporated into the teaching–learning interaction. See Chapter 4, Chart 4-7, which describes cultural assessment components to consider when formulating a teaching plan.

A person's values include beliefs about behaviors that are desirable and undesirable. The nurse must know what value the patient places on health and health care. In clinical situations, patients express their values through their actions and the level of knowledge pursued (deChesnay & Anderson, 2020). When the nurse is unaware of the patient's values (cultural and personal), misunderstanding, lack of cooperation, and negative health outcomes may occur (McFarland & Wehbe-Alamah, 2018). A person's values and behaviors can be either an asset or a deterrent to readiness to learn. Therefore, patients are unlikely to accept health education unless their values and beliefs about health and illness are respected (Kersey-Matusiak, 2018).

Physical readiness is of vital importance, because until the person is physically capable of learning, attempts at teaching and learning may be both futile and frustrating. For example, a person in acute pain is unable to focus attention away from the pain long enough to concentrate on learning. Likewise, a person who is short of breath concentrates on breathing rather than on learning.

Emotional readiness also affects the motivation to learn. A person who has not accepted an existing illness or the threat of illness is not motivated to learn. A person who does not accept a therapeutic regimen, or who views it as conflicting with their present lifestyle, may consciously avoid learning about it. Until the person recognizes the need to learn and demonstrates an ability to learn, teaching efforts may be thwarted. However, it is not always wise to wait for the person to become emotionally ready to learn, because that time may never come unless the nurse makes an effort to stimulate the person's motivation. For example, a person with colon cancer who has a fasting blood sugar twice

the expected normal value may focus only on the cancer diagnosis and exclude or deny the health consequences of an abnormal blood sugar.

Illness and the threat of illness are usually accompanied by anxiety and stress. Nurses who recognize such reactions can use simple explanations and instructions to alleviate these anxieties and provide further motivation to learn. Because learning involves behavior change, it often produces mild anxiety, which can be a useful motivating factor.

Emotional readiness can be promoted by creating a warm, accepting, positive atmosphere and by establishing realistic learning goals. When learners achieve success and a feeling of accomplishment, they are often motivated to participate in additional learning opportunities. One example of a strategy that facilitates learner success is the teach-back technique. This technique is used to evaluate the recall and understanding of the learner after health teaching has occurred. It is a useful, in-the-moment feedback and evaluation method because it allows the educator to discover if the learner can effectively verbalize information or demonstrate a particular health behavior (Miller & Stoeckel, 2019). In addition, the teach-back strategy can be used with family members and caregivers to ascertain if they have retained and understood the health content. Having a strategy to actively involve the adult learner in making health care decisions and performing self-management skills promotes learner receptivity and motivation to integrate health principles into one's daily life. Furthermore, **feedback** (the return of information given to a person) about progress also motivates learning. Such feedback should be presented in the form of positive reinforcement when the learner is successful, and in the form of constructive suggestions for improvement when the learner is unsuccessful.

Experiential readiness refers to past experiences that influence a person's ability to learn. Previous educational experiences and life experiences in general are significant determinants of a person's approach to learning. People with little or no formal education may not be able to understand the instructional materials presented. People who have had difficulty learning in the past may be hesitant to try again. Many behaviors required for reaching maximum health potential require knowledge, physical skills, and positive attitudes. In their absence, learning may be very difficult and very slow. For example, a person who does not understand the basics of normal **nutrition** (the science that deals with food and nourishment in humans) may not be able to understand the restrictions of a specific diet. A person who does not view

the desired learning as personally meaningful may reject teaching efforts. A person who is not future oriented may be unable to appreciate many aspects of preventive health teaching. Experiential readiness is closely related to emotional readiness, because motivation tends to be stimulated by an appreciation for the need to learn and by those learning tasks that are familiar, interesting, and meaningful.

The Learning Environment

Learning may be optimized by minimizing factors that interfere with the learning process. For example, the room temperature, lighting, noise levels, use of functional assistive devices such as glasses and hearing aids, and other environmental conditions should be appropriate to the learning situation. In addition, the time selected for teaching should be suited to the needs of the individual person. Scheduling a teaching session at a time of day when a patient is fatigued, uncomfortable, or anxious about a pending diagnostic or therapeutic procedure, or when visitors are present, is not conducive to learning. However, if the family is to participate in providing care, the sessions should be scheduled when family members are present so that they can learn any necessary skills or techniques.

Teaching Techniques and Resources

Teaching techniques and methods enhance learning if they are appropriate to the patient's needs. Nurses use a variety of teaching techniques to educate patients in many different settings. Techniques that are available include the following:

- *Lectures:* Lectures are explanation methods of teaching and should be accompanied by discussion, because discussion affords learners opportunities to express their feelings and concerns, ask questions, and receive clarification.
- *Group teaching:* Group teaching allows people not only to receive needed information but also to feel secure as members of a group (promoting moral support). Assessment and follow-up are imperative to ensure that each person has gained sufficient knowledge and skills. Not all patients relate or learn well in groups.
- *Demonstration and practice:* Demonstration and practice are especially important when teaching skills. The nurse should

demonstrate the skill and then give the learner ample opportunity for practice. When special equipment is involved, such as syringes or colostomy bags, it is important to teach with the same equipment that will be used in the home setting to avoid confusion, frustration, and mistakes.

- *Reinforcement and follow-up:* Nurses must allow ample time for patients to learn and provide reinforcement. Follow-up sessions are imperative to promote the learner's confidence in their abilities and to plan for additional teaching sessions.
- *Motivational interviewing:* Pilot research suggests that using motivational interviewing as an enhanced educational method in an acute inpatient setting can increase both patient and caregiver knowledge as well as patient self-care (McKillop, Grace, de Melo Ghisi, 2018).
- *Electronic, online, or Internet information:* Electronic technologies are used to provide health information. Examples are interactive or noninteractive Internet learning, an online self-paced program, or a structured online course. There are also DVD, CD-ROM, podcasts, and recorded programs available over a television channel.
- *Teaching aids:* Teaching aids include books, pamphlets, pictures, films, slides, audiotapes, models, programmed instruction, other visual aids (e.g., charts), mobile device applications, and computer-assisted learning modules. They are invaluable when used appropriately and can save a significant amount of personnel time and related cost. However, all such aids should be reviewed before use to ensure that they meet the patient's learning needs and are free of advertisements that may confuse the patient. (See Resources section at the end of the chapter for additional information.)

The likelihood of success for educating patients is maximized when nurses, families, and other health care professionals work collaboratively to facilitate learning. Successful learning should result in improved self-care management skills, enhanced self-esteem, confidence, and a willingness to learn in the future. There are specific considerations for educating special populations. Table 3-1 outlines some of the strategies to use when educating people with disability. (See Chapters 7 and 8 for additional teaching strategies for people with disability and older adults.)

The Nursing Process in Patient Education

The nurse relies on the steps of the nursing process when constructing an individualized teaching plan to meet the patient's teaching and learning needs (Chart 3-1).

TABLE 3-1 Educating People with Disability

Type of Disability	Educational Strategy
Physical, Emotional, or Cognitive Disability	Adapt information to accommodate the person's cognitive, perceptual, and behavioral disabilities. Give clear written and oral information. Highlight significant information for easy reference. Avoid medical terminology or "jargon."
Hearing Impairment	Use slow, directed, deliberate speech. Use sign language or interpreter services if appropriate. Position yourself so that the person can see your mouth if speech reading. Use telecommunication devices (TTY or TDD) for the person with hearing impairment. Use written materials and visual aids, such as models and diagrams. Use captioned videos, films, and computer-generated materials. Speak on the side of the "good ear" if unilateral deafness is present.
Sensory Disability	Use optical devices such as a magnifying lens. Use proper lighting and proper contrast of colors on materials and equipment. Use or convert information to auditory and tactile formats if appropriate (e.g., Braille or large-print materials). Obtain audiotapes, CDs, digital audio available on smartphones or tablets, and talking books. Explain noises associated with procedures, equipment, and treatments. Arrange materials in clockwise pattern.
Learning Disabilities Input disability	If visual perceptual disorder: Explain information verbally; repeat and reinforce frequently. Use audiotapes, CDs, and digital audio. Encourage learner to verbalize information received. If auditory perceptual disorder: Speak slowly with as few words as possible; repeat and reinforce frequently. Use direct eye contact (as appropriate for the person's culture) to help focus on the task. Use demonstration and return demonstration, such as modeling, role-playing, and hands-on experiences. Use visual tools; written materials; and computers, tablets, and smartphones.
Output disability	Use all senses as appropriate.

	Use written, audiotape, and computerized or other electronic information. Review information and give time verbally to interact and ask questions. Use hand gestures and motions.
Developmental disability	Base information and teaching on developmental stage, not chronologic age. Use nonverbal cues, gestures, signing, and symbols as needed. Use simple explanations and concrete examples with repetition. Encourage active participation. Demonstrate information, and have person perform return demonstrations.

Assessment

Assessment in the teaching–learning process is directed toward the systematic collection of data about the patient's and family's learning needs and readiness to learn. The nurse identifies all internal and external variables that affect the patient's readiness to learn. Many learning assessment guides are available. Some guides are directed toward the collection of general health information (e.g., healthy eating), whereas others are specific to medication regimens or disease processes (e.g., stroke risk assessments). Such guides facilitate assessment but must be adapted to the responses, problems, and needs of each person. The nurse organizes, analyzes, synthesizes, and summarizes the assessment data collected and determines the patient's need for teaching.

Nursing Diagnosis

The process of formulating nursing diagnoses makes educational goals and evaluations of progress more specific and meaningful. Teaching is an integral intervention implied by all nursing diagnoses, and for some diagnoses, education is the primary intervention. Examples of nursing diagnoses that help in planning for educational needs are impaired health maintenance and decisional conflict. A nursing diagnosis that relates specifically to a patient's and family's learning needs serves as a guide in the development of the teaching plan.

Planning

Once the nursing diagnoses have been identified, the planning component of the teaching–learning process is established in accordance with the steps of the nursing process:

1. Assigning priorities to the diagnoses
2. Specifying the immediate, intermediate, and long-term goals of learning
3. Identifying specific teaching strategies appropriate for attaining goals
4. Specifying the expected outcomes
5. Documenting the diagnoses, goals, teaching strategies, and expected outcomes of the teaching plan

The assignment of priorities to the diagnoses should be a collaborative effort by the nurse and the patient or family members. Consideration must be given to the urgency of the patient's learning needs; the most critical needs should receive the highest priority.

Chart 3-1

Summary of the Nursing Process for Individualized Patient Education

Assessment

1. Assess the person's readiness for health education.
   a. What are the person's health beliefs and behaviors?
   b. What physical and psychosocial adaptations does the person need to make?
   c. Is the learner ready to learn?
   d. Is the person able to learn these behaviors?
   e. What additional information about the person is needed?
   f. Are there any variables (e.g., hearing or visual impairment, cognitive issues, literacy issues) that will affect the choice of teaching strategy or approach?
   g. What are the person's expectations?
   h. What does the person want to learn?
2. Organize, analyze, synthesize, and summarize the collected data.

Nursing Diagnosis

1. Formulate the nursing diagnoses that relate to the person's learning needs.
2. Identify the learning needs, their characteristics, and their etiology.

Planning

1. Assign priority to the nursing diagnoses that relate to the person's learning needs.
2. Specify the immediate, intermediate, and long-term learning goals established by teacher and learner together.
3. Identify teaching strategies appropriate for goal attainment.
4. Establish expected outcomes.
5. Develop the written teaching plan.
   a. Include diagnoses, goals, teaching strategies, and expected outcomes.
   b. Put the information to be taught in logical sequence.
   c. Write down the key points.
   d. Select appropriate teaching aids.
   e. Keep the plan current and flexible to meet the person's changing learning needs.
6. Involve the learner, family or significant others, nursing team members, and other health care team members in all aspects of planning.

Implementation

1. Put the teaching plan into action.
2. Use language that the person can understand.
3. Use appropriate teaching aids and provide Internet resources if appropriate.
4. Use the same equipment that the person will use after discharge.
5. Encourage the person to participate actively in learning.
6. Record the learner's responses to the teaching actions.
7. Provide feedback.

Evaluation

1. Collect objective data.
   a. Observe the person.
   b. Ask questions to determine whether the person understands.
   c. Use rating scales, checklists, anecdotal notes, and written tests when appropriate.
2. Compare the person's behavioral responses with the expected outcomes. Determine the extent to which the goals were achieved.
3. Include the person, family or significant others, nursing team members, and other health care team members in the evaluation.
4. Identify alterations that need to be made in the teaching plan.
5. Make referrals to appropriate sources or agencies for reinforcement of learning after discharge.
6. Continue all steps of the teaching process: assessment, diagnosis, planning, implementation, and evaluation.

Concept Mastery Alert

The nurse needs to keep in mind that before the teaching strategy can be determined, the goals of learning must be developed.

After the diagnostic priorities have been mutually established, it is important to identify the immediate and long-term goals and the teaching strategies appropriate for attaining the goals. Teaching is most effective when the objectives of both the patient and the nurse are in agreement (Bastable, 2017). Learning begins with the establishment of goals that are appropriate to the situation and realistic in terms of the patient's ability and desire to achieve them. Involving the patient and family in

establishing goals and in planning teaching strategies promotes their cooperation in the implementation of the teaching plan.

Outcomes of teaching strategies can be stated in terms of expected behaviors of patients, families, or both. Outcomes should be realistic and measurable, and the critical time periods for attaining them should be identified. The desired outcomes and the critical time periods serve as a basis for evaluating the effectiveness of the teaching strategies.

During the planning phase, the nurse must consider the sequence in which the subject matter is presented. Critical information (e.g., survival skills for a patient with diabetes) and material that the person or family identifies to be of particular importance must receive high priority. An outline is often helpful for arranging the subject matter and for ensuring that all necessary information is included. In addition, appropriate teaching aids to be used in implementing teaching strategies are prepared or selected at this time. Patient Education charts throughout this textbook guide teaching about self-care.

The entire planning phase concludes with the formulation of the teaching plan. This teaching plan communicates the following information to all members of the nursing team:

- The nursing diagnoses that specifically relate to the patient's learning needs and the priorities of these diagnoses
- The goals of the teaching strategies
- The teaching strategies that are appropriate for goal attainment
- The expected outcomes, which identify the desired behavioral responses of the learner
- The critical time period within which each outcome is expected to be met
- The patient's behavioral responses (which are documented on the teaching plan)

The same rules that apply to writing and revising the plan of nursing care apply to the teaching plan.

Implementation

In the implementation phase of the teaching–learning process, the patient, family, and other members of the nursing and health care team carry out the activities outlined in the teaching plan. The nurse coordinates these activities.

Flexibility during the implementation phase of the teaching–learning process and ongoing assessment of patient responses to the teaching strategies support modification of the teaching plan as necessary. Creativity in promoting and sustaining the patient's motivation to learn is essential. New learning needs that may arise after discharge from the hospital or after home care visits have ended should also be taken into account.

The implementation phase ends when the teaching strategies have been completed and when the patient's responses to the actions have been recorded. This serves as the basis for evaluating how well the defined goals and expected outcomes have been achieved.

Evaluation

Evaluation of the teaching–learning process determines how effectively the patient has responded to teaching and to what extent the goals have been achieved. An evaluation must be made to determine what was effective and what needs to be changed or reinforced. It cannot be assumed that patients have learned just because teaching has occurred; learning does not automatically follow teaching. An important part of the evaluation phase addresses the question, "What could be done to improve teaching and enhance learning?" Answers to this question direct the changes to be made in the teaching plan.

Various measurement techniques can be used to identify changes in patient behavior as evidence that learning has taken place. These techniques include directly observing the behavior; using rating scales, checklists, or anecdotal notes to document the behavior; and indirectly measuring results using oral questioning and written tests. All direct measurements should be supplemented with indirect measurements whenever possible. Using more than one measuring technique enhances the reliability of the resulting data and decreases the potential for error from a measurement strategy.

In many situations, measurement of actual behavior is the most accurate and appropriate evaluation technique. Nurses often perform comparative analyses using patient admission data as the baseline: Selected data points observed when nursing care is given and self-care is initiated are compared with the patient's baseline data. In other cases, indirect measurement may be used. Some examples of indirect measurement are patient satisfaction surveys, attitude surveys, and instruments that evaluate specific health status variables.

Measurement is only the beginning of evaluation, which must be followed by data interpretation and judgments about learning and teaching. These aspects of evaluation should be conducted periodically throughout the teaching–learning program, at its conclusion, and at varying periods after the teaching has ended.

Evaluation of learning after teaching that occurs in any setting (e.g., clinics, offices, nursing centers, hospitals) is essential, because the analysis of teaching outcomes must extend into aftercare. With shortened lengths of hospital stay and with short-stay and same-day surgical procedures, follow-up evaluation is especially important. Coordination of efforts and sharing of information between hospital- and community-based nursing personnel facilitate postdischarge teaching and home care evaluation.

Evaluation is not the final step in the teaching–learning process but is the beginning of a new patient assessment. The information gathered during evaluation should be used to redirect teaching actions, with the goal of improving the patient's responses and outcomes.

Health Promotion

Health teaching and health promotion are linked by a common goal—to encourage people to achieve as high a level of wellness as possible so that they can live maximally healthy lives and avoid preventable illnesses. The call for health promotion has become a cornerstone in health policy because of the need to control costs and reduce unnecessary sickness and death.

Health goals for the nation are established in the publication *Healthy People 2030.* The priorities from this initiative were identified as health promotion, health protection, and the use of preventive services. *Healthy People 2030* defines the current national health promotion and disease prevention initiative for the nation. Measurable goals for key health topics for the nation are shown in Chart 3-2. The overall goals are to (1) increase the quality and years of healthy life for people and (2) eliminate health disparities among various segments of the population (Haskins, 2017; U.S. Department of Health and Human Services, 2017).

Definition

Health promotion may be defined as those activities that assist people in developing resources that maintain or enhance well-being and improve their quality of life. These activities involve people's efforts to remain healthy in the absence of symptoms, may not require the assistance of a health care team member, and occur within or outside of the health system (Haber, 2019; O'Donnell, 2017).

Chart 3-2

Select Topics from the Proposed Objectives for *Healthy People 2030*

Access to Health Services
Adolescent Health
Arthritis, Osteoporosis, and Chronic Back Conditions
Blood Disorders and Blood Safety
Cancer
Chronic Kidney Disease
Dementias, Including Alzheimer's Disease
Diabetes
Disability and Health
Educational and Community-Based Programs

Adapted from Haskins, J. (2017). Healthy People 2030 to create objectives for health of nation: Process underway for next 10-year plan. *The Nation's Health*, *47*(6), 1–14; U.S. Department of Health and Human Services. (2017). *Healthy People 2030*. Retrieved on 7/15/2019 at: www.healthypeople.gov/2020/About-Healthy-People/Development-Healthy-People-2030/framework

The purpose of health promotion is to focus on the person's potential for wellness and to encourage appropriate alterations in personal habits, lifestyle, and environment in ways that reduce risks and enhance health and well-being. As discussed in Chapter 1, health is viewed as a dynamic, ever-changing condition that enables people to function at an optimal potential at any given time, whereas wellness, a reflection of health, involves a conscious and deliberate attempt to maximize one's health. Health promotion is an active process—that is, it is not something that can be prescribed or dictated. It is up to each person to decide whether to make changes to promote a higher level of wellness. Only the individual can make these choices.

Health Promotion Models

Several health promotion models identify health-protecting behaviors and seek to explain what makes people engage in preventive behaviors. A health-protecting behavior is defined as any behavior performed by people, regardless of their actual or perceived health condition, for the purpose of promoting or maintaining their health, whether or not the behavior produces the desired outcome (Murdaugh, Parsons, & Pender, 2019).

The Health Belief Model was designed to foster understanding of why some healthy people choose actions to prevent illness while others do not. Developed by Becker (1974), the model is based on the premise that four variables influence the selection and use of health promotion behaviors. Demographic and disease factors, the first variable, include patient characteristics, such as age, gender, education, employment, severity of illness or disability, and length of illness. Barriers, the second variable, are defined as factors leading to unavailability or difficulty in gaining access to a specific health promotion alternative. Resources, the third variable, encompass such factors as financial and social support. Perceptual factors, the fourth variable, consist of how the person views his or her health status, self-efficacy, and the perceived demands of the illness. Further research has demonstrated that these four variables have a positive correlation with a person's quality of life (Becker, Stuifbergen, Oh, et al., 1993).

Another model, the Resource Model of Preventive Health Behavior, addresses the ways in which people use resources to promote health (Murdaugh et al., 2019). It is based on Social Learning Theory and emphasizes the importance of motivational factors in acquiring and sustaining health promotion behaviors. This model explores how cognitive-perceptual factors affect the person's view of the importance of health. It also examines perceived control of health, self-efficacy, health status, and the benefits and barriers to health-promoting behaviors. Nurse educators can use this model to assess how demographic variables, health behaviors, and social and health resources influence health promotion.

The Canadian health promotion initiative, Achieving Health for All, builds on the work of Lalonde (1977), in which four determinants of health—human biology, environment, lifestyle, and the health care delivery system—were identified. Determinants of health were defined as factors and conditions that have an influence on the health of

individuals and communities. Since the 1970s, a total of 12 health determinants have been identified, and this number will continue to increase as population health research progresses. Determinants of health provide a framework for assessing and evaluating the population's health.

A model crafted to address organizational and individual health behavior change is the Awareness, Motivation, Skills, and Opportunity (AMSO) Model. The four components of this model focus on empowering people, understanding their individual priorities, and assisting them to change in personal ways that promote and maintain their optimal level of health. The dimensions of optimal health are physical, emotional, social, intellectual, and spiritual. This model promotes the process of creating and maintaining a balance among these five dimensions (O'Donnell, 2017). Optimal health is a dynamic condition kept in balance by a combination of efforts to sustain awareness, maintain motivation, build skills, and have opportunities to practice positive health behaviors.

The Transtheoretical Model of Change, also known as the Stages of Change Model, is a framework that focuses on the motivation of a person to make decisions that promote healthy behavior change (DiClemente, 2007). Table 3-2 shows the six stages in the model. Research indicates that people working with health professionals progress through these stages of change (Blake, Stanulewicz, & McGill, 2017; Chen, Palmer, & Lin, 2018; Das, Rouseff, Guzman, et al., 2019; Wen, Li, Wang, et al., 2018). Any of the models can serve as an organizing framework for clinical work and research that support the enhancement of health. Research suggests that the application of health promotion models, concepts, and frameworks increases the nurse's understanding of the health promotion behaviors of families and communities (Støle, Nilsen, & Joranger, 2019).

TABLE 3-2 Stages in the Transtheoretical Model of Change

Stage	Description
1. Precontemplative	The person is not thinking about making a change.
2. Contemplative	The person is only thinking about change in the near future.
3. Decision making	The person constructs a plan to change behavior.
4. Action	The person takes steps to operationalize the plan of action.
5. Maintenance	The person works to prevent relapse and to sustain the gains made from the actions taken.
6. Termination	The person has the ability to resist relapse back to unhealthy behavior(s).

Adapted from DiClemente, C. (2007). The transtheoretical model of intentional behavior change. *Drugs & Alcohol Today*, *7*(1), 29–33; Miller, C. A. (2019). *Nursing for wellness in older adults* (8th ed.). Philadelphia, PA: Wolters Kluwer.

Components of Health Promotion

Health promotion as an active process includes the following components: self-responsibility, nutritional awareness, stress reduction and management, and physical fitness.

Self-Responsibility

Taking responsibility for oneself is the key to successful health promotion. The concept of **self-responsibility**, personal accountability for one's actions or behavior, is based on the understanding that individuals control their lives. Each person alone must make the choices that determine the health of his or her lifestyle. As more people recognize that lifestyle and behavior significantly affect health, they may assume responsibility for avoiding high-risk behaviors, such as smoking or use of any electronic nicotine delivery systems (ENDS) (including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars), misuse of alcohol as well as prescription drugs and illegal drugs, overeating, driving under the influence, risky sexual practices, and other unhealthy habits. They may also assume responsibility for adopting routines that have been found to have a positive influence on health, such as engaging in regular exercise, wearing seat belts, and eating a healthy diet.

Various techniques have been used to encourage people to accept responsibility for their health, including public service announcements, educational programs, and reward systems. No one technique has been found to be superior to any other. Instead, self-responsibility for health

promotion is individualized and depends on a person's desires and inner motivations. Health promotion programs are important tools for encouraging people to assume responsibility for their health and to develop behaviors that improve health.

Nutritional Awareness

Nutrition, as a component of health promotion, has become the focus of considerable attention and publicity with the growing epidemic of obesity in the United States. A vast array of books and magazine articles address the topics of special diets; natural foods; and the hazards associated with certain substances, such as sugar, salt, cholesterol, trans fats, carbohydrates, artificial colors, and food additives. Research suggests that good nutrition is the single most significant factor in determining health status, longevity, and weight control (U.S. Department of Agriculture and U.S. Department of Health and Human Services, 2015).

Nutritional awareness involves an understanding of the importance of a healthy diet that supplies all essential nutrients. Understanding the relationship between diet and disease is an important facet of a person's self-care. Some clinicians believe that a healthy diet is one that substitutes "natural" foods for processed and refined ones and reduces the intake of sugar, salt, fat, cholesterol, caffeine, alcohol, food additives, and preservatives.

Chapter 4 contains further information about the assessment of a person's nutritional status. It describes the physical signs indicating nutritional status, assessment of food intake (food record, 24-hour recall), the dietary guidelines presented in the MyPlate plan (see Fig. 4-5), and calculation of body mass index (see Table 4-1).

Stress Reduction and Management

Stress management (behaviors and techniques used to strengthen a person's resources against stress), and stress reduction are important aspects of health promotion. Studies suggest the negative effects of stress on health and a cause-and-effect relationship between stress and infectious diseases, traumatic injuries (e.g., motor vehicle crashes), and some chronic illnesses. Stress has become inevitable in contemporary societies in which demands for productivity have become excessive. More and more emphasis is placed on encouraging people to manage stress appropriately and to reduce the pressures that are

counterproductive. Research suggests that including techniques such as relaxation training, exercise, yoga, and modification of stressful situations in health promotion programs assist patients in dealing with stress (Davidson, Graham, Montross-Thomas, et al., 2017; Hoogland, Lechner, Gonzalez, et al., 2018; Kim, Lee, Lee, et al., 2019; Morgan, Hourani, & Tueller, 2017; Moscoso, Goese, Van Hyfte, et al., 2019; Yadav, Yadav, Sarvottam, et al., 2017). Further information on stress management, including health risk appraisal and stress reduction methods such as the Benson Relaxation Response, can be found in Chapter 5.

Physical Fitness

Physical fitness (the condition of being physically healthy as a result of proper exercise and nutrition) is an important component of health promotion. Clinicians and researchers (Katsura, Takeda, Hara, et al., 2019; Loprinzi & Wade, 2019; Wisnieski, Dalimente-Merckling, & Robbins, 2019) who have examined the relationship between health and physical fitness have found that a regular exercise program can promote health in the following ways:

- Improve the function of the circulatory system and the lungs
- Decrease cholesterol and low-density lipoprotein levels
- Decrease body weight by increasing calorie expenditure
- Delay degenerative changes such as osteoporosis
- Improve flexibility and overall muscle strength and endurance

An appropriate exercise program can have a positive effect on a person's performance capacity, appearance, and level of stress and fatigue, as well as their general state of physical, mental, and emotional health (Gilbertson, Mandelson, Hilovsky, et al., 2019; Ma, West, Martin Ginis, et al., 2019; Pettigrew, Burton, Farrier, et al., 2019). An exercise program should be designed specifically for a given person, with consideration to age, physical condition, and any known cardiovascular or other risk factors. Exercise can be harmful if it is not started gradually and increased slowly in accordance with a person's response.

A significant amount of research suggests that people, by virtue of what they do or fail to do, influence their own health. Many diseases and disorders (e.g., diabetes, coronary artery disease, lung and colon cancer, chronic obstructive pulmonary diseases, hypertension, cirrhosis, traumatic injury, HIV infection) have been closely related to lifestyle behaviors. To a large extent, a person's health status may be reflective of

their lifestyle. For example, there is research examining how emerging adult patients with inflammatory bowel disease self-manage their chronic condition through the use of social support (Kamp, Luo, Holmstrom, et al., 2019). (See the Nursing Research Profile in Chart 3-3.)

Chart 3-3 **NURSING RESEARCH PROFILE**

Adherence to a Medication Regimen and Informational Support

Kamp, K. J., Luo, Z., Holmstrom, A., et al. (2019). Self-management through social support among emerging adults with inflammatory bowel disease. *Nursing Research*, *68*(4), 285–295.

Purpose

The purpose of this study was to examine the relationship between two conceptualizations of social support, (the first type was received social support and the second type was perceived availability of social support) and the self-management behaviors by emerging adults ages 18 to 29 years with inflammatory bowel disease (IBD).

Design

In this quantitative, cross-sectional study the researchers administered an online survey to 61 emerging adults with IBD who lived in the United States. This convenience sample was recruited from ResearchMatch, Facebook, and through word of mouth. The participants completed a composite survey consisting of a demographic data form, the Inventory of Dimensions of Emerging Adulthood, the Inventory of Socially Supportive Behaviors, the Medical Outcomes: Social Support Survey, the Medication Adherence Report Scale, and the Dietary Screener Questionnaire.

Findings

Of the 61 study participants, 90% were female and 10% were male. The sample was noted to be primarily single and educated. The major findings of the study indicated that emerging adults who had received high informational support reported greater adherence to the prescribed medication regimen as compared to participants who had received low informational support. Within this study the researchers controlled for medications, time since diagnosis, symptom frequency, and feeling in-between adolescence and adulthood. Neither one of the two types of social support were related to modification of participants' diet.

Nursing Implications

Nurses should be aware of the needs of emerging adults living with IBD. Often emerging adults allow others to make decisions about their health management. By providing informational support, the nurse may significantly influence their patients' ability to more actively learn about themselves and how to manage their IBD through the use of group interventions and peer-to-peer mentoring. From this study it was noted

that only the received social support was useful in the participants' self-management behaviors for medication adherence. More research must be directed toward the benefits of received social support for effective self-management of chronic conditions faced by emerging adults.

Unfolding Patient Stories: Vincent Brody • Part 1

Vincent Brody, a 67-year-old male with chronic obstructive pulmonary disease (COPD), is experiencing increased fatigue. He spends most of the day in a recliner chair watching television and smoking 1 to 2 packs/d. His nutritional intake is poor due to shortness of breath. What patient education can the nurse provide to promote self-care behaviors for symptom improvement and a healthier lifestyle? (Vincent Brody's story continues in Chapter 55.)

Care for Vincent and other patients in a realistic virtual environment: vSim (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Health Promotion Strategies Throughout the Lifespan

Health promotion is a concept and a process that extends throughout the lifespan. The health of a child can be affected either positively or negatively by the health practices of the mother during the prenatal period. Therefore, health promotion starts before birth and extends through childhood, adolescence, adulthood, and old age (Haber, 2019).

Health promotion includes health screening, counseling, immunizations, and preventive medications. The U.S. Preventive Services Task Force (2019) evaluates clinical research to assess the merits of preventive measures. Table 3-3 presents general population guidelines, including adult immunization recommendations (Centers for Disease Control and Prevention [CDC], 2021; U.S. Preventive Services Task Force, 2019).

Adolescents

Health screening has traditionally been an important aspect of adolescent health care. The goal has been to detect health problems at an early age so that they can be treated at that time. Today, health promotion goes beyond the mere screening for illnesses and disability and includes extensive efforts to promote positive health practices at an early age. Because health habits and practices are formed early in life, adolescents should be encouraged to develop positive health attitudes. For this reason, more programs are being offered to adolescents to help them develop good health habits. Although the negative results of practices such as smoking, risky sex, misuse of drugs and alcohol, and poor nutrition are explained in these educational programs, emphasis is also placed on values training, self-esteem, and healthy lifestyle practices. The projects are designed to appeal to a particular age group, with emphasis on learning experiences that are fun, interesting, and relevant.

Young and Middle-Aged Adults

Young and middle-aged adults represent an age group that not only expresses an interest in health and health promotion but also responds enthusiastically to suggestions that show how lifestyle practices can improve health. Adults are frequently motivated to change their lifestyles in ways that are believed to enhance their health and wellness. Many adults who wish to improve their health turn to health promotion programs to help them make the desired changes in their lifestyles. Many have responded to programs that focus on topics such as general wellness, smoking cessation, exercise, physical conditioning, weight control, conflict resolution, and stress management. Because of the nationwide emphasis on health during the reproductive years, young adults actively seek programs that address prenatal health, parenting, family planning, and women’s or men’s health issues.

TABLE 3-3 Select Health Promotion Screening for Adults

Type of Screening	Suggested Time Frame
Routine health examination	Yearly
Blood chemistry profile	Baseline at age 20 y, then as mutually determined by patient and clinician
Complete blood count	Baseline at age 20 y, then as mutually determined by patient and clinician
Lipid profile	Baseline at age 20 y, then as mutually determined by patient and clinician
Hemoccult screening	Yearly after age 50 y
Electrocardiogram	Baseline at age 40 y, then as mutually determined by patient and clinician
Blood pressure	Yearly at age 45, then as mutually determined by patient and clinician
Tuberculosis skin test	Every 2 y, or as mutually determined by patient and clinician
Chest x-ray or film	For positive PPD results
Mammogram	Every year for women beginning at age 45, or earlier or more often as indicated; women age 55 and older may continue yearly screening or transition to every 2 y
Clinical breast examination	Yearly
Gynecologic examination	Yearly
Papanicolaou (Pap) test	Every 3 y
Bone density screening	Based on identification of primary and secondary risk factors (prior to onset of menopause, if indicated)
Nutritional screening	As mutually determined by patient and clinician
Digital rectal examination	Yearly
Colonoscopy	Every 5–10 y after age 50 y or as mutually determined by patient and clinician
Prostate examination	Yearly
Testicular examination	Monthly

Skin examination	Yearly or as mutually determined by patient and clinician
Vision screening: Glaucoma	Every 2–3 y
Hearing screening	As needed
Health risk appraisal	As needed
Select Adult Immunizations	
Hepatitis B (if not received as a child)	Series of 2 doses one month apart
Human papillomavirus (HPV)	3 doses for males up to the age of 21 y, females up to the age of 26 y; men who have sex with men between 22 and 26 y; if lacking documentation of prior immunization
Influenza vaccine	Yearly
Meningococcal	1 or more doses after age 19 y
Td or Tdap vaccine (Tetanus, diphtheria, and pertussis)	Every 10 y
Zoster	After age 50 y
Pneumococcal conjugate vaccine (PCV13)	Given once to adults 65 y and older regardless of health status Given to those ages 19 to 64 y if immunocompromised, with cerebrospinal fluid (CSF) leakage or cochlear implants
Pneumococcal polysaccharide vaccine (PPSV23)	Given once to adults 65 years and older if they have previously received the PCV13, regardless of health status. For those adults 65 years and older who have not received either PCV13 or PPSV23, the PCV13 should be given first and the PPSV23 should be given at least 1 y later. Given to adults younger than 65 years who have chronic heart, lung or liver disease; diabetes; alcoholism, and smoking.
COVID-19	Administer within the scope of the Emergency Use Authorization or Biologics License Application for the particular vaccine.

Note: Any of these screenings may be performed more frequently if deemed necessary by the patient or recommended by the health care provider.

Programs that provide health screening, such as those that screen for cancer, high cholesterol, hypertension, diabetes, abdominal aneurysm, and visual and hearing impairments, are quite popular with young and middle-aged adults. Programs that involve health promotion for people with specific chronic illnesses such as cancer, diabetes, heart disease, and pulmonary disease are also popular. Chronic disease and disability do not preclude health and wellness; rather, positive health attitudes and practices can promote optimal health for people who must live with the limitations imposed by their chronic illnesses and disability.

Health promotion programs can be offered almost anywhere in the community, or in online venues. Common physical sites include local clinics, schools, colleges, recreation centers, places of worship, and even private homes. Health fairs are frequently held in civic centers and shopping malls. The outreach idea for health promotion programs has served to meet the needs of many adults who otherwise would not avail themselves of opportunities to strive toward a healthier lifestyle.

The workplace has become a center for health promotion activity for several reasons. Employers have become increasingly concerned about the rising costs of health care insurance to treat illnesses related to lifestyle behaviors, and they are also concerned about increased absenteeism and lost productivity. Some employers use health promotion specialists to develop and implement these programs, some contract with employee assistance programs, and others purchase packaged programs that have already been developed by health care agencies or private health promotion corporations.

Programs offered at the workplace usually include employee health screening and counseling, physical fitness, nutritional awareness, work safety, and stress management and stress reduction. In addition, efforts are made to promote a safe and healthy work environment. Many large businesses provide exercise facilities for their employees and offer their health promotion programs to retirees.

Gerontologic Considerations

Health promotion is as important for older adults as it is for others. Although 80% of people older than 65 years have one or more chronic illnesses and many are limited in their activity, the older adult population experiences significant gains from health promotion. Older adults are very health conscious, and most view their health positively and are willing to adopt practices that will improve their health and well-being (Touhy & Jett, 2018). Although their chronic illness and disability cannot be eliminated, these adults can benefit from activities and education that help them maintain independence and achieve an optimal level of health (Harbottle, Bartholomaeus, Van Agteren, et al., 2019).

Figure 3-2 • Health promotion for older adults includes physical fitness. Here, a nurse teaches simple exercises at a senior center.

Various health promotion programs have been developed to meet the needs of older Americans. Both public and private organizations

continue to be responsive to health promotion, and more programs that serve this population are emerging. Many of these programs are offered by health care agencies, places of worship, community centers, senior citizen residences, and various other organizations. The activities directed toward health promotion for older adults are the same as those for other age groups: physical fitness and exercise, nutrition, safety, and stress management (Fig. 3-2).

Nursing Implications of Health Promotion

By virtue of their expertise in health and health care and their long-established credibility with consumers, nurses play a vital role in health promotion. In many instances, they initiate health promotion and health screening programs or participate with other health care personnel in developing and providing wellness services in various settings.

As health care professionals, nurses have a responsibility to promote activities that foster well-being, self-actualization, and personal fulfillment. Every interaction with consumers of health care must be viewed as an opportunity to promote positive health attitudes and behaviors. Health Promotion charts and tables throughout this textbook identify opportunities for promoting health.

CRITICAL THINKING EXERCISES

1 ebp A male college student has been to the student health center three times in 2 months for sore throats, mild headaches, coughing and other cold symptoms. He tells you that he does not smoke cigarettes anymore, but he has started vaping on an almost daily basis. However, he does not think that vaping is contributing to his respiratory problems, and he thinks that his symptoms are due to stress. What health promotion factors can guide you in educating the student about his health situation? What is the evidence base to use for providing health promotion information to help this student make appropriate health decisions and engage in positive health behaviors? Identify the criteria used to evaluate the strength of the evidence for this practice.

2 ipc At the cardiology clinic where you work as a nurse navigator, a 45-year-old woman presents with a history of cardiac disease, depression, and recent addiction to alcohol due to her anxiety and self-medicating her depression. You think it prudent to consult other health team members to provide services for her health care needs. What interdisciplinary health team members are the essential providers to facilitate interdisciplinary care? How will the team best address the patient's health care needs? What care modalities must be established to treat the patient's cardiac needs, addiction, rehabilitation process, and psychological health treatment?

4 Adult Health and Physical, Nutritional, and Cultural Assessment

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the components of a holistic and comprehensive health history and assessment.
2. Describe the techniques of inspection, palpation, percussion, and auscultation to perform a basic physical assessment.
3. Discuss the techniques of measurement of body mass index, biochemical assessment, clinical examination, and assessment of food intake to assess a person's nutritional status.
4. Describe the techniques of conducting a cultural assessment.

NURSING CONCEPTS

Culture
Diversity
Health, Wellness, and Illness
Nutrition

GLOSSARY

auscultation: listening to sounds produced within different body structures created by the movement of air or fluid

body mass index (BMI): a calculation done to estimate the amount of body fat of a person

culture: the knowledge, belief, art, morals, laws, customs, and any other capabilities and habits acquired by humans as members of society

cultural assessment: a systematic appraisal or examination of individuals, families, groups, and communities in terms of their cultural beliefs, values, and practices

culturally competent care: effective, individualized care that demonstrates respect for the dignity, personal rights, preferences, beliefs, and practices of the person receiving care while acknowledging the biases of the caregiver and preventing these biases from interfering with the care provided

electronic health record (EHR): computerization of health records; also referred to as electronic medical record (EMR)

ethnicity: affiliation relating to large groups of people classed according to common racial, national, tribal, religious, linguistic, or cultural background

faith: trust in God, belief in a higher power or something that a person cannot see

health history: the collection of subjective data, most often a series of questions that provides an overview of the patient's current health status

inspection: visual assessment of different aspects of the patient (e.g., visual assessment of the patient's body systems and body movements)

palpation: examination of different organs of the body using the sense of touch

percussion: the use of sound to examine different organs of the body

physical examination: collection of objective data about the patient's health status

self-concept: a person's view of themself/themselves

spirituality: connectedness with self, others, a life force, or God that allows people to find meaning in life

substance use disorder: a maladaptive pattern of substance use that causes physical and emotional harm with the potential for disruption of daily life

The ability to assess patients in a holistic manner is a skill integral to nursing, regardless of the practice setting. Eliciting a complete health history, using appropriate physical assessment skills, while respecting spiritual and cultural considerations, is critical to identifying physical and psychological problems

and concerns experienced by the patient. As the first step in the nursing process, a holistic patient assessment is necessary to obtain data that enable the nurse to make accurate nursing diagnoses, identify and implement appropriate interventions, and assess their effectiveness. This chapter covers health assessment, including the complete health history and basic physical assessment techniques. Because a patient's nutritional status and culture are important factors in overall health and well-being, specific components of nutritional and cultural assessments are addressed.

The Role of the Nurse Conducting a Health Assessment

The role of the nurse in today's health care system is rooted in a health care model that emphasizes wellness, health promotion, and disease prevention. The professional nurse uses foundational knowledge of scientific evidence and best clinical judgment when assessing patients (Weber & Kelley, 2018). Various formats for obtaining the **health history** (the collection of subjective data about the patient's health status) and performing the **physical examination** (the collection of objective data about the patient's health status) have been developed. Regardless of the format, the information obtained by the nurse complements the data obtained by other members of the health care team and focuses on nursing's unique concerns for the patient. The nurse completes a health assessment by obtaining the patient's health history and performing a physical assessment, which can be carried out in a variety of settings. These settings may include an acute care facility, a clinic or outpatient office, a long-term care facility, a school, or the patient's home. The nursing process is a systematic process used by the nurse for assessing, planning, implementing, and evaluating care for the patient (see Chapter 1). Data are collected and documented in the patient's health record. This record may be on paper or in the **electronic health record (EHR)**, also called the electronic medical record (EMR), enabling clear communication among care team members and the collection of data for continuous improvement in patient care (Ackley, Ladwig, Flynn Makic, et al., 2019).

Effective Communication

People who seek health care for a specific problem are often anxious. Their anxiety may be increased by fear about potential diagnoses, possible disruption of lifestyle, and other concerns. With this in mind, the nurse attempts to establish rapport, put the patient at ease, encourage honest communication, make eye contact, and listen carefully to the patient's responses to questions about health issues (Fig. 4-1).

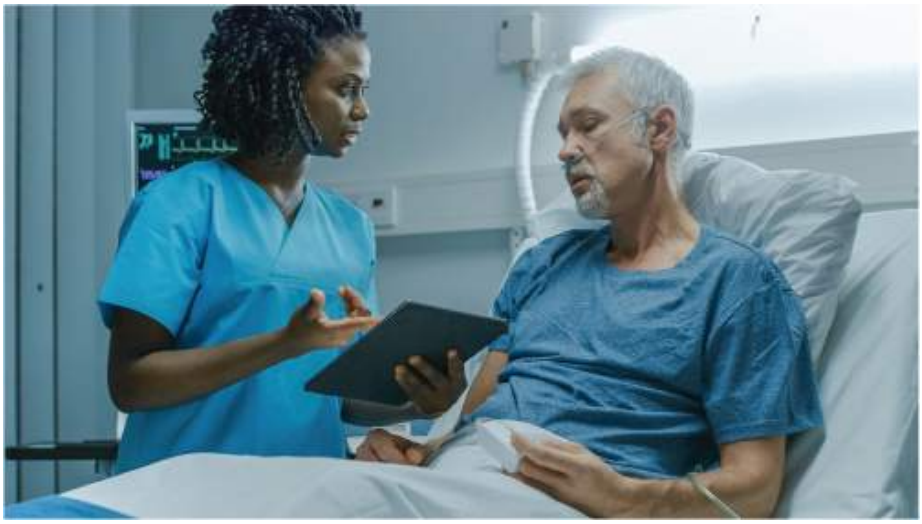

Figure 4-1 • A comfortable, relaxed atmosphere and an attentive interviewer are essential for a successful clinical interview.

When obtaining a health history or performing a physical examination, nurses must be aware of their own nonverbal communication, as well as that of the patient. The nurse should take into consideration the patient's educational background, language proficiency, and cultural background (see following discussion on Cultural Concepts and Cultural Competence). Questions and instructions to the patient should be phrased so that they are easily understandable. Technical terms and medical jargon should be avoided. In addition, the nurse must consider any disability or impairments (hearing, vision, cognitive, and physical limitations). At the end of the assessment, the nurse summarizes and clarifies the information obtained and asks the patient whether they have any questions; this gives the nurse the opportunity to correct misinformation and add facts that may have been omitted.

Cultural Concepts

The concept of culture and its relationship to the health care beliefs and practices of patients and their family or significant others provide the foundation for transcultural nursing. This awareness of culture in the delivery of nursing care has been described in different terms and phrases, including respect for cultural diversity or cultural humility; cultural awareness or sensitivity; comprehensive care; cultural consciousness or culturally congruent nursing care (Alexander-Ruff & Kinion, 2019; Henderson, Horne, Hills, et al., 2018).

Culture is commonly defined as the knowledge, belief, art, morals, laws, customs, and any other capabilities and habits acquired by humans as members of society. Such groups may distinguish themselves by socioeconomic class, race, ethnicity, religion, gender, sexual orientation, nationality, physical disability, or some other specific characteristic (Fioravanti, Puskar, Knapp, et al., 2018). During the past century, many other definitions of culture have been

offered that integrate these themes as well as the themes of ethnic variations of a population. Culture also implies that something is learned or developed, a process that occurs over time. Leininger (2002), founder of the specialty known as transcultural nursing, noted that culture involves learned and transmitted knowledge about values, beliefs, rules of behavior, and lifestyle practices that guide designated groups in their thinking and actions in patterned ways. Culture guides each person's thinking, doing, and being, and becomes patterned expressions of who that person is and becomes.

Ethnicity is defined as an affiliation relating to large groups of people classed according to common racial, national, tribal, religious, linguistic, or cultural background.

Ethnic culture has four basic characteristics:

- Learned from birth through language and socialization
- Shared by members of the same cultural group, and it includes an internal sense and external perception of distinctiveness
- Influenced by specific conditions related to environmental and technical factors and to the availability of resources
- Dynamic and ever changing

With the exception of the first characteristic, culture related to age, physical appearance, and lifestyle, as well as other less frequently acknowledged aspects, also shares these characteristics.

Cultural Competence

By the middle of the 21st century, the non–Hispanic Caucasian population is projected to proportionally decrease so that it will no longer comprise the *majority* population, and other ethnic and racial populations (i.e., *minority* populations as compared to non–Hispanic Caucasians) will collectively comprise the majority of all Americans. This projected phenomenon is called the *majority–minority* crossover (Colby & Ortman, 2015).

According to the 2017 National Nursing Workforce Survey, more than 80% of all nurses are Caucasian (Smiley, Lauer, Bienemy, et al., 2018). Progress toward increasing the percentage of culturally diverse nurses has been significantly slower than the increasing percentage of ethnic minorities in the United States. Educational institutions must prepare nurses to deliver culturally competent care and must work to increase the number of ethnic minority providers in the nursing workforce. **Culturally competent care** is defined as effective, individualized care that demonstrates respect for the dignity, personal rights, preferences, beliefs, and practices of the person receiving care while acknowledging the biases of the caregiver and preventing these biases from interfering with the care provided. Nurse educators are exploring creative ways to promote cultural competence and humanistic care in nursing students, including offering multicultural health studies in their curricula. Simulation

methods and role-playing could be effective methods to practice person-centered culturally competent care (Fioravanti et al., 2018).

Cultural diversity remains an important issue in health care today. Nurses are expected to provide culturally competent care for patients. To do so, nurses must work effectively with the increasing number of patients, nurses, and health care team members whose ancestry reflects the multicultural complexion of contemporary society.

Ethical Use of Health Assessment Data

Whenever information is elicited from a person through a health history or physical examination, the person has the right to know why the information is sought and how it will be used. Information is only shared with appropriate heath care team members (Weber & Kelly, 2018). It is also important that the person knows that the decision to participate is voluntary. A private setting for the history interview and physical examination should promote trust and encourage open, honest communication. After the history and examination are completed, the nurse selectively records the data pertinent to the patient's health status. This record of the patient's history and physical examination findings is then securely maintained and made available only to those health professionals directly involved in the care of the patient. The Health Insurance Portability and Accountability Act (HIPAA), passed in 1996, established national standards to protect individuals' medical records and other personal health information and applies to health plans, health care clearinghouses, and those health care providers that conduct certain health care transactions electronically. The act requires appropriate safeguards to protect the privacy of personal health information and sets limits and conditions on the uses and disclosures that may be made of such information without patient authorization. HIPAA outlines patients' rights over their health information, including rights to examine and obtain a copy of their health records and to request corrections (U.S. Department of Health & Human Services [HHS], 2019a).

The Role of Technology

The use of technology to augment the information-gathering process, particularly through the use of EHRs, has become an increasingly important aspect of obtaining a health history and physical examination. An EHR offers convenient access to health data for the patient and for providers who can use the information more effectively to improve the quality and efficiency of patient care. The information in EHRs also can be shared with other organizations involved in care of the patients if the systems interface (HHS, 2019b). Nurses must be sensitive to the needs of older adults and others who may not be comfortable with newer technology. Nurses may need to allow extra time, provide detailed instructions, explanations, or assistance. It is important to

establish and maintain eye contact with the patient during the health history and to not focus solely on the computer screen for data entry.

Assessment in the Home or Community

Assessment of patients in community settings, including the home, consists of collecting information specific to existing health problems, including data on the patient's physiologic and emotional status, the community and home environment, the adequacy of support systems or care given by family and other care providers, and the availability of needed resources. In addition, it is important to evaluate the ability of the person and the family to cope with and address their respective needs. The physical assessment in the community and the home consists of similar techniques to those used in the hospital, outpatient clinic, or office setting. Privacy is provided, and the patient is made as comfortable as possible. See Chapter 2 for more information on community-based nursing practice.

Health History

The health history is a series of questions used to provide an overview of the patient's current health status. Many nurses are responsible for obtaining a detailed history of the patient's current health problems, past health history and family history, and a review of the patient's functional status. This results in a total health profile that focuses on lifestyle and health, as well as on illness.

While obtaining the health history, attention is focused on the impact of psychosocial and cultural background and ethnicity on a patient's health, illnesses, and health promotion behaviors. The interpersonal and physical environments, as well as the patient's lifestyle and activities of daily living, are explored in depth.

The format of the health history traditionally combines the medical history and the nursing assessment. Both the review of systems and the patient profile are expanded to include individual and family relationships, lifestyle patterns, health practices and nutritional assessment, and coping strategies. These components of the health history are the basis of nursing assessment and can be easily adapted to address the needs of any patient population in any setting, institution, or agency (Hogan-Quigley, Palm, & Bickley, 2017; Weber & Kelley, 2018).

The health history format discussed in this chapter is only one approach that is useful in obtaining and organizing information about a patient's health status. Some experts consider this traditional format to be inappropriate for nurses, because it does not focus exclusively on the assessment of human responses to actual or potential health problems. Several attempts have been made to develop an assessment format and database with this focus in mind. One example is a

nursing database developed by NANDA International and its 13 domains: health promotion, nutrition, elimination and exchange, activity/rest, perception/cognition, self-perception, role relationships, sexuality, coping/stress tolerance, life principles, safety/protection, comfort, and growth/development (Ackley et al., 2019) (see Chapter 1, Chart 1-6 for further details). Although there is support in nursing for using this approach, no consensus for its use has been reached.

The National Information Center on Health Services Research and Health Care Technology (NICHSR) and other groups from the public and private sectors have focused on assessing not only biologic health but also other dimensions of health. These dimensions include physical, functional, emotional, mental, and social health. Efforts to assess health status have focused on the manner in which disease or disability affects a patient's functional status—that is, the ability of patients to function normally and perform their usual physical, mental, and social activities. An emphasis on functional assessment is viewed as more holistic than the traditional medical history. Instruments to assess health status in these ways may be used by nurses along with their own clinical assessment skills to determine the impact of illness, disease, disability, and health problems on functional status (U.S. National Library of Medicine, 2019).

Regardless of the assessment format used, the focus of nurses during data collection is different from that of primary providers and other health care team members. Combining the information obtained by the primary provider and the nurse into one health history prevents duplication of information and minimizes efforts on the part of the patient to provide this information repeatedly. This also encourages collaboration among members of the health care team who share in the collection and interpretation of the data.

The Informant

The informant, or the person providing the health history, may not always be the patient, as in the case of a patient with a developmental or cognitive disability or those who are disoriented, confused, unconscious, or comatose. The interviewer should assess the reliability of the informant and the usefulness of the information provided. For example, a patient who is disoriented is often unable to provide reliable information; people who use alcohol and illicit drugs often deny using these substances. The interviewer must make a clinical judgment about the reliability of the information (based on the context of the entire interview) and include this assessment in the record. Chart 4-1 provides special considerations for obtaining a health history from an older adult.

Chart 4-1

Health Assessment in the Older Adult

- Obtain the health history from older adult patients in a calm, unrushed manner.
- Consider possible vision or hearing impairments. Ensure that lighting is adequate but not glaring, and keep distracting noises to a minimum.
- Assume a position that enables the older adult patient to read lips and facial expressions. Sometimes sitting at a 90-degree angle to the patient is helpful because some visual impairments, such as macular degeneration, can limit the patient's vision to only peripheral vision. It is best to ask the patient where the interviewer should sit in relation to the patient to optimize the patient's view of the interviewer.
- Determine if the patient uses a hearing aid and ask the patient to use it during the interview. Check if the patient usually wears glasses and ensure that they are worn as well.
- Be aware that older adults often assume that new physical problems are a result of age rather than a treatable illness. Some of these problems may limit their activities of daily living and lifestyle patterns.
- Ask questions related to changes in the level of functioning. The signs and symptoms of illness in older adults are often more subtle than those in younger adults and may go unreported. A question such as "What interferes most in your daily activities?" may be useful in focusing the clinical evaluation.
- Obtain a complete history of medications used, because many older adult patients take many different kinds of prescription and over-the-counter (OTC) medications.
- Consider including a member of the family in the interview process. Although older adults may experience a decline in mental function, it should not be assumed that they are unable to provide an adequate history. Including a spouse, adult child, sibling, or caretaker may validate information and provide missing details. However, this should be done after obtaining the patient's permission (further details about assessment of the older adult are provided in Chapter 8).

Adapted from Weber, J. R., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Components of the Health History

When a patient is seen for the first time by a member of the health care team, the first requirement is that baseline information be obtained (except in emergency situations). The sequence and format of obtaining data about a patient may vary; however, the content, regardless of format, usually addresses

the same general topics. A traditional health history includes the following: biographical data, chief complaint, present health concern (or history of present illness), past health history, family history, review of systems, and patient profile.

Biographical Data

Biographical information puts the patient's health history into context. This information includes the person's name, address, age, gender, marital status, occupation, and ethnic origins. Some interviewers prefer to ask more personal questions at this part of the interview, whereas others wait until more trust and confidence have been established or until a patient's immediate or urgent needs are first addressed. A patient who is in severe pain or has another urgent problem is unlikely to have a great deal of patience for an interviewer who is more concerned about marital or occupational status than with quickly addressing the problem at hand.

Chief Complaint

The chief complaint is the issue that caused the patient to seek the care of the health care provider. Questions such as "Why have you come to the health center today?" or "Why were you admitted to the hospital?" usually elicit the chief complaint. However, a statement such as "My doctor sent me" should be followed up with questions that identify and clarify the chief complaint (Weber & Kelley, 2018). In the home setting, the initial question might be, "What is bothering you most today?" When a problem is identified, the person's exact words are usually recorded in quotation marks. Sometimes patients have no specific complaints. The nurse should report their goals instead. For example, patients might report that "I have come for my regular checkup" or "I've been admitted for a thorough evaluation of my heart" (Hogan-Quigley et al., 2017).

Present Health Concern or Illness

The history of the present health concern or illness is the single most important factor in helping the health care team arrive at a diagnosis or determine the patient's current needs. The physical examination is also helpful and often validates the information obtained from the history. A careful history and physical examination assist in the correct selection of appropriate diagnostic tests. Although diagnostic test results can be helpful, they often support rather than establish the diagnosis.

If the present illness is only one episode in a series of episodes, the nurse records the entire sequence of events. For example, a history from a patient whose chief complaint is an episode of chest pain should describe the entire course of their disease to put the current episode into context. The history of the present illness or problem includes information such as the date and type of onset (sudden or gradual) in which the problem occurred, the setting in which

the problem occurred (at home, at work, after an argument, after exercise), manifestations of the problem, and the course of the illness or problem. This should include self-treatment (including complementary and alternative therapies), medical interventions, progress and effects of treatment, and the patient's perceptions of the cause or meaning of the problem.

Specific symptoms such as headaches, fever, or changes in bowel habits are described in detail. The interviewer should also ask whether the symptom is persistent or intermittent, what factors aggravate or alleviate it, and whether any associated manifestations exist. If the patient complains of pain, the location, quality, severity, and duration of the pain are determined (see Chapter 9 for a more detailed discussion of pain).

Associated manifestations are symptoms that occur simultaneously with the chief complaint. The presence or absence of such symptoms may help determine the origin or extent of the problem, as well as the diagnosis. These symptoms are referred to as significant positive or negative findings and are obtained from a review of systems directly related to the chief complaint. For example, if a patient reports a vague symptom such as fatigue or weight loss, all body systems are reviewed. On the contrary, if a patient's chief complaint is something specific, such as chest pain, then the cardiopulmonary and gastrointestinal systems will be the focus of the history of the present illness. In either situation, both positive and negative findings are recorded to further define the issue.

Past Health History

A detailed summary of a patient's past health is an important part of the health history. After determining the patient's general health status, the interviewer should inquire about immunization status and compare it with the General Best Practice Guidelines for Immunization Advisory Committee on Immunization Practices (ACIP) (Ezeanolue, Harriman, Hunter, et al., 2019) (see Chapter 3, Table 3-3 for an adult immunization schedule) and then record the dates of immunization (if known). The interviewer should also inquire about any known allergies to medications or other substances, along with the nature of the allergy and associated adverse reactions. Other relevant material includes information, if known, about the patient's last physical examination, chest x-ray, electrocardiogram, eye examination, hearing test, dental checkup, Papanicolaou (Pap) smear and mammogram (if female), digital rectal examination of the prostate gland (if male), bone density testing, colon cancer screening, and any other pertinent tests.

The interviewer discusses previous illnesses and records negative as well as positive responses to a list of specific diseases. The dates of illnesses, or the age of the patient at the time, as well as the names of the primary providers and hospitals, the diagnoses, and the treatments, are noted. The interviewer elicits a history of the following areas:

- Childhood illnesses—rubeola, rubella, polio, whooping cough, mumps, measles, chickenpox, scarlet fever, rheumatic fever, strep throat
- Adult illnesses
- Psychiatric illnesses
- Injuries—burns, fractures, head injuries, traumatic injuries
- Hospitalizations
- Surgical and diagnostic procedures

If a particular hospitalization or major medical intervention is related to the present illness, the account of it is not repeated here; rather, the report refers to the appropriate part of the record, such as (see present health concern or illness) on the patient's health record.

Family History

To identify diseases that may be genetic, communicable, or possibly environmental in origin, the interviewer asks about the age and health status, or the age and cause of death, of first-order relatives (parents, siblings, spouse, children) and second-order relatives (grandparents, cousins). The nurse records the age and health, or age and cause of death, of each relative. In addition, each of the following conditions should be reviewed with the patient to determine whether they are present or absent among family members: hypertension, coronary artery disease, elevated cholesterol levels, stroke, diabetes, thyroid or renal disease, arthritis, tuberculosis, asthma or lung disease, headache, seizure disorder, mental illness, substance use disorder, cancer and the site or type, genetic diseases, and allergies; the nurse should also determine if there is a family history of suicide (Hogan-Quigley et al., 2017). One of the easiest methods of recording such data is by using the family tree, genogram, or pedigree (Fig. 4-2). The results of genetic testing or screening, if known, are recorded. Chart 4-2 provides genetic considerations related to health assessment (see Chapter 6 for a detailed discussion of genetics).

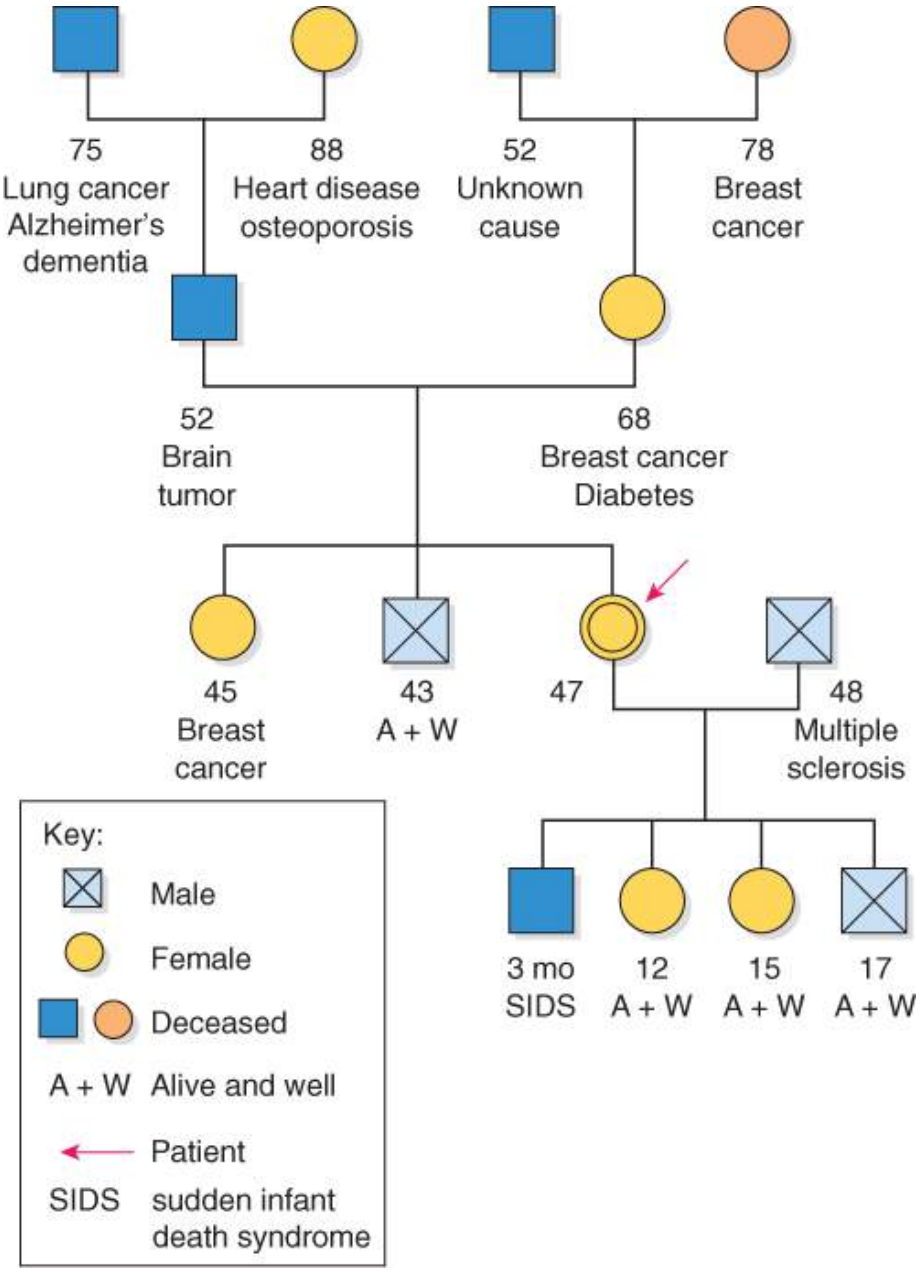

Figure 4-2 • Diagram (called a *genogram*) used to record history of family members, including their age and cause of death or, if living, their current health status.

Review of Systems

The review of systems includes an overview of general health as well as symptoms related to each body system. Questions are asked about each of the major body systems for information about past and present symptoms. Negative and positive answers should be recorded. If a patient responds positively to questions about a particular system, the information is analyzed carefully. If any illnesses were previously mentioned or recorded, it is not necessary to repeat them in this part of the history.

A review of systems can be organized in a formal checklist, which becomes part of the health history. One advantage of a checklist is that it can be easily audited and is less subject to error than a system that relies heavily on the interviewer's memory.

Patient Profile

In the patient profile, more biographical information is gathered. A complete composite, or profile, of the patient is critical to the analysis of the chief complaint and of the patient's ability to deal with the problem. A complete patient profile is summarized in Chart 4-3.

At this point in the interview, the information elicited is highly personal and subjective. People are encouraged to express feelings honestly and to discuss significant health events. It is best to begin with general, open-ended questions and to move to direct questioning when specific facts are needed. Interviews that progress from information that is less personal (birthplace, occupation, education) to information that is more personal (sexuality, body image, coping abilities) often reduce anxiety.

A general patient profile consists of the following content areas: past life events related to health; current medications; complementary, alternative and integrative health therapies; education and occupation; financial resources; environment (physical, spiritual, interpersonal); lifestyle patterns; presence of a physical or mental disability; self-concept; sexuality; risk for abuse or intimate partner violence (IPV); and stress and coping response.

Past Life Events Related to Health

The patient profile begins with a brief life history. Questions about place of birth and past places of residence help focus attention on the earlier years of life. Personal experiences during childhood or adolescence that have special significance may be elicited by asking a question such as, "Were there any events that occurred when you were a child or adolescent that would be helpful for me to know about?" The interviewer's intent is to encourage the patient to make a quick review of their earlier life, highlighting information of particular significance. Although many patients may not recall anything significant, others may share information such as a personal achievement, a failure, a developmental crisis, or an instance of physical, emotional, or sexual abuse. The life history should include a brief medication history as appropriate for the patient.

Current Medications

A review of the patient's current medications is necessary to complete a comprehensive health history. Particular attention is given to allergies or adverse reactions to medications. The interviewer should inquire about the use of over-the-counter (OTC) medications and herbal supplements and

complementary therapies (see next section); patients often include only prescription medications when they list their current medications.

When gathering information on use of current medications, the nurse must also consider the physiologic impact of ethnicity and culture on patients' response to medications. Data have been collected for many years regarding differences in the effect that some medications have on people of diverse ethnic or cultural origins. Genetic predispositions to different rates of metabolism cause some patients to be prone to adverse reactions to the standard dose of a medication, whereas other patients are likely to experience a greatly reduced benefit from the standard dose of the medication (Giger, 2016). For example, an antihypertensive agent may work well at reducing blood pressure to acceptable levels for a Caucasian man within a 4-week time span, but may take much longer to work or not work at all for an African American man with hypertension. In the future, genomic research may capitalize on the work of transdisciplinary teams that are building the skills needed to design and assess multilevel interventions aimed at improving the health of minorities and reducing health disparities (Agurs-Collins, Persky, Paskett, et al., 2019). Nurses must be aware that ethnicity and related factors such as values and beliefs regarding the use of herbal supplements, dietary intake, and genetic factors can affect the effectiveness of treatment and adherence to the prescribed medication regimen (Giger, 2016).

Chart 4-2 **GENETICS IN NURSING PRACTICE**

Genetic Aspects of Health Assessment

Nursing Assessments

Family History Assessment

- Obtain information about maternal and paternal sides of family for three generations.
- Obtain history of known diseases or disorders for three generations for:
  - Clustering of diseases or disorders.
  - Early onset of disease or illness (e.g., blood clots in an active, otherwise apparently healthy 30 year old, or colon cancer in a 40 year old).
  - Similar disorder or disease in two or more close relatives.
  - History of multiple miscarriages, birth defects, or developmental delays.
  - Close biologic relationship between parents.
- Assess for individual and family perceptions and beliefs around genetics topics through a cultural, social, and spiritual assessment.
- Acknowledge ethnic risk for particular genetic disorders.
- Determine whether the patient or a direct family member has had an unexpected response to medications or anesthesia.
- Recognize and evaluate for patterns of inheritance.
- Ascertain family relationships (family structure, roles, communication patterns, support system).

Patient Assessment

- Assess physical findings that may suggest a genetic condition (e.g., unusually tall stature—Marfan syndrome, low set ears, and epicanthal folds—Down syndrome).
- Is there a presence of two or more dysmorphic features?
- Is there a presence of disability (physical or intellectual) or a history of developmental delay?
- Assess for conditions that occur in a less-often affected gender (e.g., stuttering in females, breast cancer in males, inguinal hernia in females).
- Presence of disease without known risk factors (e.g., hyperlipidemia).
- Acknowledge genetic-related risk related to ethnic background.
- Identify religious health, spiritual health, beliefs, and practices.

Management Issues Specific to Genetics

- Assess patient's understanding of genetic information and factors related to their health risks.
- Refer for risk assessment when a hereditary disease or disorder is suspected.
- Determine if genetic testing has been performed and if other family members are affected.

- Educate patient and family about the *Genetic Information Nondiscrimination Act (GINA),* passed in 2008.
- Offer appropriate genetic information and resources.
- Refer to a genetic counselor.
- Ensure that consent obtained for genetic testing is voluntary and informed.
- Provide support to patients and families with known genetic test results for hereditary disease or disorders, and refer to support groups as indicated.
- Participate in the management and coordination of risk-reduction measures for those with known gene mutations.

For additional genetic resources, see Chapter 6, Chart 6-7: Components of Genetics Counseling.

Complementary, Alternative, and Integrative Health Therapies

Interventions for alterations in health and wellness vary among cultures. Interventions most commonly used in the United States have been labeled as *conventional medicine,* which is also variously referred to as allopathy, Western medicine, regular medicine, mainstream medicine, and biomedicine (National Center for Complementary and Integrative Health [NCCIH], 2019). Therapy used to supplement conventional medicine is referred to as *complementary therapy,* whereas therapy used to replace conventional medicine is referred to as *alternative therapy* (NCCIH, 2019). Interest in interventions that are not an integral part of conventional medicine prompted the National Institutes of Health to create the Office of Alternative Medicine and then to establish the National Center for Complementary and Alternative Medicine, which is now called the National Center for Complementary and Integrative Health (NCCIH, 2019). Integrative health care is viewed as a comprehensive, interdisciplinary approach to preventing and treating illness and promoting health that brings together complementary, alternative, and conventional therapies. The use of an integrative approach to health and wellness has grown within mainstream health care settings in the United States (NCCIH, 2019). More than 30% of adults use health care approaches that are not typically part of conventional medical care or that may have origins outside of usual Western practice. Most people who use nonmainstream approaches also use conventional health care (NCCIH, 2019).

Integrative health therapies are classified by product or practice type into two subgroups—natural products or mind and body practices (NCCIH, 2019):

- *Natural products* include herbs (also known as botanicals), vitamins and minerals, and probiotics. These are widely marketed to consumers

and often sold and used as dietary supplements.

- *Mind and body practices* include large and diverse procedures and techniques given or taught by trained practitioners or teachers and include practices such as yoga, meditation, chiropractic and osteopathic manipulation, massage therapy, acupuncture, relaxation techniques, and T'ai chi.

Patients may choose to seek a complementary or alternative approach to conventional medical or surgical therapies. Nurses must assess all patients for the use of complementary therapies, be alert to the danger of natural product–drug interactions or conflicting treatments, and be prepared to provide information to patients about treatments that may be harmful or helpful, based upon best evidence from research findings. However, nurses must be accepting of patients' beliefs and right to autonomy—that is, to control their own care. As patient advocates, nurses facilitate the integration of conventional medical, complementary, and alternative therapies.

Chart 4-3 **ASSESSMENT**

Patient Profile

Past Life Events Related to Health

Place of birth
Places lived
Significant childhood/adolescent events

Current Medications

Prescription, over-the-counter, home remedies, complementary and alternative therapies

Education and Occupation

Jobs held in past
Current position/job
Length of time at position
Educational preparation
Work satisfaction and career goals

Financial Resources

Income
Insurance coverage
Concerns

Environment

Physical—living arrangements (type of housing, neighborhood, presence of hazards)
Spiritual—extent to which religion or spirituality is a part of a person's life; religious or spiritual beliefs related to perception of health and illness; religious or spiritual practices
Interpersonal—ethnicity (language spoken, customs and values held, folk practices used to maintain health or cure illness); support systems (family relationships and friendships)

Lifestyle Patterns

Sleep (time person retires, hours per night, comfort measures, awakens rested)
Nutrition (24-h diet recall, idiosyncrasies, restrictions)
Health promotion (exercise and recreation: type, duration, frequency; health screenings)
Caffeine (type: coffee, tea, cola, chocolate), amount
Alcohol (type, amount, pattern over past year)
Smoking (type: cigarette, pipe, cigar, marijuana, or electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars; amount per day; number of years; desire to quit)
Drugs (type, amount, route of administration)

Physical or Mental Disability

Presence of a disability (physical or mental)
Effect of disability on function and health access
Accommodations needed to support functioning

Self-Concept

View of self in present
View of self in future
Body image (level of satisfaction, concerns)

Sexuality

Perception of self as a heterosexual, lesbian, gay, bisexual or transgender
Quality of sexual relationships
Concerns related to sexuality or sexual functioning

Risk for Intimate Partner Violence (IPV)

Physical injury in past
Afraid of partner, caregiver, or family member
Refusal of caregiver to provide necessary equipment or assistance

Stress and Coping Response

Major concerns or problems at present
Daily "hassles"
Past experiences with similar problems
Past coping patterns and outcomes
Present coping strategies and anticipated outcomes
Person's expectations of family/friends and health care team in problem resolution

Education and Occupation

Inquiring about a patient's current occupation can reveal much about their economic status and educational preparation. A statement such as "Tell me about your job" often elicits information about role, job tasks, and satisfaction with the position. Direct questions about past employment and career goals may be asked if the person does not provide this information.

It is important to learn about a patient's educational background. Asking what kind of educational requirements were necessary for a patient to attain their present job is a more sensitive approach than asking whether they graduated from high school.

Financial Resources

Information about the patient's general financial status may be obtained by asking questions such as "Do you have any financial concerns at this time?" Inquiries about the person's insurance coverage and plans for health care payment are also appropriate.

Environment

The concept of environment includes a person's physical environment and its potential hazards. It also includes a person's spiritual awareness, ethnicity, and support systems.

Physical Environment

Information is elicited about the type of housing (e.g., apartment, duplex, single family) in which the person lives, its location, the level of safety and comfort within the home and neighborhood, and the presence of environmental hazards (e.g., social isolation, potential fire risks, inadequate sanitation). If the patient is homeless, details about available resources are important to ascertain.

Spiritual Environment

Spirituality is defined as connectedness with self, others, a life force, or God that allows people to experience self-transcendence and find meaning in life. Spirituality helps many people discover a purpose in life, understand the ever-changing qualities of life, and develop their relationship with God or a higher power. Spirituality in nursing practice includes concerns with the personal spiritual and religious needs of the patient and nurse, as well as the spiritual dimension of the nurse–patient interaction (O'Brien, 2017).

Spiritual behavior can be expressed through devotion, sacrifice, self-discipline, and spending time in activities that focus on the inner self or the soul. Although religion and nature are two vehicles that people use to connect themselves with God or a higher power, bonds to religious institutions, beliefs, or dogma are not required to experience the spiritual sense of self. **Faith,** considered the foundation of spirituality, is trust in God and belief in a higher power or something that a person cannot see. The spiritual part of a person views life as a mystery that unfolds over one's lifetime, encompassing questions about meaning, hope, relatedness to a higher power, acceptance or forgiveness, and transcendence.

A person's spiritual environment refers to the degree to which they think about or contemplate existence, accept challenges in life, and seek and find answers to personal questions. Spirituality may be expressed through identification with a particular religion. Spiritual values and beliefs often direct a person's behavior and approach to health problems and can influence responses to sickness. A strong sense of spirituality or religious faith can have a positive impact on health. Spirituality is also a component of hope, and, especially during chronic, serious, or terminal illness, patients and their families often find comfort and emotional strength in their religious traditions or spiritual beliefs. At other times, illness and loss can cause a loss of faith or meaning in life and a spiritual crisis, which can place considerable stress on a person's internal resources and beliefs. It is important that the spiritual beliefs of people and families be acknowledged, valued, and respected for the comfort and guidance they provide. Inquiring about spirituality can identify possible support

systems as well as beliefs and customs that need to be considered in planning care. Information is gathered about the extent to which religion is a part of the person's life as well as religious beliefs and practices related to health and illness.

A spiritual assessment may involve asking the following questions:

- Is religion or spirituality important to you?
- If no, what is the most important thing in your life?
- If yes, in what way? For instance:
- Are there any religious or spiritual practices that are important to you?
- Do you belong to a faith community or have a place of worship?
- Do you have any religious or spiritual concerns because of your present health problem?

The nurse should assess spiritual strength further by inquiring about the patient's sense of spiritual well-being, hope, and peacefulness. It is also necessary to assess whether spiritual beliefs and values have changed in response to illness or loss. The nurse assesses current and past participation in religious or spiritual practices and notes the patient's responses to questions regarding spiritual needs to help determine the patient's need for spiritual care. Another simple assessment technique is to inquire about the patient's and family's desire for spiritual support (O'Brien, 2017).

Interpersonal Environment

A patient's ethnicity and support system are considered when obtaining a health history. Attitudes and beliefs about health, illness, health care, hospitalization, the use of medications, and the use of complementary and alternative therapies, which are derived from personal experiences, vary according to ethnicity. A person from another culture may have different views of personal health practices from those of the health care practitioner (Hogan-Quigley et al., 2017; Weber & Kelley, 2018) (see later discussion on Cultural Assessment).

The beliefs, customs, and practices that have been shared from generation to generation are known as ethnic patterns. The influence of these patterns on health-related behaviors and patient's perceptions of health and illness, as well as on how a patient reacts to health problems and interacts with health care providers, cannot be underestimated. Ethnic patterns can be expressed through language, dress, dietary choices, and role behaviors. The following questions may assist in obtaining relevant information:

- Where did your parents or ancestors come from? When?
- What language do you speak at home?
- Are there certain customs or values that are important to you?
- Do you have any specific practices to keep in good health or for treating illness?

Support systems are another important aspect of a patient's interpersonal environment. The evaluation of a patient's family structure (members, ages, and

roles), patterns of communication, and the quality of the patient's relationships is an integral part of assessing support systems. Although the traditional family is recognized as a mother, a father, and children, many different types of living arrangements exist within our society. "Family" may mean two or more people bound by emotional ties or commitments. Live-in companions, roommates, and close friends can also play a significant role in a person's support system. Keeping this in mind, nurses should use neutral terms and be sensitive when evaluating family structure. For example, the interview can begin with an open-ended question, such as "Tell me about your family and social support system." Neutral terms should also be used when asking follow-up questions about partners/significant others and parents/guardians (for further discussion, see Chapter 54, Table 54-1).

Lifestyle Patterns

The lifestyle section of the patient profile provides information about health-related behaviors. These behaviors include patterns of sleep, nutrition, and health promotion, as well as personal habits such as smoking and the use of illicit drugs, alcohol, and caffeine. Adequate sleep and nutrition are important to maintain optimal health; therefore, it is important to inquire about usual sleep habits and bedtime routines, as well as perform a nutritional assessment. Although most people readily describe their exercise patterns or recreational activities, many are unwilling to report their smoking, alcohol use, and illicit drug use, and many deny or understate the degree to which they use such substances. The Centers for Disease Control and Prevention (CDC) reports that abuse of prescription drugs has replaced abuse of illicit drugs as a leading cause of drug-induced deaths (CDC, 2019c). Questions such as "What kind of alcohol do you enjoy drinking?" may elicit more accurate information than "Do you drink?" Determining the specific type of alcohol (e.g., wine, liquor, beer) the patient drinks and the last time they had a drink is an important aspect of the assessment. Every patient should be asked about alcohol use, substance use disorder, and misuse of prescription drugs (Hogan-Quigley et al., 2017).

The lifestyle of some people includes the use of mood-altering substances. People with **substance use disorder** (SUD) use illegally obtained drugs, prescribed or OTC medications, and alcohol alone or in combination with other drugs in ineffective attempts to cope with the pressures, strains, and burdens of life. Over time, physiologic, emotional, cognitive, and behavioral problems develop as a result of SUD.

If alcohol abuse is suspected, additional information may be obtained by using common alcohol screening questionnaires such as the CAGE (Cutting down, Annoyance by criticism, Guilty feeling, and Eye-openers) (Ewing, 1984), AUDIT (Alcohol Use Disorders Identification Test), or the shorter AUDIT-C questionnaire (Drug and Alcohol Clinical Advisory Service [DACAS], 2019).

Similar questions can be used to elicit information about smoking and caffeine consumption. Questions about illicit drug use follow naturally after

questions about smoking, caffeine consumption, and alcohol use. A nonjudgmental approach makes it easier for a person to respond truthfully and factually. If street names or unfamiliar terms are used to describe drugs, the person is asked to define the terms used.

Investigation of the patient's lifestyle patterns should also include questions about complementary, alternative, and integrative health therapies, which may include energy and breath work, botanical and manual healing, and mind–body therapies (Fontaine, 2018).

Marijuana is used for the management of symptoms, especially pain and anorexia, in several chronic conditions. Since the marijuana plant contains chemicals, called cannabinoids, that may help treat a range of illnesses or symptoms, many people have argued that it should be legal for medical purposes. This has led to the legalization of marijuana for medical use in many states. The U.S. Food and Drug Administration (FDA) has not recognized or approved the marijuana plant as medicine; however, the FDA has approved medications that contain cannabinoids in pill form. Currently, the two main cannabinoids from the marijuana plant that are of medical interest are delta-9-tetrahydrocannabinol (THC) and cannabidiol (CBD). The FDA-approved drugs dronabinol and nabilone both contain THC. They are indicated specifically to treat nausea caused by chemotherapy and to increase appetite in patients with extreme weight loss caused by acquired immune deficiency syndrome (AIDS). THC also may decrease pain, inflammation, and muscle control problems. Unlike THC, drugs that contain CBD are not intoxicating and do not make people "high." CBD is useful in reducing pain, inflammation, controlling epileptic seizures, and possibly even treating mental illness and addiction (National Institute on Drug Abuse, 2019).

The assessment of a patient's lifestyle patterns also includes questions about continuing health promotion and health-screening practices. The health history assessment should include the type, frequency, and duration of exercise and recreational activities. Inquiry should also include the types of health screenings the patient has completed. If the person has not been involved in these practices in the past, they should be educated about their importance and referred to the appropriate health care providers. Nurses should recognize the importance of encouraging culturally competent care and health promotion activities (Giger, 2016).

Disability

The general patient profile needs to contain information about any hearing, vision, or other type of physical disability. In addition, developmental, intellectual, sensory, or cognitive disabilities need to be addressed. The presence of an obvious physical limitation (e.g., using crutches to walk or using a wheelchair to get around) necessitates further investigation. The initial cause or onset of the disability, as well as the impact on functional ability, should be established. Chart 4-4 presents specific issues that the nurse should consider

when obtaining health histories and conducting physical assessments of patients with disability.

Veterans Considerations

When conducting a health assessment, a key part of the nurse's role is to ask all adult patients if they have served in the U.S. military, and, if so, their branch of service, length of service, and assigned duty stations (i.e., geographic locations and type of assignments). Patients who are veterans should be specifically asked about their experiences with violence and war, regardless of their ages, genders, lengths of service, and assignments. Asking about violent experiences works best when it is viewed as a normal and natural part of the nursing assessment. The nurse's approach to gathering this information should be similar to that used when asking patients about sleep or activity difficulties or dietary or sexual concerns. It is important to try to establish a connection with the patient first. Taking time to listen in a nonjudgmental, nondirective way and noting that confidentiality of responses will be ensured helps create a safe, supportive atmosphere. Traumatic experiences from witnessing violence are common for combat veterans and veterans who have experienced other forms of violence, placing them at risk for posttraumatic stress disorder (PTSD), alcohol abuse (Possemato, Maisto, Wade, et al., 2015), pain (Flynn, Cook, Kallen, et al., 2017), and increased suicide risk compared with nonveterans (Kang, Bullman, Smolenski, et al., 2015). Pain is a leading cause of disability among active duty service members and veterans (Flynn et al., 2017) (see Chapter 9 for further discussion).

Veterans may be eligible for Veterans Administration (VA) benefits, including access to VA financial aid services and health care through the Veterans Health Administration (VHA), the largest integrated health care system in the United States. The VHA provides care to veterans at more than 1200 health care facilities, including 170 medical centers and 1000 outpatient sites that provide health care services of varying complexity. In addition, benefits-eligible veterans who reside in rural areas may opt to receive some VHA services through mobile vans and telehealth services. Less than half of the 20 million benefits-eligible U.S. veterans are enrolled in VA benefits services (Chokshi & Sommers, 2015).

Self-Concept

Self-concept, a person's view of themself/themselves, is an image that develops over many years. To assess self-concept, the interviewer might ask how a person views life, using a question such as "How do you feel about your life in general?" A person's self-concept can be threatened very easily by changes in physical function, appearance, or other threats to health. The impact of certain medical conditions or surgical interventions, such as a colostomy or a mastectomy, can threaten body image. In addition, patients with implantable

devices may have body image concerns, particularly those with implantable cardioverter defibrillators (ICDs) and ventricular assist devices (VADs) (Alonso, Mollard, Zimmerman, et al., 2019; Frydensberg, Skovbakke, Pedersen, et al., 2018). The question, "Do you have any particular concerns about your body?" may elicit useful information about self-image.

Chart 4-4 **ASSESSMENT**

Assessing the Health of People with Disability

Overview

People with disability are entitled to the same level of health assessment and physical examination as people without disability. Physical and mental disability should be explained in the health history. Patients with mental disability are often marginalized from mainstream health care services because of the complexities of their disability. It is appropriate to ask the patient, or caregiver when necessary, what assistance they need rather than assuming that help is needed for all activities or that, if assistance is needed, the patient will ask for it.

Health History

Communication between the nurse and the patient is essential. To ensure that the patient is able to respond to assessment questions and provide needed information, interpreters, assistive listening devices, or other alternative formats (e.g., Braille, large-print forms) may be required.

When interpreters are needed, interpretation services should be arranged. Health care facilities have a responsibility to provide these services without charge to the patient. Family members (especially children) should *not* be used as interpreters, because doing so violates the patient's right to privacy and confidentiality.

The nurse should speak directly to the patient and not to family members or others who have accompanied the patient. If patients have impaired hearing, they should be encouraged to use their hearing aids or hearing assistance technology during the assessment. The patient should be able to see the nurse's face clearly during the health history so that speech reading and nonverbal clues can be used to aid communication.

The health history should address general health issues that are important to all patients, including sexual history and risk for abuse, including intimate partner violence. It should also address the impact of the patient's disability on health issues and access to care, as well as the effect of the patient's current health problem on their disability. An assessment of whether the patient's quality of life meets their expectations should be included in the health history.

The nurse should verify what the patient has said; if the patient has difficulty communicating verbally, the nurse should ask for clarification rather than assume that it is too difficult for the patient to do so. Most people would rather be asked to explain again than run the risk of being misunderstood.

Physical Examination

Inaccessible facilities remain a major barrier to health care for people with disability. Barriers include lack of ramps and grab bars, inaccessible restrooms, small examination rooms, and examination tables that cannot be lowered to allow the patient to move himself or herself onto, or be transferred easily and safely to, the examination table. The patient may need help getting undressed for the physical examination (and dressed again), moving on and

off the examination table, and maintaining positions usually required during physical examination maneuvers. It is important to ask the patient what assistance is needed.

If the patient has impaired sensory function (e.g., lack of sensation, hearing or vision loss), it is important to inform the patient that you will be touching them. Furthermore, it is important to explain all procedures and maneuvers.

Gynecologic examinations should *not* be deferred because a patient has a disability or is assumed to be sexually inactive. Explanations of the examination are important for all women, and even more so for women with disability, because they may have had previous negative experiences. Slow, gentle moving and positioning of the patient for the gynecologic examination and warming the speculum before attempting insertion often minimize spasticity in women with neurologically related disability.

Health Screenings and Testing

Many people with disability report that they have not been weighed for years or even decades because they are unable to stand for this measurement. Alternative methods (e.g., use of wheelchair scales) are needed to monitor weight and body mass index. This is particularly important because of the increased incidence of obesity and its effects on health status and transfer of people with disabilities.

Patients with disability may require special assistance if urine specimens are to be obtained as part of the visit. They are often able to suggest strategies to obtain urine specimens based on previous experience.

If it is necessary for the nurse to wear a mask during a procedure or if the patient is unable to see the face of the nurse during a procedure, it is important to explain the procedure and the expected role of the patient ahead of time. If the patient is unable to hear or communicate with the nurse or other health care provider verbally during an examination or diagnostic test, a method of communication (e.g., signaling the patient by tapping the arm, signaling the nurse by using a bell) should be established beforehand.

People with disability experience difficulties related to obtaining care, challenges accessing health care facilities, perceptions that health professionals are insensitive to their needs, and concerns about the quality of care they receive. Therefore, it is important to ask about health screening and recommendations for screening. In addition, people with disability should be asked about their participation in health promotion activities, because inaccessible environments and other barriers may limit their participation in exercise, health programs, and other health promotion efforts such as health screenings.

Sexuality

The sexual history is an extremely personal area of assessment. Interviewers are frequently uncomfortable with such questions and ignore this area of the patient profile or conduct a very cursory interview about this subject. It is the nurse's professional and clinical responsibility to discuss issues of sexuality with patients.

Sexual function may be affected negatively by disease (or treatment), surgery, or aging. In order for the patient to maintain sexual function and optimize quality of life, sexual issues must be addressed. In addition, the interviewer should project a positive attitude related to sexual orientation or toward those who may be lesbian, gay, bisexual, transgender, or queer (LGBTQ). In addition, if a patient's sexual orientation and gender identity is not yet known, use of neutral language will help put the patient at ease and enhance the therapeutic relationship (see Chapter 54, Table 54-1, for examples of gender neutral language and assessment questions).

Sexual assessment can be approached at the end of the interview or at the time interpersonal or lifestyle factors are assessed; otherwise, it may be easier to discuss sexuality as a part of the genitourinary history within the review of systems. In cisgender female patients, a discussion of sexuality could follow questions about menstruation. In cisgender male patients, a similar discussion could follow questions about the urinary system.

Obtaining the sexual history provides an opportunity to discuss sexual matters openly and gives the person permission to express sexual concerns to an informed professional. The assessment begins with an orienting sentence such as "Next, I would like to ask about your sexual health and practices." This type of opening may lead to a discussion of concerns related to sexual expression or the quality of a relationship, or to questions about contraception, risky sexual behaviors, and safer sex practices. Examples of other questions include "Do you have one or more sexual partners?" and "Are you satisfied with your sexual relationships?"

Determining whether a person is sexually active should precede any attempts to explore issues related to sexuality and sexual function. Care should be taken to initiate conversations about sexuality with older adult patients and patients with disability and not to treat them as asexual people. Questions should be worded in such a way that the person feels free to discuss sexuality regardless of marital status or sexual orientation. Direct questions are usually less threatening when prefaced with such statements as "Some people feel that…" or "Many people worry about…." This suggests the normalcy of such feelings or behavior

and encourages the person to share information that might otherwise be omitted because of fear of seeming "different."

If a person answers abruptly or does not wish to carry the discussion any further, then the interviewer should move to the next topic. However, introducing the subject of sexuality indicates to the person that a discussion of sexual concerns is acceptable and can be approached again in the future if so desired (further discussion of the sexual history is presented in Chapters 50, 53, and 54).

Gerontologic Considerations

Effective health care for older adults requires assessment of sexual health (Weber & Kelley, 2018). Older adults may be stereotyped by misconceptions that they are sick and disabled, have dementia, have lower intelligence and are resistant to change, are not able to have sexual intercourse, or are not interested in sex (Eliopoulos, 2018); however, sexual activity continues in later life, and sexual satisfaction depends on age-related changes (Skałacka & Gerymski, 2019). Literature supports that people not only remain sexually active for a long time into their old age, but also that various forms of sexual activity is associated with their global life satisfaction (Lee, Vanhoutte, Nazroo, et al., 2016; Skałacka & Gerymski, 2019). Many older adults prefer to engage in more subtle forms of sexual activity (e.g., kissing, cuddling) rather than having intercourse. The frequency of intercourse may diminish because of body changes and health issues that may result from the aging process and/or sexual dysfunction in one or both partners (Skałacka & Gerymski, 2019).

Risk for Intimate Partner Violence

Physical, sexual, and psychological violence affects people of both genders and those who identify as gender fluid or nonbinary, as well as people of all ages and from all socioeconomic and ethnic groups. IPV, also called domestic violence, is common in the United States. One in four women in the United States experiences IPV (Smith, Chen, Basile, et al., 2017). IPV includes physical, sexual, or emotional abuse, as well as sexual coercion and stalking by a current or former intimate partner (HHS, 2019c). Patients rarely discuss this topic unless specifically asked about it. Therefore, it is important to ask direct questions, such as:

- Is anyone physically hurting you or forcing you to engage in sexual activities?
- Has anyone ever hurt you physically or threatened to do so?
- Are you ever afraid of anyone close to you (your partner, caregiver, or other family members)?

Patients who are older or have disability are at increased risk for IPV and should be asked about it as a routine part of assessment (Truong, Burnes, Alaggia, et al., 2019). However, when older patients are questioned directly,

they rarely admit to abuse. Health care professionals should assess for risk factors, such as high levels of stress or alcoholism in caregivers, or evidence of violence, emotional outbursts, or financial, emotional, or physical dependency in patients.

Two additional questions have been found to be effective in uncovering specific types of IPV that may occur only in people with disability:

- Does anyone prevent you from using a wheelchair, cane, respirator, or other assistive device?
- Does anyone you depend on refuse to help you with an important personal need, such as taking your medicine, getting to the bathroom, getting in or out of bed, bathing, dressing, or getting food or drink?

If a person's response indicates that IPV is a risk, further assessment is warranted, and efforts are made to ensure the patient's safety and provide access to appropriate community and professional resources and support systems (further discussion of IPV is presented in Chapters 50 and 67).

Stress and Coping Responses

Each person handles stress differently. How well people adapt to stress depends on their ability to cope. During a health history, past coping patterns and perceptions of current stresses and anticipated outcomes are explored to identify the person's overall ability to handle stress. It is especially important to identify the expectations that a person may have related to family, friends, and caregivers in terms of providing financial, emotional, or physical support (further discussion of stress and coping is presented in Chapter 5).

Physical Assessment

Physical assessment, or the physical examination (collection of objective data about the patient's health status), is an integral part of nursing assessment. The basic techniques and tools used in performing a physical examination are described in general in this chapter. The examinations of specific systems, including special maneuvers, are described in the respective system assessment chapters throughout the book.

Examination Considerations

The physical examination is usually performed after the health history is obtained. It is carried out in a well-lighted, warm area. The patient is asked to (or helped to) undress and is draped appropriately so that only the area to be examined is exposed. The patient's physical and psychological comfort are considered at all times. It is necessary to describe procedures to the patient and explain what sensations to expect before each part of the examination. The

examiner washes his or her hands before and immediately after the examination. Fingernails are kept short to avoid injuring the patient. If there is a possibility of coming into contact with blood or other body secretions during the physical examination, gloves should be worn.

An organized and systematic examination is the key to obtaining appropriate data in the shortest time. Such an approach encourages cooperation and trust on the part of the patient. The patient's health history provides the examiner with a health profile that guides all aspects of the physical examination.

A "complete" physical examination is not routine. Many of the body systems are selectively assessed on the basis of the presenting problem. For example, if a healthy 20-year-old college student requires an examination to study abroad and reports no history of neurologic abnormality, the neurologic assessment is brief. Conversely, a history of transient numbness and diplopia (double vision) usually necessitates a complete neurologic investigation. Similarly, a patient with chest pain receives a much more intensive examination of the chest and the heart than one with an earache. In general, the health history guides the examiner in obtaining additional data for a complete picture of the patient's health.

The process of learning to perform a physical examination requires repetition and reinforcement in a simulated or clinical setting. Only after basic physical assessment techniques are mastered can the examiner tailor the routine examination to include thorough assessments of particular systems, including special maneuvers (Hogan-Quigley et al., 2017; Weber & Kelley, 2018).

Components of the Physical Examination

The components of a physical examination include general observations and then a more focused assessment of the pertinent body systems. The tools of the physical examination are the human senses of vision, hearing, touch, and smell. These may be augmented by special tools (e.g., stethoscope, ophthalmoscope, reflex hammer) that are extensions of the human senses; they are simple tools that anyone can learn to use well. Expertise comes with practice, and sophistication comes with the interpretation of what is seen and heard.

Initial Observations

General inspection begins with the first contact with the patient. Introducing oneself and shaking hands provide opportunities for making initial observations: Is the person old or young? How old? How young? Does the person appear to be their stated age? Is the person thin or obese? Does the person appear anxious or depressed? Is the person's body structure normal or abnormal—in what way and how different from normal? It is essential to pay attention to the details in observation. Vague, general statements are not a substitute for specific descriptions based on careful observation. Consider the following examples:

- "The patient appears sick." In what way do they appear sick? Is the skin clammy, pale, jaundiced, or cyanotic? Is the patient grimacing in pain or having difficulty breathing? Do they have edema? What specific physical features or behavioral manifestations indicate that the patient is "sick?"
- "The patient appears chronically ill." In what way do they appear chronically ill? Does the patient appear to have lost weight? Patients who lose weight secondary to muscle-wasting diseases (e.g., AIDS, malignancy) have a different appearance than those who are merely thin, and weight loss may be accompanied by loss of muscle mass or atrophy. Does the skin have the appearance of chronic illness (i.e., is it pale, or does it give the appearance of dehydration or loss of subcutaneous tissue)?

These important specific observations are documented in the patient's chart or health record. Among general observations that should be noted in the initial examination of the patient are posture, body movements, nutritional status, speech pattern, and vital signs.

Posture

The posture that a patient assumes often provides valuable information. Patients who have dyspnea (breathing difficulties) secondary to cardiac disease prefer to sit and may report feeling short of breath when lying flat for even a brief time. Patients with abdominal pain owing to peritonitis prefer to lie perfectly still; even slight jarring of the bed or examination table causes agonizing pain. In contrast, patients with abdominal pain owing to renal or biliary colic are often restless and may pace the room.

Body Movements

There are two kinds of abnormalities of body movement: generalized disruption of voluntary or involuntary movement and asymmetry of movement. The first category includes various tremors; some tremors may occur at rest (Parkinson's disease), whereas others occur only on voluntary movement (cerebellar ataxia). Other tremors may exist during both rest and activity (alcohol withdrawal syndrome, thyrotoxicosis). Some voluntary or involuntary movements are fine and others are quite coarse. Extreme examples include the convulsive movements of generalized seizures and the choreiform (involuntary and irregular) movements of patients with rheumatic fever or Huntington disease.

Asymmetry of movement, in which only one side of the body is affected, may occur with disorders of the central nervous system (CNS), primarily in those patients who have had a stroke. Patients may have drooping of one side of the face, weakness or paralysis of the extremities on one side of the body, or a foot-dragging gait.

Nutritional Status

Nutritional status is important to note. Obesity may be generalized as a result of excessive intake of calories, or it may be specifically localized to the trunk in patients who have an endocrine disorder (Cushing's disease) or who have been taking corticosteroids for long periods. Loss of weight may be generalized as a result of inadequate caloric intake, or it may be seen in loss of muscle mass with disorders that affect protein synthesis. Nutritional assessment is discussed in more detail later in this chapter.

Speech Pattern

Speech may be slurred because of CNS disease or because of damage to cranial nerves. Recurrent damage to the laryngeal nerve results in hoarseness, as do disorders that produce edema or swelling of the vocal cords. Speech may be halting, slurred, or interrupted in flow in patients with some CNS disorders (e.g., multiple sclerosis, stroke).

Vital Signs and Pain Assessment

The recording of vital signs is a part of every physical examination (Hogan-Quigley et al., 2017). Blood pressure, pulse rate, respiratory rate, and body temperature measurements are obtained and recorded. Acute changes and trends over time are documented, and unexpected changes and values that deviate significantly from a patient's normal values are brought to the attention of the patient's primary provider. Pain is also assessed and documented, if indicated (see Chapter 9 for further discussion).

Focused Assessment

Following the general inspection, a more focused assessment is conducted. Although the sequence of physical examination depends on the circumstances and the patient's reason for seeking health care, the complete examination usually proceeds as follows:

- Skin
- Head and neck
- Thorax and lungs
- Breasts
- Cardiovascular system
- Abdomen
- Rectum
- Genitalia
- Neurologic system
- Musculoskeletal system

In clinical practice, all relevant body systems are tested throughout the physical examination, not necessarily in the sequence described (Weber & Kelley, 2018). For example, when the face is examined, it is appropriate to check for facial asymmetry and, thus, for the integrity of the fifth and seventh cranial nerves; the examiner does not need to repeat this as part of a neurologic examination. When systems are combined in this manner, the patient does not need to change positions repeatedly, which can be exhausting and time-consuming.

The traditional sequence in the focused portion of the examination is inspection, palpation, percussion, and then auscultation, except in the case of an abdominal examination (in which auscultation precedes palpation and percussion).

Inspection

The first fundamental technique is **inspection**, or observation of each relevant body system in more detail as indicated from the health history or the general inspection. Characteristics such as skin color, presence and size of lesions, edema, erythema, symmetry, and pulsations are noted. Specific body movements that are noted on inspection include spasticity, muscle spasms, and an abnormal gait (Norris, 2019).

Palpation

Palpation, which utilizes the sense of touch, is a vital part of the physical examination. Many structures of the body, although not visible, may be assessed through the techniques of light and deep palpation (Fig. 4-3). Examples include the superficial blood vessels, lymph nodes, thyroid gland, organs of the abdomen and the pelvis, and rectum. When the abdomen is examined, auscultation is performed before palpation and percussion to avoid altering bowel sounds (Hogan-Quigley et al., 2017; Weber & Kelley, 2018).

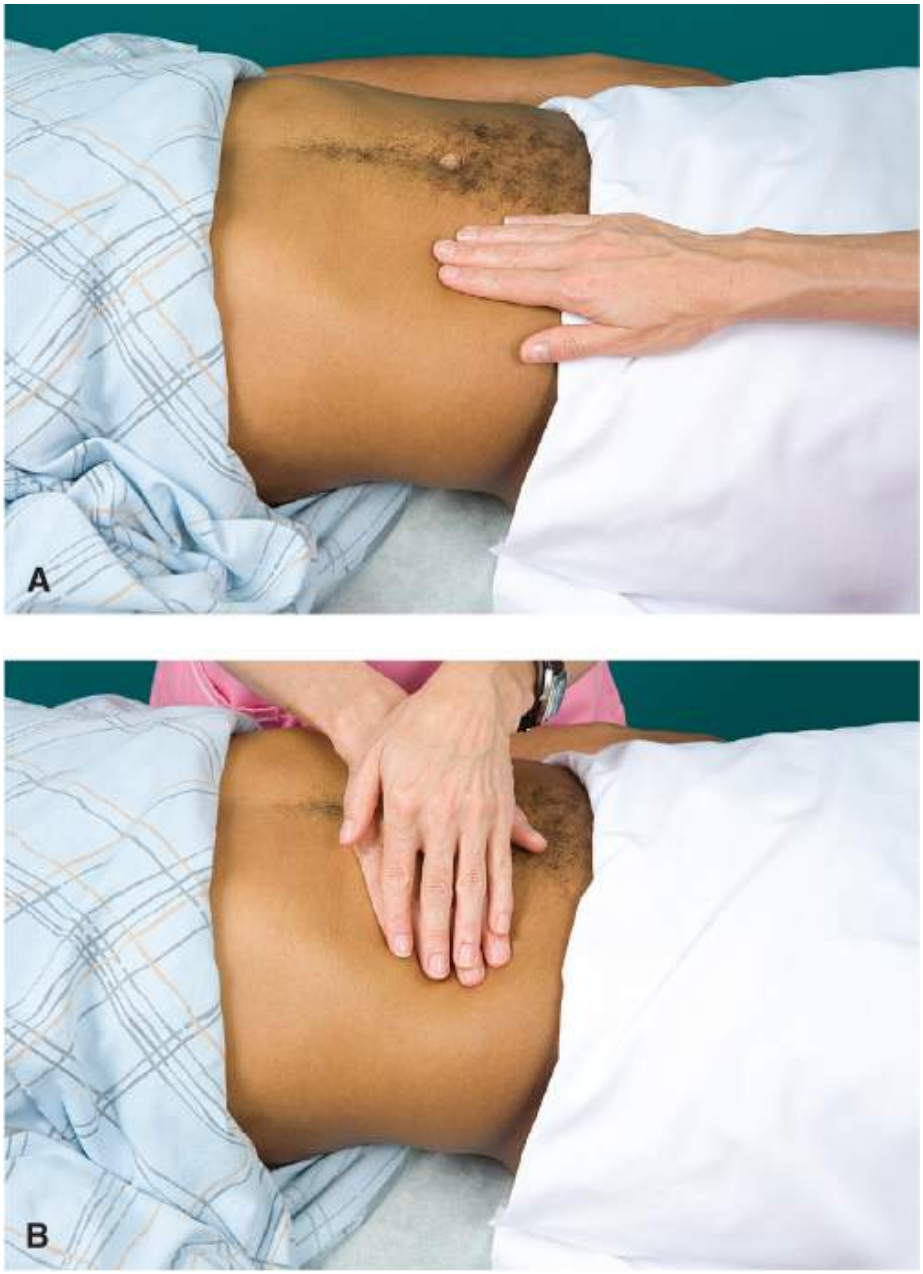

Figure 4-3 • **A.** Light palpation. **B.** Deep palpation.

Some sounds generated within the body, if within specified frequency ranges, may also be detected through touch. For example, turbulent flow in the heart or within blood vessels (thrills) may be detected. Thrills cause a sensation to the hand much like the purring of a cat. Voice sounds are transmitted along the bronchi to the periphery of the lung. These may be perceived by touch and may be altered by disorders affecting the lungs. The phenomenon is called *tactile fremitus* and is useful in assessing diseases of the chest. The significance of these findings is discussed in Chapters 17 and 21.

Percussion

The technique of **percussion** translates the application of physical force into sound. It is a skill requiring practice that yields much information about disease processes in the chest and the abdomen (Hogan-Quigley et al., 2017; Weber & Kelley, 2018). The principle is to set the chest wall or abdominal wall into vibration by striking it with a firm object. The sound produced reflects the density of the underlying structure. Certain densities produce sounds as percussion notes. These sounds, listed in a sequence that proceeds from the least to the densest, are tympany, hyperresonance, resonance, dullness, and flatness. Tympany is the drumlike sound produced by percussing the air-filled stomach. Hyperresonance is audible when one percusses over inflated lung tissue in a person with emphysema. Resonance is the sound elicited over air-filled lungs. Percussion of the liver produces a dull sound, whereas percussion of the thigh produces a flat sound.

Percussion allows the examiner to assess such normal anatomic details as the borders of the heart and the movement of the diaphragm during inspiration. It is also possible to determine the level of a pleural effusion (fluid in the pleural cavity) and the location of a consolidated area caused by pneumonia or atelectasis (collapse of alveoli). The use of percussion is described further with disorders of the thorax and the abdomen (see Chapters 17 and 38).

Concept Mastery Alert

Whereas auscultation involves listening to sounds produced within the body by the movement of air, percussion involves applying physical force to the body in order to discern what sounds are made, thereby assessing internal organs. Hyperresonance is audible when one percusses over inflated lung tissue in a person with emphysema.

Auscultation

Auscultation is the skill of listening to sounds produced within the body created by the movement of air or fluid (Fig. 4-4). A stethoscope is typically used to enhance this technique. Examples include breath sounds, the spoken voice, bowel sounds, heart sounds, and cardiac murmurs. Physiologic sounds may be normal (e.g., first and second heart sounds) or pathologic (e.g., heart murmurs in diastole, crackles in the lung). Some normal sounds may be distorted by abnormalities of structures through which the sound must travel (e.g., changes in the character of breath sounds as they travel through the consolidated lung of a patient with lobar pneumonia).

Figure 4-4 • Auscultation of the heart in forward sitting position.

Sound produced within the body, if of sufficient amplitude, may be detected with the stethoscope, which functions as an extension of the human ear and channels sound. The nurse must avoid touching the tubing or rubbing other surfaces (hair, clothing) during auscultation to minimize extraneous noises. Sounds detected by auscultation are classified according to their intensity (loud or soft), pitch (high or low), duration (length), and quality (musical, raspy, crackling) (Hogan-Quigley et al., 2017; Weber & Kelley, 2018).

Nutritional Assessment

Nutrition is important to maintain health and to prevent disease and premature death. When illness or injury occurs, optimal nutrition is essential for recovery, healing, and for resisting infection and other complications. An in-depth nutritional assessment is often integrated into the health history and physical examination. Assessment of a patient's nutritional status provides information about obesity, undernutrition, and malnutrition.

Certain signs that suggest possible nutritional deficiency, such as muscle wasting, poor skin integrity, loss of subcutaneous tissue, and obesity, are easy to note because they are evident and objective. Other physical signs may be subtle, or the patient may report subjective symptoms, which must be carefully assessed. It is important to note that some signs and symptoms that appear to

indicate nutritional deficiency may actually reflect other systemic conditions (e.g., endocrine disorders, infectious disease). Others may result from impaired digestion, absorption, excretion, or storage of nutrients in the body (Norris, 2019; Weber & Kelley, 2018). Disorders caused by nutritional deficiency, overeating, or eating unhealthy foods are among the leading causes of illness and death in the United States today. Examples of health problems associated with poor nutrition include obesity, osteoporosis, cirrhosis, diverticulitis, and eating disorders.

Obesity is a major concern for children, adolescents, and adults in the United States and globally. The World Health Organization (WHO) defines obesity as abnormal or excessive fat accumulation that may impair health. Obesity and being overweight are leading risk factors for global deaths; most of the world's population lives in countries where overweight and obesity kill more people than underweight. In addition, coronary artery disease, diabetes, musculoskeletal disorders, and certain cancers can be attributable to obesity (WHO, 2019) (see Chapter 42 for a detailed discussion of obesity).

Lifespan Considerations

When the nurse conducts a nutritional assessment, two age groups merit special consideration: adolescents and older adults. Key considerations for each group are highlighted below.

Adolescents

Adolescence is a time of critical growth and when lifelong eating and exercise habits are established. Nutritional assessment is particularly important during this time period. In general, adolescents gain 40% of their adult weight and 15% of their adult height during this developmental stage of life (Lassi, Moin, & Bhutta, 2017). It is vital to assess for obesity in adolescents to prevent complications from obesity as they grow and develop, as well as when they enter adulthood.

Adolescent girls should consume approximately 1400 to 2400 calories daily; whereas, adolescent boys require between 1600 to 3200 calories each day to support their greater growth needs in terms of both overall size and muscle mass. Athletes of either gender may need to consume up to 5000 calories daily to support their metabolic demands. In adolescents of both genders, sufficient micronutrients such as calcium, B-complex vitamins, iron, and folate are necessary to support increased metabolic activity during this time of growth. Adolescent girls are at particular nutritional risk, because they are thought to be exposed to expectations to diet and maintain a thin body. As a consequence, many adolescent girls are purposely deficient in their intake of dairy products, because they are caloric-rich. However, dairy products provide an important

source of calcium that is necessary in order to build bone mass. Adolescents of both genders are at risk for behavioral eating disorders, such as anorexia, bulimia, and binge-eating disorders, although girls are at greater risk (Lassi et al., 2017).

Older Adults

Older adults are also at risk for altered nutrition. Nutritional assessment in the older adult should include inquiry about the patient's current dietary practices as well as a nutritional screening to assess for adequate nutrition. The Mini Nutritional Assessment is a commonly used, well-validated tool developed specifically for this purpose (Chart 4-5). Many older adults adhere to specific diets, such as those low in saturated fat or sodium, for improving or maintaining health. Proper nutrition for an older adult meets daily requirements, maintains ideal body weight, and addresses specific health concerns such as cardiovascular or renal disease (Eliopoulos, 2018).

Older adults are particularly at high risk for poor nutrition due to factors that may include social isolation, frailty, cognitive impairment, polypharmacy (i.e., use of multiple prescription and OTC medications), reduced functional status, and financial instability (Astrup & O'Connor, 2018). Disorders affecting any part of the gastrointestinal tract can alter nutritional requirements and health status in people of any age; however, such disorders are likely to occur more quickly and more frequently in older adults. Acute and chronic diseases may affect the metabolism and utilization of nutrients, which already are altered by the aging process. Even well older adults may be nutritionally at risk because of decreased odor perception, poor dental health, limited ability to shop and cook, financial hardship, and the fact that they often eat alone (Eliopoulos, 2018).

Polypharmacy also may place older adults at risk nutritionally. The number of adverse reactions increases proportionately with the number of medications taken. Age-related physiologic and pathophysiologic changes may alter the metabolism and elimination of many medications (Eliopoulos, 2018). Medications can influence food intake by producing side effects such as nausea, vomiting, decreased appetite, and changes in cognition. They may also interfere with the distribution, utilization, and storage of nutrients.

Components of Nutritional Assessment

The sequence of the assessment may vary; however, evaluation of a patient's nutritional status includes the use of one or more of the following methods: measurement of body mass index (BMI) and waist circumference, biochemical assessment, clinical examination findings, and dietary data. Measurement of BMI and waist circumference is recommended to determine whether a patient has obesity (CDC, 2019a).

Body Mass Index, Ideal Weight, and Waist Circumference

Body mass index (BMI) is a ratio based on body weight and height (Table 4-1). The obtained value is compared to established standards; however, trends or changes in values over time are considered more useful than isolated or one-time measurements. BMI is highly correlated with body fat, although increased lean body mass or a large body frame can also increase the BMI. People who have a BMI lower than 18.5 (or who are 80% or less of their desirable body weight for height) are at increased risk for problems associated with poor nutritional status. In addition, a low BMI is associated with a higher mortality rate among hospitalized patients and community-dwelling older adults. Those who have a BMI between 25 and 29.9 are considered overweight. Obesity is defined as a BMI of greater than 30 (WHO, 2019). Although there are no current standard recommendations for BMI based on race or ethnicity, there is literature to support that BMI and body fat percentages can vary between genders and among people of different ages and from different ethnic groups (McConnell-Nzunga, Naylor, Macdonald, et al., 2018). In analyzing BMI, the nurse must be aware that there may be weight variance that could be dependent upon age, gender, and ethnicity.

TABLE 4-1 How Is BMI Calculated?[a]

Measurement Units	Formula and Calculation
Kilograms and meters (or centimeters)	Formula: weight (kg)/[height (m)]^2 With the metric system, the formula for BMI is weight in kilograms divided by height in meters squared. Because height is commonly measured in centimeters, divide height in centimeters by 100 to obtain height in meters. Example: Weight = 68 kg, Height = 165 cm (1.65 m) Calculation: 68/(1.65)^2 = 24.98
Pounds and inches	Formula: weight (lb)/[height (in)]^2 × 703 Calculate BMI by dividing weight in pounds (lb) by height in inches (in) squared and multiplying by a conversion factor of 703. Example: Weight = 150 lb, Height = 65 in Calculation: [150/(65)^2] × 703 = 24.96

[a]BMI is calculated the same way for both adults and children. The calculation is based on formulas within this table.

BMI, body mass index.

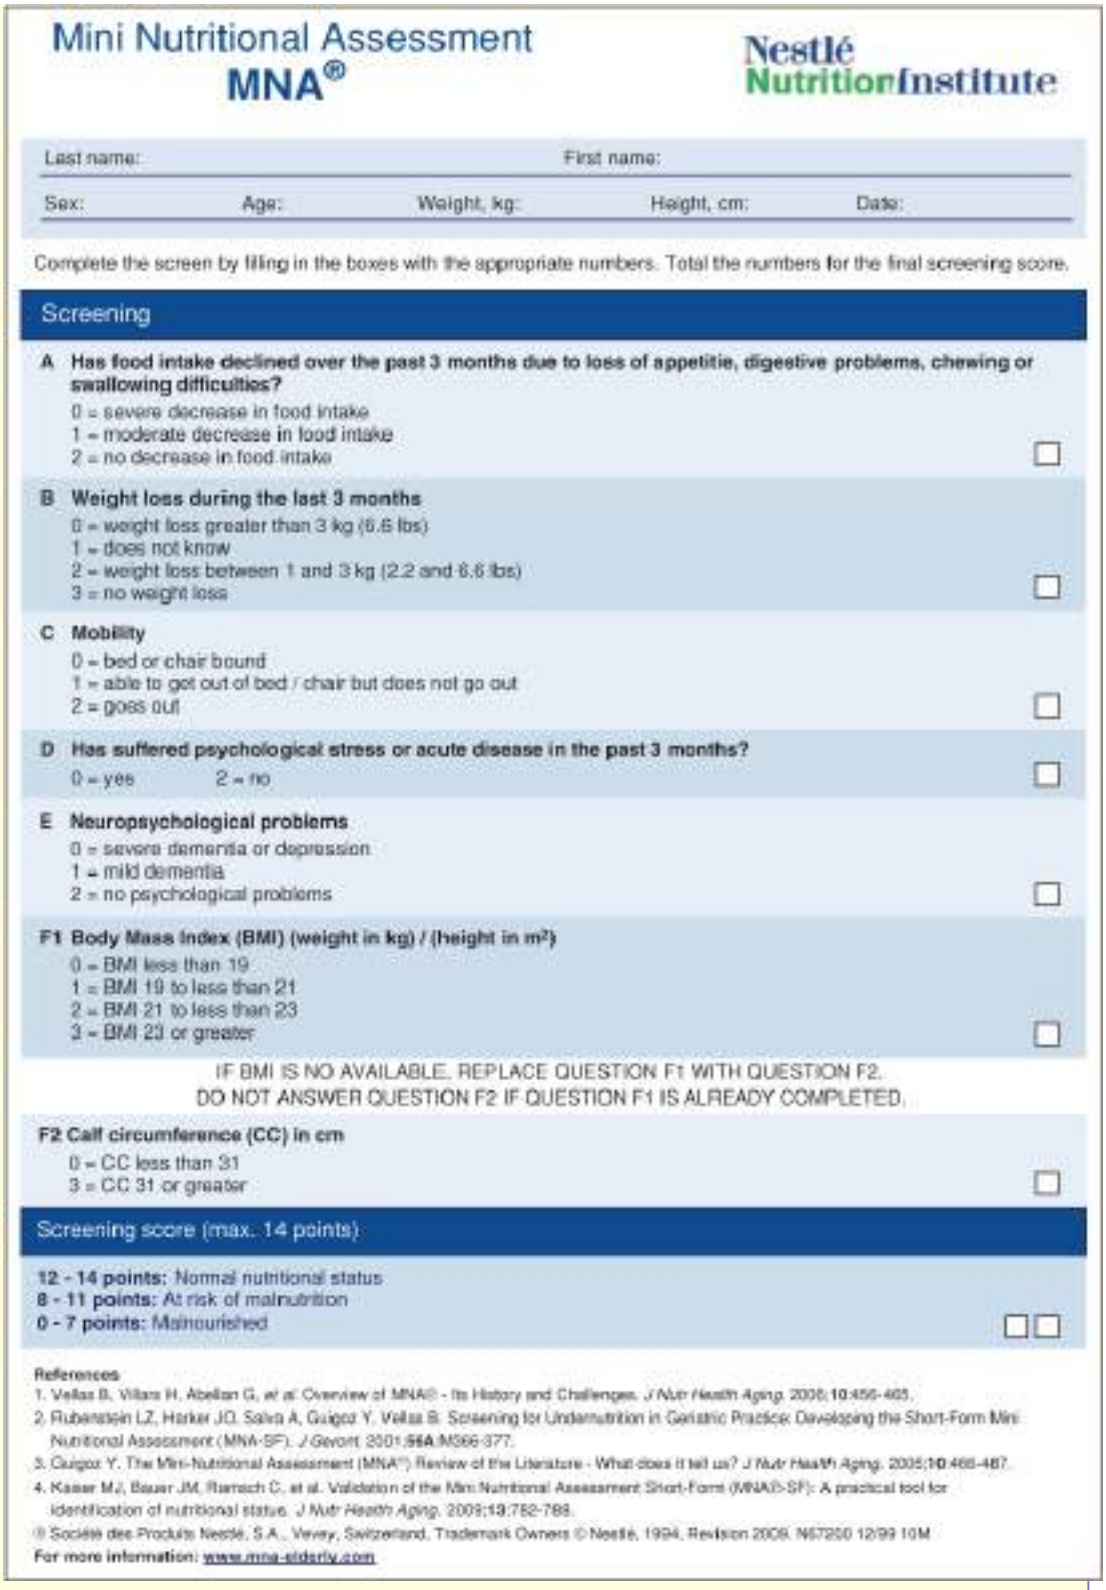
Chart 4-5

Mini Nutritional Assessment

The Mini Nutritional Assessment (MNA) is a six-item tool designed to identify adults aged 65 y and older who are either malnourished or at risk for becoming malnourished. It is available in several languages and there are several methods of delivery, including self-assessment as well as an electronic health record (EHR) version. It provides a more sensitive measure than body mass index (BMI) in identifying older adults in long-term care facilities at risk for malnutrition (Nestlé Nutrition Institute, 2011).



Mini Nutritional Assessment
MNA®

Nestlé Nutrition Institute

Last name: First name:

Sex: Age: Weight, kg: Height, cm: Date:

Complete the screen by filling in the boxes with the appropriate numbers. Total the numbers for the final screening score.

Screening

A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?
0 = severe decrease in food intake
1 = moderate decrease in food intake
2 = no decrease in food intake

B Weight loss during the last 3 months
0 = weight loss greater than 3 kg (6.6 lbs)
1 = does not know
2 = weight loss between 1 and 3 kg (2.2 and 6.6 lbs)
3 = no weight loss

C Mobility
0 = bed or chair bound
1 = able to get out of bed / chair but does not go out
2 = goes out

D Has suffered psychological stress or acute disease in the past 3 months?
0 = yes 2 = no

E Neuropsychological problems
0 = severe dementia or depression
1 = mild dementia
2 = no psychological problems

F1 Body Mass Index (BMI) (weight in kg) / (height in m²)
0 = BMI less than 19
1 = BMI 19 to less than 21
2 = BMI 21 to less than 23
3 = BMI 23 or greater

IF BMI IS NO AVAILABLE, REPLACE QUESTION F1 WITH QUESTION F2.
DO NOT ANSWER QUESTION F2 IF QUESTION F1 IS ALREADY COMPLETED.

F2 Calf circumference (CC) in cm
0 = CC less than 31
3 = CC 31 or greater

Screening score (max. 14 points)

12 - 14 points: Normal nutritional status
8 - 11 points: At risk of malnutrition
0 - 7 points: Malnourished

It is important to assess for usual body weight and height and to compare these values with ideal weight (see Chapter 42, Fig. 42-3). Current weight does

not provide information about recent changes in weight; therefore, patients are asked about their usual body weight and any recent weight loss or gain. Loss of height may be attributable to osteoporosis—an important problem related to nutrition, especially in postmenopausal women (Hogan-Quigley et al., 2017; Weber & Kelley, 2018).

In addition to the calculation of BMI, waist circumference measurement is a useful assessment tool. To measure waist circumference, a tape measure is placed in a horizontal plane around the abdomen at the level of the iliac crest. A waist circumference greater than 40 inches for men or 35 inches for women indicates excess abdominal fat. Those with a high waist circumference are at an increased risk for diabetes, dyslipidemias, hypertension, heart attack, and stroke (Hogan-Quigley et al., 2017; Weber & Kelley, 2018).

Biochemical Assessment

Biochemical measurements are applicable to a patient's nutritional assessment as they can test the level of a given nutrient and reflect abnormalities of metabolism in relation to the utilization of nutrients. Tests of serum and urine are done to determine whether the values are within an acceptable range. Some of these tests, while reflecting recent intake of the elements detected, can also identify a long-term deficiency (below-normal levels) even when there are no clinical symptoms of deficiency.

Low serum albumin and prealbumin levels are most often used as measures of protein deficit in adults. Albumin synthesis depends on normal liver function and an adequate supply of amino acids. Because the body stores a large amount of albumin, the serum albumin level may not decrease until malnutrition is severe; therefore, its usefulness in detecting recent protein depletion is limited. Decreased albumin levels may be caused by overhydration, liver or renal disease, or excessive protein loss due to burns, major surgery, infection, or cancer. Serial measurements of prealbumin levels are used to assess the effectiveness of nutritional therapy.

Additional laboratory data, such as levels of transferrin and retinol-binding protein, and complete blood and electrolyte counts, are used in many institutions. Transferrin is a protein that binds and carries iron from the intestine through the serum. Because of its short half-life, transferrin levels decrease more quickly than albumin levels in response to protein depletion. Low levels of transferrin can also lead to a deficiency in iron; low availability of iron in the body limits the synthesis of functioning hemoglobin causing anemia. Although measurement of retinol-binding protein is not available from many laboratories, it may be a useful means of monitoring acute, short-term changes in protein status. The total lymphocyte count may be reduced in people who are acutely malnourished as a result of stress and low-calorie feeding, as well as in those with impaired cellular immunity. Anergy, or the absence of an immune response to injection of small concentrations of recall antigen under the skin, may also

indicate malnutrition because of delayed antibody synthesis and response. Serum electrolyte levels provide information about fluid and electrolyte balance and kidney function.

A 24-hour urine collection can be utilized to calculate the creatinine/height index that assesses metabolically active tissue and indicates the degree of protein depletion. The amount of creatinine is measured and the index is calculated on the basis of the patient's height and gender. The patient's creatinine/height index is then compared to normal ranges based on the expected body weight by height. Values lower than normal may indicate loss of lean body mass and protein malnutrition (Fischbach & Fischbach, 2018).

Clinical Examination

The state of nutrition is often reflected in a person's appearance. Although the most obvious physical sign of good nutrition is a normal body weight with respect to height, body frame, and age, other tissues can serve as indicators of general nutritional status and adequate intake of specific nutrients; these include the hair, skin, teeth, gums, mucous membranes, mouth and tongue, skeletal muscles, abdomen, lower extremities, and thyroid gland (Table 4-2).

Dietary Data

Commonly used methods of determining individual eating patterns include the food record, the 24-hour food recall, and a dietary interview. Each of these methods helps estimate whether food intake is adequate and appropriate. If these methods are used to obtain the dietary history, instructions must be given to the patient about measuring and recording food intake.

Methods of Collecting Data

The nurse may employ multiple methods to collect a patient's dietary data. Two common methods described here include the food record and the 24-hour recall.

Food Record

The food record, also called the food diary, is used most often in nutritional status studies. A person is instructed to keep a record of food consumed over a period of time, varying from 3 to 7 days, and to accurately estimate and describe the specific foods consumed. Food records are fairly accurate if the person is willing to provide factual information and is able to estimate food quantities.

TABLE 4-2 Physical Indicators of Nutritional Status

Indicator	Signs of Good Nutrition	Signs of Poor Nutrition
General appearance	Alert, responsive	Listless, appears acutely or chronically ill
Hair	Shiny, lustrous; firm, healthy scalp	Dull and dry, brittle, dyspigmentation, alopecia (hair loss)
Face	Skin color uniform; healthy appearance	Skin dark over cheeks and under eyes, skin flaky, face swollen or hollow/sunken cheeks, moon face, pallor
Eyes	Bright, clear, moist	Xerophthalmia (pale conjunctiva, dry mucosa), increased vascularity, xanthelasma (yellow subdermal fat deposits around the lids)
Lips	Good color (pink), smooth	Swollen and puffy, angular stomatitis (cracks at corners), cheilosis (angular lesion at corners of mouth)
Tongue	Deep red in appearance; surface papillae present	Glossitis (smooth appearance, swollen, beefy-red or magenta), sores, atrophic papillae
Teeth	Straight, no crowding, no dental caries, bright	Delayed eruption, dental caries, fluorosis (mottled appearance), malpositioned
Gums	Firm, good color (pink)	Spongy, scorbutic (bleeding), marginal redness, recession
Thyroid	No enlargement of the thyroid	Simple goiter (thyroid enlargement)
Skin	Smooth, good color, moist	Rough, dry, flaky, swollen, pale, pigmented; lack of fat under skin
Nails	Firm, pink	Spoon shaped, ridged, brittle
Skeleton	Good posture, no malformation	Stunted growth, poor posture, rachitic rosary (beading of ribs), bowed legs (rickets), narrow chest (pigeon breast), loss of fat, muscle wasting
Muscles	Well developed, firm	Flaccid, poor tone, wasted, underdeveloped
Extremities	No tenderness	Weak and tender, loss of fat, muscle wasting, edematous
Abdomen	Flat	Swollen
Nervous system	Normal reflexes	Decreased or absent ankle and knee reflexes, confusion, neuropathy, tetany
Weight	Normal for height, age, and body build	Overweight or underweight

24-Hour Recall

As the name implies, the 24-hour recall method is a recall of food intake over a 24-hour period. A person is asked to recall all foods eaten during the previous day and to estimate the quantities of each food consumed. Because information does not always represent usual intake, at the end of the interview the patient is asked whether the previous day's food intake was typical. To obtain supplementary information about the typical diet, it is also necessary to ask how frequently the person eats foods from the major food groups.

Dietary Interview

The success of the interviewer in obtaining information for dietary assessment depends on effective communication, which requires that good rapport be established to promote respect and trust. The interview is conducted in a nondirective and exploratory way, allowing the respondent to express feelings and thoughts while encouraging them to answer specific questions. The manner in which questions are asked influences the respondent's cooperation. The interviewer must be nonjudgmental and avoid expressing disapproval by verbal comments or facial expression.

Several questions may be necessary to elicit the information needed. When attempting to elicit information about the type and quantity of food eaten at a particular time, open-ended questions should be utilized. In addition, assumptions should not be made about the size of servings; instead, questions are phrased to clearly determine the quantities. For example, to help determine the size of one hamburger, the patient may be asked, "How many servings were prepared with the pound of meat you bought?" Another approach to determining quantities is to use food models of known sizes in estimating portions of meat, cake, or pie, or to record quantities in common measurements, such as cups or spoonfuls (or the size of containers when discussing intake of bottled beverages).

In recording a particular combination dish, such as a casserole, it is useful to ask about the ingredients, recording the largest quantities first. When recording quantities of ingredients, the interviewer notes whether the food item was raw or cooked and the number of servings provided by the recipe. When a patient lists the foods for the recall questionnaire, it may help read back the list of foods and ask whether anything was forgotten, such as condiments, fruit, cake, candy, between-meal snacks, or alcoholic beverages.

Cultural, Ethnic, and Religious Considerations

Individuals' culture, ethnicity, or personal beliefs determine to a large extent which foods are eaten and how they are prepared and served. Cultural and religious practices can determine whether certain foods are prohibited (Chart 4-

6) and whether certain foods and spices are eaten on holidays or at specific family gatherings. Because of the value of food pattern choices to many individuals, the nurse must be sensitive to these choices when obtaining a dietary history. Equally important, the nurse must not stereotype individuals and assume that because they are from a certain culture or religious group, they adhere to specific dietary customs. Specific eating patterns, such as vegan or vegetarian, should be explored so that appropriate dietary recommendations can be offered (U.S. Department of Agriculture [USDA] & HHS, 2019). Deficiencies in certain diets may cause disorders such as anemia (see Chapter 29 for further discussion).

Chart 4-6

Prohibited Foods and Beverages of Select Religious Groups

Hinduism

All meats
Animal shortenings/fats

Islam

Pork
Alcoholic products and beverages (including extracts, such as vanilla and lemon)
Animal shortenings
Gelatin made from pork, marshmallow, and other confections made with gelatin
Note: Halal is lawful food that may be consumed according to tenets of the Koran, whereas *Haram* is food that is unlawful to consume.

Judaism

Pork
Predatory fowl
Shellfish and scavenger fish (e.g., shrimp, crab, lobster, escargot, catfish). Fish with fins and scales are permissible.
Mixing milk and meat dishes at same meal
Blood by ingestion (e.g., blood sausage, raw meat).
Note: Packaged foods will contain labels identifying kosher ("properly preserved" or "fitting") and pareve (made without meat or milk) items.

Church of Jesus Christ of Latter-Day Saints (formerly known as Mormonism)

Alcohol
Beverages containing caffeine stimulants (coffee, tea, colas, and selected carbonated soft drinks)

Seventh-Day Adventism

Alcohol
Beverages containing caffeine stimulants (coffee, tea, colas, and selected carbonated soft drinks)
Pork
Certain seafood, including shellfish
Fermented beverages
Note: Optional vegetarianism is encouraged.

The cultural context of food varies widely but usually includes one or more of the following: relief of hunger; promotion of health and healing; prevention

of disease or illness; expression of caring for another; promotion of interpersonal closeness among individual people, families, groups, communities, or nations; and promotion of kinship and family alliances. Food is also associated with strengthening of social ties; observance of life events (e.g., birthdays, marriages, funerals); expression of gratitude or appreciation; recognition of achievement or accomplishment; validation of social, cultural, or religious ceremonial functions; facilitation of business negotiations; and expression of affluence, wealth, or social status.

Culture influences which foods are served and when they are served, the number and frequency of meals, who eats with whom, and who receives the choicest portions. Culture also may influence how foods are prepared and served, how they are eaten (with chopsticks, hands, or fork, knife, and spoon), and where people shop (e.g., ethnic grocery stores, specialty food markets). Culture also determines the impact of excess weight and obesity on self-esteem and social standing. In some cultures, physical bulk is viewed as a sign of affluence and health (e.g., a chubby baby is a healthy baby).

Religious practices may include fasting (e.g., Catholics, Buddhists, Jews, Muslims) and abstaining from selected foods at particular times (e.g., Catholics abstain from meat on Ash Wednesday and on Fridays during Lent). Practices may also include the ritualistic use of food and beverages (e.g., Passover dinner, consumption of bread and wine during religious ceremonies; see Chart 4-6).

Most groups feast, often in the company of family and friends, on selected holidays. For example, many Christians eat large dinners on Christmas and Easter and consume other traditional high-calorie, high-fat foods, such as seasonal cookies, pastries, and candies. These culturally based dietary practices are especially significant in the care of patients with diabetes, hypertension, gastrointestinal disorders, obesity, and other conditions in which diet plays a key role in the treatment and health maintenance regimen.

Evaluating Dietary Information

After obtaining basic dietary information, the nurse evaluates the patient's dietary intake and communicates the information to the dietitian and the rest of the health care team for more detailed assessment and clinical nutrition intervention. If the goal is to determine whether the patient generally eats a healthful diet, their food intake may be compared with the dietary guidelines outlined in the USDA's Center for Nutrition Policy & Promotion's MyPlate (Fig. 4-5). Foods are divided into five major groups (fruits, vegetables, grains, protein foods, and dairy), plus oils. Recommendations are provided related to variety in the diet, proportion of food from each food group, and moderation in eating fats, oils, and sweets. A patient's food intake is compared with recommendations based on various food groups for different age groups and activity levels (Weber & Kelley, 2018).

If nurses or dietitians are interested in knowing about the intake of specific nutrients, such as vitamin A, iron, or calcium, the patient's food intake is

analyzed by consulting a list of foods and their composition and nutrient content. The diet is analyzed in terms of grams and milligrams of specific nutrients. The total nutritive value is then compared with the recommended dietary allowances specific for the patient's age category, gender, and special circumstances such as pregnancy or lactation.

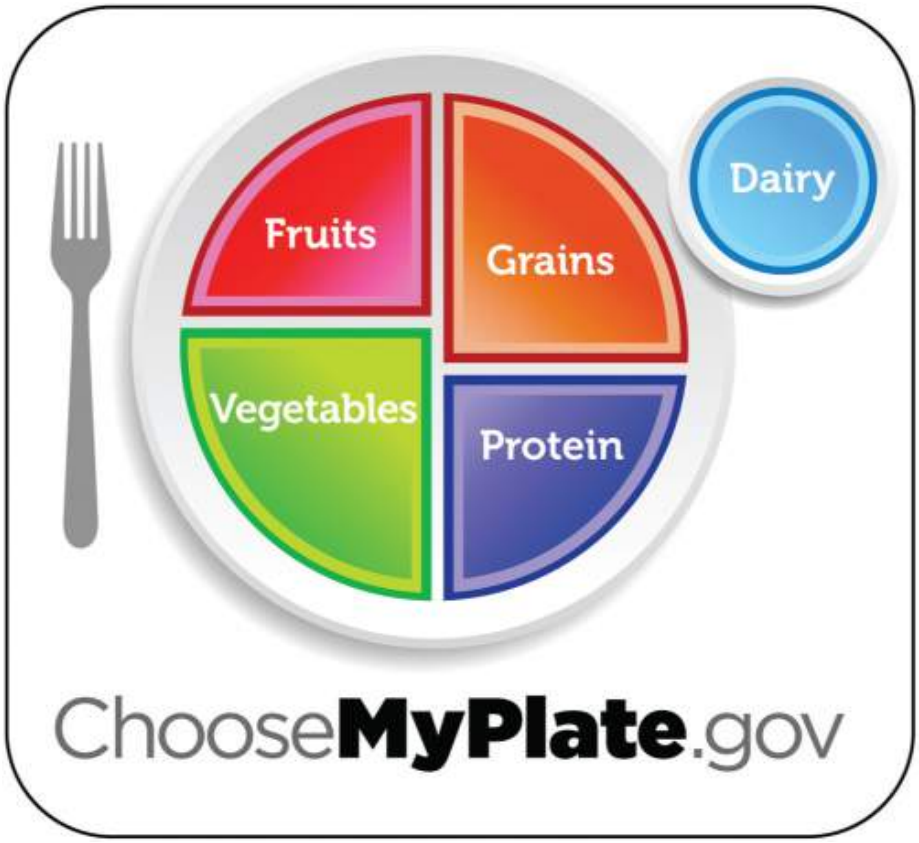

Figure 4-5 • MyPlate, a simple reminder for healthy eating. From the U.S. Department of Agriculture's Center for Nutrition Policy & Promotion. Retrieved on 7/24/2019 at: www.choosemyplate.gov

Fat intake and cholesterol levels are additional aspects of the nutritional assessment. Trans fats are produced when hydrogen atoms are added to monounsaturated or polyunsaturated fats to produce a semisolid product, such as margarine. Partially hydrogenated oils (PHOs), the primary source of industrially produced trans fats, are found in many popular processed foods, such as baked goods and frozen foods. This is a concern because increased amounts of trans fats have been associated with increased risk for heart disease and stroke. In 2015, the FDA released its final determination that PHOs were not *Generally Recognized as Safe (GRAS)*.

At that time, the FDA announced that manufacturers must stop adding PHOs to processed food, providing a 3-year compliance period so that food manufacturers could gradually phase out the use of PHOs. However, to allow

for an orderly transition in the marketplace, FDA extended the compliance date for these foods (FDA, 2019).

Factors Influencing Nutritional Status in Various Situations

Patients who are hospitalized may have an inadequate dietary intake because of the illness or disorder that necessitated the hospital stay. Patients who are at home may feel too sick or fatigued to shop and prepare food, or they may be unable to eat because of other physical problems or limitations. Limited or fixed incomes or the high costs of medications may result in insufficient money to buy nutritious foods. Culturally influenced food patterns can also affect nutritional status. Because complex treatments (e.g., mechanical ventilation, intravenous infusions, chemotherapy) once used only in the hospital setting are now being provided in the home and outpatient settings, nutritional assessment of patients in these settings is an important aspect of home and community-based care. Many of the factors that contribute to poor nutritional status are identified in Table 4-3.

Analysis of Nutritional Status

Physical measurements (BMI, waist circumference) and biochemical and dietary data are used in combination to determine a patient's nutritional status. Often, these data provide more information about the patient's nutritional status than the clinical examination, which may not detect subclinical deficiencies unless they become so advanced that overt signs develop. A low intake of nutrients over a long period may lead to low biochemical levels and, without nutritional intervention, may result in characteristic and observable signs and symptoms. A plan of action for nutritional intervention is based on the results of the dietary assessment and the patient's clinical examination. To be effective, the plan should include a healthy diet, maintenance (or control) of weight, and compensation for increased nutritional needs.

Cultural Assessment

Cultural assessment refers to a systematic appraisal or examination of individuals, families, groups, and communities in terms of their cultural beliefs, values, and practices. Nurses need to ensure that patients of all cultures understand what the nurse is trying to accomplish by gathering cultural data during the assessment process in order to avoid misunderstanding (Holland, 2018). In an effort to establish a database for determining a patient's cultural background, nurses have developed cultural assessment tools or modified existing assessment tools (Leininger, 2002) to ensure that transcultural

considerations are included in the plan of care. Giger and Davidhizar's Transcultural Assessment Model can be used to help nurses perform cultural assessments. Questions derived from this model may be used to direct nursing assessment of a person's ethnic, cultural, or religious beliefs and its relationship to their personal and health care traditions (Chart 4-7) (Giger, 2016). In addition, nurses should gather data on patients' cultural perceptions and family ancestry throughout the assessment process. Nurses should recognize that advancing knowledge about culturally congruent care is important for promoting care that is consistent with the cultural needs of each patient's heritage (Jakub, Turk, Fapohunda, et al., 2018) (see Chart 4-8 for a Nursing Research Profile).

Culturally Mediated Considerations

Nurses should be aware that patients act and behave in various ways, in part because of the influence of culture on behaviors and attitudes. However, although certain attributes and attitudes are frequently associated with particular cultural groups, it is important to remember that not all people from the same cultural background share the same behaviors and views. Although nurses who fail to consider patients' cultural preferences and beliefs are considered insensitive and possibly indifferent, nurses who assume that all members of any one culture act and behave in the same way run the risk of stereotyping people. As stated previously, the best way to avoid stereotyping is to view each patient as a person and to assess the patient's cultural preferences. A thorough cultural assessment using a culture assessment tool or questionnaire can be beneficial.

TABLE 4-3 Factors Associated with Potential Nutritional Deficits

Factor	Possible Consequences
Dental and oral problems (missing teeth, ill-fitting dentures, impaired swallowing or chewing)	Inadequate intake of high-fiber foods
Nothing by mouth (NPO) for diagnostic testing	Inadequate caloric and protein intake; dehydration
Prolonged use of glucose and saline intravenous fluids	Inadequate caloric and protein intake
Nausea and vomiting	Inadequate caloric and protein intake; loss of fluid, electrolytes, and minerals
Diarrhea	Loss of fluid, electrolytes, and minerals; malabsorption of nutrients
Stress of illness, surgery, and/or hospitalization	Increased protein and caloric requirement; increased catabolism
Wound drainage	Loss of protein, fluid, electrolytes, and minerals
Pain	Loss of appetite; inability to shop, cook, eat
Fever	Increased caloric and fluid requirement; increased catabolism
Gastrointestinal intubation	Loss of protein, fluid, and minerals
Tube feedings	Inadequate amounts; variation of nutrients in each formula
Gastrointestinal disease	Inadequate intake and malabsorption of nutrients
Alcoholism	Inadequate intake of nutrients; increased consumption of calories without other nutrients; vitamin deficiencies
Depression	Loss of appetite; inability to shop, cook, eat
Eating disorders (anorexia, bulimia)	Inadequate caloric and protein intake; loss of fluid, electrolytes, and minerals
Medications	Inadequate intake due to medication side effects, such as dry mouth, loss of appetite, decreased taste perception, difficulty swallowing, nausea and vomiting, malabsorption of nutrients
Restricted ambulation or disability	Limited ability to shop, cook, or help self to food, liquids, other nutrients

Chart 4-7 ASSESSMENT

Assessing for Patients' Cultural Beliefs

Communication

- Do you like communicating with friends, family, and acquaintances?
- When asked a question, do you usually respond?
- If you have something important to discuss with your family, how would you approach them?

Space

- When you talk with family members, how close do you stand?
- When you talk with acquaintances, how close do you stand?
- If a stranger touches you, how do you react or feel?
- If a loved one touches you, how do you react or feel?
- Are you comfortable with the distance between us now?

Social Organization

- What are some activities that you enjoy?
- What are your hobbies, or what do you do when you have free time?
- Do you believe in a Supreme Being?
- How do you worship that Supreme Being?
- What is your role in your family/unit system?

Time

- Do you wear a timepiece daily?
- If a nurse tells you that you will receive a medication "in about a half hour," how much time will you allow before calling the nurse?

Environmental Control

- Is it acceptable for you to have visitors drop in unexpectedly?
- Do you use home remedies? Which home remedies worked? Will you use them in the future?
- What is your definition of "good health"?
- What is your definition of illness or "poor health"?

Biologic Variations

- What diseases or illnesses are common in your family?
- Who usually helps you to cope during a difficult time?
- What foods do you and your family like to eat? What foods are family favorites or are considered traditional?

Nursing Process Utilization

- Note whether the patient has become culturally assimilated or observes own cultural practices.
- Incorporate data into the plan of nursing care.

Adapted from Giger, J. (2016). *Transcultural nursing: Assessment and intervention* (6th ed.). St. Louis, MO: Elsevier.

Chart 4-8 NURSING RESEARCH PROFILE

Cultural Beliefs, Perceptions, and Practices of Adult Children of African Immigrants

Jakub, K. E., Turk, M. T., Fapohunda, A., et al. (2018). Cultural beliefs, perceptions, and practices of young adult offspring of African immigrants regarding healthy eating and activity. *Journal of Transcultural Nursing, 29*(6), 548–554.

Purpose

The purpose of this study was to understand and explore the beliefs, perceptions, and practices of young adult offspring of African immigrants regarding healthy eating and activities in the context of their environment and culture. The researchers also examined what influences the beliefs, perceptions, and practices of the study population.

Design

Using a focused ethnography design, five small group interviews consisting of two to six participants were conducted yielding a total of 20 college-age students who were offspring of African immigrants. Focused group semistructured interviews were digitally recorded during the data collection. Data collection was completed upon determination of data saturation. Leininger's four phases of qualitative data analysis were used to analyze the data.

Findings

The 20 participants, between the ages of 18 and 23, reported parental ancestry from eight different countries of the African continent: 11 from Nigeria, 3 from Ghana, and 1 participant each from Ethiopia, Cameroon, Egypt, Sudan, Liberia, and Eritrea. Seventeen categories, six patterns, and four themes emerged from the data. The four themes included (1) family, community, and religious ties to traditional African foods; (2) traditional African cuisine as healthy and American foods as nonhealthy; (3) eating patterns vary according to availability and resources; and (4) exercise patterns have familial, peer-driven, and generational influences significant to this college-age group. Participants also reported balancing acculturation into a university setting. Food choices were influenced by living arrangements, availability, financial resources, and time constraints.

Nursing Implications

Nurses should assess cultural perceptions and family ancestry that may affect a patient's perceptions of health and activity levels. Advancing knowledge about culturally congruent care is important and may promote healthy behaviors that include better eating habits and activity for college-age offspring of immigrants. Efforts should be made to identify the country of origin of patients and develop educational or health promoting programs to manage wellness specific to each patient's heritage.

Information Disclosure

Many aspects of care may be influenced by the diverse cultural perspectives held by health care providers, patients, families, or significant others. One example is the issue of communication and full disclosure. In general, nurses may argue that patients have the right to full disclosure concerning their disease and prognosis and may believe that advocacy means working to provide that disclosure. However, family members in some cultural backgrounds may believe that it is their responsibility to protect and spare the patient (their loved one) knowledge about a terminal illness. In some cultures, the head of the family group, older adult, or husband is expected to receive all information and make decisions. Patients may in fact not want to know about their condition and may expect their family members to "take the burden" of that knowledge and related decision making. Nurses should not decide that a family or patient is simply wrong or that a patient must know all of the details of their illness regardless of the patient's preference. Similar concerns may be noted when patients refuse pain medication or treatment because of cultural beliefs regarding pain or beliefs in divine intervention or faith healing.

Determining the most appropriate and ethical approach to patient care requires an exploration of the cultural aspects of these situations. Self-examination and recognition of one's own cultural bias and worldview play a major part in helping the nurse resolve cultural and ethical conflicts. Nurses must promote open dialogue and work with patients, families, primary providers, and other health care providers to reach the culturally appropriate solution for the individual patient.

Space and Distance

Personal space is the area that surrounds a person's body and includes the space and the objects within the space (Giger, 2016). People tend to regard the space in their immediate vicinity as an extension of themselves. The amount of space that they need between themselves and others to feel comfortable is a culturally determined phenomenon.

Because nurses and patients usually are not consciously aware of their personal space requirements, they frequently have difficulty understanding different behaviors. For example, one patient may perceive the nurse sitting close to them as an expression of warmth and care; another patient may perceive the nurse's act as a threatening invasion of personal space. Research reveals that people from the United States, Canada, and Great Britain require the most personal space between themselves and others, whereas those from Latin America, Japan, and the Middle East need the least amount of space and feel comfortable standing close to others (Giger, 2016).

If the patient appears to position himself or herself too close or too far away, the nurse should consider cultural preferences for space and distance. Ideally, the patient should be permitted to assume a position that is comfortable to them

in terms of personal space and distance. The nurse should be aware that the wheelchair of a person with a disability is considered an extension of the person; therefore, the nurse should ask the person's permission before moving or touching the wheelchair. Because a significant amount of communication during nursing care requires close physical contact, the nurse should be aware that having personal space promotes self-identity by allowing opportunities for patient self-expression (Giger, 2016).

Eye Contact

Eye contact is also a culturally determined behavior. Although most nurses have been taught to maintain eye contact when speaking with patients, some people from certain cultural backgrounds may interpret this behavior differently. For example, some Asians, Native Americans, Indo-Chinese, Arabs, and Appalachians may consider direct eye contact impolite or aggressive, and they may avert their own eyes when talking with nurses and others whom they perceive to be in positions of authority. Some Native Americans stare at the floor during conversations—a cultural behavior conveying respect and indicating that the listener is paying close attention to the speaker. Some Hispanic patients maintain downcast eyes as a sign of culturally appropriate deferential behavior toward others on the basis of age, gender, social position, economic status, and position of authority (Giger, 2016). Eye contact is an important tool in a transcultural assessment and is used for both observation and to initiate interaction (Giger, 2016). The nurse who is aware that eye contact may be culturally determined can better understand the patient's behavior and provide an atmosphere in which the patient can feel comfortable.

Time

Attitudes about time vary widely among cultures and can be a barrier to effective communication between nurses and patients. Views about punctuality and the use of time are culturally determined, as is the concept of waiting. Symbols of time, such as watches, sunrises, and sunsets, represent methods for measuring the duration and passage of time (Giger, 2016).

For most health care providers, time and promptness are extremely important. For example, nurses frequently expect patients to arrive at an exact time for an appointment, although patients may be kept waiting by health care providers who are running late. Health care providers are likely to function according to an appointment system in which there are short intervals. However, for patients from some cultures, time is a relative phenomenon, with little attention paid to the exact hour or minute. Time may also be determined according to traditional times for meals, sleep, and other activities or events. For people from some cultures, the present is of the greatest importance, and time is viewed in broad ranges rather than in terms of a fixed hour. Being flexible in regard to schedules is the best way to accommodate these differences.

Value differences also may influence a person's sense of priority when it comes to time. For example, responding to a family matter may be more important to a patient than meeting a scheduled health care appointment. Allowing for these different views is essential in maintaining an effective nurse–patient relationship. Scolding or acting annoyed at patients for being late undermines their confidence and may result in further missed appointments or indifference to health care suggestions.

Touch

Touch is the most personal of all sensations, is central to the human communication process, and is often used as a method of communication (Giger, 2016). The meaning that people associate with touching is culturally determined to a great degree. In some cultures (e.g., Hispanic, Arab), male health care providers may be prohibited from touching or examining certain parts of the female body. Similarly, it may be inappropriate for females to care for males. Among many Asians, it is impolite to touch a person's head because the spirit is believed to reside there. Therefore, assessment of the head or evaluation of a head injury requires permission of the patient or a family member, if the patient is not able to give permission.

The patient's culturally defined sense of modesty must also be considered when providing nursing care. For example, some Jewish and Muslim women believe that modesty requires covering their head, arms, and legs with clothing. It is important for the nurse to recognize cultural variances and to understand that touch can be perceived as intrusive to some patients.

Observance of Holidays

People from all cultures observe certain civil and religious holidays. Nurses should familiarize themselves with major observances for members of the cultural groups they serve. Information about these observances is available from various sources, including religious organizations, hospital chaplains, and patients themselves. Routine health appointments, diagnostic tests, surgery, and other major procedures should be scheduled to avoid observances that patients identify as significant. If not contraindicated, efforts should also be made to accommodate patients and families or significant others who wish to perform cultural and religious rituals in the health care setting.

CRITICAL THINKING EXERCISES

1 pq You are conducting an admission assessment on a 66-year-old Vietnamese woman who was recently discharged from the hospital with a diagnosis of congestive heart failure. The patient's blood pressure is elevated, and the patient has a productive cough. The patient speaks very little English, but the patient's son is able to interpret. What types of assessments are necessary to complete a comprehensive admission assessment? What are the priorities in this patient's care? What interventions should you incorporate into the plan of care for this patient?

2 ebp A 28-year-old woman is admitted to the hospital with diverticulitis. She is visibly undernourished with poor skin turgor and loss of subcutaneous tissue. After calculating her ideal body weight, you note that her weight is well below average for her height. What standardized assessment tools would you use to determine her health risk? Identify her health risks, given her decreased weight, based on the most recent evidence. Evaluate the strength of the evidence for these risks.

5 Stress and Inflammatory Responses

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the significance of the principles of internal constancy, homeostasis, stress, and adaptation in promoting and maintaining steady state in the body.
2. Describe the General Adaptation Syndrome and the sympathetic–adrenal–medullary and hypothalamic-pituitary responses to stress.
3. Identify ways in which maladaptive responses to stress can increase the risk of illness and cause disease.
4. Compare the adaptive processes of atrophy, hypertrophy, hyperplasia, metaplasia, and dysplasia within the body's inflammatory and reparative processes.
5. Assess the health patterns of individuals and families, identifying strategies that are useful in reducing stress.

NURSING CONCEPTS

Anxiety
Cellular Regulation
Communication
Family
Immunity
Inflammation
Stress and Coping

GLOSSARY

adaptation: a change or alteration designed to assist in adjusting to a new situation or environment

adrenocorticotropic hormone (ACTH): a hormone produced by the anterior lobe of the pituitary gland that stimulates the secretion of cortisol and other hormones by the adrenal cortex

antidiuretic hormone (ADH): a hormone secreted by the posterior lobe of the pituitary gland that constricts blood vessels, elevates blood pressure, and reduces the excretion of urine

catecholamines: any of the group of amines (such as epinephrine, norepinephrine, or dopamine) that serve as neurotransmitters

coping: the cognitive and behavioral strategies used to manage the stressors that tax a person's resources

corticosteroids: the group of steroid hormones, such as cortisol, that are produced by the adrenal cortex; they are involved in carbohydrate, protein, and fat metabolism and have anti-inflammatory properties

disease: an abnormal variation in the structure or function of any part of the body

dysplasia: bizarre cell growth resulting in cells that differ in size, shape, or arrangement from other cells of the same tissue type

family: a group whose members are related by reciprocal caring, mutual responsibilities, and loyalties

fight-or-flight response: the alarm stage in the General Adaptation Syndrome described by Selye

gluconeogenesis: the formation of glucose by the liver from noncarbohydrate sources, such as amino acids and the glycerol portion of fats

guided imagery: the mindful use of a word, phrase, or visual image to achieve relaxation or direct attention away from uncomfortable sensations or situations

homeostasis: a steady state within the body; the stability of the internal environment

hyperplasia: an increase in the number of new cells in an organ or tissue

hypoxia: inadequate supply of oxygen to the cell

inflammation: a localized reaction of tissue to injury, irritation, or infection that is manifested by five cardinal signs of redness, warmth, swelling, pain, and loss of function

metaplasia: a cell transformation in which one type of mature cell is converted into another type of cell

negative feedback: mechanisms that monitor the internal environment and restore homeostasis when conditions shift out of the normal range

positive feedback: mechanisms that perpetuate a chain of events

steady state: a stable condition that does not change over time, or when change in one direction is balanced by change in an opposite direction

stress: a disruptive condition that occurs in response to adverse influences from the internal or external environments

stressor: an internal or external event or situation that creates the potential for physiologic, emotional, cognitive, or behavioral changes

When the body is threatened or suffers an injury, its response may involve functional and structural changes; these changes may be adaptive (having a positive effect) or maladaptive (having a negative effect). The defense mechanisms that the body uses determine the difference between adaptation and maladaptation—health and disease. This chapter addresses individual homeostasis, stress, adaptation, health problems associated with maladaptation, and ways that nurses intervene with patients and families to reduce stress and its health-related effects.

Fundamental Concepts

Each body system performs specific functions to sustain optimal life for an organism. Compensatory mechanisms for adjusting internal conditions promote the steady state of the organism, ensure its survival, and restore balance in the body. Pathophysiologic processes result when cellular injury occurs at such a rapid rate that the body's compensatory mechanisms cannot make the adaptive changes necessary to remain healthy.

Physiologic mechanisms must be understood in the context of the body as a whole. Each person has both an internal and external environment, between which information and matter are continuously exchanged. Within the internal environment, each organ, tissue, and cell is also a system or subsystem of the whole, each with its own internal and external environment, each exchanging information and matter (Fig. 5-1). The goal of the interaction of the body's subsystems is to produce a dynamic balance or **steady state** (even in the presence of change) so that all subsystems are in harmony with each other. Four concepts—constancy, homeostasis, stress, and adaptation—are key to the understanding of steady state.

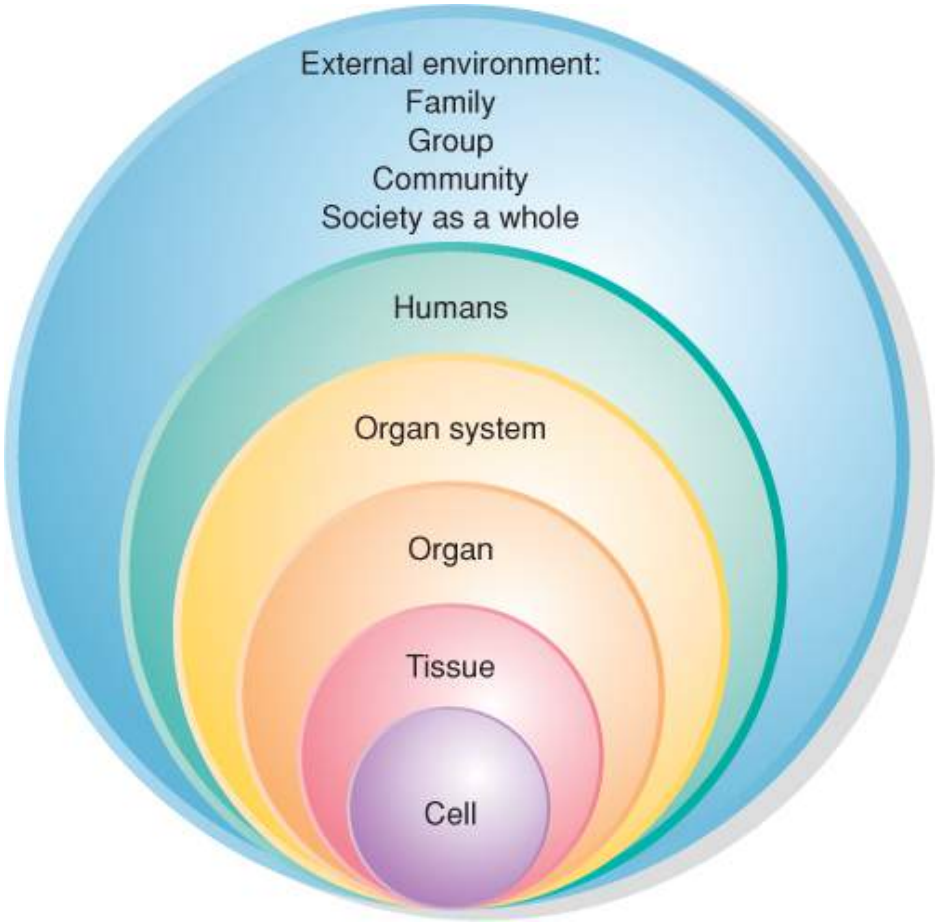

Figure 5-1 • Constellation of systems. Each system is a subsystem of the larger system (suprasystem) of which it is a part. The cells represent the smallest system and are a subsystem of all other systems.

Constancy and Homeostasis

Claude Bernard, a 19th-century French physiologist, first developed the biologic principle that for life there must be a constancy or "fixity of the internal milieu" despite changes in the external environment. The internal milieu is the fluid that bathed the cells, and the constancy the balanced internal state maintained by physiologic and biochemical processes. His principle implies a static process.

Bernard's principle of "constancy" underpins the concept of **homeostasis,** which refers to a steady state within the body. When a change or stress occurs that causes a body function to deviate from its stable range, processes are initiated to restore and maintain dynamic balance. An example of this restorative effort is the development of hyperpnea (rapid breathing) after intense exercise in an attempt to compensate for an oxygen deficit and excess lactic acid accumulated in the muscle tissue. When these adjustment processes or compensatory mechanisms are not adequate, steady state is threatened,

function becomes disordered, and dysfunctional responses occur. For example, in heart failure, the body reacts by retaining sodium and water and increasing venous pressure, which worsens the condition. Dysfunctional responses can lead to **disease** (an abnormal variation in the structure or function of any part of the body), which is a threat to steady state.

Stress and Adaptation

Stress is a disruptive condition produced by a change in the environment that is perceived as challenging, threatening, or damaging to a person's dynamic balance or equilibrium. The person may feel unable to meet the demands of the new situation. The change or stimulus that evokes this state is the stressor. A person appraises and copes with changing situations. The desired goal is **adaptation** or adjustment to the change so that the person is again in equilibrium and has the energy and ability to meet new demands. This is the process of coping with the stress, a compensatory process that uses cognitive and behavioral strategies.

Because both stress and adaptation may exist at different levels of a system, it is possible to study these reactions at the cellular, tissue, and organ levels. Biologists are concerned mainly with subcellular components or with subsystems of the total body. Behavioral scientists, including many nurse researchers, study stress and adaptation in individuals, families, groups, and societies; they focus on how a group's organizational features are modified to meet the requirements of the social and physical environment in which the group exists. In any system, the desired goals of adaptation are survival, growth, and reproduction.

Overview of Stress

Each person operates at a certain level of adaptation and regularly encounters a certain amount of change. Such change is expected; it contributes to growth and enhances life. A stressor can upset this equilibrium. A **stressor** may be defined as an internal or external event or situation that creates the potential for physiologic, emotional, cognitive, or behavioral changes.

Types of Stressors

Stressors exist in many forms and categories. They may be described as physical, physiologic, or psychosocial. Physical stressors include cold, heat, and chemical agents; physiologic stressors include pain and fatigue. An example of a psychosocial stressor is fear (e.g., fear of failing an examination, losing a job, waiting for a diagnostic test result). Stressors can also occur as

normal life transitions that require some adjustment, such as going from childhood into puberty, getting married, or giving birth.

Stressors have also been classified as day-to-day frustrations or hassles, major complex occurrences involving large groups, and stressors that occur less frequently and involve fewer people. Day-to-day stressors include common occurrences as getting caught in a traffic jam, experiencing computer downtime, and having an argument with a spouse or roommate. These experiences vary in effect. For example, encountering a rainstorm while you are vacationing at the beach will most likely evoke a more negative response than it might at another time. These daily hassles have been shown to have a greater health impact than major life events because of the cumulative effect they have over time. They can lead to high blood pressure, palpitations, or other physiologic problems (Sarid, Slonim-Nevo, Sergienko, et al., 2018; Terrill & Molton, 2019).

Major stressors influence larger groups of individuals, families, and sometimes even entire nations. These include events of history, such as terrorism and war, experienced either directly in the war zone or indirectly through live news coverage. The demographic, economic, and technologic changes occurring in society also serve as stressors. The tension produced by any stressor is sometimes a result not only of the change itself, but also of the speed with which the change occurs.

Stressors concerning relatively infrequent situations that directly affect people have been studied extensively. This category includes the influence of life events such as death, birth, military service, marriage, divorce, and retirement. It also includes the psychosocial crises that occur in the life cycle stages of the human experience. More enduring chronic stressors may include having a permanent disability or coping with the need to provide long-term care for a child who has a developmental disability or for an older parent who is frail.

Duration may also be used to categorize stressors, as in the following:

- An acute, time-limited stressor, such as studying for final examinations
- A stressor sequence—a series of stressful events that result from an initial event such as job loss or divorce
- A chronic intermittent stressor, such as daily hassles
- A chronic enduring stressor that persists over time, such as chronic illness, a disability, or poverty

Stress as a Stimulus for Disease

Relating life events to illness (the theoretical approach that defines stress as a stimulus) has been a major focus of psychosocial studies. Research suggests

that people under constant stress have a high incidence of disease (Kalinowski, Taylor, & Spruill, 2019; Kibler, Ma, Tursich, et al., 2018).

Holmes and Rahe (1967) developed life events scales that assign numerical values, called *life-change units,* to typical life events. Because the items in the scales reflect events that require a change in a person's life pattern, and stress is viewed as an accumulation of changes in one's life that require psychological adaptation, one can theoretically predict the likelihood of illness by checking off the number of recent events and deriving a total score. The Recent Life Changes Questionnaire (RLCQ) (Tausig, 1982) contains 118 items such as death, birth, marriage, divorce, promotions, serious arguments, and vacations. The items include both desirable and undesirable events. Both the life events scale and the RLCQ have formed the basis for the development of two additional scales: the Positive–Negative Relationship Quality Scale (PNRQS) (Fincham & Rogge, 2010), which measures stress related to relationship quality, and the Stress Overload Scale (SOS) (Amirkhan, 2012; Amirkhan, Urizar, & Clark, 2015), which measures excessive stress. A tool developed by Vohra and colleagues (2019) called the Stressometer® (SOM) was designed to measure stress and mental health. This instrument is composed of subscales related to a person's individual nature, personal circumstances, clinical symptoms, home life and work life. The underlying premise of the PNRQS, SOS, and SOM instruments is that sources of stress, such as stressful life events and a person's personal vulnerabilities, can influence and even undermine engaging in adaptive processes.

Sources of stress for people have been well researched (Anniko, Boersma, & Tillfors, 2019; Pitt, Oprescu, Tapia, et al., 2018). People typically experience distress related to alterations in their physical and emotional health status, changes in their level of daily functioning, and decreased social support or the loss of significant others (Albdour, Hong, Lewin, et al., 2019; Benham & Charak, 2019; Reblin, Stanley, Galligan, et al., 2019; Sikes & Hall, 2017). Fears of immobilization, isolation, loneliness, sensory changes, financial problems, and death or disability increase a person's anxiety level. Loss of one's role or perceived purpose in life can cause intense discomfort. Any of these identified variables, plus a myriad of other conditions or demands, are likely to cause ineffective coping, and a lack of effective coping skills is often a source of additional distress for the person. When a person endures prolonged or unrelenting suffering, the outcome is frequently the development of a stress-related illness. Nurses have the skills to assist people to alter their distressing circumstances and manage their responses to stress, as discussed later in the chapter.

Psychological Responses to Stress

After recognizing a stressor, a person consciously or unconsciously reacts to manage the situation. This is termed the *mediating process*. A theory developed by Lazarus (1991) emphasizes cognitive appraisal and coping as important mediators of stress. Appraisal and coping are influenced by antecedent variables, including the internal and external resources of the individual person.

Appraisal of the Stressful Event

Cognitive appraisal (Lazarus, 1991; Lazarus & Folkman, 1984) is a process by which an event is evaluated with respect to what is at stake (primary appraisal) and what might and can be done (secondary appraisal). What a person sees as being at stake is influenced by their personal goals, commitments, or motivations. Important factors include how important or relevant the event is to the person, whether the event conflicts with what the person wants or desires, and whether the situation threatens the person's own sense of strength and ego identity.

Primary appraisal results in the situation being identified as either nonstressful or stressful. Secondary appraisal is an evaluation of what might and can be done about the situation. Reappraisal—a change of opinion based on new information—may occur. The appraisal process is not necessarily sequential; primary and secondary appraisal and reappraisal may occur simultaneously.

The appraisal process contributes to the development of an emotion. Negative emotions such as fear and anger accompany harm/loss appraisals, and positive emotions accompany challenge. In addition to the subjective component or feeling that accompanies a particular emotion, each emotion also includes a tendency to act in a certain way. For example, unprepared students may view an unexpected quiz as threatening. They might feel fear, anger, and resentment and might express these emotions through hostile behavior or comments.

Lazarus (1991) expanded his initial ideas about stress, appraisal, and coping into a more complex model relating emotion to adaptation. He called this model a "cognitive–motivational–relational theory," with the term *relational* "standing for a focus on negotiation with a physical and social world" (p. 13). A theory of emotion was proposed as the bridge to connect psychology, physiology, and sociology: "More than any other arena of psychological thought, emotion is an integrative, organismic concept that subsumes psychological stress and coping within itself and unites motivation, cognition, and adaptation in a complex configuration" (p. 40).

Coping with the Stressful Event

Coping consists of the cognitive and behavioral efforts made to manage the specific external or internal demands that tax a person's resources and may be emotion focused or problem focused. Emotion-focused coping seeks to make the person feel better by lessening the emotional distress. Problem-focused coping aims to make direct changes in the environment so that the situation can be managed more effectively. Both types of coping usually occur in a stressful situation. Even if the situation is viewed as challenging or beneficial, coping efforts may be required to develop and sustain the challenge—that is, to maintain the positive benefits of the challenge and to ward off any threats. In harmful or threatening situations, successful coping reduces or eliminates the source of stress and relieves the emotion generated.

Appraisal and coping are affected by internal characteristics such as health, energy, personal belief systems, commitments, or life goals, self-esteem, control, mastery, knowledge, problem-solving skills, and social skills. The characteristics that have been studied in nursing research are health-promoting lifestyles and resilience (Callaghan, Fellin, & Alexander, 2019; Marques, Perolta, Santos, et al., 2019; Shen, 2019; Sima, Yu, Marwitz, et al., 2019). Resilience is considered both a personal trait and a process. Researchers have defined resilience as the ability of a person to function well in stressful situations such as traumatic events and other types of adverse situations (Kim, Lin, Kim, et al., 2019). A resilient person maintains flexibility even in difficult circumstances and controls strong emotional reactions using appropriate communication and problem-solving skills. Factors that play a role in building a person's resilience are having strong, supportive relationships with family members and other individuals and being exposed to positive role models. A resilient person knows when to act, when to step back and rely on others, and when to stop to re-energize and nurture the self. Researchers have found positive support for resilience as a significant variable that positively influences rehabilitation and overall improvement after a challenging or traumatic experience (Kok, Reed, Wickham, et al., 2019; Liu, Zhou, Zhang, et al., 2019; McNeil, Bartram, Cregan, et al., 2019; Vaughan, Koczwara, Kemp, et al., 2019).

A health-promoting lifestyle buffers the effect of stressors. From a nursing practice standpoint, this outcome—buffering the effect of stressors—supports nursing's goal of promoting health. In many circumstances, promoting a healthy lifestyle is more achievable than altering the stressors.

Physiologic Response to Stress

The physiologic response to a stressor, whether it is physical, psychological, or psychosocial, is a protective and adaptive mechanism to maintain the body's homeostatic balance. When a stress response occurs, it activates a series of

neurologic and hormonal processes within the brain and body systems. The duration and intensity of the stress can cause both short- and long-term effects.

Selye's Theory of Adaptation

Selye (1976) developed a theory of adaptation to biologic stress that profoundly influenced the scientific study of stress.

General Adaptation Syndrome

Selye's theory, called the *General Adaptation Syndrome* (GAS), has three phases: alarm, resistance, and exhaustion. During the alarm phase, the sympathetic **fight-or-flight response** is activated with release of **catecholamines** (i.e., epinephrine, norepinephrine, and dopamine), that serve as neurotransmitters and the onset of the **adrenocorticotropic hormone (ACTH)**–adrenal cortical response. ACTH is produced by the anterior lobe of the pituitary gland and stimulates the secretion of cortisol as well as other hormones by the adrenal cortex. The alarm reaction is defensive and anti-inflammatory but self-limited. Because living in a continuous state of alarm would result in death, people move into the second stage—resistance. During the resistance stage, adaptation to the noxious stressor occurs, and cortisol activity is still increased. If exposure to the stressor is prolonged, the third stage—exhaustion—occurs. During the exhaustion stage, endocrine activity increases, and this has negative effects on the body systems (i.e., the circulatory, digestive, and immune systems) that can lead to death. The first two stages of this syndrome are repeated, in different degrees, throughout life as the person encounters stressors.

Selye compared the GAS with the life process. During childhood, too few encounters with stress occur to promote the development of adaptive functioning, and children are vulnerable. During adulthood, numerous stressful events occur, and people develop resistance or adaptation. During the later years, the accumulation of life's stressors and wear and tear on the organism again decrease people's ability to adapt, resistance falls, and eventually death occurs.

Local Adaptation Syndrome

According to Selye, a *Local Adaptation Syndrome* also occurs. This syndrome includes the inflammatory response and repair processes that occur at the local site of tissue injury. This syndrome occurs in small, topical injuries, such as contact dermatitis. If the local injury is severe enough, the GAS is activated as well.

Selye emphasized that stress is the nonspecific response common to all stressors, regardless of whether they are physiologic, psychological, or psychosocial. The many conditioning factors in each person's environment account for why different demands are experienced by different people as

stressors. Conditioning factors also account for differences in the tolerance of different people for stress: Some people may develop diseases of adaptation, such as hypertension and migraine headaches, whereas others are unaffected.

Interpretation of Stressful Stimuli by the Brain

Physiologic responses to stress are mediated by the brain through a complex network of chemical and electrical messages. The neural and hormonal actions that maintain homeostatic balance are integrated by the hypothalamus, which is located in the center of the brain, surrounded by the limbic system and the cerebral hemispheres. The hypothalamus is made up of a number of nuclei and integrates autonomic nervous system mechanisms that maintain the chemical constancy of the internal environment of the body. Together with the limbic system, which contains the amygdala, hippocampus, and septal nuclei, along with other structures, the hypothalamus regulates emotions and many visceral behaviors necessary for survival (e.g., eating, drinking, temperature control, reproduction, defense, aggression).

Each of the brain structures responds differently to stimuli. The cerebral hemispheres are concerned with the cognitive functions of thought processes, learning, and memory. The limbic system has connections with both the cerebral hemispheres and the brain stem. In addition, the reticular activating system, a network of cells that forms a two-way communication system, extends from the brain stem into the midbrain and limbic system. This network controls the alert or waking state of the body.

In the stress response, afferent impulses are carried from sensory organs (eye, ear, nose, skin) and internal sensors (baroreceptors, chemoreceptors) to nerve centers in the brain. The response to the perception of stress is integrated in the hypothalamus, which coordinates the adjustments necessary to return to homeostatic balance. The degree and duration of the response vary; initially, there is a sympathetic nervous system discharge, followed by a sympathetic–adrenal–medullary discharge. If the stress persists, the hypothalamic-pituitary system is activated (Fig. 5-2).

Sympathetic Nervous System Response

The sympathetic nervous system response is rapid and short-lived. Norepinephrine is released at nerve endings that are in direct contact with their respective end organs to cause an increase in function of the vital organs and a state of general body arousal (Norris, 2019). Heart rate increases and peripheral vasoconstriction occurs, raising the blood pressure. Blood is also shunted away from abdominal organs. The purpose of these responses is to provide better perfusion of vital organs (brain, heart, skeletal muscles). Blood glucose is increased, supplying more readily available energy. The pupils dilate, and mental activity increases; a greater sense of awareness exists. Constriction of the blood vessels of the skin limits bleeding in the event of

trauma. The person is likely to experience cold feet, clammy skin and hands, chills, palpitations, and "knots" in the stomach. Typically, the person appears tense, with the muscles of the neck, upper back, and shoulders tightened; respirations may be rapid and shallow, with the diaphragm tense.

Sympathetic–Adrenal–Medullary Response

In addition to directly affecting major end organs, the sympathetic nervous system stimulates the adrenal medulla to release the hormones epinephrine and norepinephrine into the bloodstream. These hormones act similarly to the sympathetic nervous system, sustaining and prolonging its actions. Because these hormones are catecholamines, they stimulate the nervous system and produce metabolic effects that increase the blood glucose level and metabolic rate. The effect of the sympathetic–adrenal–medullary responses is summarized in Table 5-1. This effect is called the *fight-or-flight response* (Norris, 2019).

Hypothalamic-Pituitary Response

The longest-acting phase of the physiologic response, which is more likely to occur in persistent stress, involves the hypothalamic-pituitary pathway. The hypothalamus secretes corticotropin-releasing factor, which stimulates the anterior pituitary to produce ACTH, which in turn stimulates the adrenal cortex to produce **corticosteroids,** primarily cortisol (Norris, 2019). Cortisol stimulates protein catabolism, releasing amino acids; stimulates liver uptake of amino acids and their conversion to glucose (**gluconeogenesis**); and inhibits glucose uptake (anti-insulin action) by many body cells but not those of the brain and the heart (Norris, 2019). These cortisol-induced metabolic effects provide the body with a ready source of energy during a stressful situation. This effect has some important implications. For example, a person with diabetes who is under stress, such as that caused by an infection, needs more insulin than usual. Any patient who is under stress (e.g., illness, surgery, trauma, prolonged psychological stress) catabolizes body protein and needs supplements.

The actions of the catecholamines (epinephrine and norepinephrine) and cortisol are the most important in the general response to stress. Other hormones that play a role are **antidiuretic hormone (ADH)** released from the posterior pituitary and aldosterone released from the adrenal cortex. ADH and aldosterone promote sodium and water retention, which is an adaptive mechanism in the event of hemorrhage or loss of fluids through excessive perspiration. ADH constricts blood vessels, elevates blood pressure, and reduces the excretion of urine. ADH has also been shown to influence learning and may thus facilitate coping in new and threatening situations. Secretion of growth hormone and glucagon stimulates the uptake of amino acids by cells, helping to mobilize energy resources. Endorphins, which are endogenous

opioids, increase during stress and enhance the threshold for tolerance of painful stimuli. They may also affect mood and have been implicated in the so-called high that long-distance runners experience. The secretion of other hormones is also affected; however, their adaptive function is less clear.

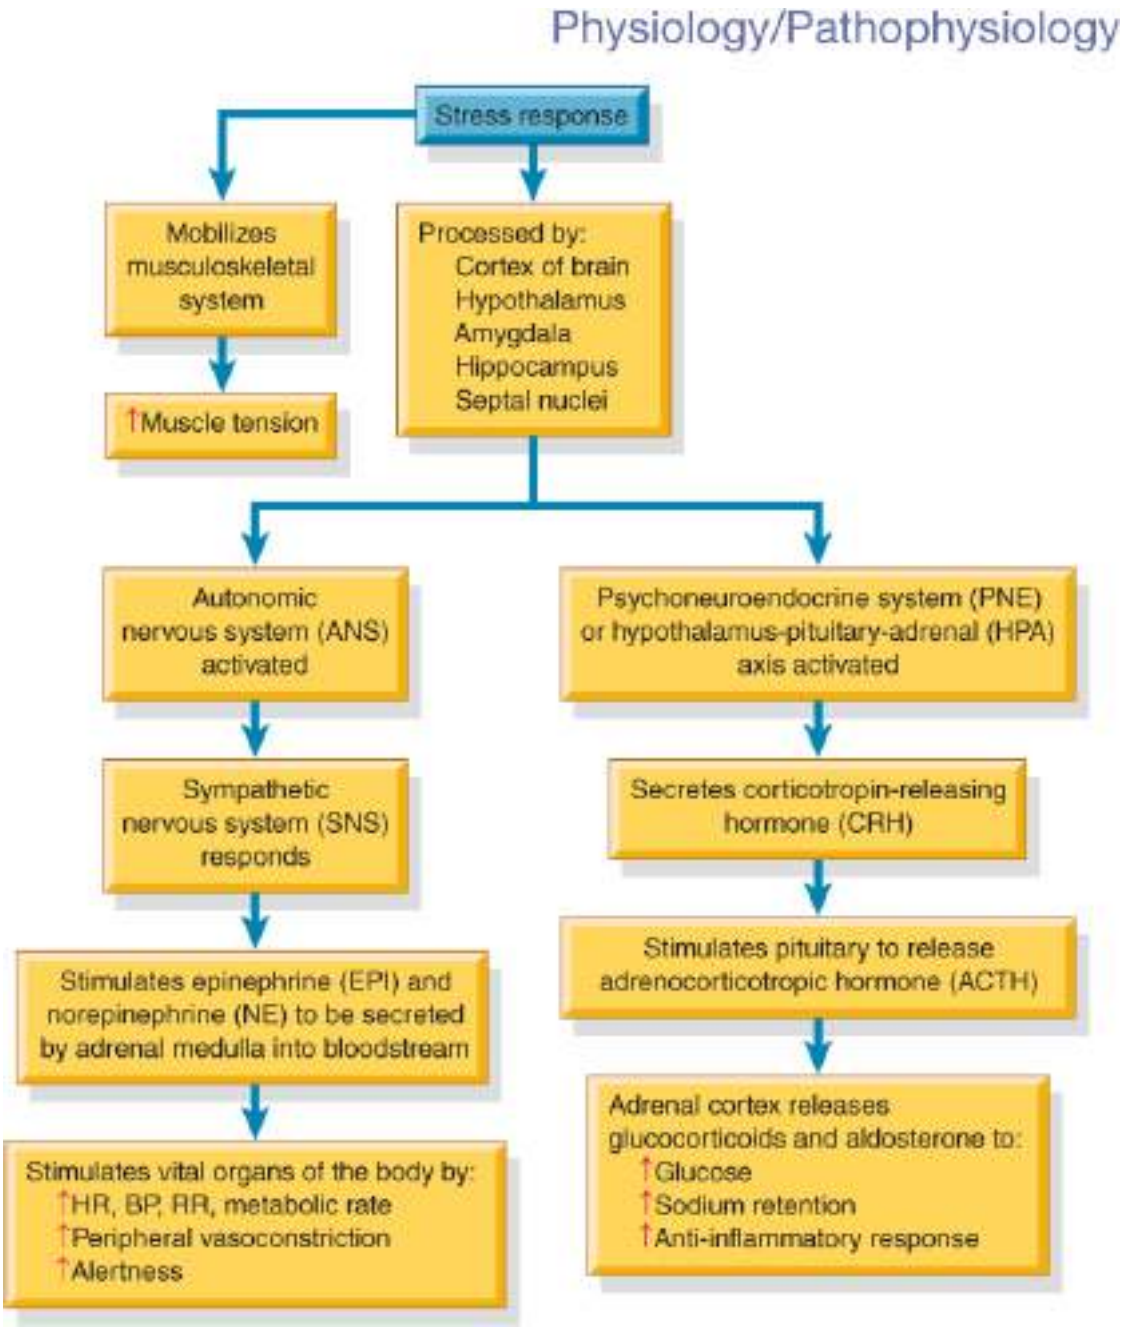

Figure 5-2 • The physiologic response to stress. The body is prepared through brain activation of the autonomic nervous system and psychoneuroendocrine system commonly referred to as the hypothalamus–pituitary–adrenal axis to cope with stress.

TABLE 5-1 Sympathetic–Adrenal–Medullary Reaction to Stress or Fight-or-Flight Response

Effect	Purpose	Mechanism
Increased heart rate and blood pressure	More perfusion to vital organs	Increased cardiac output owing to increased myocardial contractility and heart rate; increased venous return (peripheral vasoconstriction)
Increased blood glucose level	Increased available energy	Increased liver and muscle glycogen breakdown; increased breakdown of adipose tissue triglycerides
Mental acuity	Alert state	Increase in amount of blood shunted to the brain from the abdominal viscera and skin
Dilated pupils	Increased awareness	Contraction of radial muscle of iris
Increased tension of skeletal muscles	Preparedness for activity, decreased fatigue	Excitation of muscles; increase in amount of blood shunted to the muscles from the abdominal viscera and skin
Increased ventilation (may be rapid and shallow)	Provision of oxygen for energy	Stimulation of respiratory center in medulla; bronchodilation
Increased coagulability of blood	Prevention of hemorrhage in event of trauma	Vasoconstriction of surface vessels

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health status* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Immunologic Response

The immune system is connected to the neuroendocrine and autonomic systems. Lymphoid tissue is richly supplied by autonomic nerves capable of releasing a number of different neuropeptides that can have a direct effect on leukocyte regulation and the inflammatory response. Neuroendocrine hormones released by the central nervous system and endocrine tissues can inhibit or stimulate leukocyte function. The various stressors a person experiences may result in different alterations in autonomic activity and subtle variations in neurohormone and neuropeptide synthesis. All of these possible autonomic and neuroendocrine responses can interact to initiate, weaken, enhance, or terminate an immune response.

The study of the relationships among the neuroendocrine system, the central and autonomic nervous systems, and the immune system and the effects of these relationships on overall health outcomes are called *psychoneuroimmunology.* Because one's perception of events and one's coping styles determine whether, and to what extent, an event activates the stress

response system, and because the stress response affects immune activity, one's perceptions, ideas, and thoughts can have profound neurochemical and immunologic consequences. Some studies have demonstrated altered immune function in people who are under stress (Atkinson, Rodman, Thuras, et al., 2019; Christensen, Flensborg-Madsen, Garde, et al., 2019; Frishman, 2019; Ubel & Rosenthal, 2019). Other studies have identified certain personality traits, such as decisiveness, assertiveness, compassion, helpfulness, and conscientiousness, as having positive effects on health (Antoni & Dhabhar, 2019; Champagne, 2019; Wilson, Woody, Padin, et al., 2019). As research continues, this field of study will likely uncover to what extent and by what mechanisms people can consciously influence their immunity.

Maladaptive Responses to Stress

The stress response, as indicated earlier, facilitates adaptation to threatening situations and is retained from humans' evolutionary past. The fight-or-flight response, for example, is an anticipatory response that mobilized the bodily resources of our ancestors to deal with predators and other harsh factors in their environment. This same mobilization comes into play in response to emotional stimuli unrelated to danger. For example, a person may get an "adrenaline rush" when competing over a decisive point in a ball game or when excited about attending a party.

When responses to stress are ineffective, they are referred to as *maladaptive.* Maladaptive responses are chronic, recurrent responses or patterns of response that do not promote the goals of adaptation. The goals of adaptation are somatic or physical health (optimal wellness); psychological health or having a sense of well-being (happiness, satisfaction with life, morale); and enhanced social functioning, which includes work, social life, and family (positive relationships). Maladaptive responses that threaten these goals include faulty appraisals and inappropriate coping (Lazarus, 1991).

The frequency, intensity, and duration of stressful situations contribute to the development of emotions and subsequent patterns of neurochemical discharge. By appraising situations adequately and coping appropriately, it is possible to anticipate and defuse some of these situations. For example, frequent stressful encounters (e.g., marital discord) might be avoided with better communication and problem solving, or a pattern of procrastination (e.g., delaying work on tasks) could be corrected to reduce stress when deadlines approach.

Coping processes that include the use of alcohol or drugs to reduce stress increase the risk of illness. Other inappropriate coping patterns may increase the risk of illness less directly. For example, people who demonstrate "type A" behaviors, including impatience, competitiveness, and achievement orientation, have an underlying aggressive approach to life. Type A behaviors

increase the output of catecholamines, the adrenal–medullary hormones, with their attendant effects on the body. Additional forms of inappropriate coping include denial, avoidance, and distancing.

Models of illness frequently include stress and maladaptation as precursors to disease. A general model of illness, based on Selye's theory, suggests that any stressor elicits a state of disturbed physiologic equilibrium. If this state is prolonged or the response is excessive, it increases the susceptibility of the person to illness. This susceptibility, coupled with a predisposition in the person (from genetic traits, health, or age), leads to illness. If the sympathetic–adrenal–medullary response is prolonged or excessive, a state of chronic arousal develops that may lead to high blood pressure, arteriosclerotic changes, and cardiovascular disease. If the production of ACTH is prolonged or excessive, behavior patterns of withdrawal and depression are seen. In addition, the immune response is decreased, and infections and tumors may develop.

Selye (1976) proposed a list of disorders known as diseases of maladaptation: high blood pressure (including hypertension of pregnancy), diseases of the heart and blood vessels, diseases of the kidney, rheumatic diseases and inflammatory diseases of the skin and eyes, infections, allergic and hypersensitivity diseases, nervous and mental diseases, sexual dysfunction, digestive diseases, metabolic diseases, and cancer. Research continues on the complex interconnections between stress, coping (adaptive and maladaptive), and disease (Torkzadeh, Danesh, Mirbagher, et al., 2019; Tormohlen, Tobin, & Latkin, 2019).

Indicators of Stress

Indicators of stress and the stress response include both subjective and objective measures. Chart 5-1 lists signs and symptoms that may be observed directly or reported by a person. They are psychological, physiologic, or behavioral and reflect social behaviors and thought processes. Some of these reactions may be coping behaviors. Over time, each person tends to develop a characteristic pattern of behavior during stress to warn that the system is out of balance.

Chart 5-1 **ASSESSMENT**

Assessing for Stress

Be alert for the following:

Bruxism (grinding of teeth)
Changes in menstrual cycle
Change in appetite
Concentration difficulties
Diarrhea
Difficulty sleeping
Dry mouth
Emotional lability
Excessive perspiration
Fatigue
Feeling weak or dizzy
Gastrointestinal distress
Headaches
Hyperactivity
Increased substance use or misuse
Increased use of tobacco products or electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars
Increased body tension
Intense or increased anxiety
Impulsive behaviors
Loss of interest in life activities
Nausea or vomiting
Nervous habits
Nervous laughter
Overpowering urge to act out
Pain in back, neck, or other parts of the body
Palpitations
Prone to injury
Restlessness
Strong startle response
Tremors
Unintentional weight loss or gain
Urinary frequency

Adapted from Rice, V. H. (Ed.). (2012). *Handbook of stress, coping, and health: Implications for theory, research, and practice* (2nd ed.). Thousand Oaks, CA: Sage; Selye, H. (1976). *The stress of life, Rev. ed.* New York: McGraw-Hill.

Laboratory measurements of indicators of stress have helped in understanding this complex process. Blood and urine analyses can be used to demonstrate changes in hormonal levels and hormonal breakdown products.

Blood levels of catecholamines, corticosteroids, ACTH, and eosinophils are reliable measures of stress. Serum cholesterol and free fatty acid levels can be used to measure stress. Distress can cause an increase in adrenal hormones, including cortisol and aldosterone, which can lead to high serum cholesterol levels. Both physical and psychological distress can trigger an elevated cholesterol level. In addition, the results of immunoglobulin assays are increased when a person is exposed to various stressors, especially infections and immune deficiency conditions.

In addition to using laboratory tests, researchers have developed questionnaires to identify and assess stressors, stress, and coping strategies. The work of Rice (2012) includes a compilation of information gained from research on stress, coping, and health, and includes some of these questionnaires.

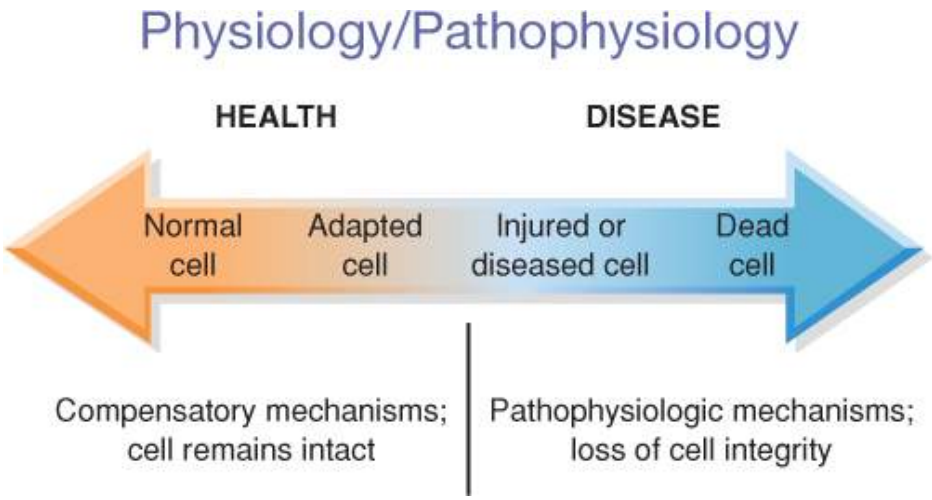

Figure 5-3 • The cell on a continuum of function and structure. Changes in the cell are not as easily discerned as the diagram depicts, and the point at which compensation subsides and pathophysiology begins is not clearly defined.

Stress at the Cellular Level

The cell exists on a continuum of function and structure, ranging from the normal cell, to the adapted cell, to the injured or diseased cell, to the dead cell (Fig. 5-3). Changes from one state to another may occur rapidly and may not be readily detectable, because each state does not have discrete boundaries, and disease represents disruption of normal processes. The earliest changes occur at the molecular or subcellular level and are not perceptible until steady-state functions or structures are altered. With cell injury, some changes may be reversible; in other instances, the injuries are lethal. For example, tanning of the skin is an adaptive, morphologic response to exposure to the rays of the

sun. However, if the exposure is continued, sunburn and injury occur, and some cells may die, as evidenced by desquamation ("peeling").

Different cells and tissues respond to stimuli with different patterns and rates of response, and some cells are more vulnerable to one type of stimulus or stressor than others. The cell involved, its ability to adapt, and its physiologic state are determinants of the response. For example, cardiac muscle cells respond to **hypoxia** (inadequate cellular oxygenation) more quickly than do smooth muscle cells.

Other determinants of cellular response are the type or nature of the stimulus, its duration, and its severity. For example, neurons that control respiration can develop a tolerance to regular, small amounts of a barbiturate; however, one large dose may result in respiratory depression and death.

Control of the Steady State

The concept of the cell as existing on a continuum of function and structure includes the relationship of the cell to compensatory mechanisms, which occur continuously in the body to maintain the steady state. Compensatory processes are regulated primarily by the autonomic nervous system and the endocrine system, with control achieved through negative feedback.

Negative Feedback

Negative feedback mechanisms throughout the body monitor the internal environment and restore homeostasis when conditions shift out of the normal range. These mechanisms sense deviations from a predetermined set point or range of adaptability and trigger a response to offset the deviation. Functions regulated through such compensatory mechanisms include blood pressure, acid–base balance, blood glucose level, body temperature, and fluid and electrolyte balance.

Most of the human body's control systems are integrated by the brain with feedback from the nervous and endocrine systems. Control activities involve detecting deviations from the predetermined reference point and stimulating compensatory responses in the muscles and glands of the body. The major organs affected are the heart, lungs, kidneys, liver, gastrointestinal tract, and skin. When stimulated, these organs alter their rate of activity or the amount of secretions they produce. Because of this, these major organs are considered the "*organs of homeostasis or adjustment*" (Norris, 2019).

In addition to the responses influenced by the nervous and endocrine systems, local responses consisting of small feedback loops in a group of cells or tissues occur. The cells detect a change in their immediate environment and initiate an action to counteract its effect. For example, the accumulation of lactic acid in an exercised muscle stimulates dilation of blood vessels in the

area to increase blood flow and improve the delivery of oxygen and removal of waste products.

The net result of negative feedback loops is homeostasis. A steady state is achieved by the continuous, variable action of the organs involved in making the adjustments and by the continuous exchange of chemical substances among cells, interstitial fluid, and blood. For example, an increase in the carbon dioxide (CO_2) concentration of the extracellular fluid leads to increased pulmonary ventilation, which decreases the CO_2 level. On a cellular level, increased CO_2 raises the hydrogen ion concentration of the blood. This is detected by chemosensitive receptors in the brain's medullary respiratory control center. The chemoreceptors then stimulate an increase in the rate of discharge of the neurons that innervate the diaphragm and intercostal muscles, which increases the respiratory rate. Excess CO_2 is exhaled, the hydrogen ion concentration returns to normal, and the chemically sensitive neurons are no longer stimulated (Norris, 2019).

Positive Feedback

Another type of feedback, **positive feedback,** perpetuates the chain of events set in motion by the original disturbance instead of compensating for it. As the system becomes more unbalanced, disorder and disintegration occur. There are some exceptions to this; blood clotting in humans, for example, is an important positive feedback mechanism.

Cellular Adaptation

Cells are complex units that dynamically respond to the changing demands and stresses of daily life. They possess a maintenance function and a specialized function. The maintenance function refers to the activities that the cell performs with respect to itself; specialized functions are those that the cell performs in relation to the tissues and organs of which it is a part. Individual cells may cease to function without posing a threat to the organism. However, as the number of dead cells increases, the specialized functions of the tissues are altered and health is threatened.

Cells can adapt to environmental stress through structural and functional changes. Some of these adaptations include cellular atrophy, hypertrophy, hyperplasia, metaplasia, and dysplasia. Such adaptations reflect changes in the normal cell in response to stress (Fig. 5-4A). If the stress is unrelenting, cellular injury and death may occur.

Atrophy can be the consequence of disease, decreased use, decreased blood supply, loss of nerve supply, or inadequate nutrition. Disuse of a body part is often associated with the aging process and immobilization. Cell size and

organ size decrease (Fig. 5-4B), and the structures principally affected are the skeletal muscles, the secondary sex organs, the heart, and the brain.

Atrophy and **hypertrophy** lead to changes in the size of cells (Fig. 5-4C) and hence the size of the organs they form. Compensatory hypertrophy is the result of an enlarged muscle mass and commonly occurs in skeletal and cardiac muscle that experiences a prolonged, increased workload. One example is the bulging muscles of an athlete.

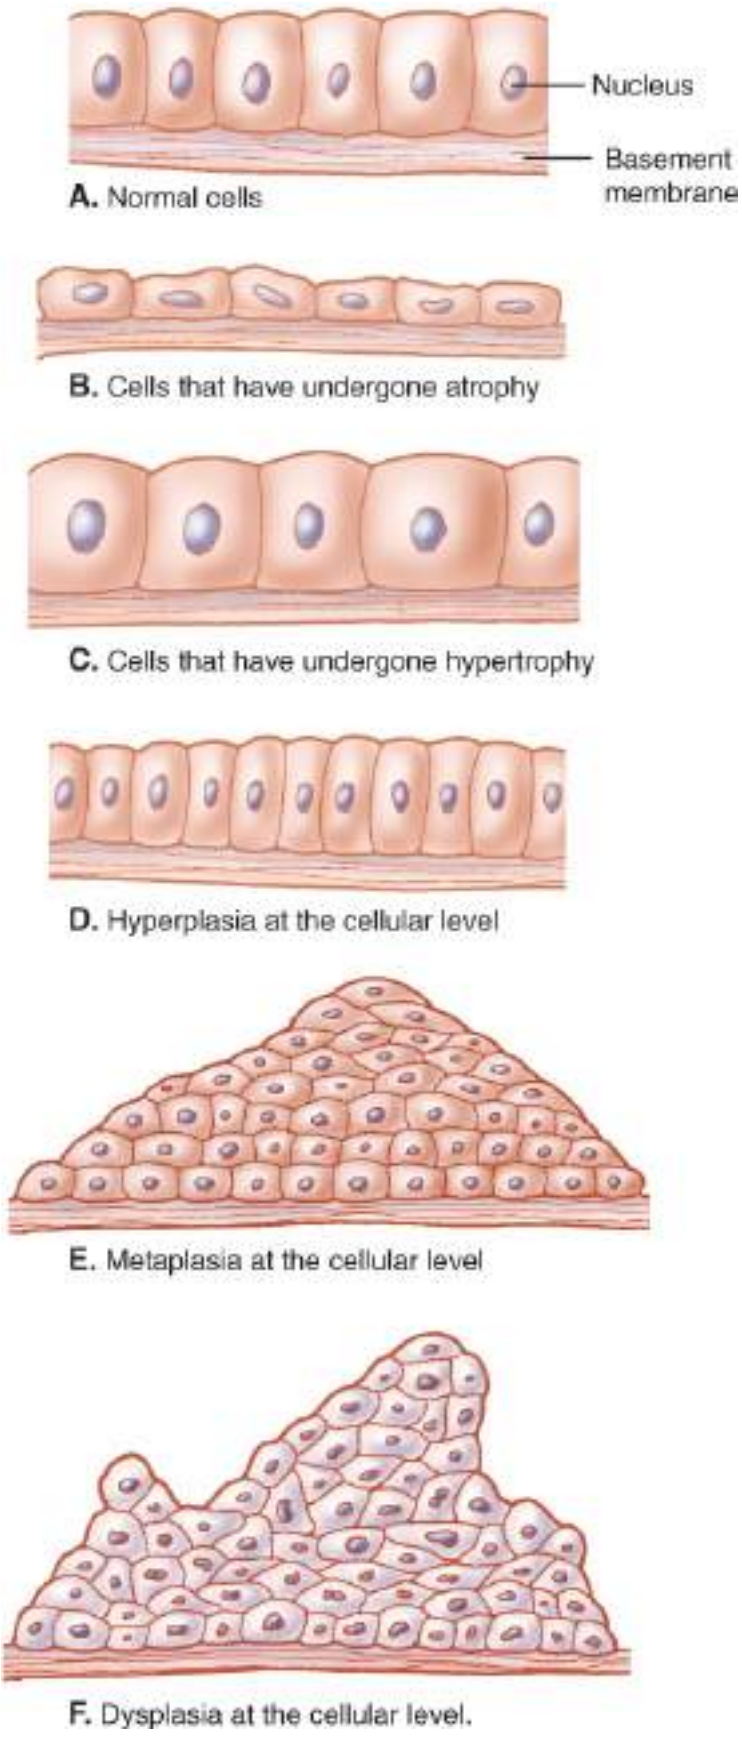

Figure 5-4 • Adaptation at the cellular level. Adapted with permission from Stewart J, Anatomical Chart Company. *Atlas of*

pathophysiology (4th ed., p. 5). Wolters Kluwer Health, Inc., 2017.

Hyperplasia is an increase in the number of new cells in an organ or tissue (Fig. 5-4D). As cells multiply and are subjected to increased stimulation, the tissue mass enlarges. This mitotic response (a change occurring with mitosis) is reversible when the stimulus is removed. This distinguishes hyperplasia from neoplasia or malignant growth, which continues after the stimulus is removed. Hyperplasia may be hormonally induced. An example is the increased size of the thyroid gland caused by thyroid-stimulating hormone (secreted from the pituitary gland) when a deficit in thyroid hormone occurs.

Metaplasia is a cell transformation in which one type of mature cell is converted into another type of cell (Fig. 5-4E). This serves a protective function, because less-transformed cells are more resistant to the stress that stimulated the change. For example, the ciliated columnar epithelium lining the bronchi of people who smoke is replaced by squamous epithelium. The squamous cells can survive; loss of the cilia and protective mucus, however, can have damaging consequences.

Dysplasia is bizarre cell growth resulting in cells that differ in size, shape, or arrangement from other cells of the same tissue type (Fig. 5-4F). Dysplastic cells have a tendency to become malignant; dysplasia is seen commonly in epithelial cells in the bronchi of people who smoke or use electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars.

Cellular Injury

Injury is defined as a disorder in steady-state regulation. Any stressor that alters the ability of the cell or system to maintain optimal balance of its adjustment processes leads to injury. Structural and functional damage then occurs, which may be reversible (permitting recovery) or irreversible (leading to disability or death). Homeostatic adjustments are concerned with the small changes within the body's systems. With adaptive changes, compensation occurs, and a new steady state may be achieved. With injury, steady-state regulation is lost and changes in functioning ensue.

Causes of disorder and injury in the system (cell, tissue, organ, body) may arise from the external or internal environment (Fig. 5-5) and include hypoxia, nutritional imbalance, physical agents, chemical agents, infectious agents, immune mechanisms, and genetic defects. The most common causes are hypoxia (oxygen deficiency), chemical injury, and infectious agents. In addition, the presence of one injury makes the system more susceptible to another injury. For example, inadequate oxygenation and nutritional deficiencies make the system vulnerable to infectious agents. These agents

damage or destroy the integrity of the cell membrane (necessary for ionic balance) as well as the cell's ability to do the following:

- Transform energy (aerobic respiration, production of adenosine triphosphate)
- Synthesize enzymes and other necessary proteins
- Grow and reproduce (genetic integrity)

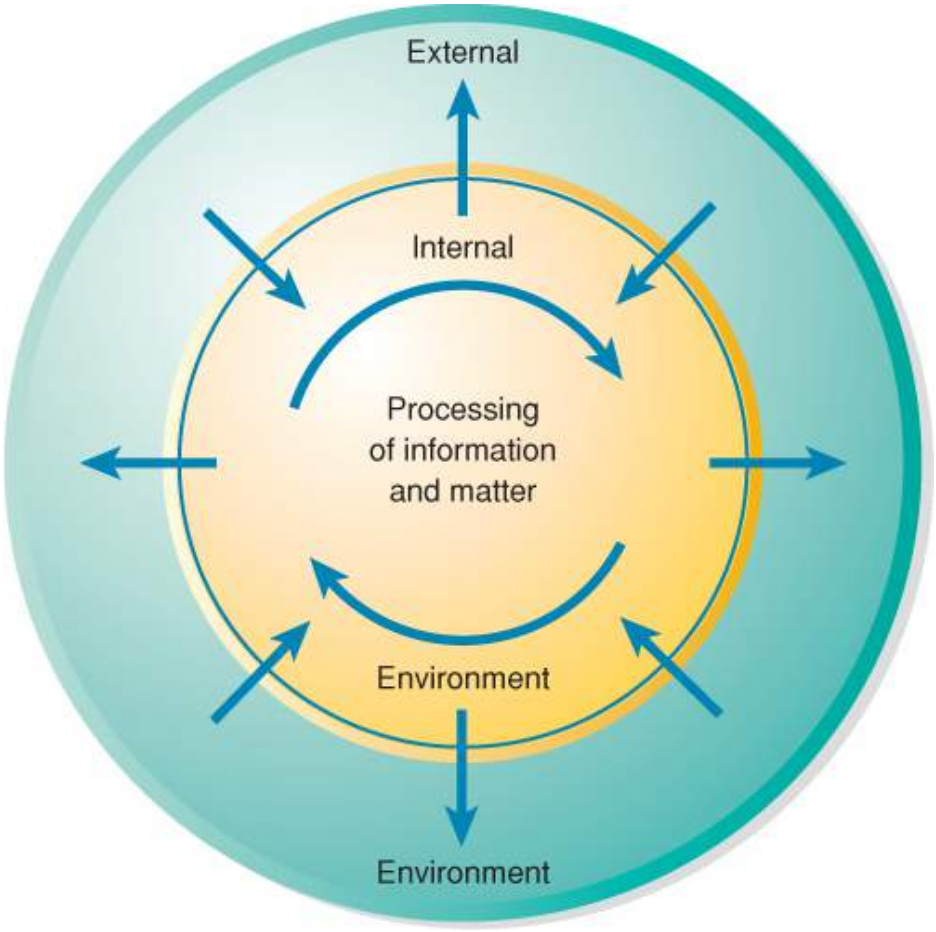

Figure 5-5 • Influences leading to disorder may arise from the internal and external environments of the system. Excesses or deficits of information and matter may occur, or there may be faulty regulation of processing.

Hypoxia

Hypoxia interferes with the cell's ability to transform energy. Hypoxia may be caused by a decrease in blood supply to an area, a decrease in the oxygen-carrying capacity of the blood (decreased hemoglobin), a ventilation–perfusion or respiratory problem that reduces the amount of arterial oxygen available, or a problem in the cell's enzyme system that makes it unable to use oxygen.

The usual cause of hypoxia is ischemia or deficient blood supply. Ischemia is commonly seen in myocardial cell injury in which arterial blood flow is

decreased because of atherosclerotic narrowing of blood vessels. Ischemia also results from intravascular clots (thrombi or emboli) that may form and interfere with blood supply. Thromboemboli are common causes of cerebrovascular disease (strokes). The length of time in which different tissues can survive without oxygen varies. For example, brain cells most often succumb in 3 to 6 minutes. If the condition leading to hypoxia is slow and progressive, collateral circulation may develop, whereby blood is supplied by other blood vessels in the area. However, this mechanism is not highly reliable.

Nutritional Imbalance

Nutritional imbalance refers to a relative or absolute deficiency or excess of one or more essential nutrients. This may be manifested as undernutrition (inadequate consumption of food or calories) or overnutrition (caloric excess). Caloric excess to the point of obesity overloads cells in the body with lipids. By requiring more energy to maintain the extra tissue, obesity places a strain on the body and has been associated with the development of disease, especially pulmonary and cardiovascular disease as well as several types of cancer. (See Chapter 42 for further discussion of obesity.)

Specific deficiencies arise when an essential nutrient is deficient or when a nutrient imbalance exists. Protein deficiencies and avitaminosis (deficiency of vitamins) are typical examples. An energy deficit leading to cell injury can occur if there is insufficient glucose or insufficient oxygen to transform the glucose into energy. A lack of insulin, or the inability to use insulin, may also prevent glucose from entering the cell from the blood. This occurs in diabetes, a metabolic disorder that can lead to nutritional deficiency, as well as a host of short- and long-term life-threatening complications. (See Chapter 46 for further discussion of diabetes.)

Physical Agents

Physical agents, including temperature extremes, radiation, electrical shock, and mechanical trauma, can cause injury to the cells or to the entire body. The duration of exposure and the intensity of the stressor determine the severity of damage.

Temperature

When a person's temperature is elevated, hypermetabolism occurs and the respiratory rate, heart rate, and basal metabolic rate increase. With fever induced by infections, the hypothalamic thermostat may be reset at a higher temperature and then return to normal when the fever abates. The increase in body temperature is achieved through physiologic mechanisms. Body temperatures greater than 41°C (106°F) indicate hyperthermia, because the physiologic function of the thermoregulatory center breaks down and the

temperature soars (Norris, 2019). This physiologic condition occurs in people who have heatstroke. Eventually, the high temperature causes coagulation of cell proteins, and cells die.

The local response to burn injury is similar. Increased metabolic activity occurs, and, as heat increases, proteins coagulate and enzyme systems are destroyed. In extreme situations, charring or carbonization occurs. See Chapter 57 for more information about burn injuries.

Extreme low environmental temperature (cold) causes vasoconstriction. Blood flow becomes sluggish and clots form, leading to ischemic damage in the involved tissues. With still lower temperatures, ice crystals may form and cells may burst.

Radiation and Electrical Shock

Radiation is used for diagnosis and treatment of diseases. Ionizing forms of radiation may cause injury by their destructive action. Radiation decreases the protective inflammatory response of the cell, creating a favorable environment for opportunistic infections. Electrical shock produces burns as a result of the heat generated when electrical current travels through the body. It may also abnormally stimulate nerves, leading, for example, to fibrillation of the heart.

Mechanical Trauma

Mechanical trauma can result in wounds that disrupt the cells and tissues of the body. The severity of the wound, amount of blood loss, and extent of nerve damage are significant factors in determining the extent of injury.

Chemical Agents

Chemical injuries are caused by poisons, such as lye, that have a corrosive action on epithelial tissue, or by heavy metals, such as mercury, arsenic, and lead, each of which has its own specific destructive action. Many other chemicals are toxic in certain amounts, in certain people, and in specific tissues. For example, excessive secretion of hydrochloric acid can damage the stomach lining; large amounts of glucose can cause osmotic shifts, affecting the fluid and electrolyte balance; and too much insulin can cause subnormal levels of glucose in the blood (hypoglycemia) and can lead to coma.

Drugs, including prescribed medications, can also cause chemical poisoning. Some people are less tolerant of medications than others and manifest toxic reactions at the usual or customary dosages. Aging tends to decrease tolerance to medications. Polypharmacy (taking many medications at one time) occurs frequently in older adults, and the unpredictable effects of the resulting medication interactions can cause injury.

Alcohol (ethanol) is also a chemical irritant. In the body, alcohol is broken down into acetaldehyde, which has a direct toxic effect on liver cells that leads to various liver abnormalities, including cirrhosis in susceptible people.

Disordered liver cell function leads to complications in other organs of the body.

Infectious Agents

Biologic agents known to cause disease in humans are viruses, bacteria, rickettsiae, mycoplasmas, fungi, protozoa, and nematodes. The severity of the infectious disease depends on the number of microorganisms entering the body, their virulence, and the host's defenses (e.g., health, age, immune responses; see Chapter 66 for further discussion of infectious diseases).

An infection exists when the infectious agent is living, growing, and multiplying in the tissues and is able to overcome the body's normal defenses. Some bacteria, such as those that cause tetanus and diphtheria, produce exotoxins that circulate and create cell damage. Others, such as gram-negative bacteria, produce endotoxins when they die. Tubercle bacilli induce an immune reaction.

Viruses are among the smallest living organisms known and survive as parasites of the living cells they invade. Viruses infect specific cells. Through a complex mechanism, viruses replicate within cells and then invade other cells, where they continue to replicate. As the body mounts an immune response to eliminate the viruses, cells harboring the viruses can be injured in the process. Typically, an inflammatory response and immune reaction are the body's physiologic responses to viral infection.

Disordered Immune Responses

The immune system is an exceedingly complex system, the purpose of which is to defend the body from invasion by any foreign object or foreign cell type, such as cancerous cells. This is a steady-state mechanism; however, like other adjustment processes, it can become disordered and cellular injury results. The immune response detects foreign bodies by distinguishing non-self substances from self substances and destroying the non-self entities. The entrance of an antigen (foreign substance) into the body evokes the production of antibodies that attack and destroy the antigen (antigen–antibody reaction).

The immune system may function normally, or it may be hypoactive or hyperactive. When it is hypoactive, immune deficiency diseases occur; when it is hyperactive, hypersensitivity disorders occur. A disorder of the immune system can result in damage to the body's own tissues. Such disorders are labeled autoimmune diseases (see Unit 7).

Genetic Disorders

There is intense interest in genetic defects as causes of disease and modifiers of genetic structure. Many of these defects produce mutations that have no recognizable effect, such as lack of a single enzyme; others contribute to more

obvious congenital abnormalities, such as Down syndrome. (For further information on genetics, see Chapter 6.)

Cellular Response to Injury: Inflammation

Cells or tissues of the body may be injured or killed by any of the agents (physical, chemical, infectious) described earlier. When this happens, an inflammatory response (or inflammation) naturally occurs in the healthy tissues adjacent to the site of injury. **Inflammation** is a localized reaction intended to neutralize, control, or eliminate the offending agent to prepare the site for repair. It is a nonspecific response (not dependent on a particular cause) that is meant to serve a protective function. For example, inflammation may be observed at the site of a bee sting, in a sore throat, in a surgical incision, and at the site of a burn. Inflammation also occurs in cell injury events, such as stroke, deep vein thrombosis, and myocardial infarction.

Inflammation is not the same as infection. An infectious agent is only one of several agents that may trigger an inflammatory response. Regardless of the cause, a general sequence of events occurs in the local inflammatory response. This sequence involves changes in the microcirculation, including vasodilation, increased vascular permeability, and leukocytic cellular infiltration (Fig. 5-6). As these changes take place, five cardinal signs of inflammation are produced: redness, warmth, swelling, pain, and loss of function (Norris, 2019).

The transient vasoconstriction that occurs immediately after injury is followed by vasodilation and an increased rate of blood flow through the microcirculation to the area of tissue damage. Local warmth and redness result. Next, the structure of the microvascular system changes to accommodate the movement of plasma protein from the blood into the tissues. Following this increase in vascular permeability, plasma fluids (including proteins and solutes) leak into the inflamed tissues, producing swelling. Leukocytes migrate through the endothelium and accumulate in the tissue at the site of the injury. The pain that occurs is attributed to the pressure of fluids or swelling on nerve endings and to the irritation of nerve endings by chemical mediators released at the site. Bradykinin is one of the chemical mediators suspected of causing pain. Loss of function is most likely related to the pain and swelling; however, the exact mechanism is not completely known.

As blood flow increases and fluid leaks into the surrounding tissues, the formed elements (red blood cells, white blood cells, and platelets) remain in the blood, causing it to become more viscous. Leukocytes (white blood cells) collect in the vessels, exit, and migrate to the site of injury to engulf offending organisms and to remove cellular debris in a process called *phagocytosis*. Fibrinogen in the leaked plasma fluid coagulates, forming fibrin for clot

formation, which serves to wall off the injured area and prevent the spread of infection.

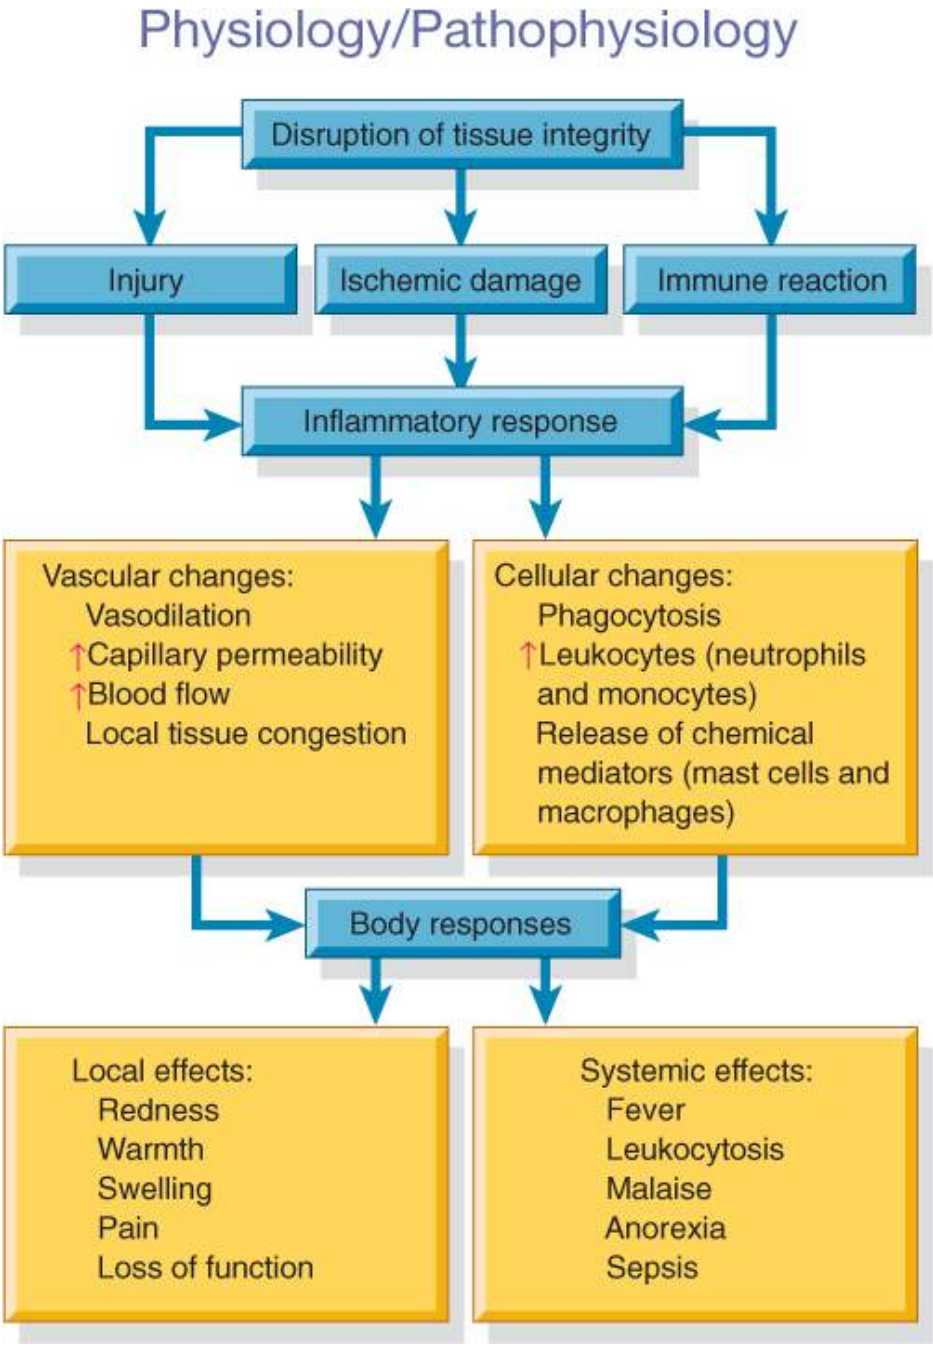

Figure 5-6 • Inflammatory response. Source: Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health status* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Chemical Mediators of Inflammation

Injury initiates the inflammatory response; however, chemical substances released at the site induce vascular changes. Foremost among these chemicals are histamine and kinins. Histamine is present in many tissues of the body but

is concentrated in the mast cells. It is released when injury occurs and is responsible for the early changes in vasodilation and vascular permeability. Kinins cause vasodilation and increased vascular permeability, and they attract neutrophils to the area. Prostaglandins—another group of chemical substances—are also suspected of causing increased vascular permeability (Norris, 2019).

Systemic Response to Inflammation

The inflammatory response is often confined to the site, causing only local signs and symptoms. However, systemic responses can also occur. Fever is the most common sign of a systemic response to injury, and it is most likely caused by endogenous pyrogens (internal substances that cause fever) released from neutrophils and macrophages (specialized forms of leukocytes). These substances reset the hypothalamic thermostat, which controls body temperature, and produce fever. Leukocytosis, an increase in the synthesis and release of neutrophils from bone marrow, may occur, enhancing the body's ability to fight infection. During this process, general, nonspecific symptoms develop, including malaise, loss of appetite, aching, and weakness.

Types of Inflammation

Inflammation is categorized primarily by its duration and the type of exudate produced. It is most often acute or chronic. Acute inflammation is characterized by the local vascular and exudative changes described previously and usually lasts less than 2 weeks. An acute inflammatory response is immediate and serves a protective function. After the causative agent is removed, the inflammation subsides and healing takes place with the return of normal or near-normal structure and function.

Chronic inflammation develops if the injurious agent persists and the acute response is perpetuated. Symptoms are present for many months or years. Chronic inflammation may also begin insidiously and never have an acute phase. The chronic response does not serve a beneficial and protective function; on the contrary, it is debilitating and can produce long-lasting effects. As the inflammation becomes chronic, changes occur at the site of injury, and the nature of the exudate becomes proliferative. A cycle of cellular infiltration, necrosis, and fibrosis begins, with repair and breakdown occurring simultaneously. Considerable scarring may occur, resulting in permanent tissue damage.

Cellular Healing

The reparative process begins at approximately the same time as the injury. Healing proceeds after the inflammatory debris has been removed. Healing

may occur by regeneration, in which the defect is gradually repaired by proliferation of the same type of cells as those destroyed, or by replacement, in which cells of another type, usually connective tissue, fill in the tissue defect and result in scar formation.

Regeneration

The ability of cells to regenerate depends on whether they are labile, permanent, or stable. Labile cells multiply constantly to replace cells worn out by normal physiologic processes; these include epithelial cells of the skin and those lining the gastrointestinal tract. Permanent cells include neurons—the nerve cell bodies, not their axons. Destruction of neurons is permanent; however, axons may regenerate. If normal activity is to return, tissue regeneration must occur in a functional pattern, especially in the growth of several axons. Stable cells in some organ systems have a latent ability to regenerate. Under normal physiologic processes, they are not shed and do not need replacement; if they are damaged or destroyed, they are able to regenerate. Examples include functional cells of the kidney, liver, and pancreas. Cells in other organs, such as the brain, do not regenerate.

Replacement

The condition of the host, the environment, and the nature and severity of the injury affect the processes of inflammation, repair, and replacement. Depending on the extent of damage, repair and replacement may occur by primary or secondary intention. In primary intention healing, the wound edges are approximated, as in a surgical wound (see Chapter 16). Little scar formation occurs, and the wound healing occurs without granulation. In secondary intention healing, there is tissue loss so the edges are not approximated and the wound fills with granulation tissue (Norris, 2019). The process of repair takes longer and may result in scar formation, with loss of specialized function. For example, people who have recovered from myocardial infarction have abnormal electrocardiographic tracings because the electrical signal cannot be conducted through the connective tissue that has replaced the infarcted area.

Nursing Management

Stress or the potential for stress is ubiquitous—that is, it is both everywhere and anywhere. It is essential for all people, particularly student nurses, to engage in strategies for stress relief. Nursing students experience stressors that can negatively affect their academic and clinical performance (Kinchen & Loerzel, 2019). See the Nursing Research Profile in Chart 5-2. Anxiety, frustration, anger, and feelings of inadequacy, helplessness, or powerlessness

are emotions often associated with stress. In the presence of these emotions, the customary activities of daily living may be disrupted—for example, a sleep disturbance may occur, eating and activity patterns may be altered, and family processes or role performance may be disrupted.

The optimal point of intervention to promote health is during the stage when a person's own compensatory processes are still functioning effectively. A major role of nurses is the early identification of both physiologic and psychological stressors. Nurses should be able to relate the presenting signs and symptoms of distress to the physiology they represent and identify a person's position on the continuum of function, from health and compensation to pathophysiology and disease.

In the assessment of people who seek health care, both objective signs and subjective symptoms are the primary indicators of existing physiologic processes. The following questions are addressed:

- Are the heart rate, respiratory rate, and temperature normal?
- What emotional distress may be contributing to the patient's health problems?
- Are there other indicators of steady-state deviation?
- What are the patient's blood pressure, height, and weight?
- Are there any problems in movement or sensation?
- Are there any problems with affect, behavior, speech, cognitive ability, orientation, or memory?
- Are there obvious impairments, lesions, or deformities?

Objective evidence can be obtained from laboratory data, such as electrolytes, blood urea nitrogen, blood glucose, and urinalysis results. Further signs of injury are seen in diagnostic studies such as computed tomography (CT) scanning, magnetic resonance imaging (MRI), and positron emission tomography (PET). Further information on diagnostic evaluation can be found in assessment chapters of each unit of this book. Many nursing diagnoses are possible for patients suffering from stress. One nursing diagnosis associated with stress is anxiety, which is defined as a vague, uneasy feeling, the source of which may be nonspecific or not known to the person. Stress may also be manifested as difficulty coping patterns, decisional conflict, or relationship problem. These human responses are reflected in the nursing diagnoses of anxiety, difficulty coping, and denial, all of which indicate poor adaptive responses. Other possible nursing diagnoses include social isolation, risk for spiritual distress, readiness for positive family processes, decisional conflict, lack of resilience, and risk for powerlessness, among others. Because human responses to stress are varied, as are the sources of stress, arriving at an accurate diagnosis allows interventions and goals to be more specific and leads to improved outcomes.

Chart 5-2 NURSING RESEARCH PROFILE

Nursing Students' Attitudes and Use of Holistic Therapies for Stress Relief

Kinchen, E. V., & Loerzel, V. (2019). Nursing students' attitudes and use of holistic therapies for stress relief. *Journal of Holistic Nursing, 37*(1), 6–17.

Purpose

The purpose of this mixed methods research study was to determine nursing students' openness to using or making recommendations to use holistic strategies to manage school or work stress, along with their perceptions of engaging in the use of holistic therapies for their own personal health.

Design

In this quasi-experimental, mixed methods study, a convenience sample of nursing students was recruited from a senior undergraduate class and provided an email to obtain information about the study, the consent form, and the survey link. Participants completed the quantitative electronic survey and answered the accompanying three open-ended questions. The questions asked the participants about their personal use or recommendation to use holistic therapies for stress relief, the strategies they utilized for managing their stress, and their perceptions of the influence that holistic therapies have on personal health. Students who participated in the study were given two extra credit points; nonparticipants who desired to obtain the extra credit points were permitted to write a one-page essay as an alternative assignment on the holistic therapy of their choice.

Findings

The reported findings were only from the qualitative portion of the study. Of the 116 participants, 81 (70%) were very open or open to using or recommending holistic therapies, while 32 (28%) were somewhat open, and 3 (2%) were not open to using or recommending holistic modalities. From the data, eight categories of stress management activities were obtained: physical activity, prayer and meditation, time management, distraction, socialization, artistic/creative pursuits, interactions with animals, and other behaviors such as napping, taking a day off, stress eating, and crying. It was noted that 62% of the identified stress management actions are designated as holistic therapies. Overall, 85 of the participants (73%) held the view that holistic therapies had a positive influence on personal health, while 25 participants (22%) believed that holistic therapies had a potential influence on their health, and the remaining 6 (5%) perceived that holistic therapies had no effect on personal health. Four recurring themes were extracted from the data: wholeness, self-empowerment, relaxation/restoration, and alternative/complement to traditional medicine. The student participants were open to recommending these strategies to others. There also were barriers identified, such as a lack of knowledge and a lack of time, which interfered with using holistic methods for managing stress.

Nursing Implications

Information from this study supports that, in addition to the traditional behavioral health and pharmacologic interventions used for managing stress, many nursing students found holistic strategies useful for managing stress in their daily lives. This study lends support to the recommendations from many nursing organizations, such as the American Holistic Nurses Association (AHNA) and the American Nurses Association (ANA), to promote self-care and stress-relief strategies while providing students with the knowledge necessary to educate their patients about the use of holistic therapies. It is important for nursing education programs to establish and implement curriculum content and practical experiences related to holistic therapies.

Stress management is directed toward reducing and controlling stress and improving coping. The need to prevent illness, improve the quality of life, and decrease the cost of health care makes efforts to promote health essential, and stress control a significant health promotion goal. Stress reduction methods and coping enhancements can derive from either internal or external sources. For example, healthy eating habits and relaxation techniques are internal resources that help reduce stress, and a broad social network is an external resource that helps reduce stress. Goods and services that can be purchased are also external resources for stress management. It may be easier for people with adequate financial resources to cope with constraints in the environment, because their sense of vulnerability to threat is decreased compared to those without adequate financial resources.

Promoting a Healthy Lifestyle

A health-promoting lifestyle provides internal resources that aid in coping, and it buffers or cushions the impact of stressors. Lifestyles or habits that contribute to the risk of illness can be identified through a health risk appraisal, which is an assessment method designed to promote health by examining a person's habits and recommending changes when a health risk is identified.

Health risk appraisals involve the use of health risk questionnaires to estimate the likelihood that people with a given set of characteristics will become ill. People who receive this information may be influenced to adopt healthy behaviors (e.g., stop smoking, have periodic screening examinations) to improve their health. Questionnaires typically address the information presented in Chart 5-3.

The personal information is compared with average population risk data, and the risk factors are identified and weighted. From this analysis, a person's risks and major health hazards are identified. Further comparisons with population data can estimate how many years will be added to a person's lifespan if the suggested changes are made. However, research has not yet

demonstrated that providing people with such information ensures that they will change their behaviors. The single most important factor for determining health status is social class, and within a social class, research suggests that the major factor influencing health is level of education (Bastable, Gramet, Jacobs, et al., 2019).

Chart 5-3

Information Addressed in Health Risk Questionnaires

Demographic data such as age, gender, race/ethnic background
Personal and family history of diseases and health problems
Lifestyle choices:

- Eating, sleeping, exercise, smoking, drinking, use of illicit drugs, sexual activity, recreation activity, and driving habits
- Stressors at home and on the job
- Roles, role relationships, and associated stressors
- Living and family situation
- Family and social supports

Physical measurements:

- Blood pressure
- Height, weight, body mass index
- Laboratory analyses of blood and urine

Participation in high-risk behaviors (e.g., engaging in unprotected sexual activity, not using seat belts while riding in a motor vehicle, using illicit drugs)

Enhancing Coping Strategies

Bulechek, Butcher, Dochterman, and colleagues (2018) identified coping enhancement as a nursing intervention and defined it as handling perceived and actual stressors, changes, or threats that affect how one meets daily life demands and roles (Chart 5-4). The nurse can build on the patient's existing coping strategies, as identified in the health appraisal, or provide education about new strategies for coping if necessary.

Chart 5-4

Coping Enhancement: Nursing Interventions

Definition

Facilitation of cognitive and behavioral efforts to manage perceived stressors, changes, or threats that interfere with meeting life's demands and roles.

Select Activities

Assist the patient in identifying appropriate short- and long-term goals.
Assist the patient to solve problems in a constructive manner.
Provide information concerning diagnosis, treatment, and prognosis.
Encourage an attitude of realistic hope as a way of dealing with feelings of helplessness.
Acknowledge the patient's spiritual/cultural background and encourage the use of spiritual resources if desired.
Foster constructive outlets for anger and hostility.
Assist the patient in examining available resources to meet goals.
Appraise the needs and desires for social support, and assist the patient to identify available support systems.
Assist the patient to identify positive strategies to deal with limitations, manage needed lifestyle or role changes, and work through the losses of chronic illness and/or disability if appropriate.

Adapted from Bulechek, G. M., Butcher, H. K., Dochterman, J. M., et al. (Eds.). (2018). *Nursing interventions classification (NIC)* (7th ed.). St. Louis, MO: Mosby-Elsevier.

The five predominant ways of coping with illness identified in a review of 57 nursing research studies were as follows (Jalowiec, 1993):

- Trying to be optimistic about the outcome
- Using social support
- Using spiritual resources
- Trying to maintain control either over the situation or over feelings
- Trying to accept the situation

Other ways of coping included seeking information, reprioritizing needs and roles, lowering expectations, making compromises, comparing oneself to others, planning activities to conserve energy, taking things one step at a time, listening to one's body, and using self-talk for encouragement.

Unfolding Patient Stories: Skyler Hansen • Part 1

Skyler Hansen is an 18-year-old male recently diagnosed with type 1 diabetes. He lives with his parents and two younger siblings and is active in high school sports. He now requires insulin injections, glucose monitoring, and a diabetic diet. Examine how the psychological, physical, and educational needs for managing a new diagnosis can be a great source of stress to the patient and the family. How can the nurse enhance his ability to cope with and adapt to diabetes management? (Skyler Hansen's story continues in Chapter 46.)

Care for Skyler and other patients in a realistic virtual environment: *vSim* (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Educating About Relaxation Techniques

Relaxation techniques are a major method used to relieve stress. The goal of using relaxation techniques is to produce a response that counters the stress response. When this goal is achieved, the action of the hypothalamus adjusts, decreasing sympathetic and parasympathetic nervous system activity. The sequence of physiologic effects and their signs and symptoms are then interrupted, thus reducing psychological stress. This is a learned response and requires practice to achieve. Commonly used techniques include progressive muscle relaxation, the Benson relaxation response, and relaxation with guided imagery (all discussed later). Other relaxation techniques include meditation, breathing techniques, massage, Reiki, music therapy, biofeedback, and the use of humor.

The different relaxation techniques share four similar elements: (1) a quiet environment, (2) a comfortable position, (3) a passive attitude, and (4) a mental device (something on which to focus one's attention, such as a word, phrase, or sound).

Chart 5-5

The Benson Relaxation Response

1. Pick a brief phrase or word that reflects your basic belief system.
2. Choose a comfortable position.
3. Close your eyes.
4. Relax your muscles.
5. Become aware of your breathing and start using your selected focus word.
6. Maintain a passive demeanor.
7. Continue for a set period of time.
8. Practice the technique twice daily.

Adapted from Benson, H. (1993). The relaxation response. In D. Goleman, & J. Gurin. (Eds.). *Mind-body medicine: How to use your mind for better health*. Yonkers, NY: Consumer Reports Books.

Progressive Muscle Relaxation

Progressive muscle relaxation involves tensing and releasing the muscles of the body in sequence and sensing the difference in feeling. It is best if the person lies on a soft cushion in a quiet room, breathing easily. Someone usually reads the instructions in a low tone in a slow and relaxed manner, or a recording of the instructions may be played. The person tenses the muscles in the entire body (one muscle group at a time), holds, senses the tension, and then relaxes. As each muscle group is tensed, the person keeps the rest of the body relaxed. Each time the focus is on feeling the tension and relaxation. When the exercise is completed, the entire body should be relaxed (Benson, 1993; Benson & Stark, 1996).

The Benson Relaxation Response

The Benson relaxation response (Chart 5-5) combines meditation with relaxation. Along with the repeated word or phrase, a passive demeanor is essential. If other thoughts or distractions (noises, pain) occur, Benson recommends not fighting the distraction but simply continuing to repeat the focus phrase. Time of day is not important; however, the exercise works best on an empty stomach (Benson, 1993; Benson & Proctor, 1984; Benson & Stark, 1996).

Guided Imagery

Simple **guided imagery** is the mindful use of a word, phrase, or visual image for the purpose of distracting oneself from distressing situations or consciously taking time to relax or re-energize. A nurse can help a person select a pleasant scene or experience, such as watching the ocean or dabbling the feet in a cool stream. The image serves as the mental device in this technique. As the person

sits comfortably and quietly, the nurse guides the person to review the scene, trying to feel and relive the imagery with all of the senses. A recording may be made of the description of the image, or commercial recordings for guided imagery and relaxation can be used.

Educating About Stress Management

Two commonly prescribed nursing educational interventions—providing sensory information and providing procedural information (e.g., preoperative education)—aim to reduce stress and improve the patient's coping ability. This preparatory education includes giving structured content, such as a lesson in childbirth preparation to expectant parents, a review of how an implantable cardioverter defibrillator works to a patient with heart disease, or a description of sensations a patient will experience during cardiac catheterization. These techniques may alter the person–environment relationship such that something that might have been viewed as harmful or a threat will now be perceived more positively. Giving patients information also reduces the emotional response so that they can concentrate and solve problems more effectively (Kittleson, 2019; Miller & Stoeckel, 2017; Rhee, Marottoli, Van Ness, et al., 2018).

Veterans Considerations

Veterans have similar educational needs to nonveterans. Yet one study revealed that, in a postsecondary education setting, women service members and veterans received less health information compared to women who were not service members or veterans (Albright, Thomas, McDaniel, et al., 2019). In this cross-sectional study, women service members and veterans received less education about alcohol and illicit drug use, depression and anxiety, sexual assault and relational violence prevention, and stress reduction. Nurses who work on college campuses should be attuned to the educational needs of women veterans.

Promoting Family Health

In addition to individual concepts of homeostasis, stress, adaptation, and health problems associated with maladaptation, the concept of family is also important. Nurses can intervene with both individuals and families to reduce stress and its health-related effects. The **family** (group whose members are related by reciprocal caring, mutual responsibilities, and loyalties) plays a central role in the life of the patient and is a major part of the context of the patient's life. It is within families that people grow, are nurtured, acquire a sense of self, develop beliefs and values about life, and progress through life's

developmental stages (Fig. 5-7). Families are also the first source for socialization and education about health and illness.

Ideally, the health care team conducts a careful and comprehensive family assessment (including coping style), develops interventions tailored to handle the stressors, implements the specified treatment protocols, and facilitates the construction of social support systems. The use of existing family strengths, resources, and education is augmented by therapeutic family interventions. The nurse's primary goals are to maintain and improve the patient's present level of health and to prevent physical and emotional deterioration. Next, the nurse intervenes in the cycle that the illness creates: patient illness, stress for other family members, new illness in other family members, and additional patient stress.

Figure 5-7 • Within families, individuals progress through life's developmental stages.

Helping the family members manage the myriad stressors that bombard them daily involves working with family members to develop coping skills. Seven traits that enhance coping of family members under stress have been identified (Burr, Klein, Burr, et al., 1994). Communication skills and spirituality were frequently useful traits. Cognitive abilities, emotional strengths, relationship capabilities, willingness to use community resources, and individual strengths and talents were also associated with effective coping. As nurses work with families, they must not underestimate the impact of their therapeutic interactions, educational information, positive role modeling, provision of direct care, and education on promoting health. Maladaptive coping may result if health care team members are not perceived as actively supporting family members. Often, denial and blaming of others occur.

Sometimes, physiologic illness, emotional withdrawal, and physical distancing are the results of severe family conflict, violent behavior, or addiction to drugs and alcohol. Substance abuse may develop in family members who feel unable to cope or solve problems. People may engage in these dysfunctional behaviors when faced with difficult or problematic situations.

Enhancing Social Support

The nature of social support and its influence on coping have been studied extensively. Social support has been demonstrated to be an effective moderator of life stress. Such support has been found to provide people with several different types of emotional information (Nicks, Wray, Peavler, et al., 2019; Warner, Roberts, Jeanblanc, et al., 2017). The first type of information leads people to believe that they are cared for and loved. This emotional support appears most often in a relationship between two people in which mutual trust and attachment are expressed by helping each other to meet their emotional needs. The second type of information leads people to believe that they are esteemed and valued. This is most effective when others in a group recognize a person's favorable position within that group, demonstrating the person's value. Known as esteem support, this elevates the person's sense of self-worth. The third type of information leads people to feel that they belong to a network of communication and mutual obligation. Members of this network share information and make goods and services available to the members as needed.

Social support also facilitates a person's coping behaviors; however, this depends on the nature of the social support. People can have extensive relationships and interact frequently; however, the necessary support comes only when people feel a deep level of involvement and concern, not when they merely touch the surface of each other's lives.

The critical qualities within a social network are the exchange of intimate communications and the presence of solidarity and trust.

Emotional support from family and significant others provides love and a sense of sharing the burden. The emotions that accompany stress are unpleasant and often increase in a spiraling fashion if relief is not provided. Being able to talk with someone and express feelings openly may help a person gain mastery of the situation. Nurses can provide this support but also must identify the person's social support system and encourage its use. People who are "loners," who are isolated, or who withdraw in times of stress have a high risk of coping failure.

Because anxiety can also distort a person's ability to process information, it helps to seek information and advice from others who can assist with analyzing the threat and developing a strategy to manage it. Again, this use of others helps people maintain mastery of a situation and self-esteem.

Thus, social networks assist with management of stress by providing people with:

- A positive social identity
- Emotional support
- Material aid and tangible services
- Access to information
- Access to new social contacts and new social roles

Recommending Support and Therapy Groups

Support groups exist especially for people in similar stressful situations. Groups have been formed by people with ostomies; women who have had mastectomies; and people with cancer or other serious diseases, chronic illness and disability. There are groups for single parents, substance abusers and their family members, homicide bereavement, and victims of child abuse. Professional, civic, and religious support groups are active in many communities (Mavandadi, Wray, & Toseland, 2019; Supiano & Overfelt, 2018). Encounter groups, assertiveness training programs, and consciousness-raising groups help people modify their usual behaviors in their transactions with their environment. Many find that being a member of a group with similar problems or goals has a releasing effect that promotes freedom of expression and exchange of ideas.

Veterans Considerations

Due to the loss of their military community and associated support systems, veterans are at higher risk compared to civilians of experiencing psychiatric symptoms (such as posttraumatic stress disorder [PTSD]) and interpersonal distress. One group of researchers reported that in a study of 117 veterans, group psychotherapy helped to reduce the symptoms of PTSD and interpersonal distress, mainly by increasing social support among the veterans (Cox, Owen, & Ogrodniczuk, 2017).

The Role of Stress in Health Patterns

As noted previously, a person's psychological and biologic health, internal and external sources of stress management, and relationships with the environment are predictors of health outcomes. These factors are directly related to the person's health patterns. The nurse has a significant role and responsibility in identifying the health patterns of patients receiving care as well as those of their families. If those patterns are not achieving physiologic, psychological,

and social balance, the nurse is obligated, with the assistance and agreement of the patient, to seek ways to promote individual and family balance.

This chapter has presented some physiologic mechanisms and perspectives on health and disease, the way that one copes with stress. Nurses should keep in mind that the way that one relates to others and the values and goals held are also interwoven into those physiologic patterns. To evaluate a patient's health patterns and to intervene if a disorder exists requires a total assessment of the person. Specific disorders and their nursing management are addressed in greater depth in other chapters.

CRITICAL THINKING EXERCISES

1 ebp You are the nurse in a student health center, and a female veteran comes in after experiencing 1 week of persistent discomfort in her shoulder after spiking a ball during a volleyball game. During the appointment, the student tells you, "I play hard as this is the only form of exercise that I get during the week. I have been putting ice on it at night, but that has stopped helping. I'm very stressed-out about this injury, and I am afraid that I may have torn my rotator cuff. How serious do you think this is?" What is the evidence base for offering guidelines for managing this student's health situation and her high level of stress? What educational information can you share to assist her to make appropriate health decisions and establish positive health behaviors? Identify the criteria used to evaluate the strength of the evidence for this practice.

2 pci An 82-year-old man recently moved out of his daughter's home into an assisted living program where you are working. His reason for coming to see you is "because I haven't been feeling well and sometimes my chest is sore." During his interview, he states, "I am a stomach cancer survivor and I have heart disease. I chose to move into assisted living rather than being with my daughter and her crazy family. Those people make me upset and anxious. They raise my blood pressure and make me sick." Identify this older man's health priorities and state the next steps you will take to meet his identified needs and other health promotion needs.

3 ipc You are the nurse working in an outpatient clinic. You tell a 30-year-old woman that during her routine physical examination a thyroid nodule was found. How will you educate this patient about this finding? What referrals do you anticipate will be made? What steps will the interdisciplinary team take to address the patient's health care needs?

6 Genetics and Genomics in Nursing

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the role of the nurse in integrating genetics and genomics in nursing care.
2. Identify the common patterns of inheritance of genetic disorders.
3. Conduct a comprehensive genetic- and genomic-based assessment.
4. Apply the principles, concepts, and theories of genetics and genomics to individuals, families, groups, and communities.
5. Identify ethical, legal, and social issues in nursing related to genetics and genomics.

NURSING CONCEPTS

Legal Issues
Reproduction

GLOSSARY

carrier: a person who is heterozygous; possessing two different alleles of a gene pair, with one allele typically altered/mutated; therefore, the expression of the altered gene may not be expressed

chromosome: microscopic structures in the cell nucleus that contain genetic information; humans have 46 chromosomes in all somatic cells

deoxyribonucleic acid (DNA): the primary genetic material in humans consisting of nitrogenous bases, a sugar group, and phosphate combined into a double helix

dominant: a genetic trait that is normally expressed when a person has a gene mutation on one of a pair of chromosomes and the "normal" form of the gene is on the other chromosome

epigenetics: the study of changes in gene expression that are not directly related to changes in the DNA genetic code

genetics: the scientific study of heredity; how specific traits or predispositions are transmitted from parents to offspring

genome: the total genetic complement of an individual genotype

genomics: the study of the human genome, including gene sequencing, mapping, and function

genotype: the genetic structure and the variations therein that a person inherits from their parents

mutation: a heritable alteration in a DNA sequence

nondisjunction: the failure of a chromosome pair to separate appropriately during cell division, resulting in abnormal chromosome numbers in daughter cells

pedigree: a diagrammatic representation of a family history

pharmacogenetics: the study of the safety and efficacy of medication administration based on a person's genotype

phenotype: a person's entire physical, biochemical, and physiologic genetic makeup that generates the physical presentation of the person

preimplantation genetic testing: a testing procedure used to identify genetic alterations in embryos

prenatal screening: testing that is used to identify whether a fetus is at risk for a birth defect (e.g., Down syndrome or spina bifida)

presymptomatic testing: genetic testing that is used to determine whether a person with a family history of a disorder, but no

current symptoms, has the gene mutation (e.g., testing for Huntington disease)

recessive: a genetic trait that is expressed only when a person has two copies of a mutant autosomal gene or a single copy of a mutant X-linked gene in the absence of another X chromosome

variable expression: variation in the degree to which a trait is manifested; clinical severity

X-linked: located on the X chromosome

The completion of the Human Genome Project, which was an international research project focused on identifying and characterizing the DNA of the human genome, generated rapid advances in the application of genetics and genomics in health care, and stimulated the growth of translational genetic research (Khoury, Bowen, Clyne, et al., 2018). This genetic revolution gave rise to understanding how genetics and genomics influence health and to the development of tests and screening tools to diagnose genetic alterations and mutations. **Pharmacogenetics,** the study of the safety and efficacy of medication administration based on a person's genotype, preimplantation genetic testing, a testing procedure used to identify genetic alterations in embryos, and the use of biobanking, the storage of genetic material for research or personal use, are just a few examples of the advances in genetic and genomic technologies since the discovery of the human genome.

The anticipated rapid growth of genetics and genomics led to the creation of the Genetic Information Nondiscrimination Act (GINA), a law created to protect the privacy and confidentiality of a person's genetic information (Rothstein, 2018). The Precision Medicine Initiative is a national effort intended to advance personalized medicine through the understanding of genetic makeup, lifestyle, and the environment (National Institutes of Health [NIH], U.S. National Library of Medicine [NLM], 2019a).

Identification of genetic and genomic factors associated with disease, including gene–gene function and gene–environment interactions, contributes to the development of more effective therapies customized to that person's genetic makeup and the genomic profile of his or her disease. The term **genetics** (i.e., the study of heredity) generally applies to single genes and their impact on relatively rare single gene disorders, whereas **genomics** is the study of the interaction of all genes in the human **genome** (i.e., the total genetic complement of a person), environmental

factors, and their interactions with each other (NIH, National Human Genome Research Institute [NHGRI], 2019a). **Epigenetics** refers to changes in the expression of a given gene due to environmental exposures or personal health activity rather than the alteration of a specific gene (NIH, NLM, 2019b). Over time, epigenetic influences can cause alterations to DNA. Genetic and genomic profiles allow health care providers to prescribe individualized and effective treatment for each patient, to identify and follow individuals at high risk for disease, and to avoid adverse drug reactions (NIH, NLM, 2019a). New genomic-based strategies for disease detection, management, and treatment are being utilized, making personalized medicine a reality (Table 6-1).

TABLE 6-1 Transition from the Medical Era to the Genomic Era of Personalized Medicine

	Medical Era	Genomic Era of Personalized Medicine
Defining characteristics	• Considers single genes • Waits for disease symptoms to appear • Treats symptoms of presenting disease • Uses trial-and-error approach to treatment • Tailors medication administration according to clinical trials	• Considers interaction of genes with each other and the environment • Identifies genetic predisposition and optimizes risk reduction to prevent disease • Treats underlying genetic cause of disease • Uses personalized approach tailored to the genetic/genomic profile of the person and the disease • Adapts medication administration per clinical trials *and* personalized genetic response to medication

Chart 6-1

Essential Nursing Competencies for Genetics and Genomics

Professional Responsibilities

- Recognition of attitudes and beliefs related to genetic and genomic science
- Advocacy for genetic and genomic services
- Incorporation of genetic and genomic technologies and information into practice
- Demonstration of personalizing genetic and genomic information and services
- Providing autonomous, informed genetics- and genomics-related decision making

Professional Practice

- Integrate and apply genetic and genomic knowledge to nursing assessment.
- Identify patients who may benefit from specific genetic and genomic resources, services, or technologies.
- Facilitate referrals for genetic and genomic services.
- Provide education, care, and support related to the interpretation of genetic or genomic tests, services, interventions, or treatments.

Adapted from Consensus Panel on Genetic/Genomic Nursing Competencies (Consensus Panel). (2009). *Essentials of genetic and genomic nursing: Competencies, curricular guidelines, and outcome indicators* (2nd ed.). Silver Spring, MD: American Nurses Association.

To meet the challenges of personalized medicine, nurses must understand how genetics and genomics can influence the health of the patient and the family. Nurses must stay abreast of new genetic and genomic technologies and understand how these influence treatments that support personalized medicine. Nurses are a vital link between the patient and health care services; patients often turn to nurses first with questions about a family history of risk factors, information regarding genetics, and genetic tests and interpretations. The incorporation of genetics and genomics is relevant to all aspects of the nursing process. For instance, genetics and genomics should be included in conducting health assessments, in devising nursing diagnoses (as appropriate) in planning nursing interventions that are specific to the patient and based on the patient's diagnosis and genetic makeup, in implementing interventions that support the identification of and in response to genetic-related health

needs, and in evaluating responses to medications based on pharmacogenetics (Consensus Panel on Genetic/Genomic Nursing Competencies [Consensus Panel], 2009). This chapter offers a foundation for the clinical application of genetic and genomic principles in medical-surgical nursing; outlines the nurse's role in genetic counseling and evaluation; addresses important legal, ethical, and social issues; and provides related information and resources for nurses and patients.

Genomic Framework for Nursing Practice

Nurses' contribution to genomic focused health care offers a holistic perspective that takes into account each person's intellectual, physical, spiritual, social, cultural, biopsychological, ethical, and aesthetic experiences. Because genomics addresses all of the genes of a given person's human genome working together as a whole, genomics expands nursing's holistic view. Genetics and genomics are the basis of normal and pathophysiologic development, human health and disease, and health outcomes. Knowledge and interpretation of genetic and genomic information, gene-based testing, diagnosis, and treatment broaden the holistic view of nursing. It is a professional expectation that nurses understand genetics and genomics, and can apply this information in the clinical setting (American Nurses Association [ANA], 2017; Rogers, Lizer, Doughty, et al., 2017).

The *Essentials of Genetic and Genomic Nursing* (Consensus Panel, 2009) provides a framework for integrating genetics and genomics into nursing practice (Chart 6-1). This document includes a philosophy of care that recognizes when genetic and genomic factors play a role or could play a role in a person's health. This means assessing predictive genetic and genomic factors using family history and the results of genetic tests effectively, informing patients about genetic and genomic concepts, understanding the personal and societal impact of genetics and genomic information, and valuing the privacy and confidentiality of genetics and genomic information. There is also formal consensus regarding higher-level competencies in the application of genetics and genomics for nurses with graduate degrees. In addition, nurses need to be aware of genetic and genomic standards of practice as it relates to their specific area of clinical practice (Kerber & Ledbetter, 2017).

A person's response to genetic and genomic information, genetic testing, or genetic-related conditions may be either empowering or disabling. Genetic and genomic information may stigmatize people if it

affects how they view themselves or how others view them. Nurses help individuals and families learn how genetic traits and conditions are passed on within families as well as how genetic and environmental factors influence health and disease (Consensus Panel, 2009). Nurses facilitate communication among family members, the health care system, and community resources, and they offer valuable support to patients and families. All nurses should be able to apply genetic and genomic knowledge by (ANA, 2017):

- providing basic genetic or genomic information to a patient or family member,
- obtaining family health histories that are inclusive of genetic information for at least three generations,
- conducting physical and developmental assessments and then correlating relevant assessment findings to genetic alterations,
- formulating nursing diagnoses based on actual or potential genetic risk,
- implementing nursing care that is reflective of genetic and genomic competencies,
- facilitating genetic and genomic referrals, and
- collaborating with other health professionals.

For example, when nurses assess patients' cardiovascular risk, they can expand their assessment to include information about family history of hypertension, hypercholesterolemia, clotting disorders, or premature sudden cardiac death. Knowledge that genes are involved in the control of lipid metabolism, insulin resistance, blood pressure regulation, clotting factors, cardiac structure, and vascular lining function helps individualize care based on the patient's genetic and genomic risk profile.

Essential to a genetic and genomic framework in nursing is the awareness of one's attitudes, experience, and assumptions about genetics and genomic concepts and how these are manifested in one's own practice (Consensus Panel, 2009). To develop awareness of these attitudes, experiences, and assumptions, nurses must examine their own:

- Beliefs or values about health as well as family, religious, or cultural beliefs about the cause of illness and how one's values or biases affect understanding of genetic conditions
- Philosophical, theologic, cultural, and ethical perspectives related to health and how these perspectives influence one's use of genetic information or services
- Level of expertise about genetics and genomics

- Experiences with birth defects, chronic illnesses, and genetic conditions, along with one's view of such conditions as disabling or empowering
- Attitudes about the right to access and other rights of individuals with genetic disorders
- View and assumptions about deoxyribonucleic acid (DNA) and beliefs about the value of information about one's risk for genetic disorders
- Beliefs about reproductive options
- View of genetic testing and engineering
- Approach to patients with disability

Integrating Genetic and Genomic Knowledge

Scientific developments and advances in technology have increased our understanding of genetics, promoted prompt genetic screening and genetic testing for common and rare genetic disorders, and improved patient health outcomes (Khoury et al., 2018). Scientists are able to characterize inherited metabolic variations that interact over time and lead to common diseases such as cancer, heart disease, and dementia. The transition from genetics to genomics has increased understanding of how multiple genes act and control biologic processes. Many diseases are the result of a combination of genetic and environmental influences (Khoury, 2019).

Genes and Their Role in Human Variation

Genes are central components of human health and disease. The Human Genome Project has linked basic human genetics to human development, health, and disease (NIH, NHGRI, 2018). Knowledge that specific genes are associated with specific genetic conditions makes diagnosis possible, even in the unborn. Many common conditions have genetic causes, and many more associations between genetics, health, and disease continue to be identified.

Genes and Chromosomes

A person's unique genetic composition, called a **genotype,** is made up of approximately 25,000 genes (NIH, NLM, 2019c). A person's **phenotype** —the observable characteristics or expression of their genotype—

includes physical appearance and other biologic, physiologic, and molecular traits. Environmental influences modify every person's phenotype, even phenotypes with a major genetic component. This concept of genotype and phenotype applies to a person's total genome and the respective traits of their genetic makeup.

The concepts of genotype and phenotype also apply to specific diseases. For example, in hypercholesterolemia, the genotype refers to specific apolipoprotein genes (*LDLR, APOB, LDLRAP1,* or *PCSK9*) that involve mutations in low-density lipoprotein (LDL) receptors which control lipid metabolism (NIH, NLM, 2019d). Whereas, phenotype is characterized by early onset of cardiovascular disease, high levels of LDL, skin xanthomas, and a family history of heart disease. A person's genotype, consisting of normal functioning genes as well as some mutations, is characterized by physical and biologic traits that may predispose to disease.

Human growth and development and disease occur as a result of both genetic and environmental influences and interactions. The contribution of genetic factors may be large or small. For example, in a person with cystic fibrosis or phenylketonuria (PKU), the genetic contribution is significant. In contrast, the genetic contribution underlying a person's response to infection may be less applicable.

A single gene is conceptualized as a unit of heredity. A gene is composed of a segment of **deoxyribonucleic acid (DNA)** that contains a specific set of instructions for making the protein or proteins needed by body cells for proper functioning. Genes regulate both the types of proteins made and the rate at which proteins are produced. The structure of the DNA molecule is referred to as a double helix. The essential components of the DNA molecule are sugar–phosphate molecules and pairs of nitrogenous bases. Each nucleotide contains a sugar (deoxyribose), a phosphate group, and one of four nitrogenous bases: adenine (A), cytosine (C), guanine (G), and thymine (T). DNA is composed of two paired strands, each made up of a number of nucleotides. The strands are held together by hydrogen bonds between pairs of bases (Fig. 6-1).

Genes are arranged in a linear order within **chromosomes,** which are microscopic structures located in the cell nucleus. In humans, 46 chromosomes occur in pairs in all body cells except oocytes (eggs) and sperm, which each contains only 23 unpaired chromosomes. Twenty-two pairs of chromosomes, called *autosomes,* are the same in females and males. The 23rd pair is referred to as the sex chromosomes. A female has

two X chromosomes, whereas a male has one X chromosome and one Y chromosome. At conception, each parent normally gives one chromosome of each pair to their child. As a result, children receive half of their chromosomes from fathers and half from mothers (Fig. 6-2).

Careful examination of DNA sequences from many people shows that these sequences have multiple versions in a population. The different versions of these sequences are called *alleles*. Sequences found in many forms are said to be polymorphic, meaning that there are at least two common forms of a particular gene.

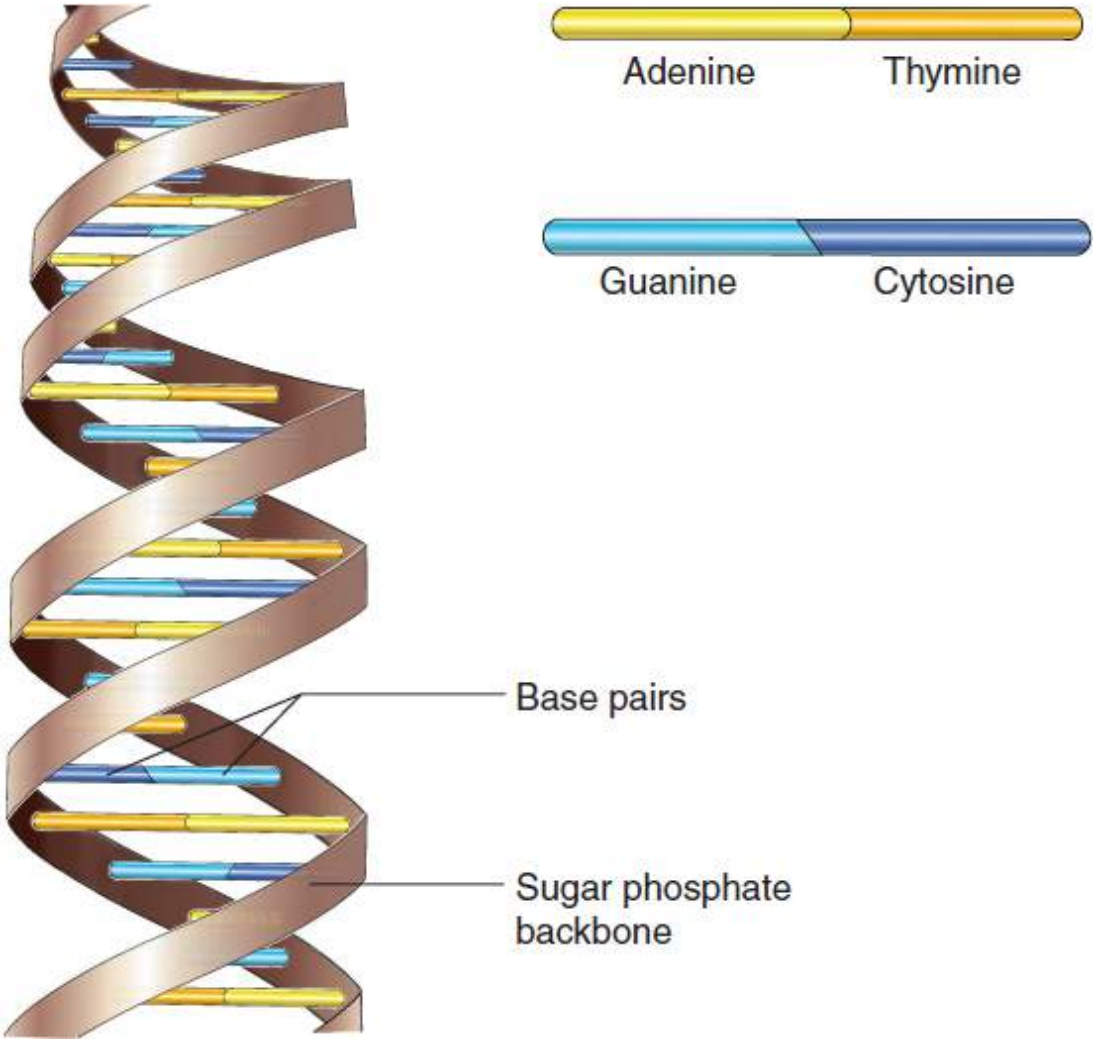

Figure 6-1 • DNA is a double helix formed by base pairs attached to a sugar-phosphate backbone. DNA carries the instructions that allow cells to make proteins. DNA is made up of four chemical bases. Redrawn from Genetics Home Reference, retrieved on 7/29/2020 at www.ghr.nlm.nih.gov/primer/basics/dna

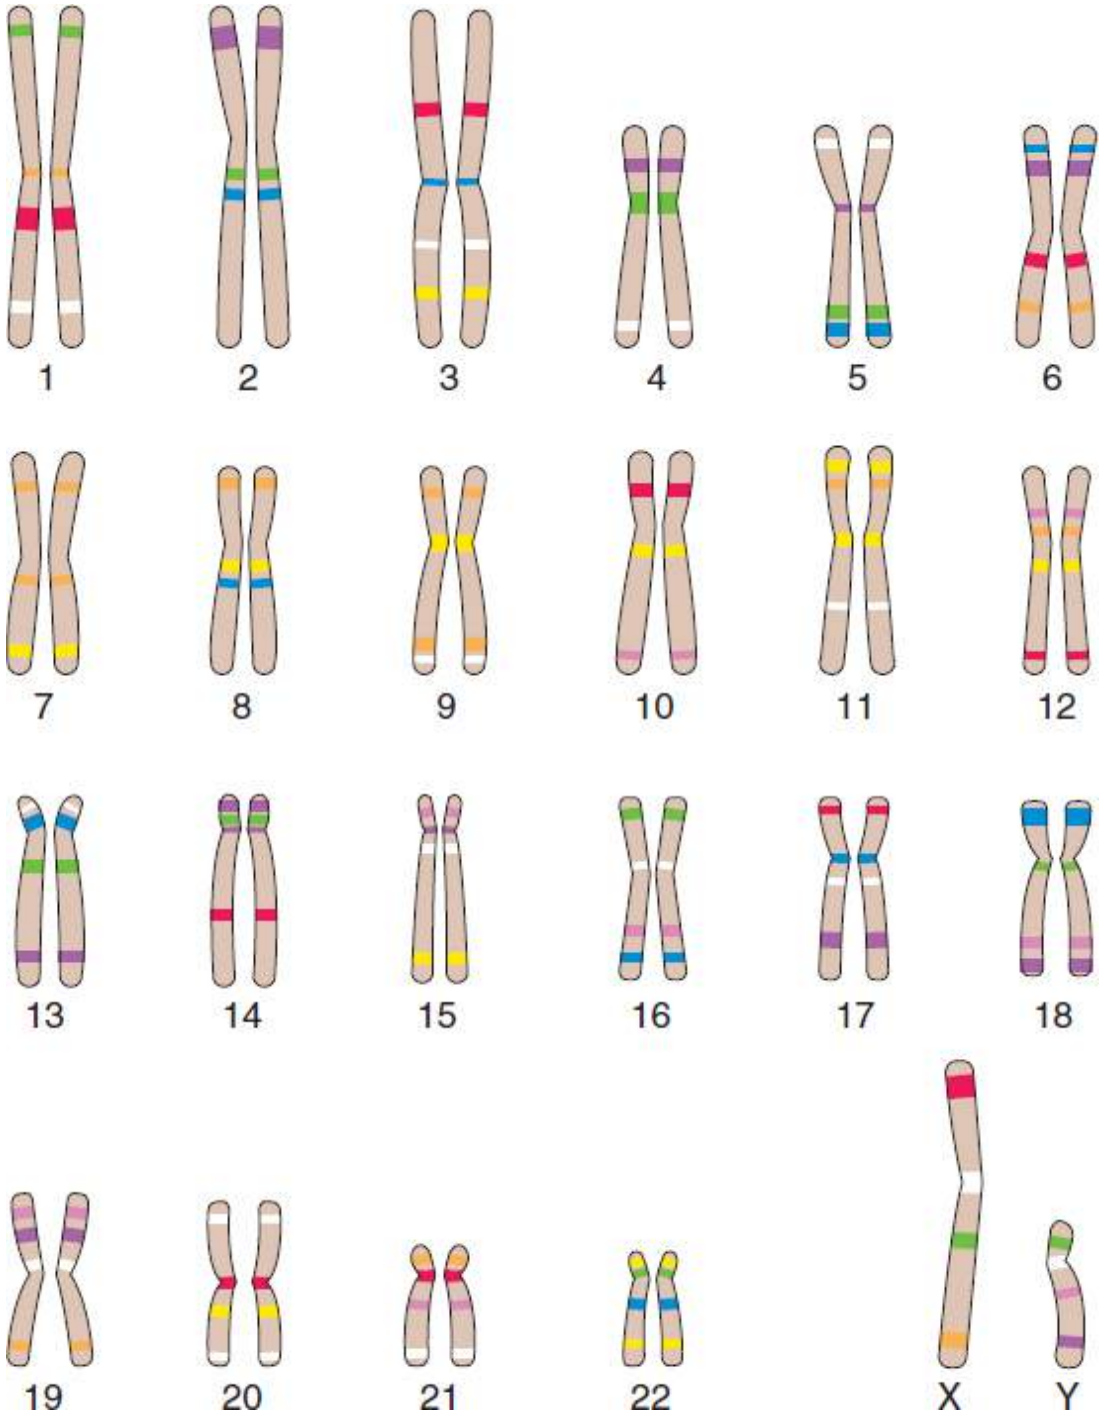

Figure 6-2 • Each human cell contains 23 pairs of chromosomes, which can be distinguished by their size and unique banding patterns. This set is from a male, because it contains a Y chromosome. Females have two X chromosomes.

Cell Division

The human body grows and develops as a result of the process of cell division. Mitosis and meiosis are two distinctly different types of cell

division.

Mitosis is involved in cell growth, differentiation, and repair. During mitosis, the chromosomes of each cell duplicate. The result is two cells, called *daughter cells,* each of which contains the same number of chromosomes as the parent cell. The daughter cells are said to be diploid because they contain 46 chromosomes in 23 pairs. Mitosis occurs in all cells of the body except oocytes and sperm.

Meiosis, in contrast, occurs only in reproductive cells and is the process by which oocytes and sperm are formed. During meiosis, a reduction in the number of chromosomes takes place, resulting in oocytes or sperm that contain half the usual number, or 23 chromosomes. Oocytes and sperm are referred to as haploid because they contain a single copy of each chromosome, compared to the usual two copies in all other body cells. During meiosis, as the paired chromosomes come together in preparation for cell division, portions cross over, and an exchange of genetic material occurs before the chromosomes separate. This event, called *recombination,* creates greater diversity in the makeup of oocytes and sperm.

During the process of meiosis, a pair of chromosomes may fail to separate completely, creating a sperm or oocyte that contains either two copies or no copy of a particular chromosome. This sporadic event, called **nondisjunction,** can lead to either a trisomy or a monosomy (Jackson, Marks, May, et al., 2018). Down syndrome is an example of trisomy, in which people have three copies of chromosome number 21. Turner syndrome is an example of monosomy, in which girls have a single X chromosome, causing them to have short stature and infertility (NIH, NLM, 2019e).

Gene Mutations

Within each cell, many intricate and complex interactions regulate and express human genes. Gene structure and function, transcription and translation, and protein synthesis are all involved. Alterations in gene structure and function and the process of protein synthesis may influence a person's health. Changes in gene structure, called **mutations,** permanently change the sequence of DNA, which in turn can alter the nature and type of proteins made (Fig. 6-3).

Some gene mutations have no significant effect on the protein product, whereas others cause partial or complete changes. How a protein is altered and its importance to body functioning determines the impact of the mutation. Gene mutations may occur in hormones, enzymes, or other

important protein products, with significant implications for health and disease. Sickle cell disease is a genetic condition caused by a small gene mutation that affects protein structure, producing hemoglobin S. A person who inherits two copies of the hemoglobin S gene mutation has sickle cell disease and experiences the symptoms of severe anemia and thrombotic organ damage resulting from hypoxia (NIH, NLM, 2019f).

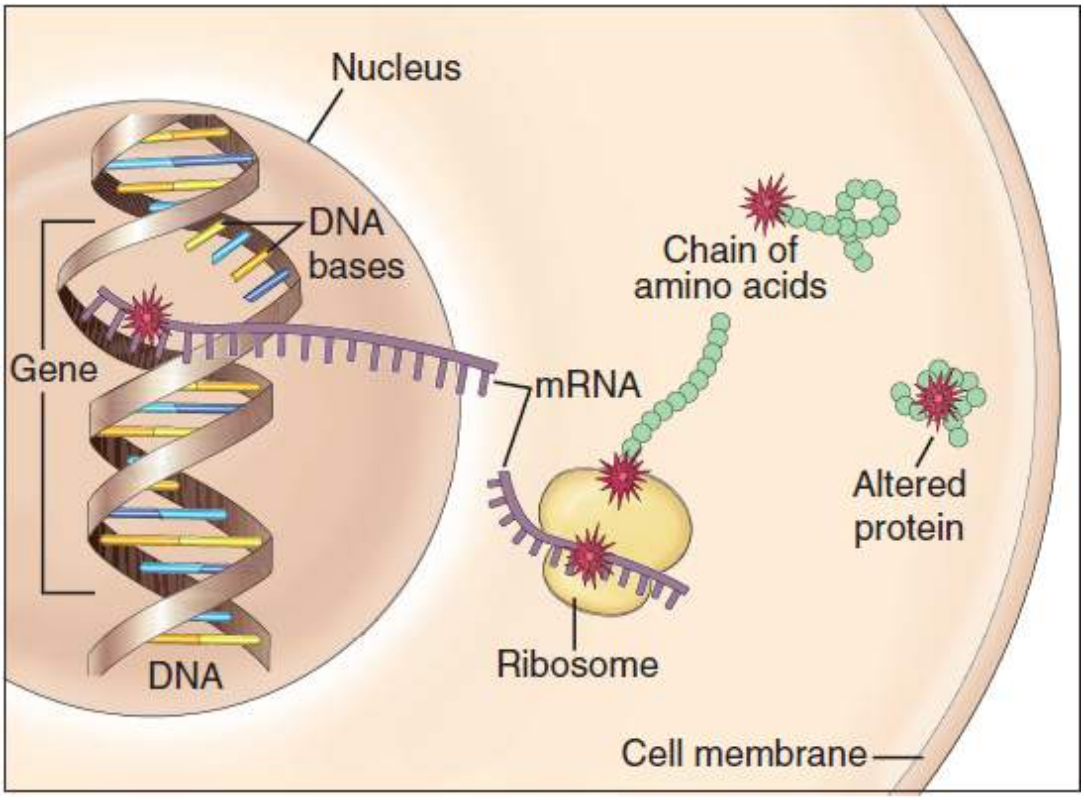

Figure 6-3 • When a gene contains a mutation, the protein encoded by that gene is likely to be abnormal. Sometimes the protein is able to function, although it does so imperfectly. In other cases, it is totally disabled. The outcome depends not only on how the mutation alters the protein's function but also on how vital that particular protein is to survival.

Other gene mutations include deletion (loss), insertion (addition), duplication (multiplication), or translocation (rearrangement) of a longer DNA segment (Jackson et al., 2018). Duchenne muscular dystrophy, myotonic dystrophy, Huntington disease, and fragile X syndrome are examples of conditions caused by gene mutations.

Gene mutations may be inherited or acquired. Inherited or germline gene mutations are present in the DNA of all body cells and are passed on in reproductive cells from parent to child. Germline or hereditary

mutations are passed on to all daughter cells when body cells replicate (Fig. 6-4). The gene that causes Huntington disease is one example of a germline mutation.

Spontaneous mutations take place in individual oocytes or sperm at the time of conception. A person who carries the new "spontaneous" mutation may pass on the mutation to his or her children. Achondroplasia, Marfan syndrome, and neurofibromatosis type 1 are examples of genetic conditions that may occur in a single family member as a result of spontaneous mutation.

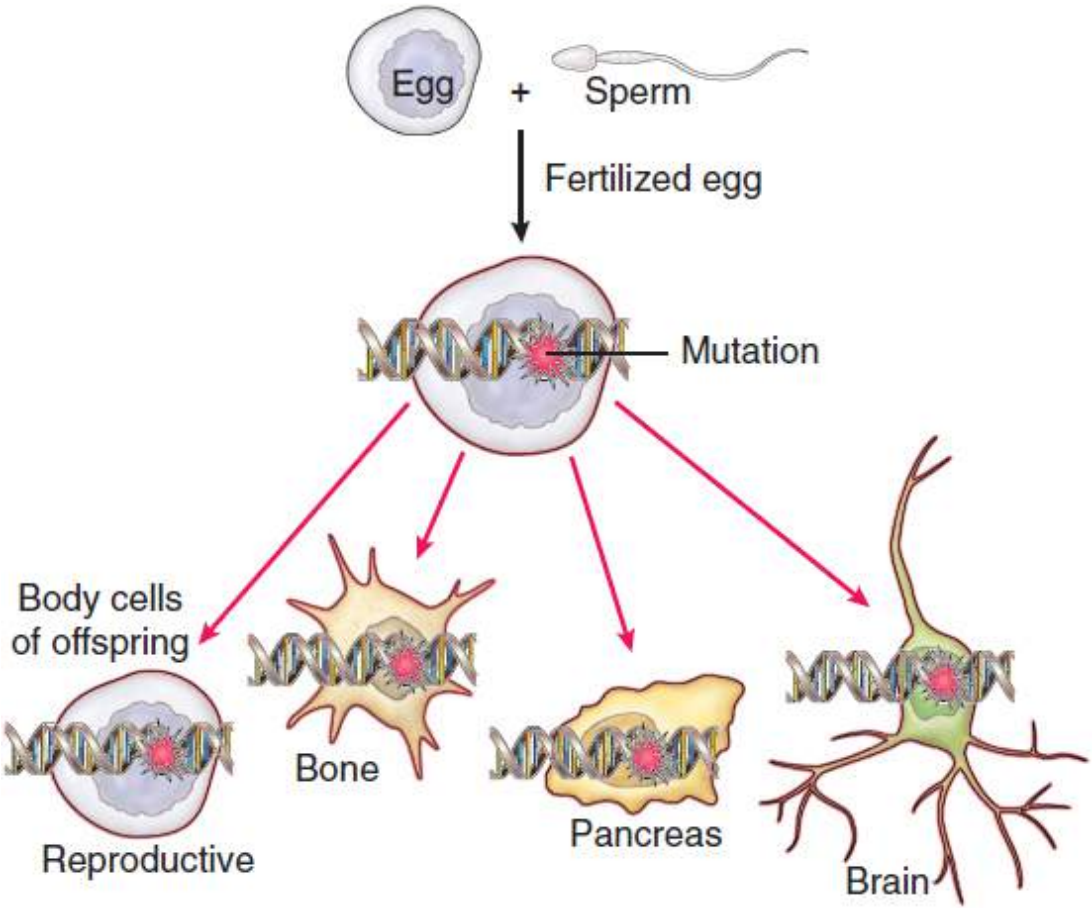

Figure 6-4 • Hereditary mutations are carried in the DNA of the reproductive cells. When reproductive cells containing mutations combine to produce offspring, the mutation is present in all of the offspring's body cells.

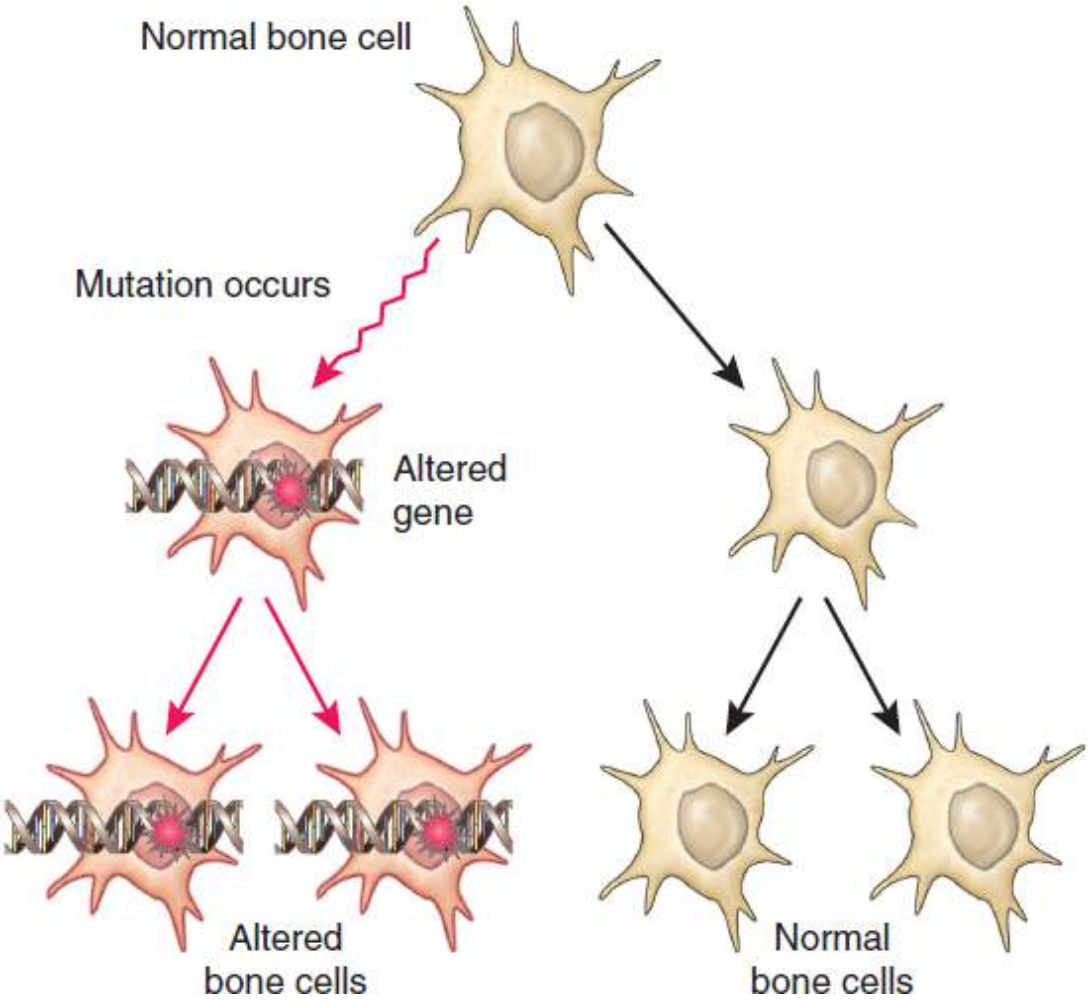

Figure 6-5 • Acquired mutations develop in DNA during a person's lifetime. If the mutation arises in a body cell, copies of the mutation will exist only in the descendants of that particular cell.

Acquired mutations take place in somatic cells and involve changes in DNA that occur after conception, during a person's lifetime. Acquired mutations develop as a result of cumulative changes in body cells other than reproductive cells (Fig. 6-5). Somatic gene mutations are passed on to the daughter cells derived from that particular cell line.

Gene mutations occur in the human body all the time. Cells have built-in mechanisms by which they can recognize mutations in DNA, and in most situations, they correct the changes before they are passed on by cell division. However, over time, body cells may lose their ability to repair damage from gene mutations, causing an accumulation of genetic changes that result in diseases such as cancer, Alzheimer's disease, and disorders associated with aging (Khoury, 2019).

Genetic Variation

Genetic variations occur among all people. Single nucleotide polymorphisms (SNPs, referred to as "snips") is the term used to identify common genetic variations that occur most frequently throughout the human genome (Jackson et al., 2018). SNPs are changes in a single nucleotide (an A, T, C, or G) of the DNA sequence. For example, a normal DNA sequence of A**A**GG could change to ATGG; in this case, there is one single nucleotide change from A to T. Most SNPs do not alter normal cell function. Some SNPs do alter gene function and may influence disease development. Knowledge about SNPs that affect biologic function will help pinpoint individuals who may be more prone to common diseases such as cancer, diabetes, and heart disease. Information on SNPs has helped to clarify why some individuals metabolize drugs differently (Centers for Disease Control and Prevention [CDC], 2018a). For example, a polymorphism or SNP can alter protein or enzyme activity of medications. If the SNP causes a variation in drug transport or drug metabolism, the drug's action, half-life, or excretion could lead to lack of drug response or drug toxicity.

Epigenetics

Epigenetics refers to generational changes within the genetic instruction (NIH, NLM, 2019b). Over time, epigenetic influences can cause cellular change throughout the lifetime of the affected person and be passed on to subsequent generations. Epigenomics, which is the study of epigenetics, is an expanding area of research that correlates epigenetics to cancer, psychiatric disorders, obesity, diabetes, and autoimmune disease (Jackson et al., 2018).

Inheritance Patterns

Nursing assessment of the patient's health includes obtaining and recording family history information in the form of a **pedigree** (i.e., a diagrammatic representation of a family history). This is a first step in establishing the pattern of inheritance. Nurses must be familiar with mendelian patterns of inheritance and pedigree construction and analysis to help identify patients and families who may benefit from further genetic counseling, testing, and treatment (Consensus Panel, 2009).

Mendelian conditions are genetic conditions that are inherited in fixed proportions among generations. They result from gene mutations that are present on one or both chromosomes of a pair. A single gene inherited

from one or both parents can cause a mendelian condition. Mendelian conditions are classified according to their pattern of inheritance: autosomal dominant, autosomal recessive, and X-linked. The terms dominant and recessive refer to the trait, genetic condition, or phenotype but not to the genes or alleles that cause the observable characteristics (Jackson et al., 2018).

Autosomal Dominant Inheritance

The term **dominant** refers to the trait of the gene that is expressed when two genes do not mirror each other on matched chromosomes. Autosomal dominant inherited conditions affect female and male family members equally and follow a vertical pattern of inheritance in families (Fig. 6-6). The presence of an autosomal dominant inherited condition only requires a genetic mutation on one of the chromosomes associated with that pair. Each of that person's offspring has a 50% chance of inheriting the gene mutation for the condition and a 50% chance of inheriting the normal version of the gene (Fig. 6-7). Offspring who do not inherit the gene mutation do not develop the condition and do not have an increased chance for having children with the same condition. Table 6-2 presents characteristics and examples of different patterns of inherited conditions.

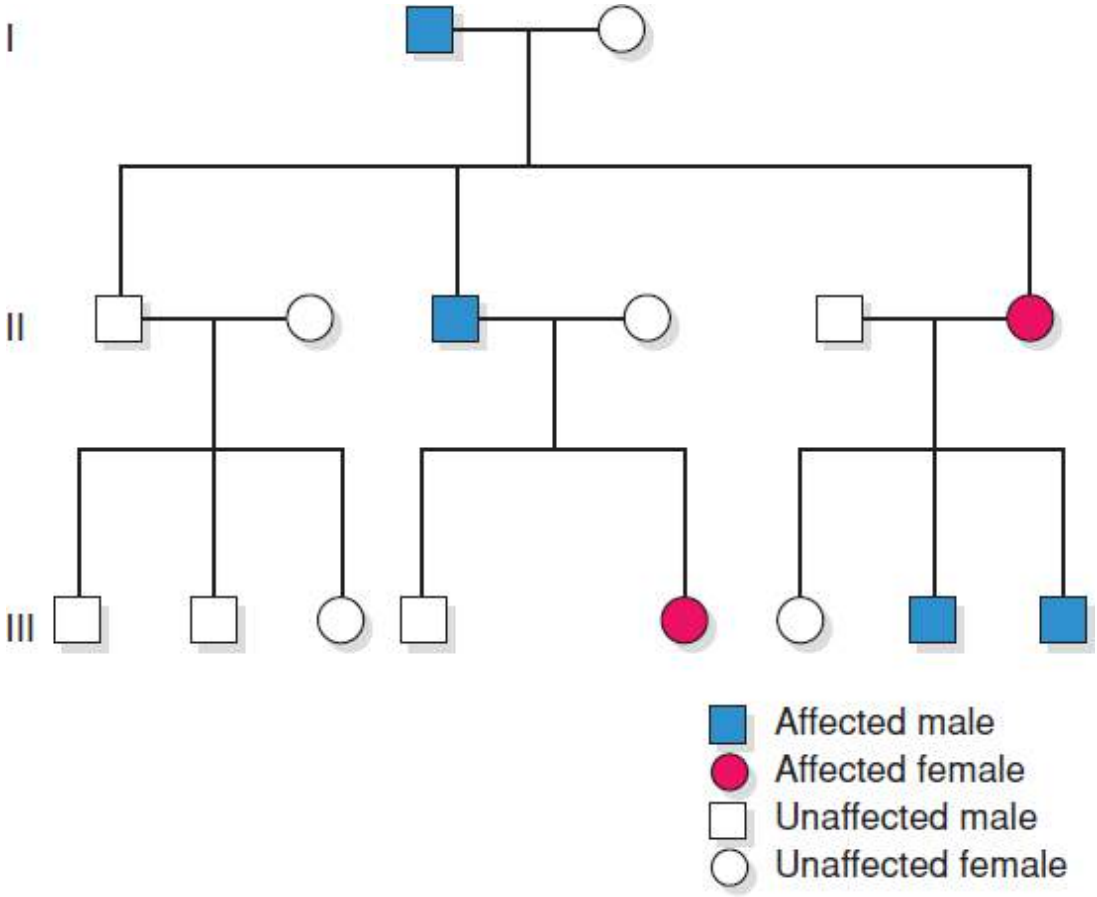

Figure 6-6 • Three-generation pedigree illustrating autosomal dominant inheritance.

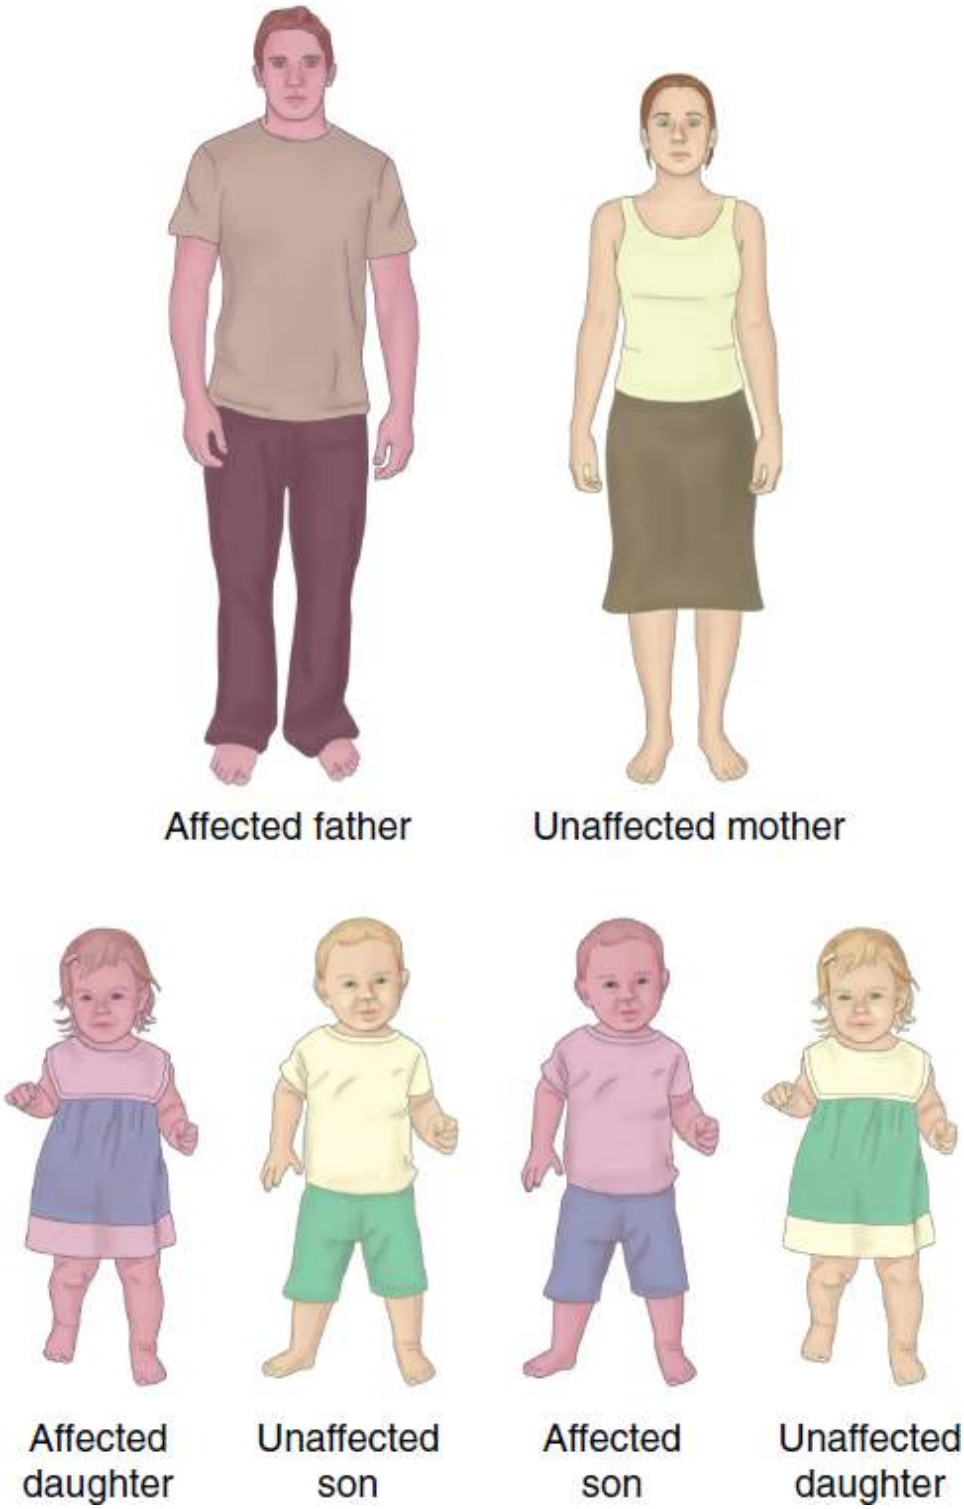

Figure 6-7 • In dominant genetic disorders, if one affected parent has a disease-causing allele that dominates its normal counterpart, each child in the family has a 50% chance of inheriting the disease allele and the disorder.

Autosomal dominant conditions often manifest with varying degrees of severity. Some affected people may have significant symptoms,

whereas others may have only mild ones. This characteristic is referred to as **variable expression;** it results from the influences of genetic and environmental factors on clinical presentation.

Another phenomenon observed in autosomal dominant inheritance is penetrance, or the percentage of people known to have a particular gene mutation who actually show the trait. Almost complete penetrance is observed in conditions such as achondroplasia, in which nearly 100% of people with the gene mutation typically display traits of the disease. However, in some conditions, the presence of a gene mutation does not invariably mean that a person has or will develop an autosomal inherited condition. For example, a woman who has the *BRCA1* hereditary breast cancer gene mutation has a lifetime risk of breast cancer that can be as high as 80%, not 100%. This quality, known as reduced or incomplete penetrance, indicates the probability that a given gene will produce disease. In other words, a person may inherit the gene mutation that causes an autosomal dominant condition but may not have any of the observable physical or developmental features of that condition. However, this person carries the gene mutation and still has a 50% chance of passing the gene for the condition to each of their children (NIH, NLM, 2019g). One of the effects of incomplete penetrance is that the gene appears to "skip" a generation, thus leading to errors in interpreting family history and in genetic counseling.

TABLE 6-2 Patterns of Inheritance

Characteristics	Examples
Autosomal Dominant Inherited Conditions	
Vertical transmission in families Males and females equally affected Variable expression among family members and others with condition Reduced penetrance (in some conditions) Advanced paternal age associated with sporadic cases	Hereditary breast/ovarian cancer syndrome Familial hypercholesterolemia Hereditary non-polyposis colorectal cancer Huntington disease Marfan syndrome Neurofibromatosis
Autosomal Recessive Inherited Conditions	
Horizontal pattern of transmission seen in families Males and females equally affected Associated with consanguinity (genetic relatedness) Associated with particular ethnic groups	Cystic fibrosis Galactosemia Phenylketonuria Sickle cell disease Tay-Sachs disease Canavan disease
X-Linked Inherited Conditions	
Vertical transmission in families Males predominantly affected	Duchenne muscular dystrophy Hemophilia A Wiskott–Aldrich syndrome Color blindness Fragile X
Mitochondrial Inherited Conditions	
Transmission occurs through the mother All children have the condition	Leber's hereditary optic neuropathy Leigh syndrome Kearns–Sayre syndrome
Multifactorial Inherited Conditions	
Occur as a result of combination of genetic and environmental factors May recur in families Inheritance pattern does not demonstrate characteristic pattern of inheritance seen with other mendelian conditions	Congenital heart defects Cleft lip and/or palate Neural tube defects (anencephaly and spina bifida) Diabetes Osteoarthritis High blood pressure Alzheimer's disease Hypothyroidism

What are the different ways in which a genetic condition can be inherited? Retrieved on 8/30/2019 at: www.ghr.nlm.nih.gov/primer/inheritance/inheritancepatterns

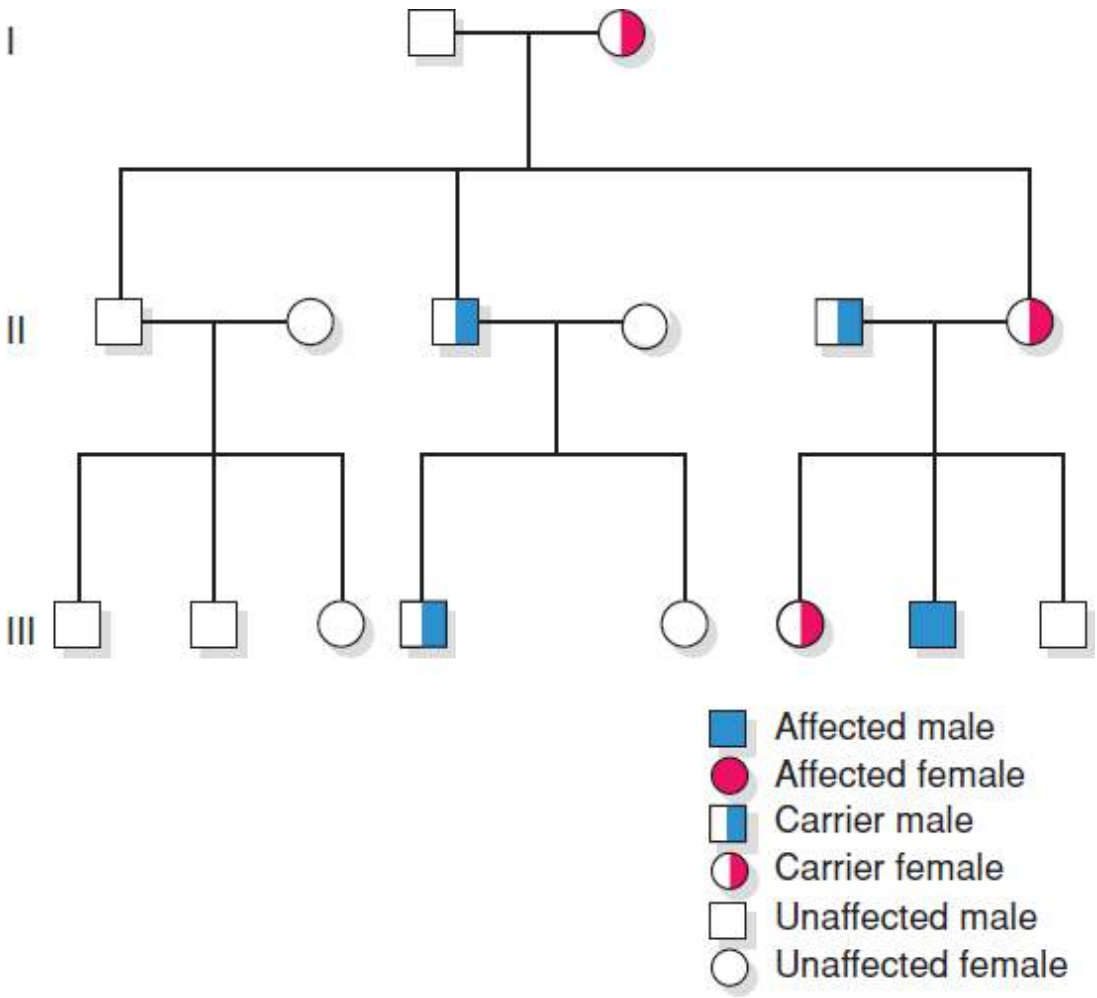

Figure 6-8 • Three-generation pedigree illustrating autosomal recessive inheritance.

Autosomal Recessive Inheritance

The term **recessive** refers to a genetic trait that is expressed only when a person has two copies of a mutant autosomal gene or a single copy of a mutant X-linked gene in the absence of another X chromosome. In contrast to autosomal dominant conditions, autosomal recessive conditions have a pattern that is more horizontal than vertical; relatives of a single generation tend to have the condition (Fig. 6-8). Autosomal recessive conditions are frequently seen among particular ethnic groups

and usually occur more often in children of parents who are related by blood, such as first cousins (see Table 6-2).

In autosomal recessive inheritance, each parent carries a gene mutation on one chromosome of the pair and a normal gene on the other chromosome. The parents are said to be **carriers** of the gene mutation. Unlike people with an autosomal dominant condition, carriers of a gene mutation for a recessive condition do not have symptoms of the genetic condition. When carriers have children together, there is a 25% chance that each child may inherit the gene mutation from both parents and have the condition (Fig. 6-9). Cystic fibrosis, sickle cell disease, and PKU are examples of autosomal recessive conditions (Jackson et al., 2018).

X-Linked Inheritance

X-linked conditions may be inherited in recessive or dominant patterns (see Table 6-2). In both, the gene mutation is located on the X chromosome. All males inherit an X chromosome from mothers and a Y chromosome from fathers for a normal sex constitution of 46, XY. Because males have only one X chromosome, they do not have a counterpart for its genes, as do females. This means that a gene mutation on the X chromosome of a male is expressed even though it is present in only one copy. Females, on the contrary, inherit one X chromosome from each parent for a normal sex constitution of 46, XX. A female may be an unaffected carrier of a gene mutation, or she may be affected if the condition results from a gene mutation causing an X-linked dominant condition. Either the X chromosome that she received from her mother or the X chromosome she received from her father may be passed on to each of her offspring, and this is a random occurrence.

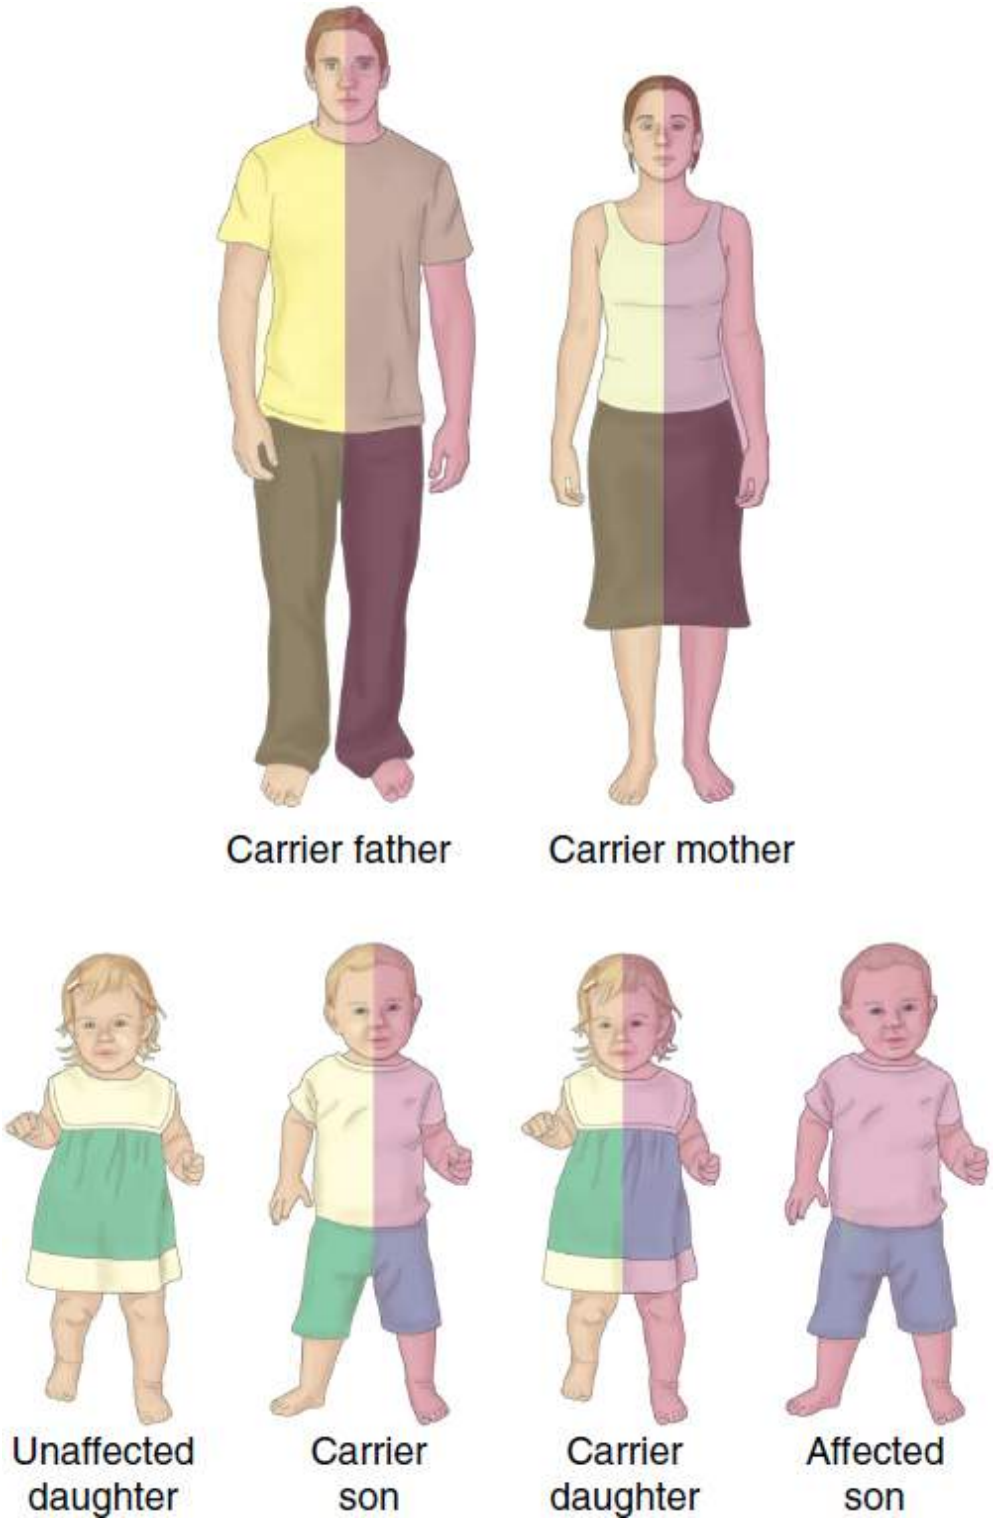

Figure 6-9 • In diseases associated with altered recessive genes, both parents—although disease free themselves—carry one normal allele and one altered allele. Each child has one chance in four of inheriting two abnormal alleles and developing the disorder; one chance in four of inheriting two normal alleles; and two chances in four of inheriting one normal

and one altered allele—therefore, being a carrier like both parents.

The most common pattern of X-linked inheritance is that in which a female is a carrier for a gene mutation on one of her X chromosomes. This is referred to as X-linked recessive inheritance, in which a female carrier has a 50% chance of passing on the gene mutation to a son, who would be affected, or to a daughter, who would be a carrier like her mother (Fig. 6-10). Examples of X-linked recessive conditions include factor VIII and factor IX hemophilia, severe combined immunodeficiency, and Duchenne muscular dystrophy (Jackson et al., 2018).

Mitochondrial Inheritance

The mitochondrium is an organelle, a cellular component associated with generating cellular energy. Although it is not a part of the nucleus, genetic alterations can occur in the mitochondria and be passed to offspring. These disorders are typically associated with muscle or nerve tissue. Unique to mitochondrial inheritance is that only the mother will pass the mitochondrial DNA to her offspring, and thus the genetic disorder to her children, and all of her children will inherit the disorder. Examples of mitochondrial inheritance include Leber's hereditary optic neuropathy, Leigh syndrome, and Kearns–Sayre syndrome (Jackson et al., 2018; see Table 6-2).

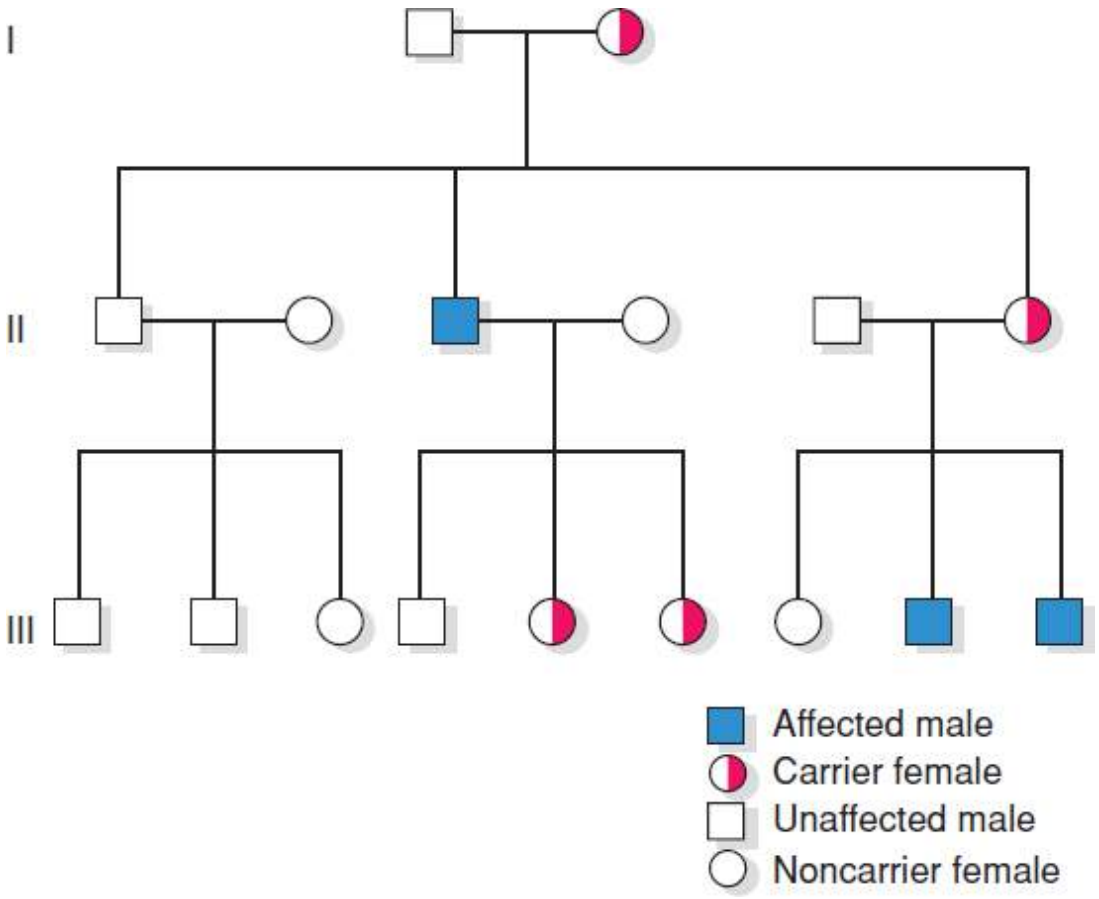

Figure 6-10 • Three-generation pedigree illustrating X-linked recessive inheritance.

Multifactorial Inheritance and Complex Genetic Conditions

Many birth defects and common health conditions such as heart disease, high blood pressure, cancer, osteoarthritis, and diabetes occur as a result of interactions of multiple gene mutations and environmental influences. Thus, they are called *multifactorial* or *complex conditions* (see Table 6-2). Other examples of multifactorial genetic conditions include neural tube defects such as spina bifida and anencephaly. Multifactorial conditions may cluster in families; however, they do not always result in the characteristic pattern of inheritance seen in families who have mendelian inherited conditions (Fig. 6-11).

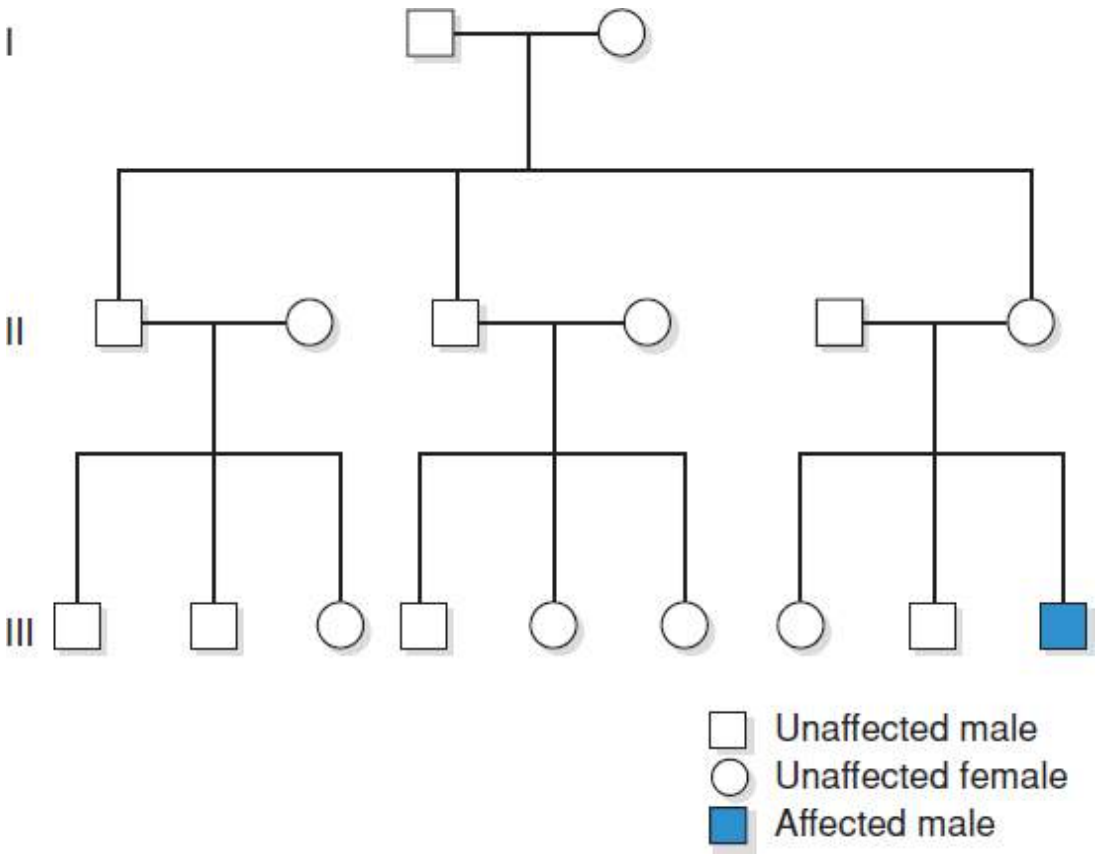

Figure 6-11 • Three-generation pedigree illustrating multifactorial conditions.

Nontraditional Inheritance

Although mendelian conditions manifest with a specific pattern of inheritance in some families, many diseases and traits do not follow these simple patterns. Various factors influence how a gene performs and is expressed. Different mutations in the same gene can produce variable symptoms in different people, as in cystic fibrosis. Different mutations in several genes can lead to identical outcomes, as in Alzheimer's disease. Some traits involve simultaneous mutation in two or more genes. A phenomenon known as genetic imprinting can determine which of a pair of genes (that of the mother or the father) is silenced or activated. This form of inheritance has been observed in Angelman syndrome, a severe form of intellectual disability and ataxia (NIH, NLM, 2019h).

Chromosomal Differences and Genetic Conditions

Differences in the number or structure of chromosomes are a major cause of birth defects, intellectual disability, and malignancies. Chromosomal differences most commonly involve an extra or missing chromosome; this

is called *aneuploidy.* These genetic alterations are neither inherited nor passed down through generations. Whenever there is an extra or missing chromosome, there is always associated intellectual or physical disability to some degree (NIH, National Center for Advancing Translational Sciences [NCATS], 2017).

Down syndrome, or trisomy 21, is a common chromosomal condition that occurs with greater frequency in pregnancies of women who are 35 years of age or older. A person with trisomy 21 has a complete extra chromosome 21, which causes a particular facial appearance and increased risk of congenital heart defects, thyroid and vision problems, and intellectual disability. Other examples of chromosomal differences include trisomy 13 and trisomy 18, both more severe than Down syndrome, and conditions involving extra or missing sex chromosomes, such as Turner syndrome (Jackson et al., 2018).

Chromosomal differences may also involve a structural rearrangement within or between chromosomes. These are less common than chromosomal conditions in which there is an extra or missing chromosome (NIH, NCATS, 2017). People who carry "balanced" chromosome rearrangements have all of their chromosomal material; however, it is rearranged. Women with a "balanced" chromosomal rearrangement have an increased risk of spontaneous pregnancy loss and of having children with an unbalanced chromosomal arrangement that may result in physical or intellectual disability. Known carriers of these chromosomal differences are offered prenatal counseling and testing.

Chromosome studies may be needed at any age, depending on the indication. Two common indications for these studies include a suspected diagnosis of Down syndrome or a history of two or more unexplained pregnancy losses. Chromosome studies are accomplished by obtaining a tissue sample (e.g., blood, skin, and amniotic fluid), preparing and staining the chromosomes, and analyzing them under a microscope. The microscopic study of chromosomes, called *cytogenetics,* is used with molecular techniques such as fluorescent in situ hybridization (FISH), which permits more detailed examination of chromosomes (Jackson et al., 2018). FISH is useful to detect small abnormalities and to characterize chromosomal rearrangements.

Genetic and Genomic Technologies in Practice

Genetic tests are used to detect a trait, to diagnose a genetic condition, or to identify people who have a genetic predisposition to a particular

disease or condition. A plethora of genetic tests are available; some may be purchased directly by the consumer. The Genetic Testing Registry recognizes genetic tests for almost 12,000 genetic conditions (National Center for Biotechnology Information [NCBI], NLM, 2019a). Advances in the application of genetic testing are noted in pharmacogenetics, preimplantation genetic diagnosis, newborn screening, direct-to-consumer testing, and prenatal screening. Forms of genetic testing or genetic screening are available across the lifespan, extending from preimplantation genetic screening during pregnancy to posthumous testing (Bilkey, Burns, Coles, et al., 2019). Future applications may include the use of gene chips to map a person's individual genome for genetic variations that may lead to disease. Nurses are involved in caring for patients who are undergoing genetic testing and gene-based treatments. Knowledge of the clinical applications of modern genetic and genomic technologies enables nurses to inform and to support patients and their family members, and to provide high-quality genetic-related health care.

Genetic Testing

Genetic testing is the primary tool used to identify individuals who are predisposed to specific genetic diseases. Genetic tests provide information leading to the diagnosis of inherited conditions or other conditions with a known genetic contribution.

Approaches to genetic testing may focus on genotype or phenotype. Genotypic methods involve analysis of the chromosomes and genes directly, using specific laboratory techniques to learn whether a genetic alteration related to a specific disease or condition is present. This testing may be DNA based, chromosomal, or biochemical. Awareness of molecular biomarkers that can enhance the sensitivity and specificity of genetic-related tests allows for early detection of genetic illness, and for researchers to understand genetic pathways that may be useful in the treatment of specific disorders (van Lanschot, Bosch, de Wit, et al., 2017). Phenotypic methods examine the familial or biologic presentation of disease and include assessment of the patient's personal or family history and medical factors influencing their disease as well as testing for gene products such as protein markers in body fluids or diseased tissues. The family history, which is considered the first genetic test, is discussed later in this chapter (see the Family History Assessment section). It is

expected that all nurses are able to create and interpret a three-generation family pedigree (Consensus Panel, 2009).

Another phenotypic approach involves searching for gene products, such as proteins and enzymes that can clinically indicate a genetic abnormality. For example, germline mutations in the repair genes *MLH1, MSH2, MSH6,* and *PMS2* are responsible for hereditary early-onset colorectal cancer or Lynch syndrome. Colorectal tumors are now tested to measure the presence or absence of these proteins using immunohistochemistry, which is a routine type of pathology test. Specific colon cancer gene mutations are used to identify other genetic forms of colon cancer which increases the likelihood of cancer in other areas of the body. These include not only Lynch syndrome, but also familial adenomatous polyposis (FAP), Peutz–Jeghers, Cowden syndrome, and juvenile polyposis syndrome (Edwards & Maradiegue, 2018).

Genetic testing can be used for various purposes in prenatal, pediatric, and adult populations. Prenatal testing is widely used for **prenatal screening** and diagnosis of conditions such as Down syndrome. **Preimplantation genetic testing,** a form of prenatal genetic testing, detects the presence of genetic abnormalities in embryos (Parikh, Athalye, Naik, et al., 2018). Carrier testing is used to determine if a person carries a recessive allele for an inherited condition (e.g., cystic fibrosis, sickle cell disease, Tay-Sachs disease) and, therefore, risks passing it on to his or her children. Genetic testing is also used widely in newborn screening. Newborn testing is performed on infants to identify conditions, such as PKU, in which interventions can be implemented to prevent severe outcomes.

Diagnostic testing is used to detect the presence or absence of a particular genetic alteration or allele to identify or confirm a diagnosis of a disease or condition (e.g., myotonic dystrophy, fragile X syndrome) (Chart 6-2). Increasingly, genetic tests are being used to predict drug response and to design specific and individualized treatment plans or personalized medicine. For example, genetic testing is used to identify specific gene variants that can predict the effectiveness of treatments of human immunodeficiency virus infection, atherothrombosis, thrombophilia, hyperlipidemia, breast cancer, pain management, hepatitis C, rheumatoid arthritis, leukemia, depression, and bipolar disorder (NCBI, NLM, 2019b). Select examples of current uses of genetic tests are shown in Table 6-3.

TABLE 6-3 Select Genetic Tests: Examples of Current Uses

Purpose of Genetic Test	Type of Genetic Test
Carrier Testing	
Cystic fibrosis	DNA analysis
Tay-Sachs disease	Hexosaminidase A activity testing and DNA analysis
Canavan disease	DNA analysis
Sickle cell disease	Hemoglobin electrophoresis
Thalassemia	Complete blood count and hemoglobin electrophoresis
Diagnosis	
Down syndrome	Chromosomal analysis
Fragile X syndrome	DNA analysis
Myotonic dystrophy	DNA analysis
Presymptomatic Testing	
Huntington disease	DNA analysis
Myotonic dystrophy	DNA analysis
Susceptibility Testing	
Hereditary breast/ovarian cancer	DNA analysis
Hereditary non-polyposis colorectal cancer	DNA analysis

DNA, deoxyribonucleic acid.

Chart 6-2 ETHICAL DILEMMA

Can Predictive Genetic Testing Threaten Patient Autonomy?

Case Scenario

M.T., a high school biology teacher, brings her 11-year-old daughter to the family practice clinic where you are employed as the nurse manager. M.T. insists that she wants her daughter to have predictive genetic testing (PGT) for familial adenomatous polyposis (FAP), an autosomal dominant disorder associated with aggressive colorectal cancer that typically evidences pathology during young adulthood. M.T. tells you that her husband's sister, who is 36 years old, was recently diagnosed with FAP and advanced colorectal cancer. She also tells you that she recently discovered that her husband's father and his father's only sibling both died of colorectal cancer before they were 50. Her husband is 34 years old; according to M.T., he has not been seen by a health care provider since he was a teenager and refuses to do so or to be tested for FAP.

Discussion

There are many legal and ethical concerns raised by health care providers regarding PGT in children. Some genetic disorders are not amenable to treatment during childhood (e.g., carrying a *BRCA* genetic mutation, which is associated with various cancers in adulthood). In these instances, it is generally advisable to forego offering PGT to a child until such time that the child reaches adulthood and is able to make the autonomous decision to either be tested or not be tested. The American College of Medical Genetics contends that ultimately, the best interest of the person tested must be the focus of PGT.

In this particular case, it is presumed that the father has not consented to be tested for the FAP genetic mutation. However, should he consent to testing and find out that he does not have the genetic mutation associated with FAP, then the daughter could not have that mutated gene, since it is conferred through autosomal dominant inheritance. By contrast, if the father does carry the gene for FAP, then the daughter would have a 50% chance of having the gene; moreover, if she has the gene, she and her parents should be advised that she should begin screening colonoscopies. Precancerous colonic polyps can be found and excised before they become malignant in children with FAP, which can be a lifesaving treatment.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Which principle do you believe should

have preeminence in deciding whether or not parents have the right to have PGT done for a child?
- In this case, do the benefits outweigh the risks of PGT for a child? Would your viewpoint on PGT be different if the child assented to be tested? What if she tells you that she would rather not be tested and wants to follow her father's example?
- Identify the stakeholders in this case. Does the father have the right to forego being tested for the genetic mutation? What if the daughter has PGT performed despite the father's refusal to be tested, and it is found that she has the genetic mutation? In that case, the father must also have the genetic mutation. Does he have the right to be told or to not be told these results and their implications?
- Are there any professional guidelines that you can turn to for help in determining the ethical issues that revolve around PGT? If so, what are they, and how can they help?

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

Nurses are increasingly involved in taking family histories and educating the patient about aspects of genetic testing. They contribute by ensuring informed health choices and consent, advocating for privacy and confidentiality with regard to genetic test results, assessing genetic risk, and helping patients understand the complex issues involved (Edwards & Maradiegue, 2018). The rapid uptake of direct-to-consumer genetic testing mandates that nurses educate patients about the pros and cons of the selected type of genetic testing, navigate the psychosocial needs of patients and their families, and make referrals to genetic specialists as indicated (Mahon, 2018).

Genetic Screening

Genetic screening, in contrast to genetic testing, is performed independent of having a positive family history or symptom manifestation based on a personal risk or based on the person having a risk associated with a specific population or group of people that they belong to. There are multiple forms of genetic screening which are useful at different points across the lifespan. Most commonly, genetic screening occurs in prenatal and newborn programs. For example, shortly after birth, newborns are screened for a variety of conditions, including PKU, congenital hypothyroidism, and galactosemia as a means to identify treatable genetic conditions that could prove dangerous to their health if left untreated. Prenatal genetic screening is provided as a reproductive option to people with a high probability of having children with severe, untreatable diseases and for whom genetic counseling, prenatal diagnosis, and other reproductive options could be helpful. Genetic screening of pregnant women is used to detect birth defects such as neural tube defects and Down syndrome. Cascade screening is a cost-effective strategy to identify those at risk for genetic illness based on the identification of another family member with the disorder (Silva, Jannes, Oliveira, et al., 2018). This form of genetic screening is most useful for autosomal dominant disorders such as familial hypercholesterolemia or Lynch syndrome. The results of genetic screening may also be used for public health purposes to determine the incidence and prevalence of a birth defect or to investigate the feasibility and value of new genetic testing methods. Table 6-4 gives examples of types of genetic screening.

Concept Mastery Alert

Genetic testing and *genetic screening* are terms that are often confused. Nurses need to remember that testing is individual; screening is population based.

TABLE 6-4 Applications for Genetic Screening

Timing of Screening	Purpose	Examples
Preconception/preimplantation screening	Preconception screening may be done to test for autosomal recessive inherited genetic conditions that occur with greater frequency among individuals of certain ethnic groups; furthermore, through the use of in vitro fertilization, embryos may be tested for specific genetic or chromosomal abnormalities	Cystic fibrosis—all couples, but especially northern European Caucasian and Ashkenazi Jewish Tay-Sachs disease—Ashkenazi Jewish Sickle cell disease—African American, Puerto Rican, Mediterranean, Middle Eastern Alpha-thalassemia—Southeast Asian, African American
Prenatal screening	For genetic conditions that are common and for which prenatal diagnosis is available when a pregnancy is identified at increased risk	Neural tube defects—spina bifida, anencephaly Down syndrome Other chromosomal abnormalities—trisomy 18
Newborn screening	For genetic conditions for which there is specific treatment	Phenylketonuria (PKU) Galactosemia Homocystinuria Biotinidase deficiency
Diagnostic screening	To determine whether a specific genetic mutation exists or to confirm diagnosis when phenotypic presentation exists	Hypertrophic cardiomyopathy
Carrier testing	To determine if a person carries a mutated gene; this type of testing is useful for	Cystic fibrosis—all couples, but especially

	couples to ascertain genetic risk of having a child with a genetic disorder; particularly useful with autosomal recessive disorders	northern European Caucasian and Ashkenazi Jewish Tay-Sachs disease—Ashkenazi Jewish Sickle cell disease—African American, Puerto Rican, Mediterranean, Middle Eastern
Predictive testing	For genetic conditions that appear later in life or for genetic disorders that have minimal phenotypic presentation	Colorectal cancer Huntington disease Hemochromatosis

Adapted from National Institutes of Health (NIH), U.S. National Library of Medicine (NLM); Genetics Home Reference. (2019l). What are the types of genetic tests? Retrieved on 8/30/2019 at: www.ghr.nlm.nih.gov/handbook/testing/uses

Population Screening

Population screening—the use of genetic testing for large groups or entire populations—to identify late-onset conditions is under development. For a test to be considered for population screening, there must be (1) sufficient information about gene distribution within populations, (2) accurate prediction about the development and progression of disease, and (3) appropriate medical management for asymptomatic people with a mutation. Currently, population screening is considered in some ethnic groups to identify cancer-predisposing genes. For example, individuals of Ashkenazi Jewish ancestry have a greater chance of inheriting breast and ovarian cancer than other ethnic groups (Manchanda & Gaba, 2019). The identification of one of these mutations gives patients options that may include cancer screening, chemoprevention, or prophylactic mastectomy or oophorectomy. In addition, population screening for this group could also include screening for conditions such as Tay-Sachs disease and Canavan disease. Population screening is being explored for other adult-onset conditions such as type 2 diabetes, heart disease, and hereditary hemochromatosis (i.e., iron overload disorder). In some countries, there is a push to conduct population screening as a form of precision medicine

focused on prevention (Silva et al., 2018; Turnball, Sud, & Houlston, 2019).

Testing and Screening for Adult-Onset Conditions

Adult-onset conditions with a genetic or genomic basis are manifested during adulthood and the disease is clearly observed to run in families. Some conditions typically associated with advanced age that manifest earlier in life may also have a genetic correlation and require further examination. For example, hypercholesterolemia is often considered an adult-onset disorder associated with a diet high in fat. A form of hypercholesterolemia with excessively high cholesterol levels and lack of lifestyle risk factors correlates with a genetic alteration referred to as familial hypercholesterolemia (Knowles, Rader, & Khoury, 2017). This is an autosomal dominant disorder, suggesting that there is a 50% likelihood that each child of a parent with the disorder will inherit this disorder. Cascade screening of children of parents with familial hypercholesterolemia would be indicated to identify whether or not they have the disorder so that they may be promptly identified and treated (Setia, Saxena, Sawhney, et al., 2018). Adult-onset genetic conditions can be attributed to specific genetic mutations and follow either an autosomal dominant or an autosomal recessive inheritance pattern; however, most adult-onset conditions are considered to be genomic or multifactorial—that is, they result from a combination of genes or gene–environment interactions. Examples of multifactorial conditions include heart disease, diabetes, and arthritis. Genomic or multifactorial influences involve interactions among several genes (gene–gene interactions) and between genes and the environment (gene–environment interactions), the person's lifestyle. Furthermore, some adult-onset conditions occur due to sporadic changes to a gene (Gael & Veltman, 2019).

Nursing assessment for adult-onset conditions is based on family history, personal and medical risk factors, and identification of associated diseases or clinical manifestations (the phenotype). Knowledge of adult-onset conditions and their genetic bases (i.e., mendelian vs. multifactorial conditions) influences the nursing considerations for genetic testing and health promotion. Table 6-5 describes select adult-onset conditions, their age of onset, patterns of inheritance, molecular genetics, and test availability.

Single Gene Conditions

If a single gene accounts for an adult-onset condition in a symptomatic person, testing is used to confirm a diagnosis to assist in the plan of care and management. Diagnostic testing for adult-onset conditions is most frequently used with autosomal dominant conditions, such as Huntington disease or Factor V Leiden thrombophilia, and with autosomal recessive conditions such as hemochromatosis. Other single gene conditions are associated with a confirmed genetic mutation in an affected family member or with a family history suggestive of an inherited pattern of adult-onset disease, such as a particular type of cancer. **Presymptomatic testing** provides information to people without symptoms about the presence of a genetic mutation and about the likelihood of developing the disease. Presymptomatic testing is considered for people in families with a known adult-onset condition in which either a positive or a negative test result indicates an increased or reduced risk of developing the disease, affects medical management, or allows earlier treatment of a condition.

Huntington disease has long served as the model for presymptomatic testing because the presence of the genetic mutation predicts disease onset and progression. Although preventive measures are not yet available for Huntington disease, the genetic information enables health care providers to develop a clinical, supportive, and psychological plan of care. Indeed, the presence of a single gene mutation has implications for the risk of developing many types of cancer; therefore, presymptomatic testing has become more common as a means to start early planning and implementation of select medical measures that may reduce that risk (Edwards & Maradiegue, 2018).

Genomic Conditions

The foremost factor that may influence the development and severity of disease is a person's genomic makeup. In the absence of a single disease-causing gene, it is thought that multiple genes and other environmental factors are related to the onset of most adult diseases. For some diseases, the interactions among several genes and other environmental or metabolic events affect disease onset and progression. Specific gene–gene interactions or SNPs can confer susceptibility to disease. Genomic testing helps distinguish variations within the same disease or response to treatment. For example, no single gene is associated with osteoporosis. Several polymorphisms on candidate genes related to the vitamin D receptor, estrogen and androgen receptors, and regulation of bone mineral

density (BMD) have been shown to contribute to osteoporosis and fracture risk. Moreover, diet and exercise have a strong interaction with the polymorphisms regulating BMD (Cho, Lee, & Kang, 2017).

TABLE 6-5 Select Adult-Onset Disorders

Clinical Description	Age of Onset	Genetic Inheritance	Associated Gene	Test Availability
Neurologic Conditions				
Alzheimer's Disease Progressive dementia, memory failure, personality disturbance, loss of intellectual functioning associated with cerebral cortical atrophy, beta-amyloid plaque formation, and intraneuronal neurofibrillary tangles	<60–65 y, often <55 y	A.D.	*APOE* *PSEN1* *APP* *PSEN2*	Presymptomatic and diagnostic
Parkinson's Disease Dementia and/or parkinsonism: Slowly progressive behavioral changes, language disturbances and/or extrapyramidal signs, rigidity, bradykinesia, and saccadic eye movements	40–60 y	A.D.	*MAPT* *PARK*	Diagnostic and presymptomatic
Huntington Disease Widespread degenerative brain change with progressive motor loss both voluntary disability and involuntary disability, cognitive decline, chorea (involuntary movements) at later stage, psychiatric disturbances	Mean age, 35–44 y	A.D.	*HTT*	Diagnostic and presymptomatic
Neuromuscular Disorders				
Spinocerebellar Ataxia Type 6 Progressive cerebellar ataxia, dysarthria, nystagmus, bulbar dysfunction, peripheral neuropathy, decreased deep tendon reflexes, dementia	Mean age, 30–52 y	A.D.	*CACNA1A* *ATXN*	Diagnostic and presymptomatic
Myotonic Muscular Dystrophy Type 1 Cataracts and myotonia or muscle wasting and weakness, frontal balding and electrocardiographic changes (heart block or arrhythmia), diabetes in 5% of all cases	20–70 y	A.D. with variable penetrance	*DMPK* *CNBP*	Diagnostic
Familial Amyotrophic Lateral Sclerosis Progressive loss of motor function with predominantly lower motor neuron manifestations	45–60 y	Both A.D. and A.R.	*ALS1* *ALS2* *SOD1* *SETX*	Diagnostic

Hematologic Conditions				
Hereditary Hemochromatosis High absorption of iron by gastrointestinal mucosa resulting in excessive iron storage in liver, skin, pancreas, heart, joints, and testes. Abdominal pain, weakness, lethargy, and weight loss are early symptoms. Untreated individuals can present with skin pigmentation, diabetes, hepatic fibrosis or cirrhosis, congestive heart failure, arrhythmias, or arthritis.	40–60 y in males; after menopause in females	A.R.	*HFE*	Diagnostic and presymptomatic
Factor V Leiden Thrombophilia Poor anticoagulant response to activated protein C with increased risk for venous thromboembolism and increased risk for fetal loss during pregnancy	30s; during pregnancy in females	A.D.	*F5*	Diagnostic and presymptomatic
Polycystic Kidney Disease Dominant Most common genetic disease in humans. Manifests with renal cysts, liver cysts, and occasionally intracranial/aortic aneurysm and hypertension. Loss of glomerular filtration can lead to kidney failure.	Variable onset; all carriers have detectable disease by ultrasonography at age 30 y	A.D.	*PKD1* *PKD2*	Diagnostic and presymptomatic
Cardiovascular Disease				
Familial Hypercholesterolemia Elevated low-density lipoprotein levels leading to coronary artery disease, xanthoma, and corneal arcus	40–50 y	A.D.	*LDLR* *PCSK* *APOB*	Diagnostic
Hyperlipidemia Elevated cholesterol and triglycerides associated with premature coronary disease and peripheral vascular disease	30–40 y	A.R.	*APOE* *APOA*	Clinical testing related to Alzheimer's/ research
Alpha$_1$-Antitrypsin Deficiency Small airway and alveolar wall destruction; emphysema, especially at base; chronic obstructive pulmonary disease	35-year-old smoker; 45-year-old nonsmoker	M.F. in A.R. fashion	*SERPINA-1*	Diagnostic and presymptomatic
Oncology Conditions				
Multiple Endocrine Neoplasia Familial medullary thyroid cancer: Medullary thyroid cancer, pheochromocytoma, and parathyroid abnormalities	Early adulthood 40–50 y	A.D.	*MEN1* *MEN2*	Presymptomatic
Breast Cancer *BRCA1/2* hereditary breast/ovarian cancer: Breast, ovarian, prostate, and colon (*BRCA1*); breast, ovarian, and other cancers (*BRCA2*)	30–70 y; often <50 y	A.D.	*BRCA1* *BRCA2*	Presymptomatic Presymptomatic
Lynch Syndrome Colorectal, endometrial, bladder, gastric, biliary, and renal cell cancers as well as atypical endometrial hyperplasia and uterine leiomyosarcoma	<50 y	A.D.	*MLH1* *MSH2* *MSH6* *PMS2*	Presymptomatic and diagnostic
Li–Fraumeni Syndrome Soft tissue sarcoma, breast cancer, leukemia, osteosarcoma, melanoma, and other cancers often including colon, pancreas, adrenal cortex, and brain	Often <40 y	A.D.	*TP53* *CHEK2*	Presymptomatic and diagnostic
Cowden Syndrome Breast, nonmedullary (papillary or follicular) thyroid cancer; breast fibroadenomas and noncancerous thyroid nodules or goiter; multiple buccal mucosa papillomas (cobblestone-like papules), facial trichilemmomas, gastrointestinal polyps; high-arched palate, thickened furrowed tongue, megalencephaly, and pectus excavatum	40–50 y for cancer; teens—20 y for mucocutaneous lesions	A.D.	*PTEN*	Presymptomatic and research

AD, autosomal dominant; AR, autosomal recessive; ME multifactorial.
Adapted from National Center for Biotechnology Information (NCBI), U.S. National Library of Medicine (NLM). (2019a). Genetic Testing Registry. Retrieved on 8/30/2019 at: www.ncbi.nlm.gov/gtr

Some genomic tests may predict treatment response. For example, people may present with similar clinical signs and symptoms of asthma but have different responses to corticosteroid treatment. Mutations in genes that regulate corticosteroid receptors can help classify people with asthma as sensitive or resistant to treatment with corticosteroids (NCBI, NLM, 2019b).

The Nursing Role in Testing and Screening for Adult-Onset Conditions

Nurses participate in explaining risk and genetic predisposition, supporting informed health decisions and opportunities for prevention and early intervention, clarifying legal protections and risks related to genetic testing or health concerns, and protecting patients' privacy. Nurses assess family histories, which may indicate that multiple generations (autosomal dominant inheritance) or multiple siblings (autosomal recessive inheritance) are affected with the same condition or that onset of disease is earlier than expected (e.g., multiple generations with early-onset hyperlipidemia). Possible adult-onset conditions are discussed with other members of the health care team for appropriate resources and referral. When a family history of disease is identified, a patient is made aware that this is a risk factor for disease; resources and referral are then provided. It is the patient's decision whether or not to pursue a genetic testing workup. For example, if a 45-year-old woman presents for her annual gynecology visit and reports a family history of colon cancer in multiple paternal relatives, including her father, the nurse should discuss the family history with the gynecologist. In addition, the woman should be alerted to the risk of colon cancer on the basis of the family history and given information about possible genetic testing and referral for a colonoscopy.

If the existence of a mutation for an adult-onset condition in a family is identified, at-risk family members can be referred for cascade screening for a specific genetic disorder based on genetic susceptibility or genetic predisposition. If the patient is found to carry the mutation, the nurse provides them with information and referral for risk-reduction measures and educates the person about the risk to other family members. In that discussion, the nurse assures the patient that the test results are private and confidential and will not be shared with others, including family members, without the patient's permission. If the patient is an unaffected family member, the nurse discusses inheritance and the risk of developing the disease, provides support for the decision making process, and offers referral for genetics services.

Concept Mastery Alert

Cascade screening is used for at-risk family members if the existence of a mutation for an adult-onset condition in a family is identified. Presymptomatic testing provides information to people without symptoms about the presence of a genetic mutation and about the likelihood of developing the disease.

Personalized Genomic Treatments

Information about genes and their variations helps researchers identify genetic differences that predispose certain people to more aggressive diseases and affect their responses to treatment. Genetics and genomics have revolutionized the field of oncology because genetic mutations are the basis for the development and progression of all cancers. In the medical era, individuals with cancer faced treatment based on the stage of the cancer, lymph node involvement, and spread to distant organs. Treatments of a particular type of cancer, stage for stage, were similar. Now, in the genomic era of personalized medicine, cancer is treated on the basis of genetic makeup. For example, women with early stage breast cancer (i.e., tumor diameter less than 2 cm, estrogen receptor–positive tumors, no lymph node involvement) have often received chemotherapy. In the past, deciding which of these women would benefit the most from chemotherapy was unclear. Currently, a gene tumor profile of these women's tumors can be used to predict which women are more likely to have an aggressive cancer. Genetic testing helps clinicians to provide personalized care and the most effective treatment based on the genetic signature of the tumor treatment, called *targeted therapy,* which tries to match the treatment to the specific malfunctioning genes expressed in the tumor, or to selectively inhibit genetic factors that promote cancer growth (Dodson, 2017; National Cancer Institute, 2019). Progressive personalized genomic treatment has expanded into genome editing, known as CRISPR (clustered regularly interspaced short palindromic repeats), which shows promise for single gene disorders and cancer by repairing, replacing, or deleting genes that are altered or damaged (Foss, Hochstrasser, & Wilson, 2019).

Pharmacogenomics

The difference between genetics and genomics, described earlier in this chapter, corresponds to the terms *pharmacogenetics* and

pharmacogenomics, which combine pharmacology and genetics or genomics. Pharmacogenetics refers to the study of the effect of variations in a single gene on drug response and toxicity. The field of pharmacogenetics has evolved so that it has become a broader genomic-based approach that recognizes the interaction of multiple genes and the environment on drug response. Pharmacogenomics refers to the study of the combined effect of variations in many genes on drug response and toxicity and involves methods that rapidly identify which genetic variations influence a drug's effect. The aim of pharmacogenomics is to deliver safe, effective medication and dosages that are specifically tailored to a person's genetic makeup (Dodson, 2017). The clinical application of pharmacogenetics has provided a better understanding of drug pathways, leading to the development of new drugs that do not have toxic side effects and that have the potential to change current standards of treatment (Conyers, Devaraja, & Elliott, 2018; Mannino, Andreozzi, & Sesti, 2019; Pickard, 2017). Drug pathways target specific gene biomarkers to elicit a specific and therapeutic response (U.S. Food and Drug Administration [FDA], 2019).

It has long been known that patients differ in their response to medications. The genetic and genomic variations in drug metabolism account largely for the differences in drug response and drug-related toxicities. Drug metabolism involves genetically controlled protein/enzyme activity for absorption, distribution, drug–cell interaction, inactivation, and excretion—metabolic processes that are known as pharmacokinetics. The cytochrome P450 (CYP) genes play a key role in the pharmacokinetic process of drug metabolism (Clinical Pharmacogenetics Implementation Consortium [CPIC], 2019). Once a drug reaches its target cell, other genes such as those regulating cell receptors and cell signaling control the drug's effect. This process is known as pharmacodynamics. Single genes may affect drug response. More commonly, drug response involves the interaction of multiple genes, the host, and the effects of other drugs. Figure 6-12 is a schematic display of the genetic and genomic influences on drug metabolism and treatment effect.

SNPs, described earlier, are common genetic variations that occur most frequently throughout the human genome and often contribute to variations in enzymatic activity that affect drug metabolism. The CYPs, a family of enzymes, play a key role in the pharmacokinetic process of drug metabolism. Numerous variations (SNPs) of genes that control CYP activation and deactivation have been identified. Researchers have created

a catalog of CYP variations because of their role in drug metabolism (CPIC, 2019).

Four classes of CYP metabolic activity levels have been identified based on a person's CYP genotype and the corresponding drug response: (1) poor metabolizers, (2) intermediate metabolizers, (3) extensive metabolizers, and (4) ultrarapid metabolizers. Poor metabolizers have a specific SNP variation in a CYP gene that causes little or no function, resulting in very little or no drug metabolism and higher blood levels of active drug because the drug cannot be absorbed or excreted. Conversely, ultrarapid metabolizers have SNP variations that cause increased enzyme activity, resulting in rapid absorption, distribution, and excretion of a drug. Ultrarapid metabolizers have lower drug blood levels, usually with inadequate therapeutic response or longer treatment time to achieve therapeutic results. Both poor metabolizers and ultrarapid metabolizers are predisposed to adverse drug reactions. Poor metabolizers may have adverse effects or toxicities from high blood levels of drugs and need a lower dose, whereas ultrarapid metabolizers have inadequate treatment response because of lower drug blood levels and may need a higher dose or more frequent dosing. Intermediate metabolizers have reduced enzyme activity levels and metabolize drugs at a slower than normal rate. Because intermediate metabolizers have some enzyme activity, they may have differences in treatment response. Extensive metabolizers have normal enzyme activity levels and normal drug metabolism. Differences in metabolism of other medications occur with other genetic variations.

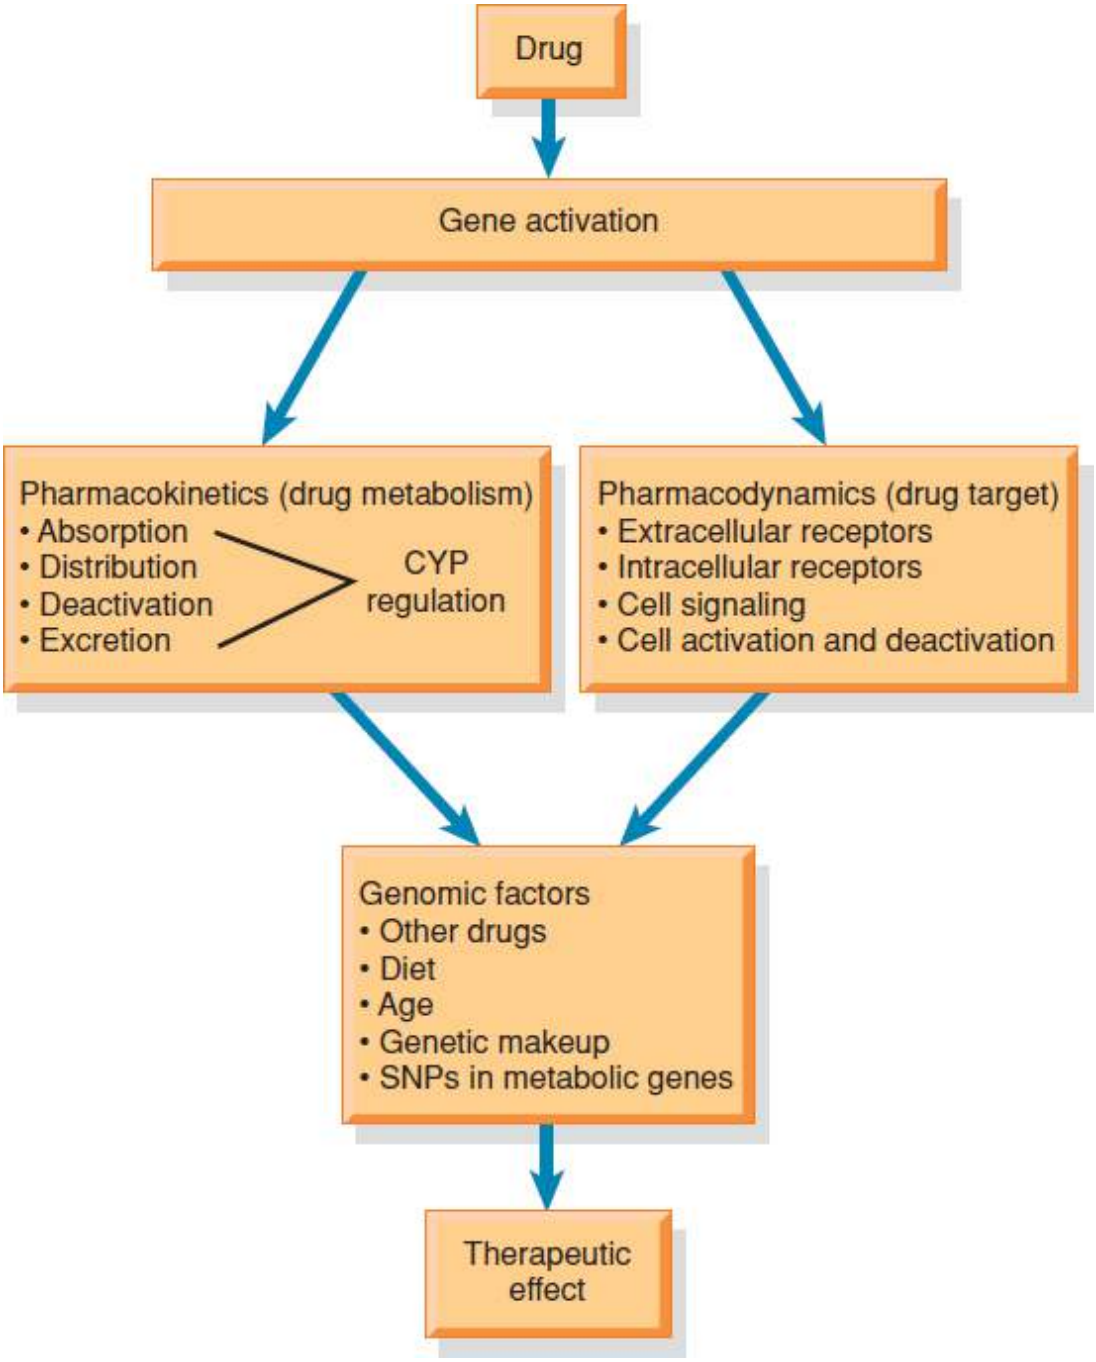

Figure 6-12 • Simplified schematic representation of the multiple, complex, genetic-regulated mechanisms involved in pharmacokinetics (cytochrome [CYP] dependent) and pharmacodynamics, along with other genomic and environmental factors affecting drug metabolism and treatment effect. SNPs, single nucleotide polymorphisms.

Nurses have traditionally monitored and reported drug response and drug adverse effects. Pharmacogenomic (drug–gene) testing is currently available for more than 16 drugs (Mayo Clinic, 2019). This type of testing

offers patients and health care providers more information about a specific drug and whether the medication is the best option for the patient based on genetic interactions that may influence the absorption, metabolism, or excretion of the drug, and the likelihood of an adverse effect from the medication. Nurses are in a position not only to provide education about a particular patient's genomic profile for drug metabolism, but also to explain the rationale for the recommended dosage and discuss associated symptoms related to potential adverse effects. Nurses will continue to incorporate information about gender differences, food interactions, and drug adherence into patient education (Consensus Panel, 2009).

Ethical, Legal, and Social Issues Surrounding Genetics

The rapid application of genetics and genomics across all sectors of health care has had implications for gathering, recording, and sharing personal health information. An ethical foundation provides nurses with a holistic framework for handling these issues with integrity and provides a basis for communicating genetic and genomic information to a patient, a family, other care providers, community agencies and organizations, and for society. Nurses must consider their responsibilities in handling genetic and genomic information and strive to ensure that informed decision making occurs, that patient and family health information is kept private and confidential, and that access to and justice in health care is available to everyone (ANA, 2017).

Ethical Concerns

Ethical principles of beneficence (i.e., to do good) and nonmaleficence (i.e., to do no harm), as well as autonomy, justice, fidelity, and veracity, are used to resolve ethical dilemmas that may arise in clinical care. Respect for persons is the ethical principle underlying all nursing care. Using these principles and the values of caring, nurses can promote thoughtful discussions that are useful when patients and families are facing genetics- and genomics-related health and reproductive decisions and consequences (ANA, 2017; Consensus Panel, 2009). The ethical principles of autonomy, fidelity, and veracity are also important (ANA, 2015). (Further information about ethics is included in Chapter 1.)

Ethical questions relating to genetics and genomics occur in all settings and at all levels of nursing practice. At the level of direct patient care, nurses participate in providing genetic information, testing, and gene-based therapeutics. They offer patient care based on the values of self-determination and personal autonomy. To be as fully informed as possible, patients need appropriate, accurate, and complete information given at a level and in a form so that they and their families can make well-informed personal, medical, and reproductive health decisions. Nurses can help patients clarify values and goals, assess understanding of information, protect their rights, and support their decisions. Nurses can advocate for patient autonomy in health decisions. Several resources and position statements have been developed to guide genetic-related nursing practice (International Society of Nurses in Genetics [ISONG], 2019).

Respecting the patient's right to self-determination—that is, supporting decisions that reflect the patient's personal beliefs, values, and interests—is a central principle in directing how nurses provide genetic and genomic information and counseling. Nurses and others participating in genetic counseling make every attempt to respect the patient's ability to make autonomous decisions. Recognizing one's own attitudes and beliefs and how communication of genetic and genomic information may be influenced by those attitudes and beliefs is a first step toward assuring patients' autonomous decision making.

Confidentiality of genetic and genomic information and respect for privacy are other essential principles underlying genetic counseling. Patients have the right to not have test results divulged to anyone, including insurers, primary providers, employers, or family members. Some patients pay for testing themselves so that insurers will not learn of the test, and others use a different name for testing to protect their privacy.

Ethical challenges may occur for family members and health care providers when the findings of one person's test may inadvertently disclose another family member's risk or carrier status. A nurse may want to disclose genetic information to family members who could experience significant harm if they do not know such information. However, the patient may have other views and may wish to keep this information from the family, resulting in an ethical dilemma for both patient and nurse. The nurse must honor the patient's wishes, while explaining to the patient the potential benefit this information may have for other family members (ANA, 2017; ISONG, 2019).

Ethical considerations must be reviewed as part of genetic and genomic research. For example, before a person participates in genetic and genomic clinical research, the research team must discuss how incidental findings will be addressed. Incidental findings are genetic-related illnesses which are found secondary to the intended goals of the research project or purpose of the test (Boardman & Hale, 2018). The American College of Medical Genetics and Genomics (American College of Medical Genetics and Genomics Policy Statement [ACMG], 2017) issued a policy statement that lists conditions known to be treatable and should be reported to the patient if found incidentally during clinical research.

Legal Aspects of Personalized Health Care

The Genetic Information Nondiscrimination Act (GINA), a law passed in 2008, protects individuals from genetic discrimination (Rothstein, 2018). Its purpose is to protect Americans against improper use of genetic and genomic information in insurance and employment decisions. GINA is particularly helpful for people who carry a gene mutation but are asymptomatic for the illness. The act prohibits health insurers from denying coverage to a healthy person or charging higher insurance rates based on a person's genetic predisposition to a disease. GINA offers legal protection with regard to health insurance and employment; however, gaps in protection exist with regard to disability, life, and long-term care insurance. The act also prevents employers from using a person's genetic and genomic information to make decisions about hiring, job placement, promotion, or firing. Protection provided by GINA does not apply to employers with less than 15 employees, to people in the military, Veterans Health Administration, Indian Health Services, and Federal Employees Health Benefits Programs (Rothstein, 2018). As a result of GINA, most Americans are free to use genetic and genomic information in health care without the fear of misuse; however, public awareness of this law is limited (Cragun, Weidner, Kechik, et al., 2019).

While not specifically intended for genetic health-related concerns, other health care laws offer some additional protection to individuals with regard to genetics. For example, the Affordable Care Act, enacted in 2010, offers some protection for a person with a genetic illness by prohibiting health insurers from discrimination based on a preexisting condition (Rich, 2018). The Americans With Disabilities Act offers legal protection related to employment concerns and physical or intellectual

impairment as a result of a genetic disorder. Finally, the Health Insurance Portability and Accountability Act (HIPAA), enacted in 1996, places restrictions on sharing identifiable health information and places stringent requirements on maintaining the privacy of health-related content and prohibits the use of genetic information to establish insurance eligibility (U.S. Department of Health and Human Services [HHS], 2017). However, HIPAA does not prohibit group plans from increasing premiums, excluding coverage for a specific condition, or imposing a lifetime cap on benefits.

The National Human Genome Research Institute, Policy and Program Analysis branch, has a summary of each state's legislation related to genomic statutes and bills (NIH, NHGRI, 2019b). See also the Resources section at the end of this chapter.

Ancestry, Cultural, Social, and Spiritual Concerns Related to Genetic and Genomic Practice

Genetic assessment addresses the ancestry of patients and families, as well as their ethnicity. This information helps identify individual patients and groups who could benefit from genetic testing for carrier identification, prenatal diagnosis, and susceptibility testing. For example, carrier testing for sickle cell disease is routinely offered to people of African American descent, and carrier testing for Tay-Sachs disease and Canavan disease is offered to people of Ashkenazi Jewish descent. The American College of Obstetricians and Gynecologists ([ACOG], 2019) recognizes the benefit of a thorough family history in correlation with the identification of personalized risks and the option of genetic testing prior to conception. Health care providers must be aware of at-risk status based on racial and ethnic population. Ideally, carrier testing is offered before conception to allow people who are carriers to make decisions about reproduction. Prenatal diagnosis is offered and discussed when both partners of a couple are found to be carriers.

It is important to inquire about the patient's ethnic backgrounds when assessing for susceptibilities to adult-onset conditions such as hereditary breast or ovarian cancer. For example, a *BRCA1* cancer–predisposing gene mutation seems to occur more frequently in women of Ashkenazi Jewish descent. Therefore, asking about ethnicity can help identify people with an increased risk of cancer gene mutations.

Nurses should consider patients' views about the significance of a genetic condition and its effect on self-concept, as well as patients'

perception of the role of genetics in health and illness, reproduction, and disability. For instance, among women without a history of breast cancer but with a strong family history of breast cancer, negative results for the *BRCA1* and *BRCA2* genetic mutations may not be a relief, since those women's risks for having breast cancer is estimated to be four times as high as women who do not have a family history. Among these women, negative findings for known genetic mutations may simply seem uninformative and cause frustration (Schroeder, Duggleby, & Cameron, 2017; see Chart 6-3: Nursing Research Profile: Living with Breast Cancer Risk). Patients' social and cultural backgrounds determine their interpretations and values about information obtained from genetic testing and evaluation and thus influence their perceptions of health, illness, and risk. Family structure, decision making, and educational background contribute in the same way (Consensus Panel, 2009).

Assessment of the patients' beliefs, values, and expectations regarding genetic testing and genetic and genomic information helps nurses provide appropriate information about the specific genetics or genomics topic. For example, in some cultures, people believe that health means the absence of symptoms and that the cause of illness is supernatural. Patients with these beliefs may initially reject suggestions for presymptomatic or carrier testing. However, by including resources such as family and cultural and religious community leaders when providing genetics- or genomics-related health care, nurses can help ensure that patients receive information in a way that transcends social, cultural, and economic barriers (Tluczek, Twal, Beamer, et al., 2019).

Chart 6-3 **NURSING RESEARCH PROFILE**

Living with Breast Cancer Risk

Schroeder, D., Duggleby, W., & Cameron, B. L. (2017). Moving in and out of the what-ifs: The experiences of unaffected women living in families where a breast cancer 1 or 2 genetic mutation was not found. *Cancer Nursing, 40*(5), 386–393.

Purpose

The genetic mutations of *BRCA1* and *BRCA2* account for approximately 15% of cases of familial breast cancer in women. For women without these mutations and without breast cancer but with a strong family history, the risk of eventually having breast cancer remains high. These risks may be related to another currently unidentified *BRCA* mutation or to a mutation in another gene not yet identified. Little is known about the effects that living with a high breast cancer risk has on these women. Therefore, the aims of this study were to discover the day-to-day lived experience of having breast cancer risk on women with a strong family history of breast cancer but who are *BRCA1* and *BRCA2* negative, and to elucidate how they cope with the knowledge of their breast cancer risk.

Design

This was a hermeneutic phenomenologic study that used van Manen's methods to explore the lived experiences among *BRCA1* and *BRCA2* negative women without breast cancer but with a strong family history of breast cancer and to uncover the meanings this knowledge had on their everyday lives. Purposive sampling was used to recruit participants eligible to be included in the study. The researchers hoped to recruit between five and eight participants. Ten patients who received care in a hereditary breast and ovarian cancer clinic (HBOC) in Western Canada consented to participate in this study, although one dropped out prior to data collection, resulting in a total of nine participants.

Findings

Participants (N = 9) engaged in a total of 20 interviews with the researchers. Each participant engaged in at least two conversations. After each session, participants were given copies of the summaries of the conversations and proposed emerging themes that researchers posited for corroboration, in order to ensure trustworthiness of findings. Researchers identified one main overarching theme of *Moving In and Out of the What-Ifs,* which identified the tensions between "normal" living, as expressed in the subtheme *Just Moving Along: Living a Normal Life,* that was juxtaposed with the "what-ifs" subthemes, which included *Moving Into Those Dark Spaces, Is There Something Wrong*

with Me? and *Markings in Time.* For instance, all participants identified that most of the time they had an awareness of their familial breast cancer risk, but kept it in the background, expressing the need to "live a normal life." The "dark spaces" were described as triggers that provoked anxiety about their risks, such as anticipating an appointment at the HBOC, or hearing news of a close relative newly diagnosed with cancer. Although all participants identified themselves as "healthy," they found that many times, others who knew of their risks tended to label them as not healthy, causing conflict within them "Is there something wrong with me?" Lastly, there were key milestones in participants' lives that caused tension, or "time marks," such as approaching or surpassing an age when a family member was diagnosed with cancer, or when a family member died of cancer. Coping through the "dark spaces" the "wrongness" and the "marks in time" was facilitated through the methods employed in the subthemes *Living in the Moment,* or slowing down to enjoy the "here and now"; *Being Cared For,* or feeling cared for by significant others as well as the staff at the HBOC; and, *Keeping Me Grounded,* expressed by having family and significant others find ways to keep them out of the "dark spaces," supporting their view of themselves as healthy, and celebrating significant "time marks" with them.

Nursing Implications

Findings from this study suggest that being *BRCA1* and *BRCA2* negative can be seen as both a blessing and a curse for women who are nonetheless at risk for familial breast cancer. These women must deal with conflicting emotions and anxieties that surround the uncertainty of living with this risk. Nurses who care for women at risk for familial breast cancer who are *BRCA1* and *BRCA2* negative should aim to foster their coping mechanisms by encouraging them to focus on the positives in the "here and now" of their lives, by keeping them grounded, and by demonstrating a caring relationship with them.

Applications of Genetics and Genomics in Nursing Practice

Nurses who provide genetics- and genomics-related health care blend the principles of human genetics with nursing care in collaboration with other professionals, including genetic specialists, to foster improvement, maintenance, and restoration of patients' health (Tluczek et al., 2019). Genetic-related nursing practice involves the care of people who have

genetic conditions, those who may be predisposed to develop or pass on genetic conditions, and those who are seeking genetic information and referral for additional genetics services. The application of genomic information has been integrated into clinical practice areas of preconception, preimplantation, and prenatal testing, newborn screening, disease susceptibility, screening and diagnosis, prognosis and therapeutic decisions, and in monitoring disease recurrence (see Table 6-4). In the near future, nurses will need to engage in public health efforts to improve genetic literacy within the public domain so that patients can make informed genetic-genomic related decisions (Boerwinkel, Yarden, & Waarlo, 2017).

Nurses are positioned to support patients and families with genetics- and genomics-related health concerns by ensuring not only that their health choices are informed ones but by also advocating for the privacy and confidentiality of genetic and genomic information and for equal access to genetic testing and treatments. Nurses are expected to attend to the genetic and genomic health care needs of the patient (ANA, 2017).

Genetics and Genomics in Health Assessment

Assessment of a person's genetic and genomic health status is an ongoing process. Nurses collect information that can help identify individuals and families who have actual or potential genetics- or genomics-related health concerns or who may benefit from further genetic information, counseling, testing, and treatment. This process can begin before conception and continue throughout the lifespan. Nurses evaluate family and past medical histories, including prenatal history, childhood illnesses, developmental history, adult-onset conditions, past surgeries, treatments, and medications; this information may relate to the genetic or genomic condition at hand or to a condition being considered (see Chapter 4 for more information on assessing past medical history). Nurses also identify the patient's ethnic background and conduct a physical assessment to gather pertinent genetic information. The assessment also includes information about culture, spiritual beliefs, and ancestry. Health assessment includes determining a patient's or family's understanding of actual or potential genetics- or genomics-related health concerns and awareness of how these issues are communicated within a family (ANA, 2017).

Family History Assessment

Nurses in any practice setting can assess families' genetics histories to identify a genetic trait, inherited condition, or predisposition. Obtaining a thorough family health history is the first, most important tool when determining the potential risk for a genetic illness. Targeted questions are used to identify genetic and genomic conditions for which further information, education, testing, or treatment can be offered (Chart 6-4). A three-generation family history should be collected that includes ages of each family member, medical illnesses, age and cause of death, history of miscarriages or stillbirths, and ethnicity (ACOG, 2018). After consultation and collaboration with other health care providers and specialists, further genetic testing and evaluation is offered for the trait or condition in question. A genetic family history is used to make a diagnosis, identify testing strategies, and establish a pattern of inheritance. Nurses can also inquire about medical conditions that are known to have a heritable component and for which genetic testing may be available. Information is obtained about the presence of birth defects, intellectual disability, familial traits, or similarly affected family members (Consensus Panel, 2009).

Nurses need to consider the closeness of the relationship (genetic relatedness or consanguinity) among family members when assessing the risk of genetic conditions in couples or families. For example, when obtaining a preconception or prenatal family history, it is important for the nurse to ask if the prospective parents have common ancestors (i.e., are they cousins?). This is key because, as noted previously, people who are related have more genes in common than those who are unrelated, thus increasing their chance of having children with an autosomal recessive inherited condition such as cystic fibrosis. Ascertaining genetic relatedness provides direction for genetic counseling and evaluation. It may also serve as an explanation for parents who have a child with a rare autosomal recessive inherited condition or for an adult who is similarly affected.

When the assessment of family history reveals that a patient has been adopted, genetic- and genomic-based health assessment becomes more challenging. Every effort is made to help the patient obtain as much information as possible about their biologic parents, including their ethnic backgrounds.

Questions about previous miscarriage or stillbirth are included in genetics health assessments to identify possible chromosomal conditions. Nurses can also inquire about any history of family members with inherited conditions or birth defects; maternal health conditions such as

type 1 diabetes, seizure disorders, or PKU, which may increase the risk for birth defects in children; and about exposure to alcohol or other drugs during pregnancy. Maternal age is also noted; women who are 35 years of age or older who are considering pregnancy and childbearing or who are already pregnant should be offered prenatal diagnosis (e.g., testing through amniocentesis) because of the association between advanced maternal age and chromosomal abnormalities such as Down syndrome. Advanced paternal age, which includes men over 40 years of age, is associated with a slightly higher risk for a child to have autism, schizophrenia, or leukemia (Mayo Clinic, 2018).

Chart 6-4 GENETICS FAMILY HISTORY

An Essential Tool for All Nurses

A Well-Documented Family History Can Be Used to:

- Assess risk of certain diseases
- Decide on testing strategies, such as what genetic and other diagnostic tests to order
- Establish a pattern of inheritance
- Identify other family members who are at increased risk
- Identify shared environmental risk factors
- Calculate risks
- Assess risk of passing on conditions to children
- Determine and recommend treatments that modify disease risk
- Make decisions about management or surveillance
- Develop patient rapport
- Educate patients

Key Questions to Ask About Each Family Member Include:

- What is the current age, or what was the age at death?
- What is the ethnic background (some genetic conditions are more common in certain ethnic groups)?
- Is there a history of:
  - Multiple pregnancy losses/stillbirths?
  - Unexplained infertility?
  - Birth defects?
  - Intellectual disability or developmental delay?
  - Learning disability?
  - Medical problems in children whose parents are closely related (second cousins or closer)?
  - Congenital or juvenile blindness, cataracts, hearing loss, or deafness?
  - Very short or very tall stature?
  - Several close relatives with the same or related conditions (e.g., breast or colon cancer, diabetes, heart disease, asthma, stroke, high blood pressure, kidney disease)?
  - Occurrence of a common condition with earlier age of onset than is usual (e.g., breast or colon cancer, hearing loss, dementia, heart disease)?

Adapted from Ginsburg, G. S., Wu, R. R., & Orlando, L. A. (2019). Family health history: Underused for actionable risk assessment. *Lancet, 394*(10198), 596–603.

Physical Assessment

Physical assessment may provide clues that a particular genetic or genomic condition is present in a person and family. Family history assessment may serve as a guide to focus the physical assessment. For example, a history of familial hypercholesterolemia would alert the nurse to assess for symptoms of hyperlipidemias (xanthomas, corneal arcus, and abdominal pain of unexplained origin). A family history of neurofibromatosis type 1, an inherited condition involving tumors of the central nervous system, would prompt the nurse to carry out a detailed assessment of closely related family members. Skin findings such as *café-au-lait* spots, axillary freckling, or tumors of the skin (neurofibromas) would warrant referral for further evaluation, including genetic evaluation and counseling (NIH, NLM, 2019i).

If a genetic or genomic condition is suspected as a result of a family history or physical assessment, the nurse, as a part of their role, and in collaboration with the health care team, may initiate further discussion of genetics and genomic information, offering and discussing genetic tests, and suggesting a referral for further genetic evaluation (Chart 6-5).

Chart 6-5

Indications for Making a Genetics Referral

Prepregnancy and Prenatal

- Maternal age of 35 y or older at expected time of delivery
- Previous child with a chromosome problem
- Positive alpha-fetoprotein profile screening test
- Previous child with a birth defect or family history of birth defects
- Pregnancy history of two or more unexplained miscarriages
- Maternal conditions such as diabetes, epilepsy, or alcoholism
- Exposures to certain medications or drugs during pregnancy
- Family history of intellectual disability
- Either member of the couple has a birth defect such as cleft lip or palate, spina bifida, or congenital heart defect
- Either member of the couple has a chromosome abnormality

Pediatric

- Positive newborn screening test
- One or more major birth defects
- Unusual (dysmorphic) facial features
- Developmental delay/intellectual disability
- Suspicion of a metabolic disorder
- Unusually tall or short stature, or growth delays
- Known chromosomal abnormality

Adult

- Intellectual disability without a known cause
- Unexplained infertility or multiple pregnancy losses
- A personal or family history of thrombotic events
- Adult-onset conditions such as hemochromatosis, hearing loss, and visual impairment
- Family history of an adult-onset neurodegenerative disorder (e.g., Huntington disease)
- Features of a genetic condition such as neurofibromatosis (*café-au-lait* spots, neurofibromas on the skin), Marfan syndrome (unusually tall stature, dilation of the aortic root), others
- Personal or family history of cardiovascular disorders known to be associated with genetic factors such as cardiomyopathy or long QT syndrome
- Family history of cancers known to be associated with specific genes such as hereditary breast/ovarian cancer or Lynch syndrome

- Family history of early-onset cancers and familial clustering of related tumors

Retrieved on 8/30/2019 at: www.cdc.gov/genomics/famhistory; McClatchey, T., Lay, E., Strassberg, M., et al. (2018). Missed opportunities: Unidentified genetic risk factors in prenatal care. *Prenatal Care, 38*, 75–79.

Chart 6-6 ASSESSMENT

Assessing Psychosocial Genetic Health

The nurse's assessment of psychosocial factors impacting a patient's genetic health is based on the nurse's professional responsibility to "demonstrate in practice the importance of tailoring genetic and genomic information and services to patients based on their culture, religion, knowledge level, literacy and preferred language." (Consensus Panel, 2009; p. 11).

The nurse assesses:

- Educational level and understanding of the genetic condition or concern in the family.
- Desired goals and health outcomes in relation to the genetic condition or concern.
- Family rules regarding disclosure of medical information (e.g., some families may not reveal a history of a disease such as cancer or mental illness during the family history assessment).
- Family rules, boundaries, and cultural practices as well as personal preference about knowing genetic information.
- Past coping mechanisms and social support.
- Ability to make an informed decision (e.g., is the patient under stress from family situations, acute or chronic illness, or medications that may impair the patient's ability to make an informed decision?).

Adapted from Consensus Panel on Genetic/Genomic Nursing Competencies (Consensus Panel). (2009). *Essentials of genetic and genomic nursing: Competencies, curricular guidelines, and outcome indicators* (2nd ed.). Silver Spring, MD: Author.

Psychosocial Assessment

Psychosocial assessment is an essential nursing component of the genetics health assessment. The assessment findings can help identify the potential impact of new genetic and genomic information on the patient and the family and how they may cope with this information (Chart 6-6).

Genetic Counseling and Evaluation Services

People seek genetic counseling for various reasons and at different stages of life. Some are seeking preconception or prenatal information, others are referred after the birth of a child with a birth defect or suspected genetic condition, and still others are seeking information for themselves or their families because of the presence of, or a family history of, a genetic condition. Regardless of the timing or setting, genetic counseling is offered to all people who have questions about genetics or genomics and their health.

As the contribution of genetics and genomics to the health–illness continuum is recognized, genetic counseling will become a responsibility of all health care professionals in clinical practice. Nurses are in an ideal position to assess the patient's health and genetics family history and to make referrals for specialized diagnosis and treatment. They offer anticipatory guidance by explaining the purpose and goals of a referral. They collaborate with other health care providers in giving support and follow-up counseling; additionally, they coordinate follow-up and case management.

Genetic Services

Genetic services provide genetic information, education, and support to patients and families. Medical geneticists, genetic counselors, and advanced practice nurses in genetics provide specific genetics services to patients and families who are referred by their primary or specialty health care providers. A team approach is often used to obtain and interpret complex family history information, evaluate and diagnose genetic conditions, interpret and discuss complicated genetic test results, support patients throughout the evaluation process, and offer professional and family support. Patients participate as team members and decision makers throughout the process. Genetics services enable patients and their families to learn and understand relevant aspects of genetics and genomics, to make informed health decisions, and to receive support as they integrate personal and family genetic and genomic information into daily living.

Genetic counseling may take place over an extended period and may entail more than one counseling session, which may include other family members. The components of genetic counseling are outlined in Chart 6-7. Although genetic counseling may be offered at any point during the lifespan, counseling issues are often relevant to the life stage in which counseling is sought (CDC, 2018b). Examples are presented in Chart 6-8.

Providing Precounseling Information

All genetic specialists, including nurses who participate in the genetic counseling process and those with access to a person's genetic information, must honor a patient's desire for confidentiality. Genetic information should not be revealed to family members, insurance companies, employers, and schools if the patient so desires, even if keeping the information confidential is difficult.

Preparing the patient and the family, promoting informed decision making, and obtaining informed consent are essential in genetic counseling. Nurses assess the patient's capacity and ability to give voluntary consent. This includes assessment of factors that may interfere with informed consent, such as hearing loss, language differences, cognitive impairment, and the effects of medication. Nurses make sure that a person's decision to undergo testing is not affected by coercion, persuasion, or manipulation. Because information may need to be repeated over time, nurses offer follow-up discussion as needed (ANA 2017; Consensus Panel, 2009).

The genetic service to which a patient or a family is referred for genetic counseling will ask the nurse for background information for evaluation. Genetic specialists need to know the reason for referral, the patient's or family's reason for seeking genetic counseling, and potential genetic-related health concerns. For example, a nurse may refer a family with a new diagnosis of hereditary breast or ovarian cancer for counseling or to discuss the likelihood of developing the disease and the implications for other family members. The family may have concerns about confidentiality and privacy. The nurse and the genetic specialist tailor the genetic counseling to respond to these concerns.

With the patient's permission, genetic specialists will request the relevant test results and medical evaluations. Nurses obtain permission from the patient and, if applicable, from other family members to provide medical records that document the genetic condition of concern. In some situations, evaluation of more than one family member may be necessary to establish a diagnosis of a genetic disorder. Nurses explain that the

medical information is needed to ensure that appropriate information and counseling (including risk interpretation) are provided.

Chart 6-7

Components of Genetic Counseling

Information and Assessment Sources

- Reason for referral
- Family history
- Medical history/records
- Relevant test results and other medical evaluations
- Social and emotional concerns
- Relevant cultural, educational, and financial factors

Analysis of Data

- Family history
- Physical examination as needed
- Additional laboratory testing and procedures (e.g., echocardiogram, ophthalmology, or neurologic examination)

Communication of Genetic Finding

- Natural history of disorder
- Pattern of inheritance
- Reproductive and family health issues and options
- Testing options
- Management and treatment issues

Counseling and Support

- Identify individual and family questions and concerns
- Identify existing support systems
- Provide emotional and social support
- Refer for additional support and counseling as indicated

Follow-Up

- Written summary to referring primary providers and family
- Coordination of care with primary providers and specialists
- Additional discussions of test results or diagnosis

Genetics Resources

Genetic and Rare Diseases Information Center: provides links with experienced information specialists who can answer questions in English and Spanish to patients, families, and health care providers regarding specific genetic diseases, rarediseases.info.nih.gov

Genetics Home Reference: provides a layman's online encyclopedic guide to understanding genetic conditions, ghr.nlm.nih.gov

National Human Genome Research Institute, Genome Statute and Legislative Database: summarizes each state's legislation on employment and insurance discrimination, www.genome.gov/about-genomics/policy-issues/Genome-Statute-Legislation-Database

National Organization for Rare Disorders (NORD): a directory of support groups and information for patients and families with rare genetic disorders, rarediseases.org

Online Mendelian Inheritance in Man (OMIM): a complete listing of inherited genetic conditions, omim.org

The genetic service asks nurses about the emotional and social status of the patient and the family. Genetic specialists want to know the coping skills of patients and families who have recently learned of the diagnosis of a genetic disorder as well as what type of genetic information is being sought. Nurses help identify cultural and other issues that may influence how information is provided and by whom. For example, for patients with hearing loss, a sign interpreter's services may have to be arranged. For those with vision loss, alternative forms of communication may be necessary. Genetics professionals prepare for the genetic counseling and evaluation with these relevant issues in mind (CDC, 2018b).

Chart 6-8

Genetic Counseling across the Lifespan

Prenatal Issues

- Understanding prenatal screening and diagnosis testing
- Implications of reproductive choices
- Potential for anxiety and emotional distress
- Effects on partnership, family, and parental–fetal bonding

Newborn Issues

- Understanding newborn screening results
- Potential for disrupted parent–newborn relationship on diagnosis of a genetic condition
- Parental guilt
- Implications for siblings and other family members
- Coordination and continuity of care

Pediatric Issues

- Caring for children with complex medical needs
- Coordination of care
- Potential for impaired parent–child relationship
- Potential for social stigmatization

Adolescent Issues

- Potential for impaired self-image and decreased self-esteem
- Potential for altered perception of family
- Implications for lifestyle and family planning

Adult Issues

- Potential for ambiguous test results
- Identification of a genetic susceptibility or diagnosis without an existing cure
- Effect on marriage, reproduction, parenting, and lifestyle
- Potential impact on insurability and employability

(Eds.). (2015). *Lashley's essentials of clinical genetics in nursing practice* (pp. 65–114). New York: Springer Publishing Company.

Preparing Patients for Genetics Evaluation

Before a genetic counseling appointment, the nurse discusses with the patient and the family the type of family history information that will be collected during the consultation. Family history collection and analysis are comprehensive and focus on information that may be relevant to the genetics- or genomics-related concern in question. The genetic analysis always includes assessment for any other potentially inherited conditions for which testing, prevention, and treatment may be possible.

A physical examination may be performed by the medical geneticist to identify specific clinical features commonly associated with a genetic condition. The examination also helps determine if further testing is needed to diagnose a genetic disorder. This examination generally involves assessment of all body systems, with a focus on specific physical characteristics. Nurses describe the diagnostic evaluations that are part of a genetics consultation and explain their purposes.

Communicating Genetic and Genomic Information to Patients

After the family history and the physical examination are completed, the genetics team reviews the information gathered before beginning genetic counseling with the patient and the family. The genetic specialists meet with the patient and the family to discuss their findings. If information gathered confirms a genetic condition in a family, genetic specialists discuss with the patient the natural history of the condition, the pattern of inheritance, and the implications of the condition for reproductive and general health. When appropriate, specialists also discuss relevant testing and management options.

Providing Support

The genetics team provides support throughout the counseling session and identifies personal and family concerns. Genetic specialists use active listening to interpret patient concerns and emotions, seek and provide feedback, and demonstrate understanding of those concerns. They suggest referral for additional social and emotional support. In addition, genetic specialists discuss pertinent patient and family concerns and needs with nurses and primary health care teams so that they can provide additional support and guidance (CDC, 2018b). Nurses assess the patient's understanding of the information given during the counseling session, clarify information, answer questions, assess patient reactions, and identify support systems.

Follow-Up After Genetic Evaluation

As a follow-up to genetic evaluation and counseling, genetic specialists prepare a written summary of the evaluation and counseling session for the patient and, with the patient's consent, send this summary to the primary provider as well as other providers identified by the patient as participants in care. The consultation summary outlines the results of the family history and physical and laboratory assessments, provides a discussion of any specific diagnosis made, reviews the inheritance and associated risk of recurrence for the patient and the family, presents reproductive and general health options, and makes recommendations for further testing and management. The nurse reviews the summary with the patient and identifies information, education, and counseling for which follow-up genetic counseling may be useful (ANA, 2017).

Follow-up genetic counseling is always offered because some patients and families need more time to understand and discuss the specifics of a genetic test or diagnosis, or they may wish to review reproductive options again later, when pregnancy is being considered. Follow-up counseling is also offered to patients when further evaluation and counseling of extended family members is recommended (ANA, 2017).

During follow-up sessions, nurses can educate patients about sources of information related to genetic and genomic issues. Some resources that provide the most up-to-date and reliable genetic and genomic information are available on the Internet (see the Resources section at the end of this chapter).

Genetics and Genomics Tomorrow

The pace of genetic and genomic research is transforming our understanding of the role of genetics and genomics in health and disease. In addition, it is increasing clinical opportunities for presymptomatic prediction of illness based on a patient's genetic makeup. Genetic research is now focused on identifying the genetic and environmental causes of common diseases such as diabetes, heart disease, and asthma. The studies are opening the doors for many advances in the prevention and treatment of both rare and common diseases (NIH, NHGRI, 2019c). Genetic testing as a part of palliative care is being discussed as having the potential to inform future generations of genetic health risk (Morrow, Jacobs, Best, et al., 2018). For example, a person dying of a rare cancer may biobank a DNA sample that could be helpful to future generations as research and technology advances to treat that specific illness. Additionally, advances are ongoing in the microbiome, the genetic

structure of the gut, which is now known to play a key role in many absorption and malabsorption disorders (Greathouse, Faucher, & Hastings-Tolsma, 2017; Sun, 2018). In addition, alterations to the telomere, the end unit or cap on each chromosome, referred to as telomeropathies, is providing insight to understanding the molecular mechanism of rare genetic disorders (Armando, Gomez, Maggio, et al., 2019).

As applications of genetics and genomics to health and disease develop, genetic testing may be used to scan all of a patient's genetic material so that disease risk variants can be identified and early interventions and treatments can be determined. It is estimated that the cost of testing a patient's entire genome is less than $1000. Personalized medicine will continue to expand, and many treatments and interventions for medical conditions will be chosen on the basis of what genetic testing indicates about a patient's genetic makeup. Nurses will be on the front line in communicating genetic and genomic information to patients, families, and communities. Patients, families, and communities will also expect that health care providers, including nurses, will use new genetic and genomic information and technologies in the provision of care. It is, therefore, imperative that all nurses become fluent in the language of genetics and genomics so that they can provide effective nursing care (ANA 2017; Consensus Panel, 2009).

CRITICAL THINKING EXERCISES

1 ipc A 34-year-old male reports urinary difficulty. Following a medical examination and subsequent laboratory work, he is diagnosed with early stages of kidney failure. After a further, more extensive workup, he is diagnosed with polycystic kidney disease, an autosomal dominant disorder. You work as a nurse in the nephrology clinic where he is now being treated. How should this inheritance pattern be explained to the patient? Utilizing knowledge of the inheritance pattern, whom should you include as part of the family assessment of this patient as it relates to this genetic condition? What comorbidities should you be alert to and include in future assessments? Understanding the progressive nature of this illness, what additional members of the health care team should be included in the care of this patient?

2 pq You work as a nurse in a family practice office setting. Linda, the mother of three children, tells you during a well-child physical that her 2-year-old son tends to have bleeding gums. She relates this to aggressive brushing because he is still learning how to brush his teeth. Through further questioning, you begin to suspect that the child may have hemophilia A, an X-linked recessive disorder. Based on the inheritance pattern of X-linked recessive disorders, what would be critical to know in this family history? Linda states that she has a brother who has two daughters, ages 9 and 12, and she has a sister with an infant son. Her father died when she was young and sadly, she doesn't recall much about his family history. Her mother is 77 years of age and has rheumatoid arthritis. How could you use knowledge of the inheritance pattern to guide the care of Linda and her family? Create a three-generation pedigree to determine if anyone else in the family should be screened for hemophilia.

3 ebp A 50-year-old female is being screened in the neurology clinic where you work for progressive neurologic impairment and physical decline. Through DNA analysis and chromosomal testing, a diagnosis of Huntington chorea is made. This illness has an autosomal dominant inheritance pattern. What is the best evidence you find to guide the care of this patient and her family? What ethical concerns must be taken into consideration when caring for a patient with this genetic disorder? This patient has two daughters who are 17 and 20 years of age. Should the age of her daughters have an impact as to whether or not they should have genetic testing?

7 Disability and Chronic Illness

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Compare and contrast the concepts of disability, chronic illness, and chronic disease.
2. Differentiate between models of disability.
3. Critically analyze the influence of disability on nursing care decisions and actions for patients.
4. Identify factors related to the increasing incidence of chronic conditions.
5. Describe characteristics of chronic conditions and nursing implications for people with chronic conditions and for their families.

NURSING CONCEPTS

Development
Diversity
Health Promotion and Legal Issues
Health, Wellness, and Illness

GLOSSARY

chronic disease: medical or health problem with associated symptoms or disabilities that require long-term management; also referred to as noncommunicable disease, chronic condition, or chronic disorder

chronic illness: the experience of living with a chronic disease or condition; the person's perception of the experience and the person's and others' responses to the chronic disease or condition

cognitive disability: limitations in mental functioning and difficulties with communication, self-care, and social skills

developmental disability: a set of heterogeneous disorders characterized by difficulties in one or more domains; can include cognitive, physical, or both cognitive and physical impairments with an onset before 22 years of age

disability: restriction or lack of ability to perform an activity in a normal manner; the consequences of impairment in terms of a person's functional performance and activity—disability represents impairment at the level of the person (e.g., bathing, dressing, communication, walking, grooming)

intellectual disability: a disability that occurs before 18 years of age characterized by significant limitations in both intellectual functioning and in adaptive behavior, which includes many everyday social and practical skills

multiple chronic conditions (MCC): presence of more than one chronic disease or condition

noncommunicable diseases: a group of conditions that are not caused by an acute infection

secondary health conditions or disorders: any physical, mental, or social disorders resulting directly or indirectly from an initial disabling condition

sensory disability: a disorder characterized by impairment of the sense of sight, hearing, smell, touch, or taste (e.g., hearing loss, deafness, vision loss, blindness)

Disability and chronic illness affect people of all ages—the very young, the middle aged, older adults, and the very old. Disability and chronic illness are found in all ethnic, cultural, racial, and socioeconomic groups, although some disorders occur more frequently in some groups than in others. Nurses in all settings will encounter patients with disability and chronic illness. This chapter presents concepts about disability and chronic illness and ways that nurses can address the health issues of these patients and their families.

Disability

Definitions of Disability

A person is considered to have a **disability** (limitation in performance or function in everyday activities) if they have difficulty talking, hearing, seeing, walking, climbing stairs, lifting or carrying objects, performing activities of daily living (ADLs), such as feeding oneself, bathing, dressing, grooming, toileting, doing school work, or working at a job. A severe disability is present if a person is unable to perform one or more activities, uses an assistive device for mobility, or needs help from another person to accomplish basic activities. People are also considered severely disabled if they receive federal benefits because of an inability to work.

According to the World Health Organization (WHO, 2018a), *disability* is the interaction between individuals with a health condition (e.g., cerebral palsy, spinal cord injury, Down syndrome) personal and environmental factors (e.g., negative attitudes on the part of society, inaccessible transportation and public buildings, and limited social supports). In 2001, WHO developed the International Classification of Functioning, Disability and Health (ICF), which defined disability as an umbrella term for impairments, activity limitations, participation restrictions, and environmental factors.

The term *impairment* describes a loss or abnormality in body structure or physiologic function, including mental function. The term *societal participation* is used in the WHO classification system in place of *handicap* to acknowledge the fact that the environment is always interacting with people to either assist or hinder participation in life activities. The environment may have a greater impact on a person's ability to participate in life activities than do physical, mental, or emotional factors or conditions (WHO, 2018a).

In the United States, federal legislation uses multiple definitions of disability, which makes common understanding of disability difficult. The Americans With Disabilities Act of 1990 (ADA; discussed later in this chapter) defines a person with a disability as one who (1) has a physical or mental impairment that substantially limits one or more major life activities, (2) has a record of such an impairment, or (3) is regarded as having such an impairment. Other phrases used to describe people with disabilities that are not universally accepted, understood or recommended are "people who are physically challenged" and "people with special needs."

Prevalence of Disability

According to the WHO (2018a), over one billion people, or about 15% of the global population, have some type of disability. Between 110 and 190 million adults worldwide have significant difficulties in function due to disability. The number of people with disabilities is increasing and is expected to continue to climb as people with early-onset disability, chronic disorders, and severe

trauma survive. People with disability comprise the world's largest minority (United Nations, n.d.).

The Centers for Disease Control and Prevention (CDC, 2017) reported that in 2016, one in four noninstitutionalized adults, or 61 million adults in the United States, had a disability that negatively affected major life activities. This reflects an increase from 2013 in which one in five noninstitutionalized adults in the United States had a disability (Okoro, Hollis, Cyrus, et al., 2018). The estimate is likely low as these figures do not include people who are living in institutions or are active duty military personnel.

The last U.S. Census indicated that more than 46% of people with one disability have other disabilities. Although the prevalence of disability is higher in men than in women for people younger than 65 years, the prevalence is higher in women than in men for people older than 65 years (U.S. Census Bureau, 2018a). In the United States, the prevalence of disability is higher among American Indians as well as Alaska Natives, adults with incomes below the federal poverty level, and people living in the southwestern U.S. census region (Okoro et al., 2018). In addition, the prevalence of disability in the United States is higher for African Americans and Whites than for Hispanics and Asians (U.S. Department of Labor, Bureau of Labor Statistics, 2019). Globally, more than 80% of the one billion people worldwide with disability live in low- and middle-income countries, in which all people have limited access to basic health care and social services. However, limited access to basic health care and support services has a more profound effect on those with disability.

The proportion of individuals with disability employed in 2018 was 19.1%. In contrast, 65.9% of those without disability were employed. About 8 in 10 people with a disability were not in the labor force in 2018, compared to about 3 in 10 of those with no disability. Individuals with disability are more likely to be employed part time than those with no disability. These discrepancies exist across all educational attainment groups (U.S. Department of Labor, Bureau of Labor Statistics, 2019). A consequence of lack of employment or only part-time employment is that those with a disability earn less money than people without disabilities. Low income along with limited access to basic health care and support services has a profound effect on those with disability. In 2017, the poverty rate of those individuals of working age, generally considered 18 to 64 years, with disability was 29.6%. In contrast, the poverty rate in 2017 of those without disability was 13.2% (Houtenville & Boege, 2019). See Chart 7-1 for a summary of additional facts about people with disabilities.

Characteristics of Disability

The characteristics of disability include an understanding of the categories, types, and models of disability. Additional characteristics include understanding the broad concept of disability.

Categories and Types of Disability

There are many categories and types of disabilities that include cognitive, developmental, intellectual, sensory, acquired, psychiatric, and physical. A **cognitive disability** is defined as limitations in mental functioning and difficulties with communication, self-care, and difficulty with social skills.

Developmental disabilities are those that occur any time from birth to 22 years of age and result in impairment of physical or mental health, cognition, speech, language, or self-care. This is an umbrella term that includes intellectual disabilities but can be a physical disability only. Examples of developmental disabilities include spina bifida, cerebral palsy, Down syndrome, muscular dystrophy, dwarfism, and osteogenesis imperfecta. Some developmental disabilities occur as a result of birth trauma or severe illness or injury at a very young age, whereas many developmental disabilities are genetic in origin (see Chapter 6). Some developmental disabilities overlap with cognitive and/or intellectual disabilities that affect intellectual functioning and adaptive behavior. An **intellectual disability** occurs before 18 years of age and is characterized by significant limitations in both intellectual functioning as well as in adaptive behavior, including many everyday social and practical skills. Because individuals with developmental and intellectual disabilities are living well into adulthood and aging with a disability, all nurses and other health care providers will encounter them in practice and must be knowledgeable and prepared to provide high quality health care.

Chart 7-1

Summary of Facts About People with Disability

- Approximately 61 million people in the United States have a disability, or one in every four people.
- The prevalence of disabilities in adults is approximately 10% of people 18–64 years of age and 38% of adults 65 years of age and older.
- The prevalence of disabilities varies by state and by gender, with higher prevalence in the South and among females.
- More than 11 million people with disabilities require personal assistance with everyday activities (e.g., getting around inside the home, bathing or showering, preparing meals, and performing light housework).
- Approximately 3.3 million people use a wheelchair; another 10 million use a walking aid such as cane, crutches, or walker.
- More than 1.8 million people report being unable to see printed words because of vision impairment, 1 million are unable to hear conversations because of hearing impairment, and 2.5 million have difficulty with their speech being understood.
- More than 16 million people have limitations in cognitive function or have a mental or emotional illness that interferes with daily activities, including those with Alzheimer's disease and intellectual disabilities.
- Self-reported health status among adults with disabilities differs from that of people without disabilities, with fewer people with disabilities describing their health as excellent or good.
- The percentage of people with disabilities who are employed ranges from 17.8% to 23.4%; of those without disabilities, the percent ranges from 63.5% to 66.2%.
- Among all age groups, people with a disability are much less likely to be employed than those without a disability. People with a disability who work are more likely than those without disability to work part time. People with a disability who were not in the labor force (neither employed nor unemployed) are about 8 in 10, compared with about 3 in 10 of those without a disability.
- Many people with disabilities would like to work but are hampered in doing so by limited access, lack of accommodations in the workplace, lack of transportation, and reluctance of employers to hire them.
- The percentage of people with disabilities below the poverty level is more than twice that of people without disabilities.

A sensory disability is characterized by impairment of the sense of sight, hearing, smell, touch, and/or taste. Sensory disabilities most commonly affect hearing or vision; however, they also include learning disabilities that affect the ability to learn, remember, or concentrate; disabilities that affect the ability to speak or communicate; and disabilities that affect the ability to work, shop, and care for oneself, or access health care. Risks associated with sensory disabilities include isolation, reduced cognitive function, poor physical and psychological health, and increased risk of falls and hospitalization (McKee, 2019).

Psychiatric disability is defined as a mental illness or impairment that substantially limits one's ability to complete major life activities, such as learning, working, and communicating (WHO, 2018b). Although psychiatric disability and mental health disorders are not the focus of this chapter, it is important to note that a person may have more than one type of disability at the same time, requiring health care providers to be prepared to care for patients with several types of disabilities.

Whether a disability is cognitive, developmental, intellectual, physical, or sensory it may also be characterized as acquired. Acquired disabilities may occur as a result of an acute and sudden injury (e.g., traumatic brain injury [TBI]; spinal cord injury; and traumatic amputation due to traffic crashes, falls, burns, or acts of violence such as intimate partner violence and war and military conflicts), acute nontraumatic disorders (e.g., stroke, myocardial infarction), or progression of a chronic disorder (e.g., arthritis, multiple sclerosis, Parkinson's disease, chronic obstructive pulmonary disease, heart disease, blindness due to diabetic retinopathy).

Many disabilities are visible; however, invisible disabilities are often as disabling as those that can be seen. Some disabilities affect only instrumental activities of living (IADLs), such as shopping for food, doing laundry, housekeeping, and handling financial matters. Other disabilities affect ADLs only. People can be temporarily disabled because of an injury or acute exacerbation of a chronic disorder but later return to full functioning.

A common challenge for people with disability is the need to hire and oversee caregivers who come into their homes to assist with ADLs and IADLs. For many, it is difficult to be in a position of hiring, supervising, and sometimes firing people who may provide them with intimate physical care. The need to balance the roles of receiving care and overseeing the person providing that care may lead to blurring of role boundaries.

Many people with disabilities are at risk for **secondary health conditions** (e.g., pressure injuries, urinary tract infections, low bone density, depression) because of a narrow margin of health. Many of these conditions are predictable and with treatment are preventable with appropriate assessment for risk, prevention and treatment strategies (WHO, 2018a). Some conditions can be both primary and secondary conditions depending on circumstances. For example, a mobility disability could lead to social isolation and absence of participation in activities. This in turn could lead to depression as a secondary condition (Krahn, 2019). Comorbidities (e.g., cardiac disease, cancer, hearing loss) are not due to disability and thus can occur in those with or without disability.

Although different impairments may result from different types of disabilities, there are some similarities across disabilities. People with disabilities are often considered by society to be dependent and needing to be cared for by others; however, many people with disabilities are highly functioning, independent, productive people who are capable of caring for themselves and others, having children and raising families, holding full-time jobs, and making significant and major contributions to society. Like other people, most individuals with disabilities prefer to live in their own homes with family members. Most of them are able to live at home independently. Some individuals with disabilities live alone in their own homes and use home care services. However, alternative living arrangements may be necessary; these include assisted living facilities, long-term care facilities, and group homes.

Chart 7-2

Models of Disability

Medical Model

The Medical Model equates people who are disabled with their disabilities and views disability as a problem of the person, directly caused by disease, trauma, or other health condition, that requires medical care provided in the form of individual treatment by professionals. Health care providers, rather than people with disabilities, are viewed as the experts or authorities. Management of the disability is aimed at cure or the person's adjustment and behavior change. The model is viewed as promoting passivity and dependency. People with disabilities are viewed as tragic.

Rehabilitation Model

The Rehabilitation Model emerged from the medical model. It regards disability as a deficiency that requires a rehabilitation specialist or other helping professional to fix the problem. People with disabilities are often perceived as having failed if they do not overcome the disability.

Social Model

The Social Model, which is also referred to as the barriers or disability model, views disability as socially constructed and as a political issue that is a result of social and physical barriers in the environment. Its perspective is that disability can be overcome by removal of these barriers.

Biopsychosocial Model

The Biopsychosocial Model integrates the medical and social models to address perspectives of health from a biologic, individual, and social perspective. Critiques of this model have suggested that the disabling condition, rather than the person and the experience of the person with a disability, remains the defining construct of the Biopsychosocial Model.

Functional Model

The Functional Model is driven by the World Health Organization's *International Classification of Functioning, Disability and Health* (*ICF*). Disability is considered an umbrella term for impairments, activity limitations, participation restrictions, and their interaction with environmental factors. The ICF addresses components of health rather than consequence of disease.

Interface Model

The Interface Model is based on the life experience of the person with a disability and views disability at the intersection (i.e., interface) of the medical diagnosis of a disability and environmental barriers. It considers rather than ignores the diagnosis. The person with a disability, rather than others, defines the problems and seeks or directs solutions.

Other Models of Disability

Other models include the Identity Model (views disability as a positive rather than negative identity), the Human Rights Model (emphasizes the human dignity of individuals with disability and policy change), the Cultural Model (focuses on different views of disability within the context of a specific culture), the Charity Model (encourages humane treatment of people with disabilities, but views people with disabilities as victims of their impairment), and the Economic Model (approaches disability from the perspective of the ability of people with disabilities to work and contribute to society). Each of these models introduces elements that affect how individuals with disability are perceived and, as a result, how they are treated. Therefore, the underlying views and implications suggested by each model need to be examined and critiqued. Importantly, an analysis of these models helps promote introspection and discussion of the concept of disability.

Models of Disability

Several models of disability have been used to address or explain the issues encountered by people with disabilities. Chart 7-2 describes several models of disability. The Interface Model (Goodall, 1995), developed by a nurse, promotes care designed to be empowering rather than care that promotes dependency. It takes into account the disabling condition and its disabling effects. Furthermore, it promotes the view that people with disabilities are capable, responsible people who are able to function effectively despite having a disability. The Interface Model can serve as a basis for the role of nurses as advocates for the removal of barriers to health care and for the examination of how society and health care professionals contribute to discrimination by viewing disability as an abnormal state. Several other models of disability exist and serve as a guide for reflection on what disability means as well as its antecedents and outcomes (Retief & Letšosa, 2018).

Disability versus Disabling Disorders

Regardless of which definition or model of disability is adopted, it is important to realize that one can understand xthe pathophysiology and physical changes related to a disabling condition or injury without understanding the concept of disability. The nurse caring for patients with preexisting disabilities or new disabilities must recognize the impact of a disability on patients' well-being and their current and future health, their ability to participate in self-care or self-management, and their ability to obtain required health care and recommended health screening. Nursing management—from assessment through evaluation of the effectiveness of nursing interventions—must be monitored frequently to ensure that appropriate modifications have been made so that people with disabilities can receive health care equal to that of people without disabilities. Furthermore, nurses as well as other health care providers need to examine their facilities and procedures to ensure that the needs of people with various disabilities can be adequately addressed. Although the health care needs of people with disabilities generally do not differ from those of the general population, some disabilities create special needs and necessitate the use of special accommodations. Chart 7-3 reviews questions to ask to ensure quality health care for people with disabilities.

Chart 7-3

Questions to Ask to Ensure Quality Health Care for People with Disability

Communication Strategies

- Does the patient with a disability require or prefer accommodations (e.g., a sign language interpreter) to ensure full participation in conversations about their health care?
- Are appropriate accommodations made to communicate with the patient?
- Are efforts made to direct all conversations to the patient rather than to others who have accompanied the patient to the health care facility?
- Is appropriate language (people-first language) used in referring to the patient?

Accessibility of the Health Care Facility

- Are clinics, hospital rooms, offices, restrooms, laboratories, and imaging facilities accessible to people with disabilities, as legally required by the Americans With Disabilities Act and Rehabilitation Act?
- Has accessibility been verified by a person with a disability?
- Is a sign language interpreter other than a family member available to assist in obtaining a patient's health history and in conducting a physical assessment?
- Does the facility include appropriate equipment to permit people with disabilities to obtain health care (including mammography, gynecologic examination and care, dental care) in a dignified and safe manner?

Assessment

Usual Health Considerations

- Does the health history address the same issues that would be included when obtaining a history from a person without disabilities, including recent preventive health screening, sexuality, sexual function, and reproductive health issues?

Disability-Related Considerations

- Does the health history address the patient's specific disability and the effect of disability on the patient's ability to obtain health care, manage self-care activities, and obtain preventive health screening and follow-up care?
- What physical modifications and positioning are needed to ensure a thorough physical examination, including pelvic or testicular and rectal examination?

Abuse

- Is the increased risk for abuse (physical, emotional, financial, and sexual) by various people (family, paid care providers, strangers) addressed in the assessment?

- If abuse is detected, are men and women with disability who are survivors of abuse directed to appropriate resources, including accessible shelters and hotlines?

Depression

- Is the patient experiencing depression? If so, is treatment offered just as it would be to a patient without a disability, without assuming that depression is normal and a result of having a disability?

Aging

- What concerns does the patient have about aging with a preexisting disability?
- What effect has aging had on the patient's disability, and what effect has the disability had on the patient's aging?

Secondary Health Conditions

- Does the patient have secondary health conditions related to their disability or its treatment?
- Is the patient at risk for secondary health conditions because of environmental barriers or lack of access to health care or health promotion activities?
- Are strategies in place to reduce the risk for secondary health conditions or to treat existing secondary health conditions?

Accommodations in the Home

- What accommodations does the patient have at home to encourage or permit self-care?
- What additional accommodations does the patient need at home to encourage or permit self-care?

Cognitive Status

- Is it assumed that the patient is able to participate in discussion and conversation rather than assuming that they are unable to do so because of a disability?
- Are appropriate modifications made in written and verbal communication strategies?

Modifications in Nursing Care

- Are modifications made during hospital stays, acute illness or injury, and other health care encounters to enable a patient with disability to be as independent as they prefer?
- Is "people-first language" used in referring to a patient with disability, and do nurses and other staff talk directly to the patient rather than to those who accompanied the patient?
- Are all staff informed about the activities of daily living for which the patient will require assistance?

- Are accommodations made to enable the patient to use his or her assistive devices (hearing/visual aids, prostheses, limb support devices, ventilators, service animals)?
- If a patient with disability is immobilized because of surgery, illness, injury, or treatments, are risks of immobility addressed and strategies implemented to minimize those risks?
- Is the patient with a disability assessed for other illnesses and health issues (e.g., other acute or chronic illness, depression, psychiatric-mental health, cognitive disorders) not related to the primary disability?

Patient Education

- Are accommodations and alternative formats of instructional materials (large print, Braille, visual materials, audiotapes) provided for patients with disabilities?
- Does patient instruction address the modifications (e.g., use of assistive devices) needed by patients with disabilities to enable them to adhere to recommendations?
- Are modifications made in educational strategies to address learning needs, cognitive changes, and communication impairment?

Health Promotion and Disease Prevention

- Are health promotion strategies discussed with people with disabilities along with their potential benefits: improving quality of life and preventing secondary health conditions (health problems that result because of preexisting disability)?
- Are patients aware of accessible community-based facilities (e.g., health care facilities, imaging centers, public exercise settings, transportation) to enable them to participate in health promotion?

Independence versus Dependence

- Is independence, rather than dependence, of the patient with a disability the focus of nursing care and interaction?
- Are care and interaction with the patient focused on empowerment rather than promoting dependence of the patient?
- Is the patient aware of available resources and supports and do they know how to access them?

Insurance Coverage

- Does the patient have access to the health insurance coverage and other services for which they qualify?
- Is the patient aware of various insurance and other available programs?
- Would the patient benefit from talking to a social worker about eligibility for Medicaid, Medicare, disability insurance, and other services?

Federal Legislation

Because of widespread discrimination against people with disabilities, the U.S. Congress has enacted legislation to address health care disparities in this population. This legislation includes the Rehabilitation Act of 1973 and the ADA. The Rehabilitation Act of 1973 protects people from discrimination based on their disability. This act applies to employers and organizations that receive financial assistance from any federal department or agency, including many hospitals, long-term care facilities, mental health centers, and human service programs. It forbids organizations from excluding or denying people with disabilities equal access to program benefits and services. It also prohibits discrimination related to availability, accessibility, and delivery of services, including health care services.

The ADA, implemented in 1990, mandates that people with disabilities have access to job opportunities and to the community without discrimination based on having a disability. The ADA also requires that "reasonable accommodations" be provided for transportation and to facilitate employment of a person with a disability. Examples of reasonable accommodations in health care settings include accessible facilities and equipment (e.g., accessible restrooms, adjustable examination tables, access ramps, grab bars, elevated toilet seats) and alternative communication methods (e.g., telecommunication devices and sign language interpreters for use by people who are deaf). Failure to make reasonable accommodations can result in poor care for patients with disabilities. For example, lack of accommodation for people who have hearing loss or are deaf can lead to failed communication and inadequate sharing of important information between them and their health care providers (McKee, 2019).

Although the ADA took effect in 1992, compliance has been slow, and some facilities continue to be inaccessible although all new construction and modifications of public facilities must address access for people with disabilities. Because some courts previously interpreted the definition of disability in the ADA so narrowly that few people could meet it, the ADA Amendments Act was signed into law in 2008 and enacted in January 2009 (U.S. Department of Justice, 2009). The act broadly defines *disability* to encompass impairments that substantially limit a major life activity. This wording states that effective use of assistive devices, auxiliary aids, accommodations, medical therapies, and supplies (other than eyeglasses and contact lenses) does not alter the determination of whether a disability qualifies under the law. The purpose of these amendments was to cover more people and to shift the attention from focusing on who has a disability to making accommodations and avoiding discrimination.

Right of Access to Health Care

People with disabilities have the right of access to health care that is equal in quality to that of other people. The United Nations Convention on the Rights of Persons with Disabilities (CRPD, 2006) identifies the rights of people with disabilities to receive the highest standard of health care, without discrimination. More than 30 years after the passage of the ADA, the United States has not ratified the CRPD. Despite the rights identified by the CRPD and the ADA in the United States, people with disabilities continue to experience health disparities (Kaye, 2019; McClintock, Kurichi, Barg, et al., 2018).

For years, people with disabilities around the world have been discriminated against in employment, public accommodations, and public and private services, including health care (WHO, 2018a). Unmet needs of people with disabilities include but are not limited to medical, dental, and prescription medication needs. The needs of people with disabilities in health care settings present challenges to health care providers: how to communicate effectively if there are communication deficits, how to address the additional physical requirements for mobility, and how to ensure sufficient time to provide assistance with self-care routines during hospitalization. Nurses and other clinicians need to be aware of the specific needs of people with disabilities and to provide appropriate care and services for them. People with disabilities have a legally mandated right to accessible health care facilities for all medical care and screening procedures. Furthermore, they have the right to health care provided by knowledgeable clinicians who are sensitive to the effects of disability on access to health care, including care that addresses their reproductive issues and sexuality. As multiple recent studies have demonstrated, however, improvements are needed to provide women with disabilities with quality care targeting their sexuality and reproductive health care needs (Hayward, Chen, Forbes, et al., 2017; LaPierre, Zimmerman, & Hall, 2017; Mitra, Smith, Smeltzer, et al., 2017; Morris, Maragh-Bass, Griffin, et al., 2017; Tarasoff, 2017).

Figure 7-1 • Examples of inappropriate communication by nurse with young woman with a disability in a wheelchair. The nurse stands instead of sitting at the patient's eye level (**A**) and talks to the patient's mother rather than directly to the patient (**B**).

Reasonable accommodations are mandated by law and are the financial responsibility of the health care provider or facility. People with disabilities should not be expected to provide their own accommodations (e.g., sign language interpreters, assistants). Family members should not be expected to serve as interpreters because of concern for the patient's privacy and confidentiality and the risk of errors in interpreting information by either the patient or the health care provider. Chart 7-4 identifies strategies to communicate effectively with people with disabilities. Figures 7-1A,B and 7-2A,B illustrate inappropriate and appropriate communication, respectively, with a person with a disability who uses a wheelchair or is seated.

Figure 7-2 • Examples of appropriate communication by nurse with young woman with a disability in a wheelchair. **A.** The nurse is sitting at patient's eye level and talks directly to the patient after asking her mother to step out of the room during the history. **B.** The nurse explains to the patient how the examination table moves up and down, which allows the patient to be as independent as possible in moving the table.

In response to continued accessibility issues, the U.S. Surgeon General issued *Call to Action to Improve the Health and Wellness of Persons with Disabilities* (Smeltzer, 2007; U.S. Department of Health and Human Services [HHS], 2005). This report recognized that all people with disabilities need to have access to comprehensive health care so that they are able to have full, engaged, and productive lives in their own communities. Among strategies to accomplish this, the call to action stipulated that health care professionals need to become knowledgeable about disability. It further recommended that schools educating health care professionals educate about disability and address the need for increased availability of methods to screen, diagnose, and treat the whole person with a disability with dignity.

Chart 7-4

Interacting and Communicating with People Who Have Disabilities

Patients will feel most comfortable receiving health care if you consider the following suggestions.

General Considerations

- Do not be afraid to make a mistake when interacting and communicating with someone with a disability or chronic medical condition. Keep in mind that a person with a disability is a person first and is entitled to the dignity, consideration, respect, and rights you expect for yourself.
- Treat adults as adults. Address people with disabilities by their first names only if extending the same familiarity to all others present. Never patronize people by patting them on the head or the shoulder.
- Relax. If you do not know what to do, allow the person who has a disability to identify how you may be of assistance and to put you at ease.
- If you offer assistance and the person declines, do not insist. If your offer is accepted, ask how you can best help, and follow directions. Do not take over.
- If someone with a disability is accompanied by another person, address the person with a disability directly rather than speaking through the accompanying companion.
- Be considerate of the extra time it might take for a person with a disability to get things done or said. Let the person set the pace.
- Do not be embarrassed to use common expressions, such as “See you later” or “Got to be running,” that seem to relate to the person’s disability.
- Use people-first language: Refer to “a person with a disability” rather than “a disabled person” and avoid referring to people by the disability or disorder they have (e.g., “the diabetic”).

Mobility Limitations

- Do not make assumptions about what a person can and cannot do.
- Do not push a person’s wheelchair or grab the arm of someone walking with difficulty without first asking whether you can be of assistance and how you can assist. Personal space includes a person’s wheelchair, scooter, crutches, walker, cane, or other mobility aid.
- Never move someone’s wheelchair, scooter, crutches, walker, cane, or other mobility aid without permission.
- When speaking for more than a few minutes to a person who is seated in a wheelchair, try to find a seat for yourself so that the two of you are at eye level (see Fig. 7-2A,B).

- When giving directions to people with mobility limitations, consider distance, weather conditions, and physical obstacles such as stairs, curbs, and steep hills.
- Shake hands when introduced to a person with a disability. People who have limited hand use or who wear an artificial limb do shake hands.

Vision Loss (Low Vision and Blindness)

- Identify yourself when you approach a person who has low vision or blindness. If a new person approaches, introduce them.
- Touch the person's arm lightly when you speak so that they know to whom you are speaking before you begin.
- Face the person and speak directly to them. Use a normal tone of voice.
- Do not leave without saying that you are leaving.
- If you are offering directions, be as specific as possible and point out obstacles in the path of travel. Use specifics such as "Left about 20 feet" or "Right 2 yards." Use clock cues, such as "The door is at 10 o'clock."
- When you offer to assist someone with vision loss, allow the person to take your arm. This will help you guide rather than propel or lead the person. When offering seating, place the person's hand on the back or the arm of the seat.
- Alert people with low vision or blindness to posted information.
- Never pet or otherwise distract a canine companion or service animal unless the owner has given you permission.

Hearing Loss (Hard of Hearing, Deaf, Deaf–Blind)

- Ask the person how they prefer to communicate.
- If you are speaking through a sign language interpreter, remember that the interpreter may lag a few words behind—especially if there are names or technical terms to be finger spelled—so pause occasionally to allow the interpreter time to translate completely and accurately.
- Talk directly to the person who has hearing loss, not to the interpreter. However, although it may seem awkward to you, the person who has hearing loss will look at the interpreter and may not make eye contact with you during the conversation.
- Before you start to speak, make sure that you have the attention of the person you are addressing. A wave, a light touch on the arm or the shoulder, or other visual or tactile signals are appropriate ways of getting the person's attention.
- Speak in a clear, expressive manner. Do not over enunciate or exaggerate words. Unless you are specifically requested to do so, do not raise your voice. Speak in a normal tone; do not shout.
- To facilitate lip reading, face the person and keep your hands and other objects away from your mouth. Maintain eye contact. Do not turn

your back or walk around while talking. If you look away, the person might assume that the conversation is over.

- Avoid talking while you are writing a message for someone with hearing loss, because the person cannot read your note and your lips at the same time.
- Try to eliminate background noise.
- Encourage feedback to assess clear understanding.
- If you do not understand something that is said, ask the person to repeat it or to write it down. The goal is communication; do not pretend to understand if you do not.
- If you know any sign language, try using it. It may help you communicate, and it will at least demonstrate your interest in communicating and your willingness to try.

Speech Disabilities or Speech Difficulties

- Talk to people with speech disabilities as you would talk to anyone else.
- Be friendly; start up a conversation.
- Be patient; it may take the person a while to answer. Allow extra time for communication. Do not speak for the person.
- Give the person your undivided attention.
- Ask the person for help in communicating with them. If the person uses a communication device such as a manual or electronic communication board, ask the person the best way to use it.
- Speak in your regular tone of voice.
- Tell the person if you do not understand what they are trying to say. Ask the person to repeat the message, spell it, tell you in a different way, or write it down. Use hand gestures and notes.
- Repeat what you understand. The person's reactions will clue you in and guide you to understanding.
- To obtain information quickly, ask short questions that require brief answers or a head nod. Avoid insulting the person's intelligence with oversimplification.
- Keep your manner encouraging rather than correcting.

Intellectual/Cognitive Disabilities

- Treat adults with intellectual/cognitive disabilities as adults.
- Be alert to the person's responses so that you can adjust your method of communication as necessary. For example, some people may benefit from simple, direct sentences or from supplementary visual forms of communication, such as gestures, diagrams, or demonstrations.
- Use concrete rather than abstract language. Be specific, without being too simplistic. When possible, use words that relate to things you both can see. Avoid using directional terms such as right, left, east, or west.

- Be prepared to give the person the same information more than once in different ways.
- When asking questions, phrase them to elicit accurate information. People with intellectual/cognitive disabilities may be eager to please and may tell you what they think you want to hear. Verify responses by repeating the question in a different way.
- Give exact instructions. For example, “Be back for lab work at 4:30,” not “Be back in 15 min.”
- Avoid giving too many directions at one time, which may be confusing.
- Keep in mind that the person may prefer information provided in written or verbal form. Ask the person how you can best relay the information.
- Using humor is fine, but do not interpret a lack of response as rudeness. Some people may not grasp subtleties of language.
- Know that people with brain injuries may have short-term memory deficits and may repeat themselves or require information to be repeated.
- Recognize that people with auditory perceptual problems may need to have directions repeated and may take notes to help them remember directions or the sequence of tasks. They may benefit from watching a task demonstrated.
- Understand that people with perceptual or “sensory overload” problems may become disoriented or confused if there is too much to absorb at once. Provide information gradually and clearly. Reduce background noise if possible.
- Repeat information using different wording or a different communication approach if necessary. Allow time for the information to be fully understood.
- Do not pretend to understand if you do not. Ask the person to repeat what was said. Be patient, flexible, and supportive.
- Be aware that some people who have an intellectual disability are easily distracted. Try not to interpret distraction as rudeness.
- Do not expect all people to be able to read well. Some people may not read at all.

Psychiatric-Mental Health Disabilities

- Speak directly to the person. Use clear, simple communication.
- Offer to shake hands when introduced. Use the same good manners in interacting with a person who has a psychiatric-mental health disability that you would with anyone else.
- Make eye contact and be aware of your own body language. Like others, people with psychiatric-mental health disabilities will sense your discomfort.
- Listen attentively, and wait for the person to finish speaking. If needed, clarify what the person has said. Never pretend to understand.

- Treat adults as adults. Do not patronize, condescend, or threaten. Do not make decisions for the person or assume that you know the person's preferences.
- Do not give unsolicited advice or assistance. Do not panic or summon an ambulance or the police if a person appears to be experiencing a mental health crisis. Calmly ask the person how you can help.
- Do not blame the person. A person with a psychiatric disability has a complex, biomedical condition that is sometimes difficult to control. The person cannot just "shape up." It is rude, insensitive, and ineffective to tell or expect a person to do so.
- Question the accuracy of media stereotypes of psychiatric-mental health disabilities: Movies and media often sensationalize psychiatric-mental health disabilities. Most people never experience symptoms that include violent behavior.
- Relax. Be yourself. Do not be embarrassed if you happen to use common expressions that seem to relate to a psychiatric-mental health disability.
- Recognize that beneath the symptoms and behaviors of psychiatric disabilities is a person who has many of the same wants, needs, dreams, and desires as anyone else. If you are afraid, learn more about psychiatric-mental health disabilities.

Health care in people with disabilities received further national attention through specific national objectives in *Healthy People 2020* (HHS, 2010). The midcourse review of those objectives indicated some improvement in health and health-related outcomes for people with disabilities (Sinclair, Fox, Jonas, et al., 2018). For example, the midcourse review revealed that national goals for health were improved or exceeded for 44.6% of objectives for people without disabilities compared to only 30.6% for people with disabilities (National Center for Health Statistics, 2016). These results indicate that work toward achieving equity in health care for individuals with disability is still needed.

Thirty years after the passage of the ADA in 1990, significant health status and health care disparities persist for people with disabilities. Furthermore, progress has been slow in ensuring that health care professionals receive adequate education about providing quality health care to them.

Barriers to Health Care

People with disabilities often encounter barriers in their daily lives and in their efforts to obtain health care, health promotion, and preventive health screening. For example, structural barriers such as stairs, lack of ramps, and narrow doorways may prevent people who are wheelchair users from entering facilities. Other structural barriers include restroom facilities that lack grab bars or sufficiently large restroom stalls, elevated toilet seats, and accessible sinks (CDC, 2018; WHO, 2018a).

Structural barriers to accessibility are most easily identified and eliminated. Other less visible barriers include negative and stereotypic attitudes (e.g., believing that all people with disabilities have a poor quality of life and are dependent and nonproductive) on the part of the public. Health care providers with similar negative attitudes make it difficult for people with disabilities to obtain health care equal in quality to that of people without disabilities. The Rehabilitation Act and the ADA were passed more than 46 and 30 years ago, respectively, to ensure equal access to people with disabilities; however, people with disabilities continue to encounter and report multiple barriers to health care facilities and providers. This legislation, the U.S. Surgeon General's call to action (HHS, 2005) and the ADA Amendments Act of 2008 are examples of efforts to eliminate barriers encountered by people with disabilities.

People with disabilities have also reported lack of access to information, transportation difficulties, inability to pay because of limited income, difficulty finding a health care provider knowledgeable about their particular disability, previous negative health care encounters, reliance on caregivers, and the demands of coping with the disability itself (HHS, 2005). These issues affect both men and women with severe disabilities; however, women are at higher risk for receiving a lower level of health care than men. Women with disabilities are significantly less likely to receive pelvic examinations than women without disabilities; the more severe the disability, the less frequent the examination. In particular, minority women and older women with disabilities are less likely to have regular pelvic examinations and Papanicolaou (Pap) tests. Reasons given by women for not having regular pelvic examinations are difficulty transferring on to the examination table, belief that they do not need pelvic examinations because of their disability, difficulty in accessing the office or the clinic, and difficulty finding transportation (HHS, 2005). Health care providers often underestimate the effect of disabilities on women's ability to access health care, including health screening and health promotion, and they focus on women's disabilities while ignoring women's general health issues and concerns. Furthermore, women with disabilities have reported lack of knowledge about disability and insensitivity on the part of health care providers.

Individuals with disabilities living in rural settings also face barriers associated with having fewer resources and less access to care than those

living in larger communities or urban settings. Therefore, establishing and maintaining involvement in their community can help ensure that they remain active and connected to others living around them, as described by Thurman, Harrison, and Walker (2019) (see the Nursing Research Profile in Chart 7-5). Additionally, those living in rural areas are less likely to have many types of recommended screenings (Goyat, Vyas, & Sambamoorthi, 2016; Magaña, Parish, Morales, et al., 2016; WHO, 2018a, 2018b).

Costs of care continue to be a factor in delaying or forgoing health care despite changes brought about by legislation, including the ADA and the Patient Protection and Affordable Care Act (ACA) (see later discussion in this chapter). Working individuals with disability are two to four times more likely to delay necessary health care than those without disabilities. Lack of transportation and being refused care are also associated with failure to obtain needed health care among those with disabilities. Further, individuals with multiple limitations and more severe disabilities are less likely to obtain or receive health care than those without disabilities and those without multiple limitations or less severe disability (Na, Hennessy, Boner, et al., 2017; Reichard, Stransky, Phillips, et al., 2017).

Race, gender, and type of disability also affect prevalence, health status and receipt of health care and screening. For example, African American women with intellectual disabilities are less likely to receive mammography than Caucasian women with intellectual disabilities.

Because of the persistence of these and other barriers, it is essential that nurses and other health care providers take steps to ensure that clinics, offices, hospitals, and other health care facilities are accessible to people with disabilities. This includes removal of structural barriers by the addition of ramps, designation of accessible parking spaces, and modification of restrooms to make them usable by people with disabilities. Alternative communication methods (e.g., sign language interpreters, teletypewriter devices, assistive listening devices) and types of patient education (e.g., audiotapes, large print, Braille) are essential to provision of appropriate health-related information to people with disabilities. Such accommodations are mandated by the ADA, which requires their provision without cost to the patient.

People with intellectual and developmental disabilities often need assistance in obtaining health care, including preventive health screening. They often lack knowledge about cancer screening, including breast cancer screening. Educational materials and interventions modified to accommodate patients with intellectual and developmental disabilities are needed to enable them to make informed decisions about screening. Major barriers to breast cancer screening by this population of women include fear, anxiety, and embarrassment, primarily due to lack of understanding about cancer and the importance of its early detection.

Federal Assistance Programs

Lack of financial resources, including health insurance, is an important barrier to health care for people with chronic illness and disabilities. However, several federal assistance programs provide financial assistance for health-related expenses for people with some chronic illnesses, acquired disabling acute and chronic diseases, and childhood disabilities.

Medicare is a federal health insurance program that is available to most people 65 years of age and older, people with permanent kidney injury, and qualified people with disabilities. Title II of the Social Security Disability Insurance program pays benefits to those people who meet medical criteria for disability, who have worked long enough (40 quarters of covered employment) to qualify, and who have paid Social Security taxes. Title II also provides benefits to people disabled since childhood (younger than 22 years), who are dependents of a deceased insured parent or a parent entitled to disability or retirement benefits, and disabled widows or widowers, 50 to 60 years of age, if their deceased spouse was insured under Social Security. Title XVI of the Social Security Disability Insurance program provides supplemental security income payments to people who are disabled and have limited income and resources.

Chart 7-5 **NURSING RESEARCH PROFILE**

Well-Being among Adults with Disabilities in Rural Settings

Thurman, W. A., Harrison, T. C., Walker, V. G., et al. (2019). Pursuing well-being among rural-dwelling adults with disabilities. *Qualitative Health Research, 29*(12), 1699–1710.

Purpose

The rate of disabilities is higher in rural areas globally than in more urban settings across gender, race, and type of disability or impairment. Individuals with disability who reside in rural communities are at a greater disadvantage for receiving services than those who live in urban settings. Although sociocultural and environmental factors affect the well-being of individuals with disabilities, little is known about the experience of adults with disabilities who live in rural areas. This qualitative study was conducted to explore the experience of living with a disability in rural America with the goal of greater understanding of how disability affects social roles, adaptation to impairments, and use of resources to improve well-being in individuals. The researchers' goal was to examine how working-age adults (35–70 years of age) with mobility and sensory disabilities living in rural areas of the United States define and pursue well-being.

Design

The researchers used a constructivist grounded theory approach with constant comparison analysis to study the well-being of community-residing adults with disabilities living in rural settings, defined as communities with fewer than 10,000 residents. The study participants were recruited through community organizations, newspaper announcements, word of mouth, and professional networks of the researchers. Twelve individuals who met inclusion criteria, including the ability to understand spoken or written English, participated in up to three one-to-one interviews. The interview questions addressed participants' perceptions of how their disability affected their lives over time, activities they enjoyed, qualities of their rural communities, and people who interacted with them regularly. Demographic data (e.g., age, race/ethnicity, length of time they lived in their rural setting, level of education, income, housing, employment status, occupation, age at onset of their disability, and the structure of their family) were collected to describe the sample. The study participants had a variety of mobility and sensory impairments, including osteoarthritis, paraplegia, multiple sclerosis, hearing loss, diabetes, and heart disease. Ten of the participants used some type of assistive device.

Findings

Six concepts related to well-being were identified: values, rural attitude, demands, set expectations, strategic participation, and membership. Membership in the rural community, identified as the core category, refers to a feeling of belonging and being part of something greater than one's self.

This was sustained by ongoing contributions to the rural community. Establishing and maintaining membership in the community described participants' sense of belonging to a group, and they felt that they were regarded as contributing participants in their communities. Membership also provided access to support from other community members when needed. These findings support previous research on rural settings indicating the importance of a sense of belonging to well-being. In the rural setting, social processes are used to mobilize resources needed to overcome functional limitations secondary to disability to establish group membership and create a sense of well-being. Meaningful social relationships contributed to participants' well-being, self-confidence, and self-valuing.

Nursing Implications

The findings indicate the importance of having social support, being a member of a group, and belonging to a network in which there is a reciprocal exchange of support and services for individuals with disabilities from rural communities. Thus, nurses and other health professionals working in rural settings could encourage individuals with disabilities to maintain social relationships, memberships, and participation in meaningful activities. Such participation could promote confidence and a sense of well-being and facilitate access to material and psychological support.

Medicaid provides home and community-based services to people with disabilities and long-term illnesses to enable them to lead meaningful lives in their families and communities (Krahn, Walker, & Correa-De-Araujo, 2015). The ACA has expanded insurance options for people with disabilities and made these options more affordable. Furthermore, although the ACA stipulates that people with preexisting chronic conditions and disabilities can no longer be dropped by insurance companies and no longer have a lifetime cap on benefits, comparison of pre-ACA and post-ACA access to health care indicates that health disparities based on disability status persist (Kaye, 2019). Because of differences in states' implementation of the ACA, differences in access to health care among people with disability also differ (Lindner, Rowland, Spurlock, et al., 2018). See later discussion of the ACA in this chapter, and the Resources section at the end of this chapter.

Despite the availability of these federal programs, people with disabilities often have health-related costs and other expenses related to disability that result in low-income status. Furthermore, people must undergo a disability determination process to establish eligibility for benefits, and the process can be prolonged and cumbersome for those who may need assistance in establishing their eligibility.

Nursing Care of Patients with Disability

As active members of society, people with disabilities are no longer an invisible minority. An increased awareness of their needs will bring about changes to improve access and accommodations. Modification of the physical environment permits access to public and private facilities and services, including health care, and nurses can serve as advocates for people with disabilities to eliminate discriminatory practices.

Nursing Considerations during Hospitalization

During hospitalization, as well as during periods of acute illness or injury or while recovering from surgery, patients with preexisting disabilities may require assistance with carrying out ADLs that they could otherwise manage at home independently and easily. Patients should be asked preferences about approaches to carrying out their ADLs, and assistive devices they require should be readily available. Careful planning with patients to ensure that the hospital room is arranged with their input enables them to manage as independently as possible. For example, patients who have paraplegia may be able to transfer independently from bed to their wheelchair; however, if the bed is left in an elevated position, they may be unable to do so. If patients usually use service animals to assist them with ADLs, it is necessary to make arrangements for the accommodation of these animals.

If patients with hearing loss or vision impairment are hospitalized, it is essential to establish effective communication strategies. Alternative methods for these patients to communicate with the health care team must be put in place and used, and all staff members must be aware that some patients are not able to respond to the intercom or telephone. If patients have vision impairment, it is necessary to orient them to the environment and talk to them in a normal tone of voice. When a patient has a disability that affects speech, referral with a speech-language therapist or communication specialist may assist in identifying alternative communication methods (use of sounds, gestures, eye movements) between the nurse and the patient. When a person with intellectual, cognitive, or psychiatric-mental health disability is hospitalized, the health care team must determine what strategies are effective in ensuring that the patient understands what is happening and can communicate his or her needs, promoting a safe and nonstressful environment, adhering as closely as possible to the patient's daily patterns, and consulting with the patient's family caregiver.

Health Promotion and Prevention

Health care providers often neglect health promotion concerns of people with disabilities, who may be unaware of these concerns. For example, people who have had hearing loss since childhood may lack exposure to information about

new immunizations through television and podcasts. People with lifelong disabilities may not have received information about general health issues as children, and people with new onset as well as lifelong disabilities may not receive encouragement to participate in health promotion activities. Because individuals with disabilities, including those with intellectual and developmental disabilities, are living longer and aging with their disability, the need for health promotion takes on increasing importance. Therefore, nurses should take every opportunity to emphasize the importance of participation in health promotion activities (e.g., healthy diet, exercise, social interactions) and preventive health screening.

The management of some disabilities increases the risk of illness, and in some people, health screening (e.g., bone density testing, gynecologic examinations, mammography) may be required earlier in life or more frequently (HHS, 2005). Referrals by nurses to accessible sites for screening may be needed, because many imaging centers are inaccessible or staff are unprepared to make modifications for women who need assistance for screening (McClintock et al., 2018). In addition, nursing consultation with physical therapists may be needed to identify creative ways of enabling people with disabilities to exercise safely, because exercise facilities are also often inaccessible for people with disabilities.

General health promotion strategies and health-screening recommendations for all men and women also apply to those with disabilities. Although physical limitations, cognitive impairments, and structural and attitudinal barriers existing in clinical facilities may make it difficult for some men and women to obtain health care and preventive health screening, the presence of a disability should not be used as a reason or excuse to defer recommended screening. Rather, the presence of a disability may *increase* the risk of secondary health conditions or disorders that require screening and follow-up. Just as people without disabilities should have regular screening tests, such as mammography or testicular and prostate examinations, so should people with disabilities. Nurses are often in a position to influence decisions about how equipment and procedures can be adapted to meet the special needs of their patients, whether these needs are cognitive, motor, or communicative.

The effect of the disabling condition on health risks should be considered. For example, the risk of osteoporosis may be increased in women and men whose disabilities limit their ability to participate in weight-bearing exercise or who use medications that contribute to bone loss (Smeltzer & Qi, 2014). Individuals with intellectual disabilities have several additional risk factors, such as taking medications to treat seizures that contribute to bone loss. Although people with certain disabilities have an increased risk of osteoporosis at a younger age than people without disabilities, little attention is given to prevention, detection, and treatment of osteoporosis, despite the increased risk for falls associated with many disabling disorders.

Nurses can provide expert health promotion education classes that are targeted to people with disabilities and refer them to accessible online resources. Classes on nutrition and weight management are extremely important to people who are wheelchair users and need assistance with transfers. Safer sex classes are needed by adolescents and young adults who have spinal cord injury, TBI, or developmental disabilities, because the threats of sexually transmitted infections and unplanned pregnancy exist for these populations just as they do for the population in general.

The need for health promotion in the areas of establishing relationships, sex, pregnancy, and childbearing is as great in people with disabilities, including those with intellectual and cognitive disabilities, as in people without disabilities. However, societal attitudes and biases against sexual relationships and childbearing in people with disabilities often result in health care providers either excluding such individuals from discussions about these issues, or failing to take their interest and questions seriously. Approaching these topics at the point of interest and knowledge level of a patient with a disability is important for sexual health. Furthermore, addressing sexual issues is important to prepare people with disabilities, who are at risk for sexual and other forms of abuse, to distinguish between healthy and abusive or exploitative sexual interactions and relationships. The increased risk for abuse and violence affects both men and women with disabilities; such abuse and violence has potential physical and psychological consequences that must be assessed and addressed (Dembo, Mitra, & McKee, 2018).

Other healthy behaviors about which people with neurologic disabilities need education include avoiding alcohol and nonprescription medications while taking antispasmodic and anticonvulsant medications, which are commonly prescribed for those with disabilities.

Veterans Considerations

Growing attention has addressed health issues of veterans, those individuals who have served in the military, including service-connected disability and chronic illness. There are currently 18.5 million U.S. veterans. Over 41% of those who served in the military after September 11, 2001 (“911”) in Afghanistan, Iraq, and other war zones have disabilities, which is significantly higher than the rate of 25% of veterans from earlier eras (U.S. Census Bureau, 2018b). Many have more severe disabilities than previous veterans, because of survival of those who previously would have died from their injuries. In addition, the increased use of explosive devices in warfare has increased the number of veterans with limb loss and TBI. The impact of disability on the lives of veterans and their families is considerable and multifaceted and must be considered when providing care to them. Asking patients, “Have you ever served in the military?” is the first step to identifying health-related issues that

veterans face when seeking health care; asking this question also acknowledges the importance of military service to veterans.

Significance of "People-First" Language

It is important to all people, both those with and those without disabilities, that they not be equated with their illness or physical condition. Therefore, nurses should refer to all people using "people-first" language. That means referring to the person first: "the patient with diabetes" rather than "the diabetic" or "the diabetic patient," "the person with a disability" rather than the "disabled person," "women with disabilities" rather than "disabled women," and "people who are wheelchair users" rather than "the wheelchair bound." This simple use of language conveys the message that the person, rather than the illness or disability, is of greater importance to the nurse.

Gerontologic Considerations

The demographic profile in the United States reflects an increased number of older adults with disabilities, with two thirds of Americans 85 years of age and older experiencing functional limitations. Age-related disabilities are those that occur in the older adult population and are thought to be attributable to the aging process. Examples of age-related disabilities include osteoarthritis, osteoporosis, and hearing loss.

Although disability is often perceived as being associated with old age, it occurs across the lifespan; in fact, the majority of people with disabilities are younger than 65 years, with one third between 44 and 65 years of age (Krahn et al., 2015). While many people with intellectual and developmental disabilities (cerebral palsy, Down syndrome, autism spectrum disorder) have a slightly shorter lifespan than other people from their age cohort, others live well into adulthood and old age. The number of adults with intellectual and developmental disabilities aged 60 years and older is expected to nearly double from 850,600 in 2010 to 1.4 million by 2030 (Heller, 2017).

Aging is an important issue that affects people with preexisting disabilities, as they often develop changes associated with aging at a younger age than do those without disabilities. Therefore, people with preexisting disability should be evaluated for early onset of changes related to aging. The nurse must also consider the effects of aging on a preexisting disability and in turn the effects of disability on aging. The following are examples of changes that occur with aging in people with preexisting disabilities:

- People who use crutches for ambulation because of spina bifida, polio, and lower extremity amputation may experience muscle or joint problems as they age because of long-time overuse of the upper

extremities; symptoms may not occur for many years but may cause discomfort and interfere with the person's ability to perform ADLs.

- People who experienced respiratory compromise with the onset of polio decades earlier may experience increasing respiratory symptoms with aging (National Institute of Neurological Disorders and Stroke, 2019). Others experience increased muscle weakness and fatigue, making it necessary to begin to use more extensive assistive devices for mobility (Duncan & Batliwalla, 2018).
- Women with long-standing mobility limitations, lack of weight-bearing exercise, and issues associated with intellectual disabilities may experience bone loss and osteoporosis prior to menopause, yet their rate of screening is low (Dreyfus, Lauer, & Wilkinson, 2014; Heller, 2017; Smeltzer & Qi, 2014).

Concern about what the future holds is common in people aging with preexisting disabilities, who may have questions about what physical, financial, and emotional supports they will have as they age (Nosek, 2000). For example, if their disability becomes more severe, they may be concerned about entering an assisted living or a long-term care facility. The nurse should recognize the concerns of people with disabilities about their future and encourage them to make suitable plans, which may relieve some of their fears about what will happen to them as they age.

Aging parents of adult children with intellectual or developmental disabilities often fear what will happen when they are no longer available and able to care for their children. Limited long-term care resources, increased life expectancy for people with developmental disabilities, changing family patterns, and competition with the older adult population for similar resources increase the fears of these parents. Thus, nurses must identify needed community resources and services. Identifying these issues and concerns and assessing arrangements made by aging parents of adult children with disabilities can help reduce some of parents' fears about their children's futures.

Disability in Medical-Surgical Nursing Practice

Disability is often considered an issue that is specific or confined to rehabilitation, pediatrics, or gerontologic nursing. However, as noted previously, disability can occur across the lifespan and is encountered in all settings. Patients with preexisting disabilities due to conditions that have been present from birth or to illnesses or injuries experienced as an adolescent or young adult or during middle age often require health care and nursing care in medical-surgical settings. It is important to note that even if a disability has been present for patients' entire lives and they have adapted to it, the disability

may still have implications for nursing care and needs to be considered in planning and providing care.

Although in the past many people with lifelong disabilities or adult onset of severe disabilities may have had shortened lifespans, today most can expect to have normal or near-normal lifespans and to live productive and meaningful lives. They are also at risk for the same acute illnesses that can affect all people and are at increased risk for aging-related chronic diseases due to smoking, obesity, and lack of physical activity. In addition, they are at increased risk for unintentional injuries, with fall-related injuries the most common type of injury.

Because of unfavorable interactions with health care providers, including negative attitudes, insensitivity, and lack of knowledge, people with disabilities may avoid seeking medical intervention or health care services. For this reason, and because the number of people with disabilities is increasing, nurses must acquire knowledge and skills and be available to assist them in maintaining a high level of wellness. Nurses are in key positions to influence the architectural design of health care settings and the selection of equipment that promotes ease of access and health. Padded examination tables that can be raised or lowered make transfers easier for people with disabilities. Birthing chairs benefit women with disability during yearly pelvic examinations and Pap smears and during urologic evaluations. Ramps, grab bars, and raised and padded toilet seats benefit many people who have neurologic or musculoskeletal disabilities and need routine physical examination and monitoring. When a patient with a disability is admitted to the hospital for any reason, the patient's needs for these modifications should be assessed and addressed.

Men and women with disabilities may be encountered in hospitals, clinics, offices, and nursing centers when they seek health care to address a problem related to their disability. However, they may also be encountered in these settings when they seek care for a health problem that is not related in any way to their disability. For example, a woman with spina bifida, spinal cord injury, or post-polio syndrome might seek health care related to a gynecologic issue, such as vaginal bleeding. Although her disability should be considered in the course of assessment and delivery of health and nursing care, it should not be the exclusive focus of the assessment or care that she receives. Furthermore, neither a severe physical disability that affects a woman's ability to transfer to an examination table for a gynecologic examination nor a cognitive disability should be a reason to defer a complete health assessment and physical examination, including a pelvic examination. Reproductive care for women with disabilities is notoriously lacking due to absence of appropriate accessible equipment and facilities, health care providers' unfamiliarity with health issues of women with disabilities, and negative attitudes toward women with disabilities who are sexually active or who are pregnant or considering

pregnancy (Hasson-Ohayon, Hason-Shaked, Silberg, et al., 2018; Hayward et al., 2017; LaPierre et al., 2017; Mitra et al., 2017; Nosek, 2000; Tarasoff, 2017). Nurses who are knowledgeable about these issues and other barriers can make a significant impact on the quality of health care these women receive.

Health care, including preventive health screening and health promotion, is essential to enable people with disabilities to live the highest quality of life within the limitations imposed by their disabling conditions. Men and women with disabilities have the same needs and same rights for health care and preventive health screening as others, although in some cases, the consequences of their disability increase rather than decrease their need for health screening and participation in health-promoting activities. Therefore, it is essential that medical-surgical nurses be knowledgeable about disability and how it affects people across the lifespan as well as how to provide sensitive and quality nursing care for patients with preexisting and new-onset disability. In an effort to address these issues, specific information on health care of people with disabilities has been included throughout this book.

Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Chart 7-6 contains points the nurse should consider when educating patients about managing disability at home. A major and often overlooked issue in educating patients about a health problem, a treatment regimen, or health promotion strategies is the need for alternative formats to accommodate people with various disabilities. Patients with disabilities are in need of the same information as other patients; however, they often require large print, Braille, audiotapes, or the assistance of a sign language interpreter. Materials may be obtained from a variety of sources for patients who need these educational strategies and for patients with cognitive impairments attributable to developmental disabilities or newly acquired disabilities.

Nurses should ensure that all people—whether or not they have disabilities—recognize the warning signs and symptoms of stroke, heart attack, and cancer, as well as how to access help. In addition, nurses should educate all patients who are stroke survivors and those with diabetes how to monitor their own blood pressure or glucose levels.

Continuing and Transitional Care

When caring for patients with disabilities and helping them plan for discharge and continuing care in the home, it is important to consider how a particular disability affects a patient's ability to adhere to recommended treatment regimens and keep follow-up appointments. Furthermore, it is important to

consider how the health issue or treatment regimen affects the disability. Although many people with disabilities are independent and able to make decisions, arrangements for transportation, and appointments to accessible facilities, others may have difficulty doing so, particularly if they are experiencing a health problem. The nurse should recognize the effect that the disability has on the patient's ability to follow-up. The nurse should ask the patient whether they anticipate having any difficulties arranging for follow-up care. It is important for the nurse to assist the patient with disabilities to identify unmet needs and to find and use resources (community and social resources, and transportation services) that enable the patient to obtain needed services while remaining in his or her home, if preferred. The nurse should have a list of accessible sites and services available and share those resources with the patient and the family. In collaboration with other health care providers (occupational and physical therapists, speech therapists), the nurse can identify needed home modifications, including those that are simple and inexpensive, that will enable the patient to participate in self-care at home.

Chart 7-6 **HOME CARE CHECKLIST**

Managing Disability and Chronic Illness at Home

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of disability or chronic illness on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in lifestyle (e.g., diet, activity) necessary to maintain health.
- State the name, dose, side effects, frequency, and schedule for all medications.
- State how to carry out prescribed regimens (e.g., skin care, bladder/bowel care, daily weights).
- State how to obtain medical supplies after discharge.
- Identify durable medical equipment needs, proper usage, and maintenance necessary for safe utilization.
- Demonstrate safe usage of adaptive equipment for ADLs.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community)
  - Identify phone numbers of support groups for people with chronic illness/disabilities and their caregivers/families
  - State meeting locations and times
- Demonstrate safe mobility skills and/or how to access transportation.
- Identify community resources for recreation:
  - State local recreation centers that offer programs for people with disabilities
  - Identify leisure activities that can be pursued in the community
- State how to reach health care provider with questions or complications.
- State time and date of follow-up appointments.
- Identify the need for health promotion, disease prevention, and preventive screening activities.

Transitional care, if available, is ideal for patients with severe disabilities being discharged home. Patients hospitalized for an acute or secondary health condition may be more vulnerable to deterioration in health status or developing other health conditions because of their narrow margin of health or deconditioning that occurs with hospitalization. Important roles of the transitional care nurse are to ensure that required services are available in the home at the time of the patient's discharge, to assess and monitor the patient through home visits, and to provide support and assistance to the patient and

the family in the aftermath of hospitalization and discharge (Naylor, Shaid, Carpenter, et al., 2017).

Chronic Disease and Chronic Illness

Chronic disease refers to **noncommunicable diseases** (conditions not caused by an acute infection or injury), chronic conditions, or chronic disorders. In contrast, **chronic illness** refers to the human experience of living with a chronic disease or condition. Chronic illness includes the person's perception of the experience of having a chronic disease or condition and the person's and others' responses to it, including health care professionals (Larsen, 2019). Persons' and their families' values and previous experiences determine their perceptions and beliefs about the condition, which in turn affect their illness and wellness behaviors. Their values are influenced by a number of demographic, socioeconomic, technologic, cultural, and environmental variables. Only the person and the family really know what it is like to live with chronic illness (Larsen, 2019).

The following section of this chapter discusses chronic illness and its implications for nursing practice. Because some degree of disability is often present in severe or advanced chronic illness, the previous discussion about disability is relevant to chronic disease as well.

Chronic diseases are long-term health conditions that affect one's well-being and function in an episodic, continuous, or progressive way over many years of life. Although each chronic disease or condition has its own specific physiologic characteristics, many chronic conditions share common features. For example, common symptoms typically include pain, fatigue, sleep disturbances, and difficulty adjusting to the onset and uncertainty of a chronic condition (Larsen, 2019). Many people with chronic health conditions and disability function independently with little or no inconvenience to their everyday lives; others, however, require frequent and close monitoring or placement in long-term care facilities. Certain conditions require advanced technology for survival, as in the late stages of chronic obstructive lung disease or end-stage renal disease, or intensive care or mechanical ventilation for periods of weeks, months, or years. People with disorders such as these have been described as being chronically critically ill, although there is no consensus on a definition of chronic critical illness. An overview of chronic disease in the United States is presented in Chart 7-7.

Multiple Chronic Conditions

Having **multiple chronic conditions (MCC)** increases the complexity of care and often necessitates care by multiple health care specialists, a variety of

treatment regimens, and prescription medications that may not interact. Thus, patients with MCC are at risk for conflicting medical advice, adverse effects of medications, unnecessary and duplicative tests, and preventable hospitalizations, all of which can negatively affect their health (CDC, 2019b). Patients with MCC and their families may have to keep track of different medications with different schedules and multiple appointments with various health care professionals. Costs of health care increase with the number of chronic conditions a person has; those with five or more chronic conditions account for 41% of total health expenditures in the United States (Buttorff, Ruder, & Bauman, 2017). Approximately 80% of health care costs in the United States are associated with having MCC. Approximately 93% of the total health care expenditures for those who are covered by Medicare are associated with MCC. In addition, out-of-pocket health-related expenses increase with the number of MCC. Facts about MCC are summarized in Chart 7-8.

Chart 7-7

Overview of Chronic Illness in the United States

- Chronic diseases are the leading causes of death and disability in the United States.
- Chronic disease and conditions (e.g., heart disease, stroke, cancer, diabetes, obesity, arthritis) are among the most common, costly, and preventable of all health problems.
- Heart disease, cancer, stroke, chronic lower respiratory diseases, Alzheimer's disease, and diabetes pose greater risks as people age.
- Chronic disease, specifically diabetes, is the leading cause of kidney failure, amputation of lower extremities, and new causes of blindness among adults.
- Obesity is a serious health concern with one third of adults and one of five youths having obesity.
- Lack of exercise or physical activity, poor nutrition, use of tobacco, and excessive alcohol use contribute to the growing prevalence of chronic diseases and resulting disability. Tobacco remains the leading cause of six million preventable deaths per year globally. Although cigarette smoking among U.S. youths has declined steadily over the past two decades, the recent introduction of electronic nicotine delivery systems (ENDS) has resulted in increased exposure of youth to nicotine, considered an epidemic by the U.S. Surgeon General's office.
- Americans living in rural communities are more likely to have chronic disease, such as high blood pressure, heart disease, and diabetes, than those living in nonrural areas.
- Eighty-six percent of all health care spending is related in general to chronic disease.
- People with chronic disease may have other health problems that may or may not be related to the primary chronic disease; these include alcohol abuse and substance use or addiction disorders, mental illness, dementia or other cognitive impairments, and developmental disabilities.

Chart 7-8

Facts About Multiple Chronic Conditions (MCC)

- About half of all adults—117 million people—have one or more chronic health conditions. One of every four adults has two or more chronic health conditions.
- The occurrence of MCC increases with age. Three in every four Americans 65 years of age and older have MCC.
- The number of people with MCC is predicted to increase substantially over the next decade, adding to the pressures on the health care system to deliver high quality of care, at optimal cost, while improving the health of this complex population.
- Women are more likely than men to have MCC.
- Non-Hispanic White adults, non-Hispanic Black adults, and non-Hispanic adults of other races have a high prevalence of MCC.
- As the number of chronic conditions a person has increases, the greater the risk of dying prematurely, being hospitalized, and having poor day-to-day functioning.
- Many patients with MCC have mobility limitations and require assistance with dressing, bathing, or preparing meals.
- People with MCC account for the majority of health care visits, prescriptions, home health visits, and hospital stays in the United States.

Health Disparities and Chronic Disease

Although chronic disease occurs in all socioeconomic groups, people from low-income and disadvantaged backgrounds are more likely to report poor health. Factors such as poverty and inadequate health insurance decrease the likelihood that people with chronic illness or disability receive health care and preventive health-screening measures such as mammography, cholesterol testing, and routine checkups (National Academies of Sciences, Engineering, and Medicine [NASEM], 2017; Raghupathi & Raghupathi, 2018). In addition, chronic conditions can lead to poverty for the patient and the family. There also are implications for society or the nation as a whole, because chronic conditions or subsequent premature deaths occur most commonly during the most productive years for people with chronic conditions.

Disparities in health and health outcomes are associated with social, economic, and environmental disadvantages. Although the gap between health outcomes in African Americans and Caucasians has decreased in some areas, in others (e.g., mortality due to breast cancer) the gaps have increased. Disparities in health and health outcomes are associated with higher incidence and prevalence, earlier onset, faster progression, and poorer outcomes of disease and conditions (NASEM, 2017; Raghupathi & Raghupathi, 2018).

Some chronic conditions have little effect on quality of life, whereas others have a major effect because they result in disability. However, not all disabilities are a result of chronic illness, and not all chronic illnesses cause disability. Unlike the term *acute,* which implies a curable and relatively short disease course, the term *chronic* describes a long disease course that may be incurable. This often makes managing chronic conditions difficult for those who live with them. Yet nurses can and do make a difference in the experience of chronic illness by providing quality nursing care in the absence of a cure (Larsen, 2019).

Psychological and emotional reactions of patients to acute and chronic conditions and changes in their health status are described in Chapter 5. People who develop chronic conditions or disabilities may react with shock, disbelief, anger, resentment, or other emotions. How people react to and cope with chronic illness is usually similar to how they react to other events in their lives, depending, in part, on their understanding of the condition and their perceptions of its potential impact on their own and their family's lives. Adjustment to chronic illness (and disability) is affected by various factors:

- Suddenness, extent, and duration of lifestyle changes necessitated by the illness
- Uncertainty related to the course and outcome of chronic illnesses
- Family and individual resources for dealing with stress
- Availability of support from family, friends, and the community
- Stages of individual/family life cycle
- Previous experience with illness and crises

- Underlying personality characteristics
- Unresolved anger or grief from the past

Psychological, emotional, and cognitive reactions to chronic conditions are likely to occur at their onset and to recur if symptoms worsen or return after a period of remission. Symptoms associated with chronic health conditions are often unpredictable and may be perceived as crisis events by patients and their families, who must contend with both the uncertainty of chronic illness and the changes it brings to their lives. The possible effects of chronic conditions can guide nursing assessment and interventions for the patient who has a chronic illness.

Definitions of Chronic Diseases or Conditions

Chronic diseases or conditions are often defined as medical conditions or health problems with associated symptoms or disabilities that require long-term management. Chronic diseases are those that persist for months or years rather than days or weeks (Larson, 2019). The National Center for Health Statistics defines chronic disease as a condition lasting 3 or more months; the CDC's National Center for Chronic Disease Prevention and Health Promotion (NCCDPHP) (CDC, 2019a) defines it as a condition that lasts for a year or more and that can usually be controlled but not cured. Definitions of chronic disease or chronic illness share the characteristics of being irreversible, having a prolonged course, and remaining unlikely to resolve spontaneously (Larsen, 2019). The specific chronic condition may be a result of illness, genetic factors, or injury; it may be a consequence of conditions or unhealthy behaviors that began during childhood and young adulthood.

The social determinants of health (SDOH) provide a useful framework to identify factors that affect a person's or a population's health, including the prevalence of chronic disease, its management, the quality of health care that is available, and the outcomes of chronic disease. The main SDOH that have been identified include income and social status, employment and working conditions, education and literacy, childhood experiences, physical environment, social supports and coping skills, healthy behaviors, access to health services, biology and genetic makeup, gender, culture, race and ethnicity (Office of Disease Prevention and Health Promotion, 2019).

The effect of SDOH is illustrated by large discrepancies in life expectancy, up to a 48-year difference among countries and 20 years or more within countries. Deaths due to chronic disease are expected to increase globally, from 41 million deaths reported in 2016 (many of which were premature) to 52 million per year by 2030 (Raghupathi & Raghupathi, 2018; WHO, 2018c, 2019).

Management of chronic conditions includes learning to live with symptoms or resulting disabilities and coming to terms with identity changes resulting

from having a chronic condition. Management also consists of carrying out the lifestyle changes and regimens designed to control symptoms and prevent complications. Although some people assume what might be called a "sick role" identity, most people with chronic conditions do not consider themselves to be sick or ill and try to live as normal a life as possible. Only when complications develop or symptoms interfere with ADLs do most people with chronic health conditions think of themselves as being sick or having a disability.

Prevalence and Causes of Chronic Conditions

Chronic conditions occur in people of every age group, socioeconomic level, race, and culture. Six in 10 adults in the United States have a chronic disease. Chronic diseases are the most common causes of death in the United States; the most frequently occurring chronic diseases account for 7 of the 10 leading causes of death, with cancer and heart disease together accounting for nearly half of all deaths. Globally, chronic diseases are responsible for more than two thirds of deaths. Chronic diseases include cancers, cardiovascular disease, diabetes, and chronic lung diseases (CDC, 2019a).

Chronic diseases or disorders are one of the major health and development challenges of this century because of their global impact on human, social, and financial well-being and status. Although chronic diseases affect all countries, their impact is more severe in low- and middle-income countries, with devastating consequences in poor and vulnerable populations. Chronic diseases cause more deaths than all other causes combined, and lifespan is shortened by chronic illnesses in those countries.

It is predicted that by the year 2030, about half the population will have a chronic disease or disorder. One fifth of those with chronic disease also have an activity limitation. As the incidence of chronic diseases increases, the costs associated with these chronic conditions (e.g., hospital costs, equipment, medications, supportive services) also increase. These costs represent four of every five health care dollars expended. In the United States, chronic diseases are also leading drivers of the nation's $3.5 trillion in annual health care costs (NCCDPHP, 2020; Raghupathi & Raghupathi, 2018).

Although some chronic diseases are associated with nonmodifiable factors, including genetic and physiologic factors, many are the result of unhealthy lifestyles. Most chronic diseases are caused by four major behaviors: use of tobacco, electronic nicotine delivery systems (ENDS), and exposure to secondhand smoke; poor nutrition (diets high in sodium and saturated fats and low in fruits and vegetables); lack of physical activity; and excessive consumption of alcohol (CDC, 2019a; WHO, 2018c). Because these behaviors are modifiable, nurses have a major role in the prevention of chronic disorders

associated with these behaviors (for more detailed information, see later discussion in section on Prevention of Chronic Disease).

Some chronic health conditions cause little or no inconvenience; others are severe enough to cause major activity limitations that may prevent people from meeting their needs for health care and personal services. For example, they may be unable to carry out their therapeutic regimens or have their prescriptions filled on time, may miss appointments and office visits with their health care providers, and may be unable to manage ADLs.

Chronic diseases are a global issue that affects both rich and poor nations. The total number of people dying from chronic disease is twice that of patients dying from infectious (including human immunodeficiency virus infection), maternal, and perinatal conditions, and nutritional deficiencies combined (WHO, 2019). Most of these chronic diseases and complications of chronic illness are preventable, emphasizing the importance of health promotion across the globe. Although chronic diseases or illnesses are common, people have many myths or misunderstandings about them (Table 7-1).

Causes of the increasing number of people with chronic conditions include the following:

- A decrease in mortality from infectious diseases (e.g., smallpox, diphtheria, acquired immune deficiency syndrome [AIDS]–related infections) because of immunizations and new drug development and from acute conditions (e.g., myocardial infarction, trauma) because of prompt and aggressive management.
- Lifestyle factors such as smoking, chronic stress, poor nutrition, and sedentary lifestyle that increase the risk of chronic health problems such as respiratory disease, hypertension, cardiovascular disease, and obesity. Although signs and symptoms of chronic illness often first appear during older age, risks typically begin earlier in life, even during fetal development.
- Obesity, often due to lifestyle issues, has become a major health issue across the lifespan and across the globe with about 2.1 billion people overweight and one third of them having obesity. Obesity is no longer limited to high-income countries but increasingly occurs in low- and middle-income countries. The proportion of adults with a body mass index (BMI) of 25 or greater increased between 1980 and 2013 from about 29% to 37% in men and about 30% to 38% in women (Kushner & Kahan, 2018). It is estimated that unless this trend is reversed, almost half of the world's population will be overweight or have obesity by 2030. Approximately 5% of deaths worldwide are due to obesity (Tremmel, Gerdtham, Nilsson, et al., 2017). The increasing prevalence of obesity has increased the incidence of heart disease, strokes, diabetes,

and hypertension. Obesity also affects one's self-esteem, achievement, and emotional state. In 2015, high BMI contributed to four million deaths globally, which was over 7% of deaths from any cause (Kushner & Kahan, 2018).

TABLE 7-1 Myths and Truths About Chronic Disease

Common Misconceptions About Chronic Disease	The Reality About Chronic Disease
1. Everyone dies of something.	Chronic illnesses typically do not result in sudden death but often result in progressive illness and disability. People with chronic disease often die slowly, painfully, and prematurely.
2. People can live to old age even if they lead unhealthy lives (smoke, have obesity).	While there are exceptions (some people who live unhealthy lives live to old age, and some people who live healthy lives develop chronic illnesses), most chronic illnesses can be traced to modifiable risk factors and can be prevented by eliminating these risks.
3. Solutions for chronic disease prevention and control are expensive and not feasible for low- and middle-income countries.	A full range of chronic disease interventions are very cost-effective for all regions of the world, including the poorest. Many of these interventions are inexpensive to implement.
4. Nothing can be done to prevent chronic diseases.	The major causes of chronic diseases are known, and if these risk factors were eliminated, at least more than 80% of heart disease, stroke, and type 2 diabetes and more than 40% of cancers would be prevented.
5. If individuals develop chronic disease as a result of unhealthy "lifestyles," they have only themselves to blame.	Individual responsibility can have its full effect only if individuals have equal access to a healthy life and are supported to make healthy choices. People who are poor often have limited choices about the food they eat, their living conditions, and access to education and health care.
6. Certain chronic diseases primarily affect men.	Chronic diseases, including heart disease, affect women and men almost equally. Almost half of all deaths attributed to chronic illness occur in women.
7. Chronic diseases primarily affect people who are old.	Almost half of chronic disease deaths occur prematurely in people younger than 70 years of age.
8. Chronic diseases mainly affect people who are rich (affluent).	People who are poor are much more likely than those who are wealthy to develop chronic diseases and as a result are more likely to die prematurely. Chronic diseases cause substantial financial burden and result in extreme poverty.
9. The priority of low- and middle-income countries should be on control of infectious diseases.	Although infectious diseases are an issue, low- and middle-income countries are experiencing a dramatic increase in chronic disease risk factors and deaths, especially in urban settings.
10. Chronic diseases affect mostly high-income countries.	Eighty percent of deaths attributed to chronic disease are in low- and middle-income countries. The prevalence of chronic diseases in low- and middle-income countries is rapidly growing.

Adapted from World Health Organization (WHO). (2005). Face the facts #2: Widespread misunderstandings about chronic disease—and the reality. Retrieved on 7/15/2019 at: www.who.int/chp/chronic_disease_report/media/Factsheet2.pdf

- Longer lifespans because of advances in technology and pharmacology, improved nutrition, safer working conditions, and greater access (for some people) to health care.
- Improved screening and diagnostic procedures enabled early detection and treatment of diseases, resulting in improved outcomes of management of cancer and other disorders.

Physiologic changes in the body often occur before the appearance of symptoms of chronic disease. Therefore, the goal of emphasizing healthy lifestyles early in life is to improve overall health status and slow the development of such disorders. In addition, serious psychiatric or mental illness disorders puts people at greater risk for chronic illness than the general population and leads to higher morbidity and mortality rates of chronic diseases (National Prevention Council, 2016).

Prevention of Chronic Disease

The CDC (2019a) has identified risk factors for common chronic diseases and pointed out that most American adults have more than one of the following risk factors:

- Hypertension (high blood pressure)
- Tobacco and ENDS use or exposure to secondhand smoke
- Overweight or obesity (high BMI)
- Lack of physical activity
- Excessive alcohol use
- Consumption of diets low in fruits and vegetables
- Consumption of food high in sodium and saturated fats

The WHO (2005, 2013) has identified high-impact, cost-effective interventions to prevent premature death due to chronic disease or chronic conditions that can be implemented even in settings with limited resources. These interventions, summarized in Chart 7-9, are consistent with the risk factors for chronic disease identified by the CDC.

Patient education to prevent chronic disease or reduce its severity or effects is another important component of the nurse's role in working with patients to identify risks for chronic disease and to identify strategies to reduce those risks. Health promotion and patient education are discussed in detail in Chapter 3 in this book.

Characteristics of Chronic Conditions

Sometimes it is difficult for people who are disease free to understand the profound effect that chronic illness often has on the lives of patients and their families. It is easy for health professionals to focus on the illness or disability itself while overlooking the person who has the disorder. In all illnesses, but even more so with chronic conditions, the illness cannot be separated from the person. People with chronic illness must contend with it daily (Larsen, 2019). To properly manage their chronic condition, individuals often have to find the time, as well as the social and financial resources, to participate in physically and psychologically beneficial activities, work with health care professionals to follow treatment guidelines, monitor their health and make decisions about their health and lifestyle and those of their family, and manage the effects of the illness on their physical, psychological, and social well-being. To relate to what people must cope with or to plan effective interventions, nurses must understand the multiple characteristics of a chronic illness.

Chart 7-9

Interventions According to Risk Factors

Tobacco

- Reduce affordability of tobacco and electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars by increasing their costs.
- Legally mandate smoke-free environments in all indoor workplaces, public places, and public transport.
- Disseminate warnings about dangers of tobacco, tobacco smoke, and ENDS through mass media campaigns and ban all forms of tobacco advertising, promotion, and sponsorship.

Harmful Use of Alcohol

- Reduce affordability of alcohol by increasing its costs.
- Limit availability of alcohol.
- Ban all forms of alcohol advertising and promotions.

Diet and Physical Activity

- Promote reduction of dietary salt intake and replacement of trans fats with unsaturated fats.
- Implement public awareness programs on diet and physical activity.
- Promote and protect breast-feeding (reduces risk of obesity later in life).

Cardiovascular Disease and Diabetes

- Promote glycemic control for diabetes and control of hypertension using medication therapy.
- Counsel individuals who have had a heart attack or stroke and those people at high risk of a fatal and nonfatal cardiovascular event in the next 10 years.
- Initiate acetylsalicylic acid (aspirin) use for acute myocardial infarction.

Cancer

- Promote hepatitis B immunization to prevent liver cancer.
- Promote screening, immunization with the HPV vaccine, and early treatment of precancerous lesions to prevent cervical cancer.

Adapted from World Health Organization (WHO). (2013). Global action plan for the prevention and control of noncommunicable diseases, 2013–2020. Geneva, Switzerland: Author.

- Psychological and social issues: Managing chronic illness involves more than treating medical problems. Associated psychological and social issues must also be addressed, because living for long periods

with illness symptoms and disability can threaten identity, bring about role changes, alter body image, and disrupt lifestyles, work, and family life. These changes require continuous adaptation and accommodation, depending on the patient's age and situation in life. Each change or decline in functional ability requires physical, emotional, and social adaptation for patients and their families (Corbin, 2003; Larsen, 2019).

- Course of chronic disease: Chronic health conditions usually involve many different phases over the course of a person's lifetime. There can be acute periods, stable and unstable periods, flare-ups, and remissions. Each phase brings its own set of physical, psychological, and social problems, and each requires its own regimens and types of management. Individuals with chronic illnesses may experience high levels of stress or anxiety with each change in the course of their illness.
- Progression of chronic disease: The rate of progression of chronic diseases can vary from a rapid downhill course leading quickly to disability and death within a few months of onset to those with a slow downhill progression over years. Others may be characterized by disappearance of signs and symptoms with a return to "normal" with later return of symptoms, or relapses.
- Therapeutic regimens: Keeping chronic conditions under control requires persistent adherence to therapeutic regimens that may be complex and may interfere with usual activities or even life goals. Failing to adhere to a treatment plan or to do so consistently increases the risks of developing complications and accelerating the disease process. However, the realities of daily life, including the impact of culture, values, and socioeconomic factors, affect the degree to which people adhere to a treatment regimen. Managing a chronic illness takes time, requires knowledge and often planning, and can be uncomfortable and inconvenient. It is not unusual for patients to stop taking medications or alter dosages because of side effects that are more disturbing or disruptive than symptoms of the illness, or to cut back on regimens they consider overly time-consuming, fatiguing, or costly (Corbin, 2003; Larsen, 2019).
- Development of other chronic conditions: One chronic disease can lead to the development of other chronic conditions. Diabetes, for example, can lead to neurologic and vascular changes that may result in visual, cardiac, and kidney diseases and erectile dysfunction. The presence of a chronic illness also contributes to a higher risk of morbidity and mortality in patients admitted to the intensive care unit with acute health conditions as well as greater utilization of clinical services during hospitalization.

- Family life: Chronic illness affects the entire family. Family life can be dramatically altered as a result of role reversals, unfilled roles, loss of income, time required to manage the illness, decreases in family socialization activities, and the costs of treatment. Family members often become caregivers for the person with chronic illness while trying to continue to work and keep the family intact. Over 16.6% of the U.S. adult population are considered caregivers for a family member with a chronic illness, or with a disability, or who is an older adult. Although many caregivers derive positive effects from providing care, many are employed and attempting to maintain as normal a life as possible for their families. Stress, depression, fatigue, and loss of sleep as well as missed days of work are not uncommon. Thus, the wellbeing of caregivers merits attention by nurses and other health care providers (Hopps, Iadeluca, & McDonald, 2017).
- Home life: The day-to-day management of illness is largely the responsibility of people with chronic disorders and their families. As a result, the home, rather than the hospital, is the center of care in chronic conditions. Hospitals, clinics, primary care providers' offices, nursing homes, nursing centers, and community agencies (home care services, social services, and disease-specific associations and societies) are considered adjuncts or backup services to daily home management.
- Self-management: The management of chronic conditions is a continual process. People can be taught how to manage their conditions. However, each patient must discover how his or her own body reacts under varying circumstances—for example, what it is like to be hypoglycemic, what activities are likely to bring on angina, and how these or other conditions can best be prevented and managed.
- Collaborative process: Managing chronic conditions must be a collaborative process that involves many different health care professionals working together with patients and their families to provide the services and supports that are often needed for management at home. The medical, social, and psychological aspects of chronic health problems are often complex, especially in severe conditions.
- Health care costs: The management of chronic conditions is expensive. Many expenses incurred by an individual patient (e.g., costs for hospital stays, diagnostic tests, equipment, medications, and supportive services) may be covered by health insurance and by federal and state agencies. The Patient Protection and Affordable Care Act (ACA), passed in 2010, the most significant change to health care policy in the United States since the establishment of

Medicare and Medicaid, has made available health insurance for many previously uninsured individuals who were unable to obtain health insurance. The ACA has ended lifetime and most annual limits on health care, provided patients with access to recommended preventive services, and banned the practice of denying coverage because of the presence of a preexisting health condition (Krahn et al., 2015).

- Lost income: Direct out-of-pocket expenses can represent a significant percent of income, especially in low- and middle-income families. These expenses include high copays and deductibles that must be paid out of pocket. Those with serious chronic disorders may have difficulty paying for care, resulting in bankruptcy or having to rely on family or friends to pay for health insurance or health care. People from low-income groups who do not receive adequate health care get sicker and die sooner from chronic diseases than those from groups with higher levels of education, greater financial resources, and access to care (WHO, 2017a). If a family's primary income earner becomes ill, chronic diseases can result in drastic loss in income with inadequate funds for food, education, and health care. Furthermore, affected families may become unstable and impoverished.
- Ethical issues: Chronic conditions raise difficult ethical issues for patients, families, health care professionals, and society. Issues include how to control costs, how to allocate scarce resources (e.g., organs for transplantation), what constitutes quality of life, and if and when life support should be withdrawn.
- Living with uncertainty: Having a chronic illness means living with uncertainty. Although health care providers may be aware of the usual progression of a chronic disease such as Parkinson's disease or multiple sclerosis, no one can predict with certainty the course of a person's illness. Even when a patient is in remission or symptom free, the person often fears that symptoms will reappear.

Implications of Managing Chronic Conditions

Chronic conditions have implications for everyday living and management for people and their families as well as for society at large (Larsen, 2019). Most importantly, individual efforts should be directed at preventing chronic conditions, because many—but not all—chronic illnesses or disorders are linked to unhealthy lifestyles or behaviors such as smoking and overeating. Therefore, changes in lifestyle can prevent some chronic disorders or at least delay onset until a later age. Because most people resist change, bringing about alterations in people's lifestyles is a major challenge for nurses.

Once a chronic condition has occurred, the focus shifts to managing symptoms, avoiding complications (e.g., eye complications in a person with diabetes), and preventing other acute illnesses (e.g., pneumonia in a person with chronic obstructive lung disease). Quality of life—often overlooked by health care professionals in their approach to people with chronic conditions—is also important. Health-promoting behaviors, such as exercise, are essential to quality of life even in people who have chronic illnesses or disabilities, because it helps maintain functional status (Larsen, 2019).

Although coworkers, extended family, and health care professionals are affected by chronic illnesses, the problems of living with chronic conditions are most acutely experienced by individuals and their immediate families. They experience the greatest impact, with lifestyle changes that directly affect quality of life. Nurses provide not only direct care, especially during acute episodes, but also education and they help secure the resources and other supports that enable people to integrate their illness into their lives and to have an acceptable quality of life despite their chronic condition. To understand essential nursing care, it is important to recognize and appreciate the issues that people with chronic illness and their families contend with and manage, often on a daily basis (Larsen, 2019). Ultimately the course of the chronic illness and its outcomes, including end-of-life decisions, are determined in large part by the patient and family.

Many people with chronic disease or chronic illness must face an additional challenge: the need to deal with more than one chronic condition at a time (CDC, 2019b; Raghupathi & Raghupathi, 2018). The symptoms or treatment of a second chronic condition may aggravate the first chronic condition. Patients need to be able to deal with their various chronic conditions separately as well as in combination and to coordinate the health care and directions they receive, often from more than one health care professional.

Often challenging for many people with chronic illness is the need to hire and oversee caregivers who come into their homes to assist with ADLs and IADLs, such as shopping for food, doing laundry, housekeeping, and handling financial matters. It is difficult for many people to be in a position of hiring, supervising, and sometimes firing people who may provide them with intimate physical care. The need to balance the role of recipient of care and oversight of the person providing care may lead to blurring of role boundaries.

The challenges of living with and managing a chronic illness are well known, and people with chronic illnesses often report receiving inadequate care, information, services, and counseling. This provides an opportunity for nurses to assume a more active role in addressing many of the issues experienced, coordinating care, and serving as advocates for patients who need additional assistance to manage their illness while maintaining a quality of life that is acceptable to them.

Veterans Considerations

Gulf War Illness (GWI) is a chronic illness or syndrome that has been reported in veterans who served in the U.S. military in the Gulf War following the September 11, 2001 ("911") terrorist attacks (Baldwin, Rudquist, Lava-Parmele, et al., 2019). Similar to GWI, the term chronic multisymptom illness (CMI) defines a set of nonspecific symptoms experienced by veterans who served in the Gulf War in 1990–1991 and report one or more symptom lasting more than 6 months in at least two of three categories: fatigue, depressed mood and altered cognition, and musculoskeletal pain. The term, CMI, may be employed when the symptoms are moderate to severe and have no other explanation. There is speculation that GWI and CMI may be a consequence of exposure of veterans to biologic and chemical toxins during their military service. Veterans with symptoms of both GWI and CMI want and need to be taken seriously by health care professionals.

Gerontologic Considerations

The U.S. demographic profile reflects an increased number of older adults with chronic illnesses and those with MCC. By 2060, the number of older adults is expected to more than double to 98.2 million; the number of people 85 years of age and older is expected to triple to 19.7 million. The ratio of women and men who are 65 years of age and older is 127 women for every 100 men. In 2014, there were 75.4 million baby boomers (people born between 1946 and 1964) accounting for almost one quarter of the population. Baby boomers began turning 65 years old in 2011, contributing to the increase in numbers of older adults. Most older adults have at least one chronic condition and three in every four older Americans have MCC (AARP, 2017; Raghupathi & Raghupathi, 2018). Some of the most frequently occurring conditions among older Americans are arthritis, cancer, cardiac disease, type 2 diabetes, and hypertension.

Treatment for older adults with chronic illness accounts for 66% of total U.S. health care expenditures (CDC, 2018). The cost of providing health care for a person 65 years of age or older is estimated to be three to five times higher than costs for someone younger than 65 years. Chronic conditions increase the risk for death due to influenza and pneumonia among older adults, although effective vaccines for them exist. The WHO (2017b) has issued guidelines for community-level interventions aimed at preventing declines in older people as they age.

In 2014, about 28% (12.6 million) of all older adults in the United States lived alone (8.8 million women, 3.8 million men). They represented 35% of older women and 19% of older men. Almost half of women aged 75 and older

live alone; many of them live below the poverty level (Administration for Community Living, 2018). The living arrangements of older adults with chronic illness have important nursing implications for preparing those who are hospitalized for discharge and for ensuring coordination of services.

Nursing Care of Patients with Chronic Conditions

Nursing care of patients with chronic conditions is varied and occurs in a variety of settings. Care may be direct or supportive. Direct care may be provided in the clinic or primary care provider's office, a nurse-managed center or clinic, a hospital, long-term care facility, or the patient's home. Direct care includes assessing the patient's physical status, providing wound care, managing and overseeing medication regimens, providing education to the patient and family, and performing technical tasks. The availability of this type of nursing care may allow the patient to remain at home and return to a more normal life after an acute episode of illness.

Because much of the day-to-day responsibility for managing chronic conditions rests with the patient and the family, nurses often provide supportive care at home. Supportive care may include ongoing monitoring, education, counseling, serving as an advocate for the patient, making referrals, and case management. Giving supportive care is just as important as giving direct physical care. For example, through ongoing monitoring either in the home or in a clinic, a nurse might detect early signs of impending complications and make a referral (e.g., contact the primary health care clinician or consult the medical protocol in a clinic) for medical evaluation, thereby preventing a lengthy and costly hospitalization.

Keeping in mind the many facets and implications of chronic health conditions and their potential impact on patients and families will enable the nurse to provide direct physical care to the patient when warranted, to address the emotional and psychological needs of the patient and family, and to prepare and assist patients and family caregivers to assume management of the condition. By doing so, the nurse can help patients and families maintain as normal a life as possible and as they desire.

Working with people with chronic illness requires not only dealing with the medical aspects of their disorder but also working with the whole person—physically, emotionally, and socially. This holistic approach to care requires nurses to draw on their knowledge and skills, including knowledge from the social sciences and psychology, in particular. People often respond to illness, health education, and regimens in ways that differ from the expectations of health care providers. Although quality of life is usually affected by chronic illness, especially if the illness is severe, patients' perceptions of what constitutes quality of life often drive their management behaviors or affect how

they view advice about health care. Nurses and other health care professionals need to recognize this, even though it may be difficult to see patients make unwise choices and decisions about lifestyles and disease management. People have the right to receive care without fearing ridicule or refusal of treatment, even if their behaviors (e.g., smoking, substance abuse, overeating, failure to follow health care providers' recommendations) may have contributed to their chronic disorder.

Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Because chronic conditions are so costly to people, families, and society, two of the major goals of nursing are the prevention of chronic conditions and the care of people with them. This requires promoting healthy lifestyles and encouraging the use of safety and disease prevention measures, such as wearing seat belts and obtaining immunizations. Prevention should also begin early in life and continue throughout life. Education on self-care may need to address interactions among the patient's chronic conditions as well as skills necessary to manage the individual diseases and their interactive effects.

Patient and family education is an important nursing role that may make the difference in the ability of the patient and the family to adapt to chronic conditions. Well-informed, educated patients are more likely than uninformed patients to be concerned about their health and do what is necessary to maintain it. They are also more likely to manage symptoms, recognize the onset of complications, and seek health care early. Knowledge is the key to making informed choices and decisions during all phases of the chronic illness trajectory.

Despite the importance of educating the patient and the family, the nurse must recognize that patients recently diagnosed with serious chronic conditions and their families may need time to understand the significance of their condition and its effect on their lives. Education must be planned carefully so that it is not acute. Furthermore, it is important to assess the impact of a new diagnosis of chronic illness on a patient's life and the meaning of self-management to the patient.

The nurse who cares for patients with chronic conditions in the hospital, clinic, home, or any other setting should assess patient's knowledge about their illness and its management; the nurse cannot assume that patients with a long-standing chronic condition have the knowledge necessary to manage the condition. Patients' learning needs change as the chronic condition changes and their personal situations change. The nurse must also recognize that patients may know how their body responds under certain conditions and how

best to manage their symptoms. Contact with patients in any setting offers nurses the ideal opportunity to reassess patients' learning needs and provide additional education about a chronic condition and its management.

Educational strategies and materials should be adapted to the individual patient so that the patient and the family can understand and follow recommendations from health care providers. For instance, educational materials should be tailored for people with low literacy levels and available in several languages and in various alternative formats (e.g., Braille, large print, audiotapes). It may be necessary to provide sign language interpreters.

Continuing and Transitional Care

Chronic illness management is a collaborative process between the patient, family, nurse, and other health care providers. Collaboration extends to all settings and throughout the illness trajectory. Keeping an illness stable over time requires careful monitoring of symptoms and attention to management regimens. Detecting problems early and helping patients develop appropriate management strategies can make a significant difference in outcomes.

Most chronic conditions are managed in the home. Therefore, care and education during hospitalization should focus on essential information about the condition so that management can continue once the patient is discharged home. Nurses in all settings should be aware of the resources and services available in a community and should make the arrangements (before hospital discharge, if the patient is hospitalized) to secure those resources and services. When appropriate, home care services are contacted directly. The home health nurse reassesses how the patient and the family are adapting to the chronic condition and its treatment and continues or revises the plan of care accordingly.

Because chronic conditions occur worldwide and the world is increasingly interconnected, nurses should think beyond the personal level to the community and global levels. In terms of illness prevention and health promotion, this entails wide-ranging efforts to assess people for risks of chronic illness (e.g., blood pressure and diabetes screening, stroke risk assessments) and group education related to illness prevention and management. In addition, nurses should remind patients with chronic illnesses or disabilities and their families about the need for ongoing health promotion and preventive health screening recommended for all people, because chronic illness and disability are often considered the main concern while other health-related issues are ignored (see Chart 7-6).

Telehealth or telehomecare (use of electronic data and telecommunications technologies to support long-distance clinical health care, patient and professional health-related education, public health, and health administration) has been used effectively to provide care for patients with chronic illness. It is particularly useful in monitoring patients with chronic conditions living in

rural areas (Health Resources & Services Administration, 2013). It has also been used to deliver select medical and nursing interventions (e.g., counseling) and provide ongoing education and support.

Transitional care, if available, should be considered and implemented when the patient has MCC, has impaired cognitive status as well as physical limitations, has complex therapies, or is frail or unstable prior to discharge from the hospital to home. Transitional care nurses serve as the primary coordinator of care. These nurses conduct assessments of the patient as well as the family caregivers' ability to assist in management of the patient in the home. Nurses in this role help the patient and the family set goals during hospitalization, identify the reasons for the patient's current health status, design a plan of care that addresses them, make home visits, provide telephone support, and coordinate various care providers and services (Naylor et al., 2017) (see Chapter 2).

Nursing Care for Special Populations with Chronic Illness

When providing care and education, the nurse must consider multiple factors (e.g., age; gender; culture and ethnicity; cognitive status; the presence of physical, sensory, and cognitive limitations; health literacy) that influence susceptibility to chronic illness and the ways patients respond to chronic disorders. Certain populations, for example, tend to be more susceptible to certain chronic conditions. Populations at high risk for specific conditions can be targeted for special education and monitoring programs; this includes those at risk because of their genetic profile (see Chapter 6 for further discussion of genomics and genetics). People of different cultures and genders may respond to illness differently, and being aware of these differences is essential. For cultures in which patients rely heavily on the support of their families, the families must be involved and made part of the nursing plan of care. As the United States becomes more multicultural and ethnically diverse, and as the general population ages, nurses need to be aware of how a person's culture and age affect chronic illness management and be prepared to adapt their care accordingly.

It is important to consider the effect of a preexisting disability, or a disability associated with recurrence of a chronic condition, on the patient's ability to manage ADLs, self-care, and the therapeutic regimen. These issues were discussed earlier in this chapter.

CRITICAL THINKING EXERCISES

1 ebp A 70-year-old man is hospitalized for congestive heart failure. He has an above-the-knee amputation because of an injury that occurred 40 years ago as well as significant hearing loss due to exposure to loud noise in his work and lack of ear protection. In providing discharge planning for him, what evidence-based education is warranted to ensure that he is able to monitor his cardiac status? What evidence-based safety precautions are warranted? How would you modify education because of his hearing loss?

2 ipc A 28-year-old woman with paraplegia experienced since she was 14 years of age is hospitalized with a large sacral pressure injury due to her failure to relieve pressure points when in her wheelchair. She is scheduled for surgery to débride the pressure injury followed by placement of a graft to the area. She acknowledges that she has difficulty following medical advice and is eager to be discharged from the hospital as soon as possible to return home because she becomes depressed when she is away from her home and her boyfriend. What nursing and interprofessional assessments are indicated during your initial interactions with her? What interventions, including education, will you implement during her postoperative recovery? What other interprofessional services might you try to engage so she can make the best transition back to her home setting?

3 pq A 48-year-old woman with multiple sclerosis has experienced frequent relapses, increasing mobility limitations with each relapse, and mild cognitive impairment. She is now hospitalized with a diagnosis of possible pneumonia and a urinary tract infection. Her daughter has asked you, her mother's primary nurse, for assistance in making alternative living arrangements for her mother; the daughter tells you she is exhausted and frustrated by providing care for her mother and her own two children while trying to maintain her full-time job as an administrative assistant. How would you approach this situation? What is your priority in assessing the situation and taking action to assist this family?

8 Management of the Older Adult Patient

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Specify the demographic trends and the physiologic aspects of aging in the United States.
2. Describe the significance of preventive health care and health promotion for the older adult.
3. Compare and contrast the common physical and mental health problems of aging and their effects on the functioning of older adults and their families.
4. Identify the role of the nurse in meeting the health care needs of the older patient.
5. Examine common health issues of older adults and their families in the home and the community, in the acute care setting, and in the long-term care facility.

NURSING CONCEPTS

Development
Ethics and Legal Issues
Family
Health, Wellness, and Illness

GLOSSARY

activities of daily living (ADLs): personal care activities such as bathing, dressing, grooming, eating, toileting, and transferring

ageism: a bias that discriminates, stigmatizes, and disadvantages older adults based solely on their chronologic age

comorbidity: having more than one illness at the same time (e.g., diabetes, congestive heart failure)

depression: the most common affective (mood) disorder of old age; results from changes in reuptake of the neurochemical serotonin in response to chronic illness and emotional stresses

durable power of attorney: a formal, legally endorsed document that identifies a proxy decision maker who can make decisions if the signer becomes incapacitated

elder abuse: the physical, emotional, or financial harm to an older person by one or more of the person's children, caregivers, or others; includes neglect

geriatric syndromes: common conditions found in older adults that tend to be multifactorial and do not fall under discrete disease categories; these conditions include falls, delirium, frailty, dizziness, and urinary incontinence

geriatrics: a field of practice that focuses on the physiology, pathology, diagnosis, and management of the disorders and diseases of older adults

gerontologic/geriatric nursing: the field of nursing that relates to the assessment, planning, implementation, and evaluation of older adults in all environments, including acute, intermediate, and skilled care, as well as within the community

gerontology: the combined biologic, psychologic, and sociologic study of older adults within their environment

instrumental activities of daily living (IADLs): complex skills needed for independent living, such as shopping, cooking, housework, using the telephone, managing medications and finances, and being able to travel by car or public transportation

orientation: a person's ability to recognize who and where they are in a time continuum; used to evaluate one's basic cognitive status

polypharmacy: the use of multiple prescription and over-the-counter (OTC) medications

presbycusis: decreased ability to hear high-pitched tones that naturally begins in midlife as a result of irreversible inner ear changes

presbyopia: decrease in visual accommodation that occurs with advancing age

urinary incontinence: unplanned, involuntary, or uncontrolled loss of urine

Aging, the normal process of time-related change, begins with birth and continues throughout life. Americans are living longer than any previous generation. With the baby boomers turning 65 years of age beginning in 2010, older Americans are the most rapidly expanding portion of the population. In 2016, 3.5 million people celebrated their 65th birthdays. It is projected that 10,000 older adults will celebrate their 65th birthday each year until the year 2030 (Administration on Aging [AoA], 2020). Whenever nurses work with adults, they are likely to encounter older adult patients. This chapter presents demographics of aging, normal age-related changes, health problems associated with aging, and ways that nurses can influence the quality of life and address the health issues of older adults.

Overview of Aging

Demographics of Aging

The proportion of Americans 65 years of age and older has increased from 37 million in 2006 to 49.2 million in 2016 (a 33% increase). It is projected that by 2060, the older adult population will double to 98 million. Currently one in every seven persons is an older adult, or 15.2% of the population. As the older adult population increases, the number of people who live to a very old age is also dramatically increasing. The greatest growth in the older adult population is for those aged 85 years and older; this population is projected to more than double from 6.4 million in 2016 to 14.6 million in 2040, a 129% increase (AoA, 2020). Life expectancy—the average number of years that a person can expect to live—varies by gender and race, with women living longer than men and White women having the longest life expectancy. The difference in life expectancy between the genders is a full 5 years. Life expectancy has risen dramatically in the past 100 years. In 1900, average life expectancy was 47 years and by 2009, that figure had increased to 78.8 years. In 2016, life expectancy decreased by 0.2% to 78.6% (Xu, Murphy, Kochanek, et el., 2018).

The older adult population is becoming more diverse, reflecting changing demographics in the United States. Although this population will increase in number for all minority groups, the rate of growth is projected to be fastest in the Hispanic population, which is expected to increase by 112% between 2016 and 2030. Proportionally, there will be a significant decline in the percentage of the White non-Hispanic population, which is anticipated to increase only by 39% by 2030 (AoA, 2020).

Health Status of the Older Adult

Although many older adults enjoy good health, most have at least one chronic illness, and many have multiple health conditions. Chronic conditions, many of which are preventable or treatable, are the major cause of disability and pain among older adults (see Fig. 8-1).

Most deaths in the United States occur in people 65 years of age and older. However, improvements in the prevention, early detection, and treatment of diseases have impacted the health of people in this age group. In the past 60 years, there has been a significant decline in overall deaths—specifically, deaths from heart disease and cancer, the two leading causes of deaths. In addition, deaths from chronic lower respiratory diseases, stroke, influenza, pneumonia, and sepsis, have declined (Xu et al., 2018). Deaths from unintentional injuries and chronic lower pulmonary diseases exchanged places, making unintentional injuries the third leading cause of death. Deaths from Alzheimer's disease (AD) have risen and are projected to quadruple by the year 2050, affecting 14 million U.S. adults aged 65 years and older (Centers for Disease Control and Prevention [CDC], 2017).

Between the years 2012 and 2014, 78% of noninstitutionalized Americans aged 65 years and older rated their health as good, very good, or excellent (AoA, 2020). Men and women reported comparable levels of health; however, positive health reports declined with advancing age. Even at the age of 85 years and more, the majority of Americans reported good or better health. Blacks, Hispanics, and Latinos appeared less likely to report good health than their White counterparts. Most Americans 75 years of age and older remained functionally independent regardless of how they perceived their health. The proportion of older Americans reporting a limitation in activities declined from 49% in 1992 to 44% in 2013 (AoA, 2020). These declines in limitations may reflect trends in health promotion and disease prevention activities, such as improved nutrition, decreased smoking, increased exercise, and early detection and treatment of risk factors such as hypertension and elevated serum cholesterol levels.

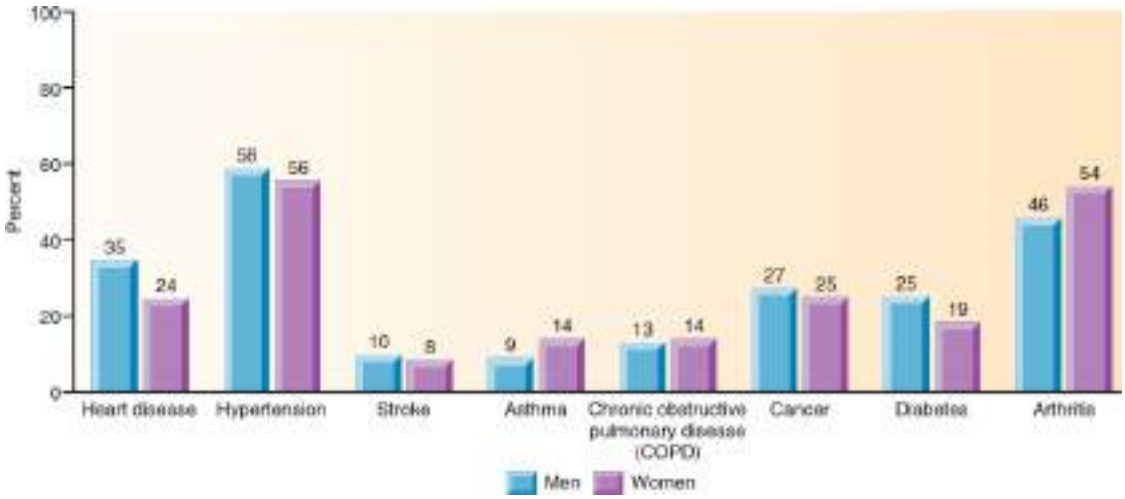

Figure 8-1 • Percentage of people 65 years of age and older who reported having selected chronic health conditions, by sex, 2018. From National Center for Health Statistics. (2020). Older Americans 2020: Key indicators of well-being. Washington, DC: U.S. Government Printing Office. Retrieved 11/30/2020 at: https://www.agingstats.gov/data.html

Many chronic conditions commonly found among older people can be managed, limited, and even prevented. Older people are more likely to maintain good health and functional independence if encouraged to do so and if appropriate community-based support services are available (Miller, 2019). Nurses need to promote positive lifelong health behaviors, because the impact of unhealthy behaviors and choices can result in chronic disease.

Nursing Care of the Older Adult

Gerontology, the study of the aging process, is a multidisciplinary field that draws from the biologic, psychologic, and sociologic sciences. **Geriatrics** is the practice (medical or nursing) that focuses on the physiology, pathology, diagnosis, and management of the disorders and diseases of older adults. Care for older adults should not be limited to one discipline but is best provided through a cooperative effort. An interdisciplinary approach to providing care combines expertise and resources to provide comprehensive geriatric assessment and intervention. Nurses collaborate with the team to obtain appropriate services for patients and provide a holistic approach to care.

Gerontologic/geriatric nursing is the field of nursing that specializes in the care of older adults. The Scope and Standards of Gerontological Nursing Practice was originally developed in 1969 by the American Nurses Association (ANA) and revised in 2010 (ANA, 2010). The nurse gerontologist can be either a specialist or a generalist providing comprehensive nursing care to older adults by combining the basic nursing process with a specialized

knowledge of aging. Gerontologic nursing is provided in acute care, skilled and assisted living, the community, and home settings. The goals of care include promoting and maintaining functional status as well as helping older adults identify and use their strengths to achieve optimal independence.

Nurses who are certified in geriatric nursing have specialized knowledge of the acute and chronic challenges specific to older adults. The use of advanced practice nurses who have been educated in geriatric nursing concepts has proved to be very effective when dealing with the complex care needs of an older patient. When best practices are used and current scientific knowledge applied to clinical problems, there is significantly less deterioration in the overall health of aging patients (ANA, 2010).

In addition to specialists, nurses who work in all areas of adult medical-surgical nursing encounter older adult patients. Nurses must be knowledgeable and skilled in meeting the complex needs of these patients. Nurses and caregivers who work with older patients must understand that aging is not synonymous with disease and that the effects of the aging process alone are not the only or even the primary contributors to disability and disease. Aging is a highly individualized and multifaceted process (Sommerlad, Sabia, Singh-Manoux, et al., 2019).

Functional assessment is a common framework for assessing older adults. Age-related changes, as well as additional risk factors such as disease and the effects of medications, can reduce function. Assessing the functional consequences of aging and proposing practical interventions helps to maintain and improve the health of older adults (Miller, 2019). The goal is to help older adults sustain maximum functional level and dignity despite physical, social, and psychological losses. Early intervention can prevent complications of many health problems and help maximize the quality of life.

Theories of Aging

Aging has been defined chronologically by the passing of time—subjectively, as in how a person feels, and functionally, as in changes in physical or mental capabilities. Many theories attempt to provide a framework in which to understand aging from different perspectives. Clinicians can use each theory to gain insight into different aspects of aging.

In addition to the biologic, developmental, and sociologic theories of aging, Miller (2019) developed the Functional Consequences Theory, which encourages nurses to consider the effects of normal age-related changes as well as the damage incurred through disease or environmental and behavioral risk factors when planning care. This theory suggests that nurses can alter the outcome for patients through nursing interventions that address the consequences of these changes. Age-related changes and risk factors may negatively interfere with patient outcomes and impair patient activity and

quality of life. For example, normal age-related changes in vision may increase sensitivity to glare. Alterations in the environment that reduce glare may enhance patient comfort and safety. In contrast, the development of cataracts, which is not a normal age-related change, also may increase sensitivity to glare. The nurse must differentiate between normal, irreversible age-related changes and modifiable risk factors. Doing so helps the nurse design appropriate nursing interventions that have a positive impact on outcomes for older patients—most importantly, for their quality of life.

Age-Related Changes

The well-being of older adults depends on physical, psychosocial, mental, social, economic, and environmental factors. A total assessment includes an evaluation of all major body systems, social and mental status, the person's ability to function independently, and their quality of life.

Physical Aspects of Aging

Intrinsic aging (from within the person) refers to those changes caused by the normal aging process that are genetically programmed and essentially universal within a species. Universality is the major criterion used to distinguish normal aging from pathologic changes associated with illness. However, people age quite differently and at different rates; thus, chronologic age is often less predictive of obvious age characteristics than other factors, such as one's genetics (see Chart 8-1) and lifestyle factors (Frishman, 2019; Seah, Kowitlawakul, Jiang, et al., 2019; Sommerlad et al., 2019).

Cellular and extracellular changes that occur with aging cause functional decline and measurable changes in physical appearance, including changes in shape and body makeup. Cellular aging and tissue deficits also diminish the body's ability to maintain homeostasis and prevent organ systems from functioning at full efficiency. As cells become less able to replace themselves, they accumulate a pigment known as lipofuscin. A degradation of elastin and collagen causes connective tissue to become stiffer and less elastic. These changes result in diminished capacity for organ function and increased vulnerability to disease and stress. Age-related changes in the hematopoietic system influence red blood cell production, leading to increased rates of anemia (Norris, 2019).

Chart 8-1 **GENETICS IN NURSING PRACTICE**

Genetics Concepts and the Older Adult

Genetic conditions in the older adult may occur from a specific gene mutation or arise as a result of a genetic predisposition combined with other factors (multifactorial). The following are examples of some adult-onset genetic conditions:

- Colon cancer
- Hemochromatosis
- Huntington disease
- Polycystic kidney disease
- Alzheimer's disease

The following are some examples of diseases with multifactorial components, which may include a genetic predisposition, in the older adult:

- Diabetes
- Emphysema
- Heart disease

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to the Older Adult

- Collect and assess family history on both maternal and paternal sides of the family for three generations.
- Determine whether genetic testing has occurred with other family members.
- Assess for individual and family perceptions and beliefs around topics related to genetics.

Patient Assessment Specific to the Older Adult and Genetic Illness

- Assess older adult patient's knowledge and understanding of genetics, genetic testing, and gene-based therapies.
- Assess the patient's understanding of genetic information and decipher health literacy needs.
- Perform cultural, social, and spiritual assessment.
- Assess patient's communication capacities so that communication strategies about genetics are tailored to their needs and abilities.
- Identify patient's support system.

Management Issues Specific to Genetics and the Older Adult

- Refer for further genetic counseling and evaluation as warranted so that family members can discuss inheritance, risk to other family members, and availability of genetic testing and gene-based interventions.

- Offer appropriate genetic information and resources that take into consideration older patient's literacy needs.
- Evaluate older patient's understanding before, during, and after the introduction of genetic information and services.
- Take the time to clearly explain the concepts of genetic testing to older patients and provide written information that reinforces the topic of discussion.
- Participate in the management and coordination of care of older patients with genetic conditions and individuals predisposed to develop or pass on a genetic condition.

Genetics Resources

See Chapter 6, Chart 6-7: Components of Genetic Counseling for additional resources.

Table 8-1 summarizes subjective and objective findings related to age-related changes in the body systems. More in-depth information about age-related changes can be found in the chapters pertaining to each organ system.

When assessing the physical aspects of aging, nurses should know that tactile sensation is reduced and changes in the ability to sense pressure, pain, and temperature all lead to a decreased ability to identify and attend to physical symptoms (Kennedy-Malone, Martin-Plank, & Duffy, 2019)

Cardiovascular System

Heart disease is the leading cause of death in older adults. Age-related changes reduce the efficiency of the heart and contribute to decreased compliance of the heart muscle. These changes include myocardial hypertrophy, which changes left ventricular strength and function; increased fibrosis and calcified tissues that infiltrate muscles and conductive tissues causing stenosis of the valves; and decreased pacemaker cells. As a result, the heart valves become thicker and stiffer, and the heart muscle and arteries lose their elasticity, resulting in a reduced stroke volume. Calcium and fat deposits accumulate within arterial walls, and veins become increasingly stiff and tortuous, increasing arterial resistance; this leads to hypertension and increases the workload of the heart (Capriotti & Frizzell, 2016).

It is difficult to differentiate between age- and disease-related changes in cardiovascular function because of the significant influence of behavioral factors on cardiovascular health. When cross-cultural studies are conducted, cardiovascular changes that in the past were thought to be age related do not consistently appear. For example, the higher blood pressure found in older adults in Western societies does not occur in less-developed societies and may be a result of different lifestyle behaviors rather than normal age-related changes (Miller, 2019). The cardiovascular system can adapt to many normal

age-related changes and often an older person is unaware of any significant decline in cardiovascular performance. However, when challenged, for instance, during exercise or stress, the cardiovascular system of an older person is less efficient and may be unable to respond sufficiently when life-sustaining activities are needed.

Careful assessment of older adults is necessary because they often present with different symptoms than those seen in younger patients. Older adults are more likely to have dyspnea or neurologic symptoms associated with heart disease, and they may experience mental status changes or report vague symptoms such as fatigue, nausea, and syncope. Rather than the typical substernal chest pain associated with myocardial ischemia, older patients may report burning or sharp pain or discomfort in an area of the upper body. Complicating the assessment is the fact that many older patients have more than one underlying disease. When a patient complains of symptoms related to digestion and breathing and upper extremity pain, cardiac disease must be considered. The absence of chest pain in an older patient is not a reliable indicator of the absence of heart disease.

TABLE 8-1 Age-Related Changes in Body Systems and Health Promotion Strategies

Changes	Subjective and Objective Findings	Health Promotion Strategies
Cardiovascular System		
Decreased cardiac output; diminished ability to respond to stress; heart rate and stroke volume do not increase with maximum demand; slower heart recovery rate; increased blood pressure	Complaints of fatigue with increased activity Increased heart rate recovery time *Optimal blood pressure:* <130/80 mm Hg	Exercise regularly; pace activities; avoid smoking; eat a low-fat, low-salt diet; participate in stress-reduction activities; check blood pressure regularly; adherence to medications; weight control (body mass index <25 kg/m^2)
Respiratory System		
Increase in residual lung volume; decrease in muscle strength, endurance, and vital capacity; decreased gas exchange and diffusing capacity; decreased cough efficiency	Fatigue and breathlessness with sustained activity; decreased respiratory excursion and chest/lung expansion with less effective exhalation; difficulty coughing up secretions	Exercise regularly; avoid smoking; take adequate fluids to liquefy secretions; receive yearly influenza immunization and pneumonia vaccine at 65 years of age; avoid exposure to upper respiratory tract infections
Integumentary System		
Decreased subcutaneous fat, interstitial fluid, muscle tone, glandular activity, and sensory receptors, resulting in atrophy and decreased protection against trauma, sun exposure, and temperature extremes; diminished secretion of natural oils and perspiration; capillary fragility	Thin, wrinkled, and dry skin; increased fragility, more easily bruised, and sunburned; complaints of intolerance to heat; prominent bone structure	Limit sun exposure to 10–15 min daily for vitamin D (use protective clothing and sunscreen); dress appropriately for temperature; stay hydrated; maintain a safe indoor temperature; take shower rather than hot tub bath if possible; lubricate skin with lotions that contain petroleum or mineral oil
Reproductive System		
Female: Vaginal narrowing and decreased elasticity; decreased vaginal secretions *Male:* Gradual decline in fertility, less firm testes, and decreased sperm production *Male and female:* Slower sexual response	*Female:* Painful penile-vaginal intercourse; vaginal bleeding following intercourse; vaginal itching and irritation; delayed orgasm *Male:* Less firm erection and delayed erection and	*Female:* May require vaginal estrogen replacement; gynecology/urology follow-up; use a lubricant with sexual intercourse

	achievement of orgasm	
Musculoskeletal System		
Loss of bone density; loss of muscle strength and size; degenerated joint cartilage	Height loss; prone to fractures; kyphosis; back pain; loss of strength, flexibility, and endurance; joint pain	Weight-bearing exercise regularly (3 times a week); recommend bone density screening; take calcium and vitamin D supplements as prescribed
Genitourinary System		
Decrease in detrusor muscle contractility, bladder capacity, flow rate, ability to withhold voiding; increase in residual urine *Male:* Benign prostatic hyperplasia *Female:* Relaxed perineal muscles; detrusor instability leads to urge incontinence; urethral dysfunction (stress urinary incontinence)	Urinary retention; irritative voiding symptoms including frequency, feeling of incomplete bladder emptying, multiple nighttime voiding Urgency/frequency syndrome; decreased "warning time"; drops of urine lost with cough, laugh, position change	Drink adequate fluids but limit drinking in evening; avoid bladder irritants (e.g., caffeinated beverages, alcohol, artificial sweeteners); do not wait long periods between voiding; empty bladder completely when voiding; wear easily manipulated clothing; consider urologic workup. Women: perform pelvic floor muscle exercises, preferably learned via biofeedback
Gastrointestinal System		
Decreased sense of thirst, smell, and taste; decreased salivation; difficulty swallowing food; delayed esophageal and gastric emptying; reduced gastrointestinal motility	Risk of dehydration, electrolyte imbalances, and poor nutritional intake; complaints of dry mouth; complaints of fullness, heartburn, and indigestion; constipation, flatulence, and abdominal discomfort; risk for aspiration	Use ice chips, mouthwash; brush, floss, and massage gums daily; receive regular dental care; eat small, frequent meals; sit up while and after eating and avoid heavy activity after eating; limit antacids; eat a high-fiber, low-fat diet; limit laxatives; toilet regularly; drink adequate fluids
Nervous System		
Decrease in brain volume and cerebral blood flow. Reduced speed in nerve conduction	Slower to respond and react; learning may take longer; increased vulnerability to delirium with illness, anesthesia, even changes in	Pace education; with hospitalization, encourage visitors; enhance sensory stimulation; with sudden confusion, look for cause; encourage slow rising from a resting position and practice fall prevention measures

	environmental cues such as a room change; increased risk of fainting and falls	
Special Senses		
Vision: Presbyopia; diminished ability to focus on close objects; decreased ability to tolerate glare; pupils become more rigid and lenses more opaque; decreased contrast sensitivity; decrease in aqueous humor	Holds objects far away from face; complains of glare; poor night vision and "dry" eye; difficulty adjusting to changes in light intensity; decreased ability to distinguish colors	Wear eyeglasses and use sunglasses outdoors; avoid abrupt changes from dark to light; use adequate indoor lighting with area lights and nightlights; use large-print books; use magnifier for reading; avoid night driving; use contrasting colors for color coding; avoid glare of shiny surfaces and direct sunlight
Hearing: Presbycusis; decreased ability to hear high-frequency sounds; tympanic membrane thinning and loss of resiliency; difficulty with sound discrimination especially in noisy environment	Gives inappropriate responses; asks people to repeat words; strains forward to hear; can result in social isolation and increases vulnerability for delirium during hospitalization	Recommend a hearing examination; reduce background noise; face person; enunciate clearly; speak with a low-pitched voice; use nonverbal cues; rephrase questions
Taste and smell: Decreased ability to taste and smell	Decreased recognition of familiar smells including recognizing spoiled food or a gas stove left on; decreased enjoyment of food; uses excessive sugar and salt	Encourage use of lemon, spices, herbs; recommend smoking cessation

Adapted from Weber, J. R., & Kelley, J. H. (2019). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

Orthostatic and postprandial hypotension may be a concern as well because of decreased baroreflex sensitivity and risk factors such as medications (Miller, 2019). Therefore, it is important to assess blood pressure in two positions. A patient experiencing hypotension should be counseled to rise slowly (from a lying, to a sitting, to a standing position), avoid straining when having a bowel movement, and consider having five or six small meals each day, rather than

three, to minimize the hypotension that can occur after a large meal. Extremes in temperature, including hot showers and whirlpool baths, should be avoided.

Respiratory System

The respiratory system compensates well for the functional changes of aging. In general, healthy, nonsmoking older adults show very little decline in respiratory function; however, there are substantial individual variations and aerobic capacity declines with each decade by about 10% from peak performance in the early to mid-20s (Capriotti & Frizzell, 2016). The age-related changes that do occur are subtle and gradual, and healthy older adults are able to compensate for these changes. Diminished respiratory efficiency and reduced maximal inspiratory and expiratory force may occur as a result of calcification and weakening of the muscles of the chest wall. Lung mass decreases and residual volume increases (Norris, 2019).

Conditions of stress, such as illness, may increase the demand for oxygen and affect the overall function of other systems. Like cardiovascular diseases, respiratory diseases manifest more subtly in older adults than in younger adults and do not necessarily follow the typical pattern of cough, chills, and fever. Older adults may exhibit fatigue, lethargy, anorexia, dehydration, and mental status changes (Miller, 2019).

Smoking is the most significant risk factor for respiratory diseases and older adults have a higher rate of smoking, about 20%, compared to the national average of 18% (Bowler, Hansel, Jacobson, et al., 2017). Therefore, a major focus of health promotion activities should be on smoking cessation and avoidance of environmental smoke. Despite marketing by manufacturers, e-cigarettes are not an effective smoking cessation aid nor do they promote health (Bowler et al., 2017).

Additional activities that help older adults maintain adequate respiratory function include regular exercise, appropriate fluid intake, pneumococcal vaccination, yearly influenza immunizations, and avoidance of people who are ill. Hospitalized older adults should be frequently reminded to cough and take deep breaths, particularly postoperatively, because their decreased lung capacity and decreased cough efficiency predispose them to atelectasis and respiratory infections.

Integumentary System

The functions of the skin include protection, temperature regulation, sensation, and excretion. Aging can interrupt all functions of the skin and affect appearance (Norris, 2019). Epidermal proliferation decreases, and the dermis becomes thinner. Elastic fibers are reduced in number and collagen becomes stiffer. Subcutaneous fat diminishes, particularly in the extremities, and less vasodilation renders the body less able to produce or conserve body heat.

These changes lead to lack of fever in circumstances in which fever would normally be present in younger individuals and reduced tolerance to temperature extremes, which increases the likelihood of hypothermia and hyperthermia (Capriotti & Frizzell, 2016). There is also a loss of resiliency with wrinkling and sagging of the skin. The skin becomes drier and more susceptible to burns, injury, and infection. Hair pigmentation may change and balding may occur; genetic factors strongly influence these changes. These changes in the integument reduce tolerance to temperature extremes and sun exposure.

Lifestyle practices have a large impact on skin changes. Strategies to promote healthy skin function include not smoking, limiting alcohol consumption, avoiding exposure to the sun, using a sun protection factor of 15 or higher, wearing protective clothing, using emollient skin cream containing petrolatum or mineral oil, avoiding hot soaks in the bathtub, and maintaining optimal nutrition and hydration (Farage, Miller, & Maibach, 2017). Older adults should be encouraged to have any changes in the skin examined, because early detection and treatment of precancerous or cancerous lesions are essential for the best outcome.

Reproductive System

An outdated perception is that older adults are asexual, but older adults report that a fairly stable and active sex life is an important quality of life issue. Sexual activity declines with the loss of a partner, primarily for women as a result of widowhood and for men as a result of poor heath, poor sleep, erectile dysfunction, medications, and emotional factors. However, although good health is a predictor of sexual activity, older adults with chronic illnesses may be able to have a sexually active life as well. Because of the many factors that influence the ability to be sexually active, nurses and the older person need to understand the physiologic, psychologic, and social factors that affect reproductive and sexual functioning as aging progresses (Bozorgmehri, Fink, Parimi, et al., 2017; Kennedy-Malone et al., 2019; Miller, 2019).

Ovarian production of estrogen and progesterone declines with menopause. Changes that occur in the female reproductive system include thinning of the vaginal wall, along with a shortening of the vagina and a loss of elasticity; decreased vaginal secretions, resulting in vaginal dryness, itching, and decreased acidity; involution (atrophy) of the uterus and ovaries; and decreased pubococcygeal muscle tone, resulting in a relaxed vagina and perineum. Without the use of water-soluble lubricants, these changes may contribute to vaginal bleeding and painful penile-vaginal intercourse.

In older men, the testes become less firm but may continue to produce viable sperm up to 90 years of age. At about 50 years of age, production of testosterone begins to diminish (Mark, 2017). Decreased libido and erectile dysfunction may develop but are more likely to be associated with factors

other than age-related changes. These risk factors include obesity, smoking, cardiovascular disease, neurologic disorders, diabetes, respiratory disease, chronic pain, and many medications (i.e., vasodilators, antihypertensive agents, and tricyclic antidepressants) (Bozorgmehri et al., 2017; Miller, 2019).

In both older men and women, it may take longer to become sexually aroused, longer to complete sexual intercourse, and longer before sexual arousal can occur again. Although a less intense response to sexual stimulation and a decline in sexual activity occurs with increasing age, sexual desire does not disappear. Many couples are unaware of the causes of decreased libido or erectile dysfunction and are often reluctant to discuss decreased sexual function. Many nonpharmacologic, pharmacologic, and surgical methods are available to improve sexual relationships. Assessment and communication require sensitivity and expert knowledge in the field of sexual dysfunction. If sexual dysfunction is present, referral to a gynecologist, urologist, or sex therapist may be warranted.

Genitourinary System

The genitourinary system continues to function adequately in older adults, although kidney mass is decreased, primarily because of a loss of nephrons. However, the loss of nephrons does not typically become significant until about 90 years of age, and changes in kidney function vary widely; approximately one third of older adults show no decrease in renal function (Mark, 2017). Changes in renal function may be attributable to a combination of aging and pathologic conditions such as hypertension. The changes most commonly seen include a decreased filtration rate, diminished tubular function with less efficiency in reabsorbing and concentrating the urine, and a slower restoration of acid–base balance in response to stress. In addition, older adults who take medications may experience serious consequences owing to decline in renal function because of impaired absorption, decreased ability to maintain fluid and electrolyte balance, and decreased ability to concentrate urine.

Certain genitourinary disorders are more common in older adults than in the general population. In the United States, **urinary incontinence** (i.e., unplanned, involuntary, or uncontrolled loss of urine) affects women more than men at a ratio of 2:1 until after age 80, when both are equally affected. This condition should not be mistaken as a normal consequence of aging (Resnick, 2019). Costly and often embarrassing, it should be evaluated, because in many cases it is reversible or can be treated. When treatable, this condition needs to be addressed as the risk of mortality associated with urinary incontinence can be as high as 44% in patients living in long-term care facilities (Damián, Pator-Barriuso, Garcia López, et al., 2017). See Chapter 49 for further discussion of urinary incontinence. Benign prostatic hyperplasia (enlarged prostate gland), a common finding in older men, causes a gradual increase in urine retention and overflow incontinence. Changes in the urinary

tract increase the susceptibility to urinary tract infections (UTIs). Adequate consumption of fluids is an important nursing intervention that reduces the risk of bladder infections and also helps decrease urinary incontinence.

Gastrointestinal System

Digestion of food is less influenced by changes associated with aging than by the risk of poor nutrition. Older adults can adjust to changes in the gastrointestinal (GI) system but may have difficulty purchasing, preparing, and enjoying their meals. The sense of smell diminishes as a result of neurologic changes and environmental factors such as smoking, medications, and vitamin B_{12} deficiencies. The ability to recognize sweet, sour, bitter, or salty foods diminishes over time, altering satisfaction with food. Salivary flow does not decrease in healthy adults; however, approximately one third of older adults may experience a dry mouth as a result of medications and diseases (Miller, 2019). Difficulties with chewing and swallowing are generally associated with lack of teeth and diseases.

Experts disagree on the extent of gastric changes that occur as a result of normal aging. However, gastric motility appears to slow modestly, which results in delayed emptying of stomach contents and early satiety (feeling of fullness). Diminished secretion of gastric acid and pepsin, seemingly the result of pathologic conditions rather than normal aging, reduces the absorption of iron, calcium, and vitamin B_{12}. Absorption of nutrients in the small intestine, particularly calcium and vitamin D, appears to diminish with age. Functions of the liver, gallbladder, and pancreas are generally maintained, although absorption and tolerance to fat may decrease. The incidence of gallstones and common bile duct stones increases progressively with advancing years.

Dysphagia, or difficulty swallowing, increases with age and is a major health care problem in older patients. Normal aging alters some aspects of the swallowing function. In addition, dysphagia is a frequent complication of stroke and a significant risk factor for the development of aspiration pneumonia that can be life-threatening. Dysphagia is caused by interruption or dysfunction of neural pathways. It may also result from dysfunction of the striated and smooth muscles of the GI tract in patients with Parkinson's disease. Aspiration of food or fluid is the most serious complication and can occur in the absence of coughing or choking.

Constipation is a common condition affecting many older adults; it is influenced by multiple risk factors rather than age-related changes alone. Symptoms of mild constipation are abdominal discomfort and flatulence; more serious constipation leads to fecal impaction that contributes to diarrhea around the impaction, fecal incontinence, and obstruction. Predisposing factors for constipation include lack of dietary bulk, prolonged use of laxatives, some medications, inactivity, insufficient fluid intake, and excessive dietary fat. Ignoring the urge to defecate may also be a contributing factor (Miller, 2019).

Practices that promote GI health include regular tooth brushing and flossing; receiving regular dental care; drinking sufficient fluids; eating small, frequent meals that are high in fiber and low in fat; avoiding heavy activity or lying flat after eating; and avoiding the use of laxatives and antacids. Understanding that there is a direct correlation between loss of smell and taste perception and food intake helps caregivers intervene to maintain the nutritional health of older patients.

Nutritional Health

The social, psychologic, and physiologic functions of eating influence the dietary habits of older adults. Increasing age alters nutrient requirements; older adults require fewer calories and a more nutrient-rich, healthy diet in response to alterations in body mass and a more sedentary lifestyle. Recommendations include reducing fat intake while consuming sufficient protein, vitamins, minerals, and dietary fiber for health and prevention of disease. Decreased physical activity and a slower metabolic rate reduce the number of calories needed by older adults to maintain an ideal weight. As stated previously, age-related changes that alter pleasure in eating include a decrease in taste and smell. Older adults are likely to require more sugar to achieve a sweet flavor due to blunted taste. They also may lose the ability to differentiate sour, salty, and bitter tastes. Apathy, immobility, depression, loneliness, poverty, inadequate knowledge, and poor oral health also contribute to suboptimal nutrient intake. Budgetary constraints and physical limitations may interfere with food shopping and meal preparation.

Health promotion for older adults is based on the person's physical, emotional, social, spiritual, and intellectual health. The main focus of health promotion is engaging the older adult in improving their health (Meiner & Yeager, 2019). The goals of nutrition therapy are to maintain or restore maximal independent functioning and health and to maintain the sense of dignity and quality of life by imposing as few restrictions as possible. Dietary changes should be incorporated into the older adult's existing food pattern as much as possible. Figure 8-2 lists modified dietary guidelines for older adults.

Women older than 50 years and men older than 70 years should have a daily calcium intake of 1200 mg. To foster the absorption of calcium, adults should have 600 IU of vitamin D until 70 years of age and 800 IU after 70 years of age to maintain bone health (National Institutes of Health [NIH], 2018a).

Undernutrition, which can lead to malnutrition, may be a problem for older adults. Hospitalized older adults are at particular risk of malnutrition, especially those with cognitive impairment or dementia (Tatum, Talebreza, & Ross, 2018). A recent unintentional weight loss may be a result of an illness or other factors, such as depression, that may have serious consequences and affect a person's ability to maintain health and fight illness (Norris, 2019). Many people are unaware of dietary deficits. Nurses are in an ideal position to

identify nutritional problems among their patients and to work within the patient's own framework of knowledge of their health status to improve health behaviors. (See Chapter 4 for more information on nutritional assessment.)

Sleep

Older adults have increased complaints about their sleep as they age, and as many as 50% of those living at home and 65% of those living in nursing homes complain of sleep disturbances (Devlin, Skrobik, Gelinas, et al., 2018; Štefan, Vrgoč, Rupčić, et al., 2018). Many factors affect sleep quality in older adults including respiratory problems during sleep, restless leg syndrome, nocturia, pain, osteoarthritis, heart failure, incontinence, prostatic hyperplasia, menopause-related problems, pruritus, allergies, AD, depression, dementia, social isolation, loneliness, being bedridden, experiences of loss, drug use, and living in nursing homes (e.g., inadequate lighting, keeping light on during the night, noises). Some of the consequences of poor sleep quality in older adults include cognitive decline, increased risk of falls, daytime fatigue, reduced physical and mental health and health-related quality-of-life status, and poor ICU outcomes (Devlin et al., 2018; Štefan et al., 2018).

The incidence of sleep apnea (a sleep disorder characterized by brief periods in which respirations are absent) increases with age. Having insomnia symptoms and a sleep-related disorder (snoring, choking, or pauses in breathing) is associated with significantly impaired daytime functioning and longer psychomotor reaction times compared with having either condition. Sleep apnea is discussed in more detail in Chapter 18.

The nurse often observes patients while they are sleeping and can identify problems. Health education can be provided on sleep hygiene behaviors such as avoiding use of the bed for activities other than sleeping (or sex), maintaining a consistent bedtime routine, avoiding or limiting daytime napping, and limiting alcohol intake to one drink a day. Additional suggestions include avoiding stimulants such as caffeine and nicotine after noon; curbing the amount of liquids in the evening to avoid nocturia; and engaging in regular physical activity, preferably in bright outside light. Aromatherapy trials have reported that the use of lavender essential oil can improve the quality of sleep (Karadag, Samancioglu, Ozden, et al., 2017).

Musculoskeletal System

Intact musculoskeletal and neurologic systems are essential for the maintenance of safe mobility, performance of **activities of daily living (ADLs)** (basic personal care activities), and **instrumental activities of daily living (IADLs)** (complex skills such as shopping, cooking, housework, using the telephone, managing medications and finances, and being able to travel by car or public transportation), thus allowing older adults to remain safe and live independently in the community. Age-related changes that affect mobility include alterations in bone remodeling, leading to decreased bone density, loss of muscle mass, deterioration of muscle fibers and cell membranes, and degeneration in the function and efficiency of joints. These factors are discussed in detail in Unit 8.

Without exercise, a gradual, progressive decrease in bone mass begins before 40 years of age. The cartilage of joints also progressively deteriorates in middle age. Degenerative joint disease is found in most adults older than 70 years, and weight-bearing joint and back pain is a common complaint. Excessive loss of bone density results in osteoporosis, which leads to

potentially life-altering hip and vertebral fractures. Osteoporosis is preventable.

The axiom "use it or lose it" is very relevant to the physical capacity of older adults. Nurses play an important role by encouraging older adults to participate in a regular exercise program. The benefits of regular exercise cannot be overstated. Aerobic exercises are the foundation of programs of cardiovascular conditioning; however, resistance and strength training and flexibility exercises are essential components of an exercise program. Even late in life, in adults who may be frail, it is believed that exercise has benefits of increasing strength, aerobic capacity, flexibility, and balance. In addition, older adults who are hospitalized benefit from getting out of bed as soon as possible and in-hospital physical activity.

Nervous System

Homeostasis is difficult to maintain with aging, but older people have a tremendous ability to adapt and function adequately, retaining their cognitive and intellectual abilities in the absence of pathologic changes. However, normal aging changes in the nervous system can affect all parts of the body. The structure, chemistry, and function of the nervous system change with advanced age. Nerve cells in the brain decrease but the decrease is compensated for by other neurons; there is high variability among individuals and the quantity of neuronal loss varies in different parts of the brain. Overall, the decreases contribute to a small loss of brain mass (Capriotti & Frizzell, 2016). Chemical changes include a decrease in the synthesis and metabolism of the major neurotransmitters. Because nerve impulses are conducted more slowly, older people take longer to respond and react (Miller, 2019). The autonomic nervous system performs less efficiently, and orthostatic hypotension, discussed earlier, may occur. Neurologic changes can affect gait and balance, which may interfere with mobility and safety. Nurses must advise older adults to allow a longer time to respond to a stimulus and to move more deliberately. Adequate nutrition and absorption of vitamin B_{12} is important for neurologic health. Nurses should advise older adults about proper nutrition and intake of vitamin B_{12}, especially for older adults who follow a vegetarian diet.

Slowed reaction time puts older adults at risk for falls and injuries, as well as driving errors. Although older adults spend less time driving than younger people, older adults are just as likely to be involved in motor vehicle crashes that result in serious injury or death. Older adults who are suspected of driving unsafely should receive a driving fitness evaluation (Miller, 2019). The evaluation is often performed by an occupational therapist in conjunction with a neuropsychologist, who conducts more detailed cognitive testing.

Mental function may be threatened by physical or emotional stresses. A sudden onset of confusion may be the first symptom of an infection or change

in physical condition (e.g., pneumonia, UTI, medication interactions, dehydration).

Sensory System

People interact with the world through their senses. Losses associated with old age affect all sensory organs, and it can be devastating not to be able to see to read or watch television, hear conversation well enough to communicate, or discriminate taste well enough to enjoy food. Nearly half of older men and one third of older women report difficulty hearing without a hearing aid. Most older adults have a decrease in visual acuity, a narrowing of the visual field, and may have trouble seeing at night. An uncompensated sensory loss negatively affects the functional ability and quality of life of the older adult. However, assistive devices such as visual and hearing aids can compensate for a sensory loss (Miller, 2019).

Sensory Loss Versus Sensory Deprivation

In contrast to sensory loss, sensory deprivation is the absence of stimuli in the environment or the inability to interpret existing stimuli (perhaps as a result of a sensory loss). Sensory deprivation can lead to boredom, confusion, irritability, disorientation, and anxiety. A decline in sensory input can mimic a decline in cognition that is in fact not present. Meaningful sensory stimulation provided to the older person is often helpful in correcting this problem. In some situations, one sense can substitute for another in observing and interpreting stimuli. Nurses can enhance sensory stimulation in the environment with colors, pictures, textures, tastes, smells, and sounds. The stimuli are most meaningful if they are appropriate for older adults and the stimuli are changed often. Cognitively impaired people tend to respond well to touch and to familiar music.

Vision

As new cells form on the outside surface of the lens of the eye, the older central cells accumulate and become yellow, rigid, dense, and cloudy, leaving only the outer portion of the lens elastic enough to change shape (accommodate) and focus at near and far distances. As the lens becomes less flexible, the near point of focus gets farther away. This common condition—**presbyopia**—usually begins in the fifth decade of life and requires the person to wear reading glasses to magnify objects (Miller, 2019). In addition, the yellowing, cloudy lens causes light to scatter and is sensitive to glare. The ability to distinguish colors decreases, particularly blue from green. The pupil dilates slowly and less completely because of increased stiffness of the muscles of the iris, thus the older person takes more time to adjust when going to and from light and dark settings and needs brighter light for close vision. Pathologic visual conditions are not a part of normal aging; however, the

incidence of eye disease (most commonly cataracts, glaucoma, diabetic retinopathy, and age-related macular degeneration) increases in older adults.

Age-related macular degeneration (AMD) is the leading cause of vision loss and blindness in older adults 65 and older. It is predicted that cases of AMD will double from 48 million to 88 million people by 2050 (CDC, 2017). Macular degeneration does not affect peripheral vision, which means that it does not cause blindness. However, it affects central vision, color perception, and fine detail, greatly affecting common visual skills such as reading, driving, and seeing faces. Risk factors include sunlight exposure, cigarette smoking, and heredity. People with fair skin and blue eyes may be at increased risk. Sunglasses and hats with visors provide some protection, and stopping smoking is paramount in preventing the disease. Although there is no definitive treatment and no cure that restores vision, several treatment options are available, depending on factors such as the location of the abnormal blood vessels. Laser photocoagulation and photodynamic therapy are commonly used (CDC, 2017). The earlier this condition is diagnosed, the greater the chances of preserving sight. See Chapter 58 for more information on altered vision.

Hearing

Auditory changes begin to be noticed at about 40 years of age. Environmental factors, such as exposure to noise, medications, and infections, as well as genetics, may contribute to hearing loss as much as age-related changes. **Presbycusis** is a gradual sensorineural loss that progresses from the loss of the ability to hear high-frequency tones to a generalized loss of hearing. It is attributed to irreversible inner ear changes. Older adults often cannot follow conversation because tones of high-frequency consonants (the sounds *f, s, th, ch, sh, b, t, p*) all sound alike. Hearing loss may cause older adults to respond inappropriately, misunderstand conversation, and avoid social interaction. This behavior may be erroneously interpreted as confusion. Wax buildup or other correctable problems may also be responsible for hearing difficulties. A systematic review reported the prevalence of under detection of hearing loss and the under use of hearing aids in long-term care facilities (Punch & Horstmanshof, 2019). A properly prescribed and fitted hearing aid may be useful in reducing some types of hearing deficits and increasing quality of life (Punch & Horstmanshof, 2019). See Chapter 59 for discussion of alterations in hearing.

Taste and Smell

The senses of taste and smell are reduced in older adults. Of the four basic tastes (sweet, sour, salty, and bitter), sweet tastes are particularly dulled in older adults. Blunted taste may contribute to the preference for salty, highly

seasoned foods, but herbs, onions, garlic, and lemon can be used as substitutes for salt to flavor food.

Changes in the sense of smell, generally greater than the loss of taste, are related to cell loss in the nasal passages and in the olfactory bulb in the brain (Norris, 2019). Environmental factors such as long-term exposure to toxins (e.g., dust, pollen, smoke) contribute to the cellular damage.

Psychosocial Aspects of Aging

Successful psychological aging is reflected in the ability of older adults to adapt to physical, social, and emotional losses and to achieve life satisfaction. Because changes in life patterns are inevitable over a lifetime, older adults need resiliency and coping skills when confronting stresses and change. A positive self-image enhances risk taking and participation in new, untested roles.

Although attitudes toward older adults differ in ethnic subcultures, a subtle theme of **ageism**—prejudice or discrimination against older adults—predominates in society, and many myths surround aging. Ageism is based on stereotypes—simplified and often untrue beliefs that reinforce society's negative image of older adults. Although older adults make up an extremely heterogeneous and increasingly a racially and ethnically diverse group, these negative stereotypes are sometimes attributed to all older adults.

Fear of aging and the inability of many to confront their own aging process may trigger ageist beliefs. Retirement and perceived nonproductivity are also responsible for negative feelings, because a younger working person may falsely see older people as not contributing to society, as draining economic resources, and may actually feel that they are in competition with children for resources. Concern about the large numbers of older people leaving the workforce (baby boomers began to turn 65 years of age in 2010) is fueling this debate.

Negative images are so common in society that older adults themselves often believe and perpetuate them. An understanding of the aging process and respect for each person as an individual can dispel the myths of aging. Nurses can facilitate successful aging by recommending health promotion strategies such as anticipatory planning for retirement, including ensuring adequate income, developing routines not associated with work, replacing work-related friends with new acquaintances, and relying on other people and groups in addition to spouse to fill leisure time (Meiner & Yeager, 2019).

Stress and Coping in the Older Adult

Coping patterns and the ability to adapt to stress develop over the course of a lifetime and remain consistent later in life. Experiencing success in younger adulthood helps a person develop a positive self-image that remains solid

through old age. A person's abilities to adapt to change, make decisions, and respond predictably are also determined by past experiences. A flexible, well-functioning person will probably continue as such. However, losses may accumulate within a short period of time and become acute. The older person often has fewer choices and diminished resources to deal with stressful events. Common stressors of old age include normal aging changes that impair physical function, activities, and appearance; disability from injury or chronic illness; social and environmental losses related to loss of income and decreased ability to perform previous roles and activities; and the deaths of significant others. Many older adults rely strongly on their families and spiritual beliefs for comfort during stressful times.

An additional aspect of coping that nurse researchers have examined is self-efficacy, which is the confidence to perform well at a particular task or life domain (Hladek, Gill, Bandeen-Roche, et al., 2019). Chart 8-2 is a Nursing Research Profile about the associations between coping self-efficacy and frailty in a group of community-dwelling older adults.

Living Arrangements

Many older adults have more than adequate financial resources and good health even until very late in life; therefore, they have many housing options. In 2017, 93% of older adults lived in the community, with a relatively small percentage (2.3%) residing in nursing homes and a comparable percentage living in some type of senior housing. Seventy-six percent of those older than 65 years own their homes. In 2018, 28% of noninstitutionalized older people lived alone, and widowed women predominated. In 2018, 70% of men older than 65 years were married compared with 40% of women in the same age group. This difference in marital status increases with age and is a result of several factors: Women have a longer life expectancy than men; women tend to marry older men; and women tend to remain widowed, whereas men often remarry (AoA, 2020).

Many older adults relocate in response to changes in their lives such as retirement or widowhood, a significant deterioration in health, or disability. The type of housing they choose depends on their reason for moving. With increasing disability and illness, older adults may move to retirement facilities or assisted living communities that provide some support such as meals, transportation, and housekeeping but otherwise allow them to live somewhat independently. If they develop a serious illness or disability and can no longer live independently or semi-independently, they may need to move to a setting where additional support is available, such as a relative's home or a long-term care or assisted living facility. Often they will seek a location near an adult child's home.

Living at Home or With Family

Most older adults want to remain in their own homes; in fact, they function best in their own environment. The family home and familiar community may have strong emotional significance for them, and this should not be ignored. However, with advanced age and increasing disability, adjustments to the environment may be required to allow older adults to remain in their own homes or apartments. Additional family support or more formal support may be necessary to compensate for declining function and mobility. Many services and organizations can assist older adults to successfully "age in place" in their own homes or in assisted living facilities (see Resources at the end of this chapter).

Chart 8-2 NURSING RESEARCH PROFILE

The Association Between Coping Self-efficacy and Frailty in Community-Dwelling Older Adults

Hladek, M.D., Gill, J., Bandeen-Roche, K., et al. (2019). High coping self-efficacy associated with lower odds of pre-frailty/ frailty in older adults with chronic disease. *Aging & Mental Health*. doi.org/10.1080/13607863.2019.1639136

Purpose

Self-efficacy is the confidence to perform well at a particular task or life domain while frailty is a state of decreased physiologic reserve and vulnerability to negative health outcomes. The purpose of this study was to evaluate associations between self-efficacy and frailty in a group of community-dwelling older adults.

Design

This quantitative study used a cross-sectional design to study 146 older adults who lived in retirement communities. Instruments included the five-item Fatigue, Resistance, Ambulation, Illness, and Loss of weight (FRAIL) scale as well as two self-efficacy instruments that measured confidence in one's ability to problem solve, emotionally regulate, and ask for support when problems in life occur. Additional variables measured included illness intrusiveness, depressive symptoms, financial strain, life events, social support, heart rate, tobacco use, and body mass index (BMI). Logistic regression was used for model development.

Findings

Approximately half of the participants were in the frail or pre-frail range on the FRAIL scale. High coping self-efficacy was associated with a 92% reduction in the odds of participants being in the frail or pre-frail range on the FRAIL scale after adjusting for age, race, comorbidities, heart rate, life events count, and BMI. This relationship remained a significant finding even after the inclusion of illness intrusiveness and depressive symptoms (OR: 0.10, *p*-value = 0.014). Higher age, number of comorbidities, heart rate, and BMI were also significantly associated with participants being in the frail or pre-frail range on the FRAIL scale.

Nursing Implications

When working with older adults, nurses should keep in mind the association of high self-efficacy with healthy aging. Nurses can be instrumental in developing interventions to help older adults increase self-efficacy, as measured by their confidence in their ability to problem solve, emotionally regulate, and ask for support when problems in life occur.

Sometimes older adults or couples move in with adult children. This can be a rewarding experience as the children, their parents, and the grandchildren

interact and share household responsibilities (see Fig. 8-3). It can also be stressful, depending on family dynamics. Adult children and their older parents may choose to pool their financial resources by moving into a house that has an attached "in-law suite." This arrangement provides security for the older adult and privacy for both families. Many older adults and their adult children make housing decisions in times of crisis, such as during a serious illness or after the death of a spouse. Caring for an older adult may also be stressful; older adults and their families often are unaware of the emotional and physical demands of shared housing and assuming care for an increasingly dependent person, especially given the uncertain and extended length of time that may be associated with caring for a person with a chronic illness. Families can be helped by anticipatory guidance and long-term planning before a crisis occurs. Older adults should participate in decisions that affect them as much as possible.

Figure 8-3 • Families are an important source of psychosocial and physical support for all people. Caring interaction among grandchildren, grandparents, and other family members typically contributes to the health of all.

Continuing Care Retirement Communities

Continuing care retirement communities (CCRCs) offer three levels of living arrangements and care that provide for aging in place (Miller, 2019). CCRCs consist of independent single-dwelling houses or apartments for people who can manage their day-to-day needs, assisted living apartments for those who

need limited assistance with their daily living needs, and skilled nursing services when continuous nursing assistance is required. CCRCs usually contract for a large down payment before the resident moves into the community. This payment gives a person or couple the option of residing in the same community from the time of total independence through the need for assisted or skilled nursing care. Decisions about living arrangements and health care can be made before any decline in health status occurs. CCRCs also provide continuity at a time in an older adult's life when many other factors, such as health status, income, and availability of friends and family members, may be changing.

Assisted Living Facilities

Assisted living facilities are an option when an older person's physical or cognitive changes necessitate at least minimal supervision or assistance. Assisted living allows for a degree of independence while providing minimal nursing assistance with administration of medication, assistance with ADLs, or other chronic health care needs. Other services, such as laundry, cleaning, and meals, may also be included. Both assisted living and CCRCs are costly and primarily paid out-of-pocket.

Long-Term Care Facilities

Many types of nursing homes, nursing facilities, or long-term care facilities offer continuous nursing care. Contrary to the myth of family abandonment and the fear of "ending up in a nursing home," the actual percentage of older adults residing in long-term care facilities has declined, from 5.4% in 1985 to 2.3% in 2018 (AoA, 2020). However, the actual number of older people who reside in long-term care facilities has risen owing to the large increase in the population of older adults and the use of nursing homes for short-term rehabilitation.

Short-term nursing facility care is often reimbursed by Medicare if the patient is recovering from an acute illness such as a stroke, myocardial infarction (MI), or cancer and requires skilled nursing care or therapy for recuperation. Usually, if an older adult suffers a major health event and is hospitalized and then goes to a nursing facility, Medicare covers the cost of the first 30 to 90 days in a skilled nursing facility as long as ongoing therapy is needed. The requirement for continued Medicare coverage during this time is documentation of persistent improvement in the condition that requires therapy, most often physical therapy, occupational therapy, respiratory therapy, or cognitive therapy. Some adults choose to have long-term care insurance as a means of paying, at least in part, for the cost of these services should they become necessary. Costs of long-term care for older adults who are living in nursing homes and are medically stable, despite having multiple chronic and debilitating health issues, are primarily paid out-of-pocket by the patient.

When a person's financial resources become exhausted as a result of prolonged nursing home care, the patient, the institution, or both may apply for Medicare and Medicaid reimbursement depending on the situation. Family members are not responsible for nursing home costs.

An increasing number of skilled nursing facilities offer subacute care. This area of the facility offers a high level of nursing care that may either avoid the need for a resident to be transferred to a hospital from the nursing home or allow a hospitalized patient to be transferred back to the nursing facility sooner.

The Role of the Family

Planning for care and understanding the psychosocial issues confronting older adults must be accomplished within the context of the family. If dependency needs occur, the spouse often assumes the role of primary caregiver. In the absence of a surviving spouse, an adult child may assume caregiver responsibilities and need help in providing or arranging for care and support.

Two common myths in American society are that adult children and their aged parents are socially alienated, and that adult children abandon their parents when health and other dependency problems arise. In reality, the family has been and continues to be an important source of support for older adults; similarly, older family members provide a great deal of support to younger family members.

Although adult children are not financially responsible for their older parents, social attitudes and cultural values often dictate that adult children should provide services and assume the burden of care if their aged parents cannot care for themselves. It is estimated that in 2018, informal caregivers provided 18.5 billion hours of unpaid care (Alzheimer's Association, 2019). Caregiving, which may continue for many years, can become a source of family stress and is a well-known risk for psychiatric and physical morbidity. Evidence-based interventions to reduce distress and enhance well-being in caregivers have been identified. Three broad types of effective programs include psychoeducational skill building, cognitive behavioral therapy, and using a combination of at least two approaches such as education, family meetings, and skill building sessions (Bakas, McCarthy, & Miller, 2018). Researchers have reported that web-based interventions are effective, efficient, and a better fit for the hectic lives of families and caregivers (Wasilewski, Stinson, & Cameron, 2017).

Cognitive Aspects of Aging

Cognition can be affected by many variables, including sensory impairment, physiologic health, environment, sleep, and psychosocial influences. Older adults may experience temporary changes in cognitive function (i.e., delirium)

when hospitalized or admitted to skilled nursing facilities, rehabilitation centers, or long-term care facilities. These changes are related to differences in the environment or in medical therapy or to alteration in role performance. A commonly used assessment tool is the Mini-Mental State Examination (MMSE) (see Chart 8-3).

Good sleep hygiene can improve cognition, as can treatment of depression and anxiety. Several researchers are evaluating memory enhancement programs for older adults. In addition, researchers have found that eating a healthy balanced diet, being physically active for at least 30 minutes each day, and getting plenty of sleep can assist in preventing chronic illnesses as well as improving cognitive function (McDougall, 2017).

When intelligence test scores from people of all ages are compared, test scores for older adults show a progressive decline beginning in midlife. However, research has shown that environment and health have a considerable influence on scores, and that certain types of intelligence (e.g., spatial perceptions and retention of nonintellectual information) decline, whereas others (e.g., problem-solving ability based on past experiences, verbal comprehension, mathematical ability) do not. Cardiovascular health, a stimulating environment, and high levels of education, occupational status, and income all appear to have a positive effect on intelligence scores in later life.

Significant age-related declines in intelligence, learning, and memory are not inevitable. Many factors affect the ability of older adults to learn and remember and to perform well in testing situations. Older adults who have higher levels of education, good sensory function, good nutrition, and jobs that require complex problem-solving skills continue to demonstrate intelligence, memory, and the capacity for learning. Part of the challenge in testing older adults is determining what is actually being tested (e.g., speed of response) and whether the test results are indicative of a normal age-related change, a sensory deficit, or poor health. However, age differences continue to emerge even with untimed tests and when the tests are controlled for variations in motor and sensory function. In general, fluid intelligence—the biologically determined intelligence used for flexibility in thinking and problem solving—declines. Preventing or managing circulatory and nervous system disorders may positively affect the decline in fluid intelligence. Crystallized intelligence—gained through education and lifelong experiences (e.g., verbal skills)—remains intact. These differences exemplify the classic aging pattern of intelligence. Despite these slight declines, many older adults continue to learn and participate in varied educational experiences. Good health and motivation are important influences on learning (see Chart 8-4).

Pharmacologic Aspects of Aging

Because an increasing number of chronic conditions affect older adults, they use more medications than any other age group. Although medications improve health and well-being by relieving pain and discomfort, treating chronic illnesses, and curing infectious processes, adverse drug reactions are common because of medication interactions, multiple medication effects, incorrect dosages, and the use of multiple medications.

Chart 8-4 HEALTH PROMOTION

Nursing Strategies for Promoting Cognitive Function

Nurses can support the processes by which older adults learn by using the following strategies:

- Supply mnemonics to enhance recall of related data.
- Encourage ongoing learning.
- Link new information with familiar information.
- Use visual, auditory, and other sensory cues.
- Encourage learners to wear prescription glasses and hearing aids.
- Provide glare-free lighting.
- Provide a quiet, nondistracting environment.
- Set short-term goals with input from the learner.
- Prioritize the most important information and focus on the priority information.
- Keep education periods short.
- Pace learning tasks according to the endurance of the learner.
- Encourage verbal participation by learners.
- Reinforce successful learning in a positive manner.

Drug Interactions and Adverse Effects

Polypharmacy is the use of multiple prescription or over-the-counter (OTC) medications. Over or incorrect prescribing occurs commonly in older adults (Miller, 2019). The potential for drug–drug interactions increases with increased medication use and with multiple coexisting diseases (**comorbidity**) that affect the absorption, distribution, metabolism, and elimination of the medications. Such interactions are responsible for numerous emergency department and primary provider visits, which cost billions of dollars annually.

Any medication is capable of altering nutritional status, and the nutritional health of an older adult may already be compromised by a marginal diet or by chronic disease and its treatment. Medications can affect the appetite, cause nausea and vomiting, irritate the stomach, cause constipation or diarrhea, and decrease absorption of nutrients. In addition, these medications may alter electrolyte balance as well as carbohydrate and fat metabolism. For example, antacids may cause thiamine deficiency; laxatives diminish absorption; antibiotics and phenytoin reduce utilization of folic acid; and phenothiazines, estrogens, and corticosteroids increase appetite and cause weight gain.

Combining multiple medications with alcohol, as well as with OTC and herbal medications, further complicates GI problems. For example, St. John's wort, a common herbal supplement effective for mild depression, decreases the anticoagulant effect of warfarin and interacts with many other medications metabolized in the liver (Miller, 2019).

Tools such as the American Geriatrics Society (AGS) Beers Criteria® are available to evaluate the patterns of drug use in older adults (Fick, Selma, Steinman, et al., 2019). The criteria rate the evidence for potentially harmful medications according to body systems. They are updated every 4 years in an attempt to improve the care of older adults by limiting their exposure to potentially inappropriate medications.

Altered Pharmacokinetics

Alterations in absorption, metabolism, distribution, and excretion occur as a result of normal aging and may also result from drug and food interactions (Comerford & Durkin, 2020). Absorption may be affected by changes in gastric pH and a decrease in GI motility. Drug distribution may be altered as a result of decrease in body water and increase in body fat. Normal age-related changes and diseases that alter blood flow, liver and renal function, or cardiac output (CO) may affect distribution and metabolism (see Table 8-2).

Nursing Implications

Principles that have been identified as appropriate for older patients include starting with a low dose, going slowly, keeping the medication regimen as simple as possible, and reconciling new and previous medication regimens at the time of discharge from an acute hospital stay (Comerford & Durkin, 2020; Fick et al., 2019). A comprehensive assessment that begins with a thorough medication history, including use of alcohol, recreational drugs, and OTC and herbal medications, is essential. It is best to ask the patient or reliable informants to provide all medications for review. Assessing the patient's understanding of when and how to take each prescription and OTC medication, as well as the purpose of each medication, allows the nurse to assess the patient's health literacy and adherence to the medication regimen. The patient's beliefs and concerns about the medications should be identified, including beliefs on whether a given medication is helpful.

TABLE 8-2 Altered Drug Responses in Older Adults

Age-Related Changes	Effect of Age-Related Changes	Applicable Medications
Absorption		
Reduced gastric acid; increased pH (less acid)	Rate of drug absorption—possibly delayed	Vitamins
Reduced gastrointestinal motility; prolonged gastric emptying	Extent of drug absorption—not affected	Calcium
Distribution		
Decreased circulating plasma proteins and total body water	Serious alterations in drug binding to plasma proteins (the unbound drug gives the pharmacologic response); highly protein-bound medications have fewer binding sites, leading to increased effects and accelerated metabolism and excretion	*Select highly protein-binding medications:* Oral anticoagulants (warfarin) Oral hypoglycemic agents (sulfonylureas) Barbiturates Calcium channel blockers Furosemide Nonsteroidal anti-inflammatory drugs (NSAIDs) Sulfonamides Quinidine Phenytoin
Reduced cardiac output	Decreased perfusion of many bodily organs	
Impaired peripheral blood flow	Decreased perfusion	
Increased or decreased percentage of body fat	Proportion of body fat increases with age, resulting in increased ability to store fat-soluble medications; this causes drug accumulation, prolonged storage, and delayed excretion	*Select fat-soluble medications:* Barbiturates Diazepam Lidocaine Phenothiazines (antipsychotics) Ethanol

		Morphine
Decreased lean body mass	Decreased body volume allows higher peak levels of medications	
Metabolism		
Decreased cardiac output; decreased size of the liver; diminished intestinal and portal vein blood flow	Decreased metabolism and delay of breakdown of medications, resulting in prolonged duration of action, accumulation, and drug toxicity	All medications metabolized by the liver
Excretion		
Decreased renal blood flow; loss of functioning nephrons; decreased renal efficiency	Decreased rates of elimination and increased duration of action; danger of accumulation and drug toxicity	*Select medications with prolonged action:* Aminoglycoside antibiotics Cimetidine Chlorpropamide Digoxin Lithium Procainamide

Adapted from Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer.

Nonadherence with medication regimens can lead to significant morbidity and mortality among older adults. The many contributing factors include the number of medications prescribed, the complexity of the regimen, difficulty opening containers, inadequate patient education, financial cost, and the disease or medication interfering with the patient's life. Visual and hearing problems may make it difficult to read or to hear directions. Multifaceted interventions tailored to the individual patient are the most effective strategies in improving adherence. Allowing enough time for the older adult to learn new skills, particularly when technology is involved, is essential (see Chart 8-5).

Mental Health Problems in the Older Adult

Severe mood swings, uncontrolled laughing or crying, changes in cognitive ability, and excessive forgetfulness are not a part of normal aging. These symptoms should not be dismissed as age-related changes; a thorough assessment may reveal a treatable, reversible condition. Changes in mental status can be related to many factors, such as alterations in diet and fluid and electrolyte balance, fever, or low oxygen levels associated with many

cardiovascular and pulmonary diseases. Older adults are less likely than younger people to acknowledge or seek treatment for mental health symptoms. Changes may be reversible when the underlying condition is identified and treated. Nurses must recognize, assess, refer, collaborate, treat, and support older adults who exhibit signs and symptoms of depression, substance abuse, delirium, or dementia.

Chart 8-5

Nursing Strategies for Improving Medication Management and Adherence

The following strategies can help patients manage their medications and improve adherence:

- Assess self-management abilities, psychomotor skills, and current medication knowledge.
- Destroy or remove old, unused medications.
- Encourage the use of standard containers without safety lids (if there are no children in the household).
- Encourage the patient to inform the primary provider about the use of OTC medications and herbal agents, alcohol, and recreational drugs.
- Encourage the patient to keep a current list of all medications, including OTC and herbal medications, in their purse or wallet to share with the primary provider at each visit and in case of an emergency.
- Explain the purpose, adverse effects, and dosage of each medication, particularly those that are newly prescribed.
- If the patient's competence is doubtful, identify a reliable family member or friend who might assist the patient with adherence.
- Provide the medication schedule in writing.
- Reconcile medication schedule upon discharge from hospital or rehabilitation facility.
- Recommend using one supplier for prescriptions; pharmacies frequently track patients and are likely to notice a prescription problem such as duplication or contraindications in the medication regimen.
- Suggest the use of a multiple-day, multiple-dose medication dispenser to help the patient adhere to the medication schedule.

OTC, over-the-counter.

Depression

Depression is the most common affective or mood disorder of old age (Eliopoulos, 2018). The percentage of older adults with depressive symptoms

varies widely depending upon the measures used and the population studied. Estimates range from 15% to 25% in community-dwelling older adults, and up to 25% of those living in long-term care facilities (Eliopoulos, 2018). Depression among older adults can follow a major precipitating event or loss and is often related to chronic illness or pain. It may also be secondary to a medication interaction or an undiagnosed physical condition. Rather than obvious sadness, an older person may exhibit more subtle signs of depression such as fatigue, diminished memory and concentration, feelings of worthlessness, sleep disturbances, appetite disturbances with excessive weight loss or gain, restlessness, impaired attention span, and suicidal ideation. Mild depression with symptoms that do not meet the criteria for a major depression is often underrecognized and undertreated, which results in reduced quality of life and function (Eliopoulos, 2018).

The risk of suicide is increased in older adults. There is a need for routine assessment of patients for depression and risk for suicide. Geriatric depression may be confused with dementia. However, the cognitive impairment resulting from depression is related to apathy rather than decline in brain function. When depression and medical illnesses coexist, as they often do, neglect of the depression can impede physical recovery. Assessing the patient's mental status, including depression, is vital and must not be overlooked. A commonly used assessment tool is the Geriatric Depression Scale (GDS) (Yesavage, Brink, Rose, et al., 1983). (See Chart 8-6.)

Older adults with depression can respond appropriately to treatment. Initial management involves evaluation of the patient's medication regimen and eliminating or changing any medications that contribute to depression. Furthermore, treatment of underlying medical conditions that may produce depressive symptoms may alleviate the depression. For mild depression, nonpharmacologic measures such as exercise, bright lighting, increasing interpersonal interactions, cognitive therapy, and reminiscence therapy are effective. However, for major depression, antidepressants and short-term psychotherapy, particularly in combination, are effective in older adults. Antidepressants, such as bupropion hydrobromide, venlafaxine hydrochloride, and mirtazapine, as well as selective serotonin reuptake inhibitors, such as paroxetine hydrochloride, can be effective (Comerford & Durkin, 2020). Tricyclic antidepressants can be useful for treating major depression in some patients. Electroconvulsive therapy is highly effective when antidepressant medications are not tolerated, not effective, or pose a significant medical risk (Miller, 2019).

Most antidepressant medications have anticholinergic, cardiac, and orthostatic adverse effects (Comerford & Durkin, 2020). They also interact with other medications and, therefore, should be used with care to avoid medication toxicity, hypotensive events, and falls. Older patients prescribed antidepressants should be carefully monitored for side effects. Good patient

education is needed to make sure older adults understand that it may take even longer than the typical 4 to 6 weeks for symptoms to diminish. During this period, nurses should offer support, encouragement, and strategies to maintain safety, such as changing positions slowly and maintaining adequate hydration (Miller, 2019).

Substance Use Disorder

Substance use disorders caused by misuse of alcohol and drugs may be related to depression. A national survey indicated that between 7% and 14% of adults age 65 and older reported alcohol abuse, dependence, binge drinking, or were at least at risk for alcohol dependence (Miller, 2019). Approximately 50% of adults age 65 and older drink alcohol on a regular basis (Kennedy-Malone et al., 2019). Moderate alcohol consumption has shown to have positive health benefits, such as lowering the risks for cardiovascular disease. Alcohol abuse is especially dangerous in older adults because of age-related changes in renal and liver function as well as the high risk of interactions with prescription medications and the resultant adverse effects. Alcohol and drug misuse in older adults often remains hidden because many older adults deny their habit when questioned. Using screening tools may help provide a rapid, sensitive, and inexpensive method for screening alcohol misuse. Alcohol use should be addressed during routine physical examinations (Resnick, 2019). See Chapter 4 for more information and specific assessment tools.

Chart 8-6

Geriatric Depression Scale

Choose the best answer for how you felt this past week.

[a]1. Are you basically satisfied with your life?	YES NO
2. Have you dropped many of your activities and interests?	YES NO
3. Do you feel that your life is empty?	YES NO
4. Do you often get bored?	YES NO
[a]5. Are you hopeful about the future?	YES NO
6. Are you bothered by thoughts you can't get out of your head?	YES NO
[a]7. Are you in good spirits most of the time?	YES NO
8. Are you afraid that something bad is going to happen to you?	YES NO
[a]9. Do you feel happy most of the time?	YES NO
10. Do you often feel helpless?	YES NO
11. Do you often get restless and fidgety?	YES NO
12. Do you prefer to stay at home, rather than going out and doing new things?	YES NO
13. Do you frequently worry about the future?	YES NO
14. Do you feel you have more problems with memory than most?	YES NO
[a]15. Do you think it is wonderful to be alive now?	YES NO
16. Do you often feel downhearted and blue?	YES NO
17. Do you feel pretty worthless the way you are now?	YES NO
18. Do you worry a lot about the past?	YES NO
[a]19. Do you find life very exciting?	YES NO
20. Is it hard for you to get started on new projects?	YES NO
[a]21. Do you feel full of energy?	YES NO
22. Do you feel that your situation is hopeless?	YES NO
23. Do you think that most people are better off than you are?	YES NO
24. Do you frequently get upset over little things?	YES NO
25. Do you frequently feel like crying?	YES NO
26. Do you have trouble concentrating?	YES NO
[a]27. Do you enjoy getting up in the morning?	YES NO
28. Do you prefer to avoid social gatherings?	YES NO
[a]29. Is it easy for you to make decisions?	YES NO
[a]30. Is your mind as clear as it used to be?	YES NO

Score: _____ (*Number of "depressed" answers*)

Norms
Normal: 5 ± 4
Mildly depressed: 15 ± 6
Very depressed: 23 ± 5

[a]Appropriate (nondepressed) answers = yes; all others = no.

From Yesavage, J., Brink, T. L., Rose, T. L., et al. (1983). Development and validation of a geriatric screening scale: A preliminary report. *Journal of Psychiatric Research*, *17*(1), 37–49.

Delirium

Delirium occurs secondary to numerous causes, including physical illness, surgery, medication or alcohol toxicity, dehydration, fecal impaction, malnutrition, infection, head trauma, lack of environmental cues, and sensory deprivation or overload. Older adults are particularly vulnerable to acute confusion because of their decreased biologic reserve and the large number of medications they may take. Nurses must recognize the symptoms of delirium and report them immediately. The Confusion Assessment Method (CAM) is a commonly used screening tool (Inouye, van Dyck, Alessi, et al., 1990). (See Chart 8-7.) Because of the acute and unexpected onset of symptoms and the unknown underlying cause, delirium is a medical emergency. If the delirium goes unrecognized and the underlying cause is not treated, permanent, irreversible brain damage or death can follow.

Alzheimer's Disease

AD is the sixth leading cause of death in the United States. For adults 65 years of age and older it is the fifth leading cause of death. AD is a progressive, irreversible, degenerative neurologic disease that begins insidiously and is characterized by gradual losses of cognitive function and disturbances in behavior and affect. AD can occur in people as young as 40 years of age but is less common before 65 years of age. Although the prevalence of AD increases dramatically with increasing age, affecting as many as half of those 85 years and older, AD is not a normal part of aging. Without a cure or any preventive measures, it is estimated that 13.8 million Americans will have this disease by 2050 (Alzheimer's Association, 2019).

There are numerous theories about the cause of age-related cognitive decline. Although the greatest risk factor for AD is increasing age, many environmental, dietary, and inflammatory factors also may determine whether a person suffers from this cognitive disease. AD is a complex brain disorder caused by a combination of various factors that may include genetics, neurotransmitter changes, vascular abnormalities, stress hormones, circadian changes, head trauma, and the presence of seizure disorders.

AD can be classified into two types: familial or early-onset AD and sporadic or late-onset AD (see Chapter 6, Table 6-5). Familial AD is rare, accounting for less than 2% of all cases, and is frequently associated with genetic mutations. It can occur in middle-aged adults. If family members have at least two other relatives with AD, then there is a familial component, which may include both environmental triggers and genetic determinants (NIH, 2017).

Chart 8-7 ASSESSMENT

Confusion Assessment Method (CAM)

Acute Onset

1. Is there evidence of an acute change in mental status from the patient's baseline?

Inattention[a]

2. **A.** Did the patient have difficulty focusing attention, for example, being easily distractible, or having difficulty keeping track of:

What was being said?

Not present at any time during interview.

Present at some time during interview but in mild form.

Present at some time during interview, in marked form.

Uncertain.

B. (If present or abnormal) Did this behavior fluctuate during the interview, that is, tend to come and go or increase and decrease in severity?

Yes.

No.

Uncertain.

Not applicable.

C. (If present or abnormal) Please describe this behavior:

Disorganized Thinking

3. Was the patient's thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject?

Altered Level of Consciousness

4. Overall, how would you rate this patient's level of consciousness?

Alert (normal).

Vigilant (hyperalert, overly sensitive to environmental stimuli, startled very easily).

Lethargic (drowsy, easily aroused).

Stupor (difficult to arouse).

Coma (unarousable).

Uncertain.

Disorientation

5. Was the patient disoriented at any time during the interview, such as thinking that they were somewhere other than the hospital, using the wrong bed, or misjudging the time of day?

Memory Impairment

6. Did the patient demonstrate any memory problems during the interview, such as inability to remember events in the hospital or difficulty remembering instructions?

Perceptual Disturbances

7. Did the patient have any evidence of perceptual disturbances, for example, hallucinations, illusions, or misinterpretations (such as thinking something was moving when it was not)?

Psychomotor Agitation

8. Part 1.
   At any time during the interview, did the patient have an unusually increased level of motor activity, such as restlessness, picking at bedclothes, tapping fingers, or making frequent sudden changes of position?

Psychomotor Retardation

8. Part 2.
   At any time during the interview, did the patient have an unusually decreased level of motor activity, such as sluggishness, staring into space, staying in one position for a long time, or moving very slowly?

Altered Sleep–Wake Cycle

9. Did the patient have evidence of disturbance of the sleep–wake cycle, such as excessive daytime sleepiness with insomnia at night?

[a]The questions listed under this topic were repeated for each topic where applicable.

From Inouye, S. K., van Dyck, C. H., Alessi, C. A., et al. (1990). Clarifying confusion: The confusion assessment method. *Annals of Internal Medicine, 113*(12), 941–948. Used with permission.

Pathophysiology

The pathogenesis of AD is uncertain but the disease includes specific neuropathologic and biochemical changes that interfere with neurotransmission. These changes consist of neurofibrillary tangles (tangled masses of nonfunctioning neurons) and senile or neuritic plaques (deposits of amyloid protein, part of a larger protein called *amyloid precursor protein* in the brain). The neuronal damage occurs primarily in the cerebral cortex and results in decreased brain size. Similar changes are found in the normal brain tissue of nonsymptomatic older adults, although to a lesser extent. Cells that use the neurotransmitter acetylcholine are principally affected by AD. At the biochemical level, the enzyme active in producing acetylcholine, which is specifically involved in memory processing, is decreased.

Scientists have been studying complex neurodegenerative diseases such as AD and have focused on two key issues: whether a gene might influence a person's overall risk of developing the disease, and whether a gene might influence some particular aspect of a person's risk, such as the age at which the disease begins (age at onset). There are genetic differences in early- and late-onset forms of AD (NIH, 2017). Researchers are investigating what predisposes people to develop the plaques and neurofibrillary tangles that can be seen at autopsy in the brains of patients with AD. Understanding the complex ways in which aging as well as genetic and nongenetic factors affect brain cells over time, eventually leading to AD, continues to increase.

Clinical Manifestations

In the early stages of AD, forgetfulness and subtle memory loss occur. Patients may experience small difficulties in work or social activities but have adequate cognitive function to compensate for the loss and continue to function independently. With further progression of AD, the deficits can no longer be concealed. Forgetfulness is manifested in many daily actions; patients may lose their ability to recognize familiar faces, places, and objects and they may become lost in a familiar environment. They may repeat the same stories or ask the same question repeatedly. Trying to reason with people with AD and using reality **orientation** (a person's ability to recognize who and where they are in a time continuum) only increase their anxiety without increasing function. Conversation becomes difficult, and word-finding difficulties occur. The ability to formulate concepts and think abstractly disappears—for example, a patient can interpret a proverb only in concrete terms. Patients are often unable to recognize the consequences of their actions and, therefore, exhibit impulsive behavior—for example, on a hot day a patient may decide to wade in the city fountain fully clothed. Patients have difficulty with everyday activities, such as operating simple appliances and handling money.

Personality changes are also usually evident. Patients may become depressed, suspicious, paranoid, hostile, and even combative. Progression of the disease intensifies the symptoms: Speaking skills deteriorate to nonsense syllables, agitation and physical activity increase, and patients may wander at night. Eventually, assistance is needed for most ADLs, including eating and toileting, because dysphagia and incontinence develop. The terminal stage, in which patients are usually immobile and require total care, may last months or years. Occasionally, patients may recognize family members or caregivers. Death occurs as a result of complications such as pneumonia, malnutrition, or dehydration.

Assessment and Diagnostic Findings

A definitive diagnosis of AD can be made only at autopsy; however, an accurate clinical diagnosis can be made in the majority of cases. The most important goal is to rule out other causes of dementia that are reversible, such as depression, delirium, alcohol or drug abuse, or inappropriate drug dosage or drug toxicity. AD is a diagnosis of exclusion; a diagnosis of probable AD is made when the medical history, physical examination, and laboratory tests have excluded all known causes of other dementias.

The health history—including medical history, family history, social and cultural history, and medication history—and the physical examination, including functional and mental health status, are essential to the diagnosis of probable AD. Diagnostic tests, including complete blood count, chemistry profile, and vitamin B_{12} and thyroid hormone levels, as well as screening with electroencephalography, computed tomography (CT), magnetic resonance imaging (MRI), and examination of the cerebrospinal fluid (CSF), may all refute or support a diagnosis of probable AD.

Depression can closely mimic early-stage AD and coexists in many patients. Therefore, assessing the patient for underlying depression is important. The GDS is a useful tool to assess for depression (see Chart 8-6). Tools such as the MMSE (see Chart 8-3) are useful for assessing cognitive status and screening for AD. Both CT and MRI of the brain are useful for excluding hematoma, brain tumor, stroke, normal-pressure hydrocephalus, and atrophy but are not reliable in making a definitive diagnosis of AD. Infections and physiologic disturbances, such as hypothyroidism, Parkinson's disease, and vitamin B_{12} deficiency, can cause cognitive impairment that may be misdiagnosed as AD. Biochemical abnormalities can be excluded through examination of the blood and CSF.

Medical Management

In AD, the primary goal is to help maintain mental function as well as manage the cognitive and behavioral symptoms, and slow down the symptoms of the disease. Although there is no cure, several medications slow the progression of the disease. Cholinesterase inhibitors such as donepezil hydrochloride and rivastigmine tartrate, for example, enhance acetylcholine uptake in the brain, thus maintaining memory skills for a period of time. Cognitive ability may improve within 6 to 12 months of therapy. Rivastigmine is indicated for severe AD and it is recommended that treatment continue as long as possible (NIH, 2018b).

Behavioral problems such as agitation and psychosis can be managed by behavioral and other interventions such as music therapy (Weise, Jakob, Töpfer, et al., 2018). Associated depression and behavioral problems can also be treated pharmacologically if other interventions fail. Because symptoms change over time, all patients with AD should be reevaluated routinely, and the

nurse should document and report both positive and negative responses to medications.

Nursing Management

Nurses play an important role in the recognition of AD, particularly in hospitalized older adults, by assessing for signs (e.g., repeating or asking the same thing over and over). Nursing interventions for AD are aimed at promoting patient function and independence for as long as possible. Other important goals include promoting the patient's physical safety, promoting independence in self-care activities, reducing anxiety and agitation, improving communication, providing for socialization and intimacy, promoting adequate nutrition, promoting balanced activity and rest, and supporting and educating family caregivers. These nursing interventions apply to all patients with AD, regardless of cause.

Supporting Cognitive Function

Because dementia of any type is degenerative and progressive, patients display a decline in cognitive function over time. In the early phase of dementia, minimal cuing and guidance may be all that are needed for the patient to function fairly independently for a number of years. However, as the patient's cognitive ability declines, family members must provide more and more assistance and supervision. A calm, predictable environment helps people with dementia interpret their surroundings and activities. Environmental stimuli are limited, and a regular routine is established. A quiet, pleasant manner of speaking, clear and simple explanations, and the use of memory aids and cues help minimize confusion and disorientation and give patients a sense of security. Prominently displayed clocks and calendars may enhance orientation to time. Color-coding the doorway may help patients who have difficulty locating their room. Active participation may help patients maintain cognitive, functional, and social interaction abilities for a longer period. Physical activity and communication have also been demonstrated to slow some of the cognitive decline of AD.

Promoting Physical Safety

A safe home and hospital environment allow the patient to move about as freely as possible and relieves the family of constant worry about safety. For the patient residing at home, in order to prevent falls and other injuries, all obvious hazards are removed and hand rails are installed. A hazard-free environment allows the patient maximum independence and a sense of autonomy. Adequate lighting, especially in halls, stairs, and bathrooms, is necessary. Nightlights are helpful, particularly if the patient has increased

confusion at night, sometimes referred to as sundowning. Driving is prohibited, and smoking is allowed only with supervision. The patient may have a short attention span and be forgetful; therefore, the nurse and the family must be patient, repeat instructions as needed, and use reminders (i.e., post-it notes, electronic reminders) for daily activities. Doors leading from the house must be secured. Outside the home, all activities must be supervised to protect the patient, and the patient should wear some type of identification in case of separation from the caregiver.

If the patient is hospitalized, additional precautionary measures should be taken. Wandering behavior, which may be worse in the hospital due to unfamiliar surroundings, can often be reduced by gentle persuasion, distraction, or by placing the patient close to the nursing station. Restraints should be avoided because they can increase agitation and lead to injury.

Promoting Independence in Self-Care Activities

Pathophysiologic changes in the brain make it difficult for people with AD to maintain physical independence. Patients should be assisted to remain functionally independent for as long as possible. One way to do this is to simplify daily activities by organizing them into short, achievable steps so that the patient experiences a sense of accomplishment. Frequently, occupational therapists can suggest ways to simplify tasks or recommend adaptive equipment. Direct patient supervision is sometimes necessary; however, maintaining personal dignity and autonomy is important for people with AD, who should be encouraged to make choices when appropriate and to participate in self-care activities as much as possible.

Reducing Anxiety and Agitation

Despite profound cognitive losses, patients are sometimes aware of their diminishing abilities. Patients need constant emotional support that reinforces a positive self-image. When loss of skills occurs, goals are adjusted to fit the patient's declining ability.

The environment should be kept familiar and noise free. Excitement and confusion can be upsetting and may precipitate a combative, agitated state known as a catastrophic reaction (overreaction to excessive stimulation). The patient may respond by screaming, crying, or becoming abusive (physically or verbally); this may be the patient's only way of expressing an inability to cope with the environment. When this occurs, it is important to remain calm and unhurried. Forcing the patient to proceed with the activity only increases the agitation. It is better to postpone the activity until later, even to another day. Frequently, the patient quickly forgets what triggered the reaction. Measures such as moving to a familiar environment, listening to music, stroking, rocking, or distraction may quiet the patient. Research suggests that the use of

activities and music therapy, both individualized and in groups, help decrease agitation (Zhang, Cai, An, et al., 2017). Becoming familiar with a particular patient's usual responses to certain stressors helps caregivers avoid stressful situations.

Improving Communication

To promote the patient's interpretation of messages, the nurse should remain unhurried and reduce noises and distractions. Use of clear, easy-to-understand sentences to convey messages is essential because patients frequently forget the meaning of words or have difficulty organizing and expressing thoughts. In the earlier stages of dementia, lists and simple written instructions that serve as reminders may be helpful. In later stages, the patient may be able to point to an object or use nonverbal language to communicate. Tactile stimuli, such as hugs or hand pats, are usually interpreted as signs of affection, concern, and security.

Providing for Socialization and Intimacy Needs

Because socialization with friends can be comforting, visits, letters, and phone calls are encouraged. Recreation is important, and people with dementia are encouraged to participate in simple activities. Realistic goals for activities that provide satisfaction are appropriate. Hobbies and activities such as walking, exercising, and socializing can improve quality of life. The nonjudgmental friendliness of a pet may provide stimulation, comfort, and contentment. Care of plants or a pet can also be satisfying and an outlet for energy.

AD does not eliminate the need for intimacy. Patients and their spouses may continue to enjoy sexual activity. Spouses should be encouraged to talk about any sexual concerns, and sexual counseling may be necessary. Simple expressions of love, such as touching and holding, are often meaningful.

Promoting Adequate Nutrition

Mealtime can be a pleasant social occasion or a time of upset and distress, and it should be kept simple and calm, without confrontations. Patients prefer familiar foods that look appetizing and taste good. Cueing may be necessary to encourage adequate nutrition and hydration. Food is cut into small pieces to prevent choking. Liquids may be easier to swallow if they are thickened. Hot food and beverages are served warm, and the temperature of the foods should be checked to prevent burns.

When lack of coordination interferes with self-feeding, adaptive equipment is helpful (see Fig. 8-4). Some patients may do well eating with a spoon or with their fingers. If this is the case, an apron or a smock, rather than a bib, is used to protect clothing. As deficits progress, it may become necessary to feed the patient. Forgetfulness, disinterest, dental problems, lack of coordination,

overstimulation, and choking all serve as barriers to good nutrition and hydration.

Promoting Balanced Activity and Rest

Many patients with dementia exhibit sleep disturbances, wandering, and behaviors that may be considered inappropriate. These behaviors are most likely to occur when there are unmet underlying physical or psychological needs. Caregivers must identify the needs of patients who are exhibiting these behaviors because further health decline may occur if the source of the problem is not corrected. Adequate sleep and physical exercise are essential. If sleep is interrupted or the patient cannot fall asleep, music, warm milk, or a back rub may help the patient relax. During the day, patients should be encouraged to participate in exercise because a regular pattern of activity and rest enhances nighttime sleep. Long periods of daytime sleeping are discouraged.

Figure 8-4 • **A.** Assistive feeding devices make it easy for patients to grasp and get food on utensils. **B.** Assistive feeding devices may

be required for patients who are weak, fatigued, or paralyzed or have neuromuscular impairment.

Promoting Home, Community-Based, and Transitional Care

The emotional burden on the families of patients with all types of dementia is enormous. The physical health of the patient is often very stable and the decline gradual. Family members may cling to the hope that the diagnosis is incorrect and that their relative will improve with greater effort. Family members provide at least 83% of the home care that is required by patients with AD (Alzheimer's Association, 2019). They are faced with numerous difficult decisions (e.g., when the patient should stop driving, when to assume responsibility for the patient's financial affairs). Aggression and hostility exhibited by the patient are often misunderstood by caregivers, who may feel unappreciated, frustrated, and angry. Feelings of guilt, nervousness, and worry contribute to caregiver fatigue, depression, and family dysfunction. Researchers have identified that a Web-based intervention can be effective in helping with anxiety and stress, reducing depressive symptoms, and identifying care needs and planning interventions that promote balance and congruence in the lives of caregivers (Ploeg, Markle-Reid, Valaitis, et al., 2017).

Neglect or abuse of the patient can occur, and this has been documented in home situations as well as in institutions. If neglect or abuse of any kind—including physical, emotional, sexual, neglect, or financial abuse—is suspected, the local adult protective services agency must be notified. The responsibility of the nurse is to report the suspected abuse, not to prove it.

The Alzheimer's Association is a coalition of family members and professionals who share the goals of family support and service, education, research, and advocacy. Family support groups, respite (relief) care, and adult day care may be available through different community resources, such as the Area Agency on Aging, in which concerned volunteers are trained to provide structure to caregiver support groups (see Resources section at the end of chapter). Respite care is a commonly provided service in which caregivers can get away from the home for short periods while someone else tends to the needs of the patient.

Vascular Dementia

Vascular dementia is the second most common cause of dementia and is characterized by an uneven, stepwise downward decline in mental function (Norris, 2019). Multi-infarct dementia, the most common form of vascular dementia, has an unpredictable course and is characterized by variable impairment depending on the affected sites in the brain. The patient may present with a deficit in only one domain such as word retrieval whereas other

cognitive abilities may be intact. Diagnosis may be even more difficult if a patient has both vascular dementia and AD.

Because vascular dementia is associated with hypertension and cardiovascular disease, risk factors (e.g., hypercholesterolemia, smoking, heart disease, diabetes) are similar. Prevention and management are also similar (see Chapter 27). Measures to decrease blood pressure, control diabetes, and lower cholesterol levels may slow cognitive decline.

Additional Aspects of Health Care of the Older Adult

The nurse needs to consider other health issues of older adults. These include geriatric syndromes, elder neglect and abuse, as well as ethical and legal issues.

Geriatric Syndromes

Older adults tend to acquire multiple problems and illnesses as they age. The decline of physical function leads to a loss of independence and increasing frailty as well as to susceptibility to both acute and chronic health problems, which generally result from several factors rather than from a single cause. When combined with a decrease in host resistance, these factors can lead to illness or injury. Some problems commonly experienced by older adults are becoming recognized as **geriatric syndromes**. These conditions do not fit into discrete disease categories and require a multidisciplinary and comprehensive assessment to identify the underlying cause or causes. Examples include skin impairment (e.g., pressure injuries), poor nutrition, falls or functional decline, urinary incontinence, defecation incontinence, cognitive impairment (e.g., delirium), and sleep disturbances (Tang, Tang, Hu, et al., 2017). Although these conditions may develop slowly, the onset of symptoms is often acute. Furthermore, the presenting symptoms may appear in other body systems before becoming apparent in the affected system. For example, an older patient may present with confusion, and the underlying disease may be a UTI, dehydration, or a heart attack (van Seben, Reichardt, Aarden, et al., 2019).

The term *geriatric triad* includes changes in cognitive status, falls, and incontinence. This term is used to focus awareness on these three conditions, which need particular attention, and the implementation of prevention measures during the hospitalization of older patients.

Impaired Mobility

The causes of decreased mobility are many and varied. Common causes include strokes, Parkinson's disease, diabetic neuropathy, cardiovascular compromise, osteoarthritis, osteoporosis, and sensory deficits. To avoid

immobility, older people should be encouraged to stay as active as possible. During illness, bed rest should be kept to a minimum, even with hospitalized patients, because brief periods of bed rest quickly lead to deconditioning and, consequently, to a wide range of complications. When bed rest cannot be avoided, patients should perform active range-of-motion and strengthening exercises with the unaffected extremities, and nurses or family caregivers should perform passive range-of-motion exercises on the affected extremities. Frequent position changes help offset the hazards of immobility. Both the health care staff and the patient's family can assist in maintaining the current level of mobility.

Dizziness

Older adults frequently seek help for dizziness, which presents a particular challenge because there are numerous possible causes. For many, the problem is complicated by an inability to differentiate between true dizziness (a sensation of disorientation in relation to position) and vertigo (a spinning sensation). Other similar sensations include near-syncope and disequilibrium. The causes for these sensations range in severity from minor (e.g., buildup of ear wax) to severe (e.g., dysfunction of the cerebral cortex, cerebellum, brain stem, proprioceptive receptors, or vestibular system). Even a minor reversible cause, such as ear wax impaction, can result in a loss of balance and a subsequent fall and injury. Because dizziness has many predisposing factors, nurses should seek to identify any potentially treatable factors related to the condition.

Falls and Falling

Inadvertent injuries rank third as a cause of death for older people, and falls are the most common cause of nonfatal injuries and hospital admissions. The incidence of falls rises with increasing age.

Many older adults who fall do not sustain an injury; however, between 20% and 30% of older adults who fall sustain moderate to serious injury such as bruises, hip fractures, or head trauma. One out of five falls in older adults results in serious injury such as broken bones or a head injury (Heron, 2019). Overall, older women who fall sustain a greater degree of injury than do older men; however, men are more likely to die of a fall injury (World Health Organization [WHO], 2019). Hip fracture is a common type of fracture that can occur as a result of a fall. Fifty percent of adults who fall but cannot get up on their own and sustain a hip fracture are then unable to return to the same functional level after this type of injury. Causes of falls are multifactorial. Both extrinsic factors such as changes in the environment or poor lighting and intrinsic factors such as physical illness, neurologic changes, or sensory impairment play a role. Mobility difficulties, medication effects, foot problems

or unsafe footwear, orthostatic hypotension, visual problems, and tripping hazards are common and treatable causes. Polypharmacy, medication interactions, and the use of alcohol precipitate falls by causing drowsiness, decreased coordination, and orthostatic hypotension. Falls have physical dangers as well as serious psychological and social consequences. It is not uncommon for an older person who has experienced a fall to become fearful and lose self-confidence (Miller, 2019).

Nurses can encourage older adults and their families to make lifestyle and environmental changes to prevent falls. Adequate lighting with minimal glare and shadow can be achieved through the use of small area lamps, indirect lighting, sheer curtains to diffuse direct sunlight, dull rather than shiny surfaces, and nightlights. Sharply contrasting colors can be used to mark the edges of stairs. Grab bars by the bathtub, shower, and toilet are useful. Loose clothing, improperly fitting shoes, scatter rugs, small objects, and pets create hazards and increase the risk of falls. Older adults function best in familiar settings when the arrangement of furniture and objects remains unchanged.

Quality and Safety Nursing Alert

In hospitalized and institutionalized older adults, physical restraints (lap belts; geriatric chairs; side rails, vest, waist, and jacket restraints) and chemical restraints (medications) precipitate many of the injuries they were meant to prevent. Because of the acute negative consequences of restraint use, accrediting agencies of nursing homes and acute care facilities now maintain stringent guidelines for correct application and use.

Urinary Incontinence

Urinary incontinence may be acute, occurring during an illness, or may develop chronically over a period of years. Older patients often do not report this very common problem unless specifically asked. Transient causes may be attributed to *d*elirium and *d*ehydration; *r*estricted mobility; *i*nflammation, *i*nfection, and *i*mpaction; and *p*harmaceuticals and *p*olyuria (the acronym *drip* may be used to remember them). Once identified, the causative factor can be eliminated.

Older patients with incontinence should be urged to seek help from appropriate health care providers because incontinence can be both emotionally devastating and physically debilitating. Nurses who specialize in behavioral approaches to urinary incontinence management can help patients regain full continence or significantly improve the level of continence. Although medications such as anticholinergics may decrease some of the symptoms of urge incontinence (detrusor instability), the adverse effects of

these medications (dry mouth, slowed GI motility, and confusion) may make them inappropriate choices for older adults (Fick et al., 2019). Various surgical procedures are also used to manage urinary incontinence, particularly stress urinary incontinence.

Detrusor hyperactivity with impaired contractility is a type of urge incontinence that is seen predominantly in the older adult population. In this variation of urge incontinence, patients have no warning that they are about to urinate. They often void only a small volume of urine or none at all and then experience a large volume of incontinence after leaving the bathroom. Nurses should be familiar with this form of incontinence and not show disapproval when it occurs. Many patients with dementia suffer from this type of incontinence, because both incontinence and dementia are a result of dysfunction in similar areas of the brain. Prompted, timed voiding can be of assistance in these patients, although clean intermittent catheterization may be necessary because of postvoid residual urine. See Chapter 49 for information on management of urinary disorders.

Increased Susceptibility to Infection

Infectious diseases present a significant threat of morbidity and mortality to older adults, in part because of the blunted response of host defenses caused by a reduction in both cell-mediated and humoral immunity (see Chapters 31 and 32). Age-related loss of physiologic reserve and chronic illnesses also contribute to increased susceptibility. Pneumonia, UTIs, GI infections, and skin infections are some of the common infections in older adults.

Because of a weakened immune response, the effects of influenza and pneumococcal infections on older adults are significant. Vaccination can help prevent both infections. There is a national goal to increase vaccination rates among people 65 years of age and older. More than 71% of those 65 years of age and older reported receiving an influenza vaccination between January and June 2018 and 69% reported that they had received a pneumococcal vaccination (AoA, 2020).

Influenza and pneumococcal vaccinations lower the risks of hospitalization and death in older adults. The influenza vaccine, which is prepared yearly to adjust for the specific immunologic characteristics of the influenza viruses at that time, should be given annually in autumn. A systematic review and meta-analysis on the effectiveness of high-dose versus standard-dose influenza vaccine suggests that better protection is provided with the high-dose, trivalent, inactivated influenza vaccine versus the standard vaccine in older adults (Lee, Lam, Shin, et al., 2018). The pneumococcal vaccine should be administered as recommended (see Chapter 3, Table 3-3). Both of these injections can be received at the same time in separate injection sites. Nurses should urge older adults to be vaccinated. All health care providers working with older adults or high-risk chronically ill people should also be immunized.

AIDS occurs across the age spectrum. It is increasingly recognized that AIDS does not spare the older segment of society, and many who are living with HIV/AIDS are aging.

Atypical Responses

Many altered physical, emotional, and systemic reactions to disease are attributed to age-related changes in older adults. Physical indicators of illness that are useful and reliable in young and middle-aged people cannot be relied on for the diagnosis of potential life-threatening problems in older adults. The response to pain in older adults may be lessened because of reduced acuity of touch, alterations in neural pathways, and diminished processing of sensory data.

Older adults who are experiencing an MI may not have chest pain but present with confusion. Hiatal hernia or upper GI distress is often the cause of chest pain. Therefore, acute abdominal conditions may go unrecognized in older adults because of atypical signs and absence of pain.

The baseline body temperature for older adults is about 1°F lower than it is for younger people (Weber & Kelley, 2019). In the event of illness, the body temperature of an older person may not be high enough to qualify as a traditionally defined fever. A temperature of 37.8°C (100°F) in combination with systemic symptoms may signal infection. A temperature of 38.3°C (101°F) almost certainly indicates a serious infection that needs prompt attention. A blunted fever in the face of an infection often indicates a poor prognosis. Temperatures rarely exceed 39.5°C (103°F). Nurses must be alert to other subtle signs of infection, such as mental confusion, increased respirations, tachycardia, and a change in skin color.

Altered Emotional Impact

The emotional component of illness in older adults may differ from that in younger people. Many older adults equate good health with the ability to perform their daily activities and believe that "you are as old as you feel." An illness that requires hospitalization or a change in lifestyle is an imminent threat to well-being. Older adults admitted to the hospital are at high risk for disorientation, confusion, change in level of consciousness, and other symptoms of delirium, as well as anxiety and fear. In addition, economic concerns and fear of becoming a burden to families often lead to high anxiety in older adults. Nurses must recognize the implications of fear, anxiety, and dependency in older patients. They should encourage autonomy, independent decision making, and early mobilization. A positive and confident demeanor in nurses and family members promotes a positive mental outlook in older patients.

Altered Systemic Response

In an older person, illness has far-reaching repercussions. The decline in organ function that occurs in every system of the aging body eventually depletes the body's ability to respond at full capacity. Illness places new demands on body systems that have little or no reserve to meet the crisis. Homeostasis is jeopardized. Older adults may be unable to respond effectively to an acute illness or, if a chronic health condition is present, they may be unable to sustain appropriate responses over a long period. Furthermore, their ability to respond to definitive treatment is impaired. The altered responses of older adults reinforce the need for nurses to monitor all body system functions closely, being alert to signs of impending systemic complication.

Elder Neglect and Abuse

Older adults are at risk for abuse and neglect both in the community setting and in nursing homes (Burnes, Pillemer, & Lachs, 2017). Because of different definitions and terminology and the pattern of underreporting, a clear picture of the incidence and prevalence of abuse among older adults is lacking. Furthermore, one of the major barriers to fully understanding elder abuse is that most professionals in all professions, including law enforcement, are not equipped to recognize and report this type of abuse. Often victims are reluctant to report the abuse and clinicians are unaware of the frequency of the problems.

Neglect is the most common type of abuse. Other forms of abuse include physical, psychological or emotional, sexual, abandonment, and financial exploitation or abuse. Burnes and colleagues (2017) reported factors associated with physical and emotional abuse included being separated or divorced, living in a low-income household, functional impairment, and younger age for community-dwelling older adults. Neglect was associated with poor health, living below the poverty level, being separated or divorced, and younger age. Neglect was lowest in Hispanic households (Burnes et al., 2017).

Physical abuse associated with staff misconduct in long-term care facilities has received much attention in the past decade. Braaten and Malmedal (2017) did a qualitative study to understand the perspective of staff regarding prevention of physical abuse of nursing home residents. Staff were asked what measures they considered useful to implement in their daily work to prevent abusive behaviors. Staff shared that there was a need for increased competence among staff about the concept of abuse, known risk factors, good communication skills, and trusting relationships, as well as a work environment/culture that promotes openness where ethical dilemmas can be discussed (Braaten & Malmedal, 2017). Factors associated with resident on resident abuse in a nursing home setting were reported as previous staff physical or emotional abuse; younger age; limitations in ADLs and IADLs; and the emotional closeness of the resident to their family (Braaten &

Malmedal, 2017). Older adults with disability of all types are at increased risk for abuse from family members, paid caregivers, and staff, whether they live in the community or a long-term care facility.

Nurses should be alert to possible **elder abuse** and neglect. During the health history, the older adult should be asked about abuse during a private portion of the interview. Most states require that care providers, including nurses, report suspected abuse. Preventive action should be taken when caregiver strain is evident—before elder abuse occurs. Early detection and intervention may provide sufficient resources to the family or the person at risk to ensure patient safety. Interdisciplinary team members, including the psychologist, social worker, or chaplain, can be enlisted to help the caregiver develop self-awareness, increased insight, and an understanding of the disease or aging process. Community resources such as caregiver support groups, respite services, and local offices of Area Agencies on Aging (AAAs) are useful for both the older adult and the caregiver.

Social Services

Many social programs exist for older Americans, including Medicare, Medicaid, the Older Americans Act, Supplemental Security Income, Social Security amendments, Section 202 housing, and Title XX social services legislation. These federal programs have increased health care options and financial support for older Americans. The Older Americans Act mandated creation of a federal aging network, resulting in the establishment of the AAAs, a national system of social services and networks providing many community services for older adults. Each state has an advisory network that is charged with overseeing statewide planning and advocacy for older adults throughout the state. Among the services provided by the AAAs are assessment of need, information and referral, case management, transportation, outreach, homemaker services, day care, nutritional education and congregate meals, legal services, respite care, senior centers, and part-time community work. The agencies target low-income, ethnic minority, rural living, and frail older adults who are at risk for institutionalization; however, the assessment and information services are available to all older adults. Similar services such as homemaker, home health aide, and chore services can be obtained at an hourly rate through these agencies or through local community nursing services if the family does not meet the low-income criteria. Informal sources of help, such as family, friends, mail carriers, church members, and neighbors, all keep an informal watch on community-dwelling senior citizens. (See Resources section at the end of the chapter.)

Other community support services are available to help older adults outside the home. Senior centers have social and health promotion activities, and some provide a nutritious noontime meal. Adult day care facilities offer daily

supervision and social opportunities for older adults who cannot be left alone. Adult day care services, although expensive, provide respite and enable family members to carry on daily activities while the older person is at the day care center.

Health Care Costs of Aging

Health care is a major expenditure for older adults, especially for those with chronic illness and limited financial resources. Older adults, who make up about 15% of the population, accounted for 38% of health care costs, particularly in the last year of life (Centers for Medicaid & Medicare Services [CMS], 2018).

The two major programs that finance health care in the United States are Medicare and Medicaid, both of which are overseen by the CMS. Both programs cover acute care needs such as inpatient hospitalization, primary provider care, outpatient care, home health services, and skilled nursing care in a nursing facility. Medicare is federally funded, whereas Medicaid is given by states; therefore, eligibility and reimbursements for Medicaid services vary from state to state. For older adults with limited incomes, even with the support of Medicare or Medicaid, paying out-of-pocket expenses can be a hardship. Out-of-pocket health care expenses represent 28% of the income of poor and near-poor older adults. Despite changes to the Medicare prescription benefit plan, out-of-pocket expenditures and prescription costs can be burdensome (AoA, 2020).

Home Health Care

The use of home care services and skilled nursing home care increases with age. Because of the rapidly growing older adult population and the availability of Medicare funding for acute care, home health care in the United States has rapidly expanded. (See Chapter 2 for more information on home health care.)

Hospice Services

Hospice and palliative care have much in common. Both are for people with serious illnesses. Both follow treatment goals that aim to relieve pain, increase comfort, and improve quality of life for the patient and family. The goal of hospice is to improve the quality of life by focusing on symptom management, pain control, and emotional support. In most hospice cases, patients are not expected to live longer than 6 months. Hospice care focuses on quality of life, and by necessity, it usually includes realistic emotional, social, spiritual, and financial preparation for death. Palliative care is for people at any stage of a serious illness, and their condition does not have to be incurable. Palliative

care aims to relieve pain and other symptoms to maintain the highest quality of life for the longest period of time (Casey, 2019). Under Medicare and Medicaid, medical and nursing services are provided to keep patients as pain free and comfortable as possible. (For an in-depth discussion of palliative and end-of-life care, see Chapter 13.)

Aging With a Disability

As the life expectancy of people with all types of physical, cognitive, and mental disability has increased, individuals must deal with the normal changes associated with aging in addition to their preexisting disability. There are still large gaps in our understanding of the interaction between disability and aging, including how this interaction varies depending on the type and degree of disability and other factors such as socioeconomics and gender. For adults without disability, the changes associated with aging may be minor inconveniences. For adults with disorders such as spinal cord injuries, aging is associated with higher rates of secondary health conditions compared to those aging without a disability (Jorgensen, Iwarsson, & Lexell, 2019). Many people with disability are greatly concerned about what will happen to them as they age and whether assistance will be available when they need care.

It has been proposed that nurses view people with disability as capable, responsible individuals who are able to function effectively despite having a disability. Both the Interface and the Biopsychosocial models of disability can serve as a basis for the role of nurses as advocates for removal of barriers to health care. The use of such models would also encourage public policies that support full participation of all citizens through greater availability of personal assistants and affordable and accessible transportation. See Chapter 7, Chart 7-2 for discussion of other disability models.

Today, children born with intellectual and physical disability and those who acquire them early in life are also living into middle and older age. Often, their care has been provided by the family, primarily by the parents. As parents age and can no longer provide the needed care, they seek additional help with the care or long-term care alternatives for their children. However, few services are available at present to support a smooth transition between caregiving by parents and then by others. Research and public policy must focus on supports and interventions that allow people with disability who are aging to increase or maintain function within their personal environment as well as in the outside community. Important questions include who will provide the care and how will it be financed. The National Institute on Aging has identified aging with a disability as a focus and is striving to provide streamlined information and access to those with a disability and their family caregivers.

Ethical and Legal Issues Affecting the Older Adult

Nurses play an important role in supporting and informing patients and families when making treatment decisions. This nursing role becomes even more important in the care of aging patients who are facing life-altering and possibly end-of-life decisions. Loss of rights, victimization, and other serious problems might occur if a patient has not made plans for personal and property management in the event of disability or death. As advocates, nurses should encourage end-of-life discussions and educate older adults to prepare advance directives before incapacitation (Miller, 2019).

An advance directive is a formal, legally endorsed document that provides instructions for care (living will) or names a proxy decision maker (**durable power of attorney**). It is to be implemented if the signer becomes incapacitated. This written document must be signed by the person and by two witnesses, and a copy should be given to the primary provider and placed in the medical record. The advance directive is not meant to be used only when certain (or all) types of medical treatment are withheld; rather, it allows for a description of health care preferences, including requesting full use of all available medical interventions. The health care proxy may have the authority to interpret the patient's wishes on the basis of medical circumstances and should be guided by the decisions or situations stated in the living will (see Chart 8-8).

When such serious decisions are made, possibilities exist for significant conflict of values among patients, family members, health care providers, and the legal representative. Autonomy and self-determination are Western concepts, and people from different cultures may view advance directives as a method for denial of care. Older adults from some cultures may be unwilling to consider the future, or they may wish to protect relatives and not want them to be informed about a serious illness. Nurses can facilitate the decision making process by being sensitive to the complexity of patients' values and respecting their decisions. Directives must be focused on the wishes of the patient, not those of the family or the designated proxy.

Chart 8-8 **ETHICAL DILEMMA**

Does Stopping of Eating and Drinking Violate the Principle of Nonmaleficence?

Case Scenario

You work as a staff nurse in a skilled nursing facility in the Alzheimer care unit. C.R. is an 82-year-old woman with advanced Alzheimer's disease who has been a resident in the facility for over a year. Her status has deteriorated significantly over the past 2 months. C.R.'s daughter has been visiting her mother at dinnertime most evenings, bringing her favorite foods and drinks to feed her by hand. One evening, C.R.'s son visits during dinnertime and finds his sister feeding their mother. This was the first time C.R.'s son has visited her in over 2 months. He reacts angrily, noting that C.R. had noted in her advance directive that she did not wish to receive nutrition and fluids if she became incapacitated. He admonishes his sister "Mom does not even recognize either one of us—she would not want to keep going on this way!" C.R.'s daughter notes that although their mother does not recognize anyone or understand what is happening, she opens her mouth and seems to enjoy the food and fluids that she is receiving. C.R.'s son is his mother's sole designated proxy; he was authorized by her with her power-of-attorney to make health care decisions during a time when she had the mental capacity to make that decision. He reminds you and C.R.'s daughter of this, and tells you that he wants his sister to stop giving food and fluids to his mother.

Discussion

Whether or not a patient may autonomously decide to forego artificial nutrition and hydration therapy (ANH) is not subject to much debate at present. Most bioethicists tend to agree that a patient with mental capacity may decide to forego ANH, even if doing so may hasten the patient's death. Advance directives for health care that specify no ANH written by patients before such time as they lose capacity is considered binding. Proxy decision makers for patients who lose capacity may also make the decision to withhold ANH.

However, decisions to voluntarily stop eating and drinking (VSED), or taking nutrition and fluids by the "natural" oral route, can be more complicated. While ANH may only be delivered using medical interventions (e.g., intravenous fluids, feeding tubes), taking food and fluids orally might not be considered "medical care." In these instances, whether or not a designated proxy or person vested with power-of-attorney for health care agrees that this type of feeding can continue may be inconsequential. The ANA (2017) declares that "VSED, with the intention of hastening death can only be made by those patients with decision making capacity, not by surrogates." (p.1). In that same position statement, however, the ANA (2017) also states that "the patient's decision regarding VSED remains binding, even if the patient subsequently loses capacity." (p.1). It is important for a person who wishes to VSED to specify that in an advance directive.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Which principle do you believe should have preeminence as you proceed to work with C.R. and her adult children? Does VSED in a patient who now lacks capacity violate the principle of nonmaleficence?
- Is C.R.'s son authorized to specify that his sister may not hand feed their mother? What if C.R.'s advance directive specifically states that, should she lose capacity, she would not wish to receive *oral* food and fluids? C.R. opens her mouth and willingly accepts the foods and fluids given to her by her daughter; does this imply that she now consents to be hand fed?
- What resources might be available to you and the health care team to help C.R.'s adult children determine what is in her best interests?

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

If no advance arrangement has been made and the older person appears unable to make decisions, the court may be petitioned for a competency hearing. If the court rules that an older adult is incompetent, the judge appoints a guardian—a third party who is given powers by the court to assume responsibility for making financial or personal decisions for that person.

People with communication difficulties or mild dementia tend to be viewed as incapable of self-determination. However, people with mild dementia may have sufficient cognitive capability to make some, but perhaps not all, decisions. For example, a patient may be able to identify a proxy decision maker and yet be unable to select specific treatment options. People with mild dementia may be competent to understand the nature and significance of different options for care.

In 1990, the Patient Self-Determination Act (PSDA), a federal law, was enacted to require patient education about advance directives at the time of hospital admission, as well as documentation of this education. Nursing homes

are also mandated to enhance residents' autonomy by increasing their involvement in health care decision making. In both nursing homes and hospitals, the documentation and placement of advance directives in the medical record and the education of patients about advance directives vary considerably. Periodically, it is important to ensure that the directives reflect the current wishes of the patient and that all providers have a copy so that they are aware of the patient's wishes.

CRITICAL THINKING EXERCISES

1 ebp You notice an increase in the number of older patients who are confused on the medical-surgical unit where you work. What do you suspect may be the cause of this increase in patients who are confused? What screening tool(s) would you recommend for these patients? Would you recommend that these tools be used for every older patient? Why? What is the strength of the evidence base guiding your assessment, actions, and recommendations?

2 ipc A 90-year-old man has been admitted to your medical unit with urinary retention. What nursing and interprofessional assessments are indicated during your initial interactions with him? What other interprofessional services might you try to engage?

3 pq During a home visit, an 81-year-old woman with diabetes and a lower limb amputation admits to you that she has fallen three times in the past 6 months. Identify priorities and strategies that may help to prevent further falls for this patient.

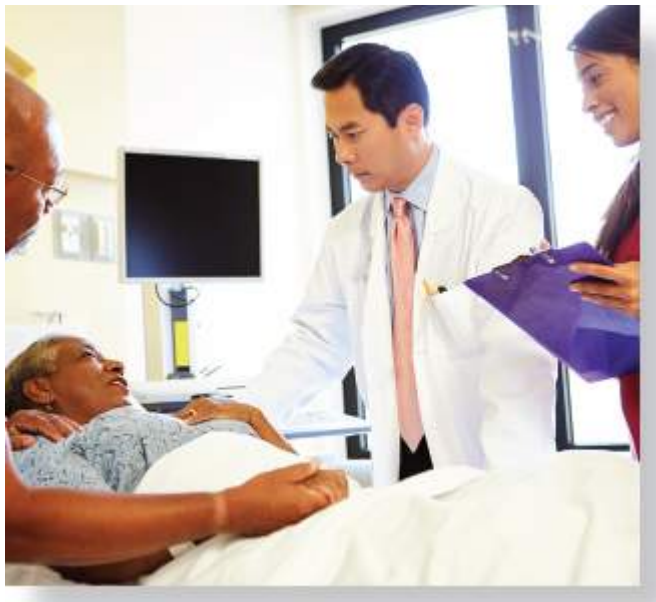
UNIT 2 Concepts and Principles of Patient Management

Case Study

PROMOTING TEAMWORK AND COLLABORATION IN PALLIATIVE CARE



A 56-year-old woman diagnosed with advanced adenocarcinoma of the lung arrives at her outpatient palliative care appointment with delirium, lethargy, and confusion. Her blood work is drawn, and she is transferred to the inpatient oncology unit where you work for further evaluation. The admission profile reports that she is prescribed gabapentin 300 mg three times daily and fentanyl 50 mcg transdermal patch to be replaced every 72 hours. Upon assessment you find the patient confused and unable to rate her pain. The family is concerned about the confusion and worried that she is unable to tolerate the medications ordered for pain. Because this patient has many underlying components to her care, you request a case conference with the family, palliative care team, pharmacist, and the oncologist to determine the best plan of care at this time.

QSEN Competency Focus: Teamwork and Collaboration

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care, interdisciplinary teamwork and collaboration, evidence-based practice, quality improvement, safety,*** and ***informatics.***

Teamwork and Collaboration Definition: Function effectively within nursing and interprofessional teams, fostering open communication, mutual respect, and shared decision-making to achieve quality patient care.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Recognize contributions of other individuals and groups in helping patient/family achieve health goals	Describe the nursing role in participating in a case conference. How do the various health care team members work with the patient and family and as a team to develop the best plan to manage care for this patient's pain while managing and minimizing the deleterious effects of delirium?
Skills	
Function competently within own scope of practice as a member of the health care team	Even though the patient is unable to rate her pain, what other methods of assessment can you use and rely on to assess pain in this patient? What interventions for pain can a nurse implement as part of a nursing care plan?
Attitudes	
Contribute to resolution of conflict and disagreement	After the case conference, the palliative care team recommends that the pain medication be administered to the patient as prescribed. The family is in conflict with the decision because the patient is confused and is not rating her pain. How can you best resolve the conflict? Are there other members of the team that may be instrumental in communicating with the family?

9 Pain Management

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the fundamental concepts of pain including the types of pain, the four processes of nociception, and neuropathic pain.
2. Explain and demonstrate methods to perform a pain assessment.
3. List the first-line agents from the three groups of analgesic agents.
4. Identify the unique effects of select analgesic agents on older adults.
5. Describe practical nonpharmacologic methods that can be used in the clinical setting in patients with pain.
6. Use the nursing process as a framework for care of the patient with pain.

NURSING CONCEPTS

Addiction
Comfort

GLOSSARY

acute pain: pain that results from tissue damage that generally abates as healing occurs; serves as a warning signal that something is wrong or needs attention

adjuvant analgesic agent: a substance or medication added to an analgesic medication regimen to improve analgesia (*synonym:* co-analgesic agent)

agonist: a medication that binds to an opioid receptor mimicking the way endogenous substances provide analgesia

agonist–antagonist: a type of opioid (e.g., nalbuphine and butorphanol) that binds to the kappa opioid receptor site acting as an agonist (capable of producing analgesia) and simultaneously to the mu opioid receptor site acting as an antagonist (reversing mu agonist effects)

allodynia: pain due to a stimulus that does not normally provoke pain, such as touch; typically experienced in the skin around areas affected by nerve injury and commonly seen with many neuropathic pain syndromes

antagonist: a medication that competes with agonists for opioid receptor binding sites; can displace agonists, thereby inhibiting their action

breakthrough pain: a transitory increase in pain that occurs in the context of otherwise controlled persistent pain

ceiling effect: an analgesic dose above which further dose increments produce no change in effect

central sensitization: a key central mechanism of neuropathic pain; the abnormal hyperexcitability of central neurons in the spinal cord, which results from complex changes induced by the incoming afferent barrages of nociceptors and results in an increased nociceptive neuron response

chronic or persistent pain: pain that may or may not be time limited but that persists beyond the usual course/time of tissue healing

co-analgesic agent: one of many medications that can either improve the effectiveness of another analgesic agent or independently have analgesic action (*synonym:* adjuvant analgesic agent)

comfort–function goal: the pain rating identified by the individual patient above which the patient experiences interference with function and quality of life (e.g., activities the patient needs or wishes to perform)

efficacy: the extent to which a medication or another treatment "works" and can produce the intended effect—analgesia in this context

half-life: the time it takes for the plasma concentration (amount of medication in the body) to be reduced by 50% (after starting a medication, or increasing its dose; four to five half-lives are required to

approach a steady-state level in the blood, irrespective of the dose, dosing interval, or route of administration; after four to five half-lives, a medication that has been discontinued generally is considered to be mostly eliminated from the body)

hydrophilic: a substance or medication that is readily absorbed in aqueous solution

hyperalgesia: an increasingly intense experience of pain resulting from a noxious stimulus

intraspinal: "within the spine"; refers to the spaces or potential spaces surrounding the spinal cord into which medications can be given

lipophilic: a substance or medication that is readily absorbed in fatty tissues

metabolite: the product of biochemical reactions during medication metabolism

mu agonist: any opioid that binds to the mu opioid receptor subtype and produces analgesic effects (e.g., morphine); used interchangeably with the terms *full agonist, pure agonist,* and *morphinelike medication*

multimodal analgesia or multimodal pain management: the intentional, concurrent use of more than one pharmacologic or nonpharmacologic intervention with different methods of action with the goal to achieve better analgesia while using lower doses of medications with fewer adverse effects

neuraxial: of the central nervous system

neuropathic (pathophysiologic) pain: pain caused by injury or dysfunction (lesion or disease) of one or more nerves of the peripheral or central nervous systems with resultant impaired processing of sensory input

neuroplasticity: the ability of the peripheral and central nervous systems to change both structure and function as a result of noxious stimuli

nociceptive (physiologic) pain: pain that is sustained by ongoing activation of the sensory system that conducts the perception of noxious stimuli; implies the existence of damage to somatic or visceral tissues sufficient to activate the nociceptive system

nociceptor: a type of primary afferent neuron that has the ability to respond to a noxious stimulus or to a stimulus that would be noxious if prolonged

nonopioid: refers to analgesic medications that include acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs)

NSAID: an acronym for nonsteroidal anti-inflammatory drug (pronounced "en said")

opioid: refers to morphine and other natural, semisynthetic, and synthetic medications that relieve pain by binding to multiple types of opioid receptors; term is preferred to “narcotic”

opioid dose–sparing effect: occurs when a nonopioid or co-analgesic medication is prescribed in addition to an opioid, enabling the opioid dose to be lower without diminishing analgesic effects

opioid-induced hyperalgesia: a phenomenon in which exposure to an opioid induces increased sensitivity, or a lowered threshold, to the neural activity conducting pain perception; it is the “flip side” of tolerance

opioid naïve: denotes a person who has not recently taken enough opioid on a regular enough basis to become tolerant to the opioid’s effects

opioid tolerant: denotes a person who has taken opioids long enough at doses high enough to develop tolerance to many of the opioid’s effects, including analgesia and sedation

pain: an unpleasant experience that is either emotional or sensory resulting from actual or possible damage to tissues and is uniquely experienced and described by each person

peripheral sensitization: a key peripheral mechanism of neuropathic pain that occurs when there are changes in the number and location of ion channels; in particular, sodium channels abnormally accumulate in injured nociceptors, producing a lower nerve depolarization threshold, ectopic discharges, and an increase in the response to stimuli

physical dependence: the body’s normal response to administration of an opioid for 2 or more weeks; withdrawal symptoms may occur if an opioid is abruptly stopped or an antagonist is given

placebo: any medication or procedure, including surgery, that produces an effect in a patient because of its implicit or explicit intent and not because of its specific physical or chemical properties

preemptive analgesic agents: pre-injury pain treatments (e.g., preoperative epidural analgesia and preincision local anesthetic infiltration) to prevent the development of peripheral and central sensitization of pain

refractory: nonresponsive or resistant to therapeutic interventions such as analgesic agents

substance use disorder (SUD): problematic use of substances such as opioids, benzodiazepines, or alcohol based on identification of at least two of the diagnostic criteria listed by the American Psychiatric Association. It is characterized by craving the substance; continuing use despite harm; inability to stop using; and experiencing withdrawal

symptoms when abruptly not using the substance; formerly known as addiction

titration: upward or downward adjustment of the amount (dose) of an analgesic agent

tolerance: a normal physiologic process characterized by decreasing effects of a medication at its previous dose, or the need for a higher dose of medication to maintain an effect

withdrawal: result of abrupt cessation or rapid decrease in dose of a substance upon which one is physically dependent. It is not necessarily indicative of substance use disorder

Pain serves as a survival tactic that guides individuals not only to avoid damage in the moment, but also to learn to avoid danger in the future (Martin, Power, Boyle, et al., 2017). Nurses in all settings play a key role in the management of pain as experts in assessment, medication administration, and patient education. They are uniquely positioned to assume this role as members of the health care team most consistently at the patient's bedside. These characteristics have led to nurses' distinction as the primary managers of patients who are experiencing pain (Curtis & Wrona, 2018).

Fundamental Concepts

Understanding the definition, effects, and types of pain lays the foundation for proper pain assessment and management.

Definition of Pain

The American Pain Society (APS, 2016) defines **pain** as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage" (p. 2). This definition describes pain as a complex phenomenon that can impact a person's psychosocial, emotional, and physical functioning. The clinical definition of pain reinforces that pain is a highly personal and subjective experience: "Pain is whatever the experiencing person says it is, existing whenever he says it does" (McCaffery, 1968, p. 8). The self-report by the patient is the standard; it is considered to be the most reliable indicator of pain and the most essential component of pain assessment (DiMaggio, Clark, Czarenecki, et al., 2018).

Effects of Pain

Pain affects individuals of every age, gender, race, and socioeconomic class (APS, 2016). It is the primary reason people seek health care and one of the

most common conditions that nurses treat (U.S. Department of Health & Human Services [HHS], 2019). Unrelieved pain has the potential to affect every system in the body and cause numerous harmful effects, some of which may last a lifetime (Table 9-1). Despite many advances in the understanding of the underlying mechanisms of pain and the availability of improved analgesic agents and technology, as well as nonpharmacologic pain management methods, all types of pain continue to be undertreated (Jungquist, Vallerand, Sicoutris, et al., 2017).

Types and Categories of Pain

Pain can be categorized in many ways, and clear distinctions are not always possible. Pain often is described from the perspective of duration, as being acute or chronic (persistent) (APS, 2016). **Acute pain** involves tissue damage as a result of surgery, trauma, burn, or venipuncture, and is expected to have a relatively short duration and resolve with normal healing. **Chronic or persistent pain** is subcategorized as being of cancer or noncancer origin and can persist throughout the course of a person's life. Examples of noncancer chronic pain include peripheral neuropathy from diabetes, back or neck pain after injury, and osteoarthritis pain from joint degeneration. Chronic pain may be intermittent, occurring with flares, or it may be continuous. Some conditions can produce both acute and chronic pain. For example, some patients with cancer have continuous chronic pain and also experience more intense acute exacerbations of pain periodically, which is called **breakthrough pain** (BTP). Patients may also endure acute pain from repetitive painful procedures during cancer treatment (APS, 2016).

Pain is also classified by its inferred pathology as being either nociceptive pain or neuropathic pain (Table 9-2). **Nociceptive (physiologic) pain** refers to the normal functioning of physiologic systems that leads to the perception of noxious stimuli (tissue injury) as being painful (International Association for the Study of Pain [IASP], 2017). This is the reason why nociception is described as "normal" pain transmission. **Neuropathic (pathophysiologic) pain** is pathologic and results from abnormal processing of sensory input by the nervous system as a result of damage to the peripheral or central nervous system (CNS) or both (IASP, 2017).

TABLE 9-1 Harmful Effects of Unrelieved Pain

Domains Affected	Specific Responses to Pain
Endocrine	↑ Adrenocorticotrophic hormone (ACTH), ↑ cortisol, ↑ antidiuretic hormone (ADH), ↑ epinephrine, ↑ norepinephrine, ↑ growth hormone (GH), ↑ catecholamines, ↑ renin, ↑ angiotensin II, ↑ aldosterone, ↑ glucagon, ↑ interleukin-1; ↓ insulin, ↓ testosterone
Metabolic	Gluconeogenesis, hepatic glycogenolysis, hyperglycemia, glucose intolerance, insulin resistance, muscle protein catabolism, ↑ lipolysis
Cardiovascular	↑ Heart rate, ↑ cardiac workload, ↑ peripheral vascular resistance, ↑ systemic vascular resistance, hypertension, ↑ coronary vascular resistance, ↑ myocardial oxygen consumption, hypercoagulation, deep vein thrombosis
Respiratory	↓ Flows and volumes, atelectasis, shunting, hypoxemia, ↓ cough, sputum retention, infection
Genitourinary	↓ Urinary output, urinary retention, fluid overload, hypokalemia
Gastrointestinal	↓ Gastric and bowel motility
Musculoskeletal	Muscle spasm, impaired muscle function, fatigue, immobility
Cognitive	Reduction in cognitive function, mental confusion
Immune	Depression of immune response
Developmental	↑ Behavioral and physiologic responses to pain, altered temperaments, higher somatization; possible altered development of the pain system, ↑ vulnerability to stress disorders, addictive behavior, and anxiety states
Future pain	Debilitating chronic pain syndromes: postmastectomy pain, post thoracotomy pain, phantom pain, postherpetic neuralgia
Quality of life	Sleeplessness, anxiety, fear, hopelessness, ↑ thoughts of suicide

Copyright 1999, Pasero, C., & McCaffery, M. Used with permission from Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacologic management*. St. Louis, MO: Mosby-Elsevier.

Patients may have a combination of nociceptive and neuropathic pain. For example, a patient may have nociceptive pain as a result of tumor growth, and also report radiating sharp and shooting neuropathic pain if the tumor is pressing against a nerve plexus. Sickle cell disease pain is usually a combination of nociceptive pain from the various hematologic changes of sickled cells as well as neuropathic pain from nerve ischemia (Belvis, Henderson, & Benzon, 2018).

Nociceptive Pain

Nociception includes four specific processes: transduction, transmission, perception, and modulation (Ellison, 2017). Figure 9-1 illustrates these processes and following is an overview of each.

TABLE 9-2 Classification of Pain by Inferred Pathology

	Nociceptive Pain	Neuropathic Pain	Mixed Pain
Physiologic Processes	Normal processing of stimuli that damages tissues or has the potential to do so if prolonged; can be somatic or visceral	Abnormal processing of sensory input by the peripheral or central nervous system or both	Components of both nociceptive and neuropathic pain; poorly defined
Categories and Examples	***Somatic Pain:*** Arises from bone joint, muscle, skin, or connective tissue. It is usually described as aching or throbbing in quality and is well localized *Examples:* Surgical, trauma; wound and burn pain; cancer pain (tumor growth) and pain associated with bony metastases; labor pain (cervical changes and uterine contractions); osteoarthritis and rheumatoid arthritis pain; osteoporosis pain; pain of Ehlers–Danlos syndrome; ankylosing spondylitis ***Visceral Pain:*** Arises from visceral organs, such as the GI tract and pancreas. This may be subdivided: • Tumor involvement of the organ capsule that causes aching and fairly well-localized pain • Obstruction of hollow viscus, which causes intermittent cramping and poorly localized pain *Examples:* Organ-involved cancer pain; ulcerative colitis; irritable bowel syndrome; Crohn's disease; pancreatitis	***Centrally Generated Pain*** *Deafferentation pain:* Injury to either the peripheral or central nervous system; burning pain below the level of a spinal cord lesion reflects injury to the central nervous system *Examples:* Phantom pain as a result of peripheral nerve damage; poststroke pain; pain following spinal cord injury *Sympathetically maintained pain:* Associated with dysregulation of the autonomic nervous system *Example:* Complex regional pain syndrome ***Peripherally Generated Pain*** *Painful polyneuropathies:* Pain is felt along the distribution of many peripheral nerves. *Examples:* Diabetic neuropathy; postherpetic neuralgia; alcohol–nutritional	No identified categories *Examples:* Fibromyalgia; some types of neck, shoulder, and back pain; some headaches; pain associated with HIV; some myofascial pain; pain associated with Lyme disease

		neuropathy; some types of neck, shoulder, and back pain; pain of Guillain–Barré syndrome *Painful mononeuropathies:* Usually associated with a known peripheral nerve injury; pain is felt at least partly along the distribution of the damaged nerve *Examples:* Nerve root compression, nerve entrapment; trigeminal neuralgia; some types of neck, shoulder, and back pain	
Pharmacologic Treatment	Most responsive to nonopioids, opioids, and local anesthetics	Co-analgesic agents, such as antidepressants, anticonvulsants, and local anesthetics, but there is wide variability in terms of efficacy and adverse-effect profiles	Co-analgesic agents, such as antidepressants, anticonvulsants, and local anesthetics, but there is wide variability in terms of efficacy and adverse-effect profiles

GI, gastrointestinal; HIV, human immune deficiency virus.

Transduction

Transduction refers to the processes by which noxious stimuli, such as a surgical incision or burn, activate primary afferent neurons called **nociceptors,** located throughout the body in the skin, subcutaneous tissue, and visceral (organ), and somatic (musculoskeletal) structures (Montgomery, Mallick-Searle, Peltier, et al., 2018). These neurons have the ability to respond selectively to noxious stimuli generated as a result of tissue damage from

mechanical (e.g., incision, tumor growth), thermal (e.g., burn, frostbite), chemical (e.g., toxins, chemotherapy), and infectious sources. Noxious stimuli cause the release of a number of excitatory compounds (e.g., serotonin, bradykinin, histamine, substance P, and prostaglandins), which move pain along the pain pathway (Ringkamp, Dougherty, & Raja, 2018) (see Fig. 9-1A). In addition, sodium, calcium, and potassium ion channels are stimulated to open, resulting in electrical impulses that are transmitted through the large, rapid conducting A-delta and smaller, peripheral C-fiber nociceptors (Ellison, 2017).

Prostaglandins are lipid compounds that initiate inflammatory responses that increase tissue swelling and pain at the site of injury (Baral, Udit, & Chiu, 2019). They form when the enzyme phospholipase breaks down phospholipids into arachidonic acid. In turn, the enzyme cyclo-oxygenase (COX) acts on arachidonic acid to produce prostaglandins (Fig. 9-2). COX-1 and COX-2 are isoenzymes of COX and play an important role in producing the effects of the **nonopioid** analgesic agents, which include the nonsteroidal anti-inflammatory drugs (**NSAIDs**) and acetaminophen. NSAIDs produce pain relief by mediating inflammation at the site of trauma, primarily by blocking the formation of prostaglandins (Leppert, Malec-Milewska, Zajaczkowska, et al., 2018). The nonselective NSAIDs, such as ibuprofen, naproxen, diclofenac, and ketorolac, inhibit both COX-1 and COX-2, and the COX-2 selective NSAIDs, such as celecoxib, inhibit only COX-2. As Figure 9-2 illustrates, both types of NSAIDs produce anti-inflammation and pain relief through the inhibition of COX-2. Acetaminophen is known to be a COX inhibitor that has minimal peripheral effect, is not anti-inflammatory, and can both relieve pain and reduce fever by preventing the formation of prostaglandins in the CNS (Slattery & Klegeris, 2018).

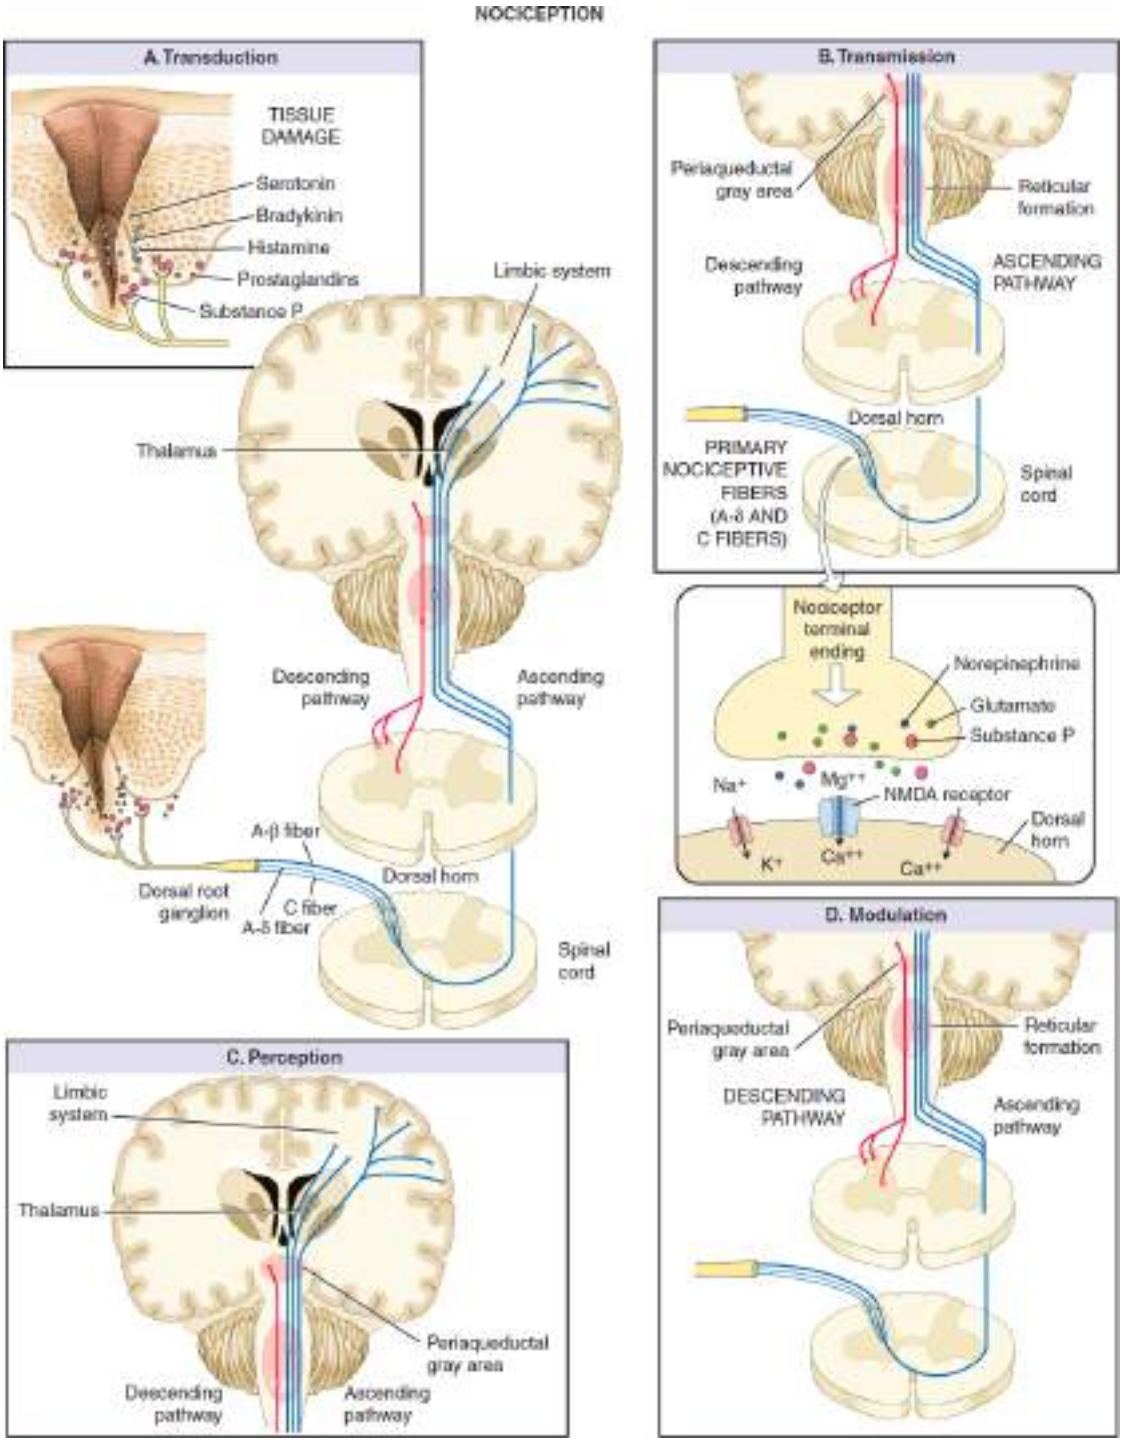

Figure 9-1 • Nociception. **A.** Transduction. **B.** Transmission. **C.** Perception. **D.** Modulation. Redrawn from Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacologic management* (p. 5). St. Louis, MO: Mosby-Elsevier. Copyright 2011, Pasero, C., & McCaffery, M. Used with permission.

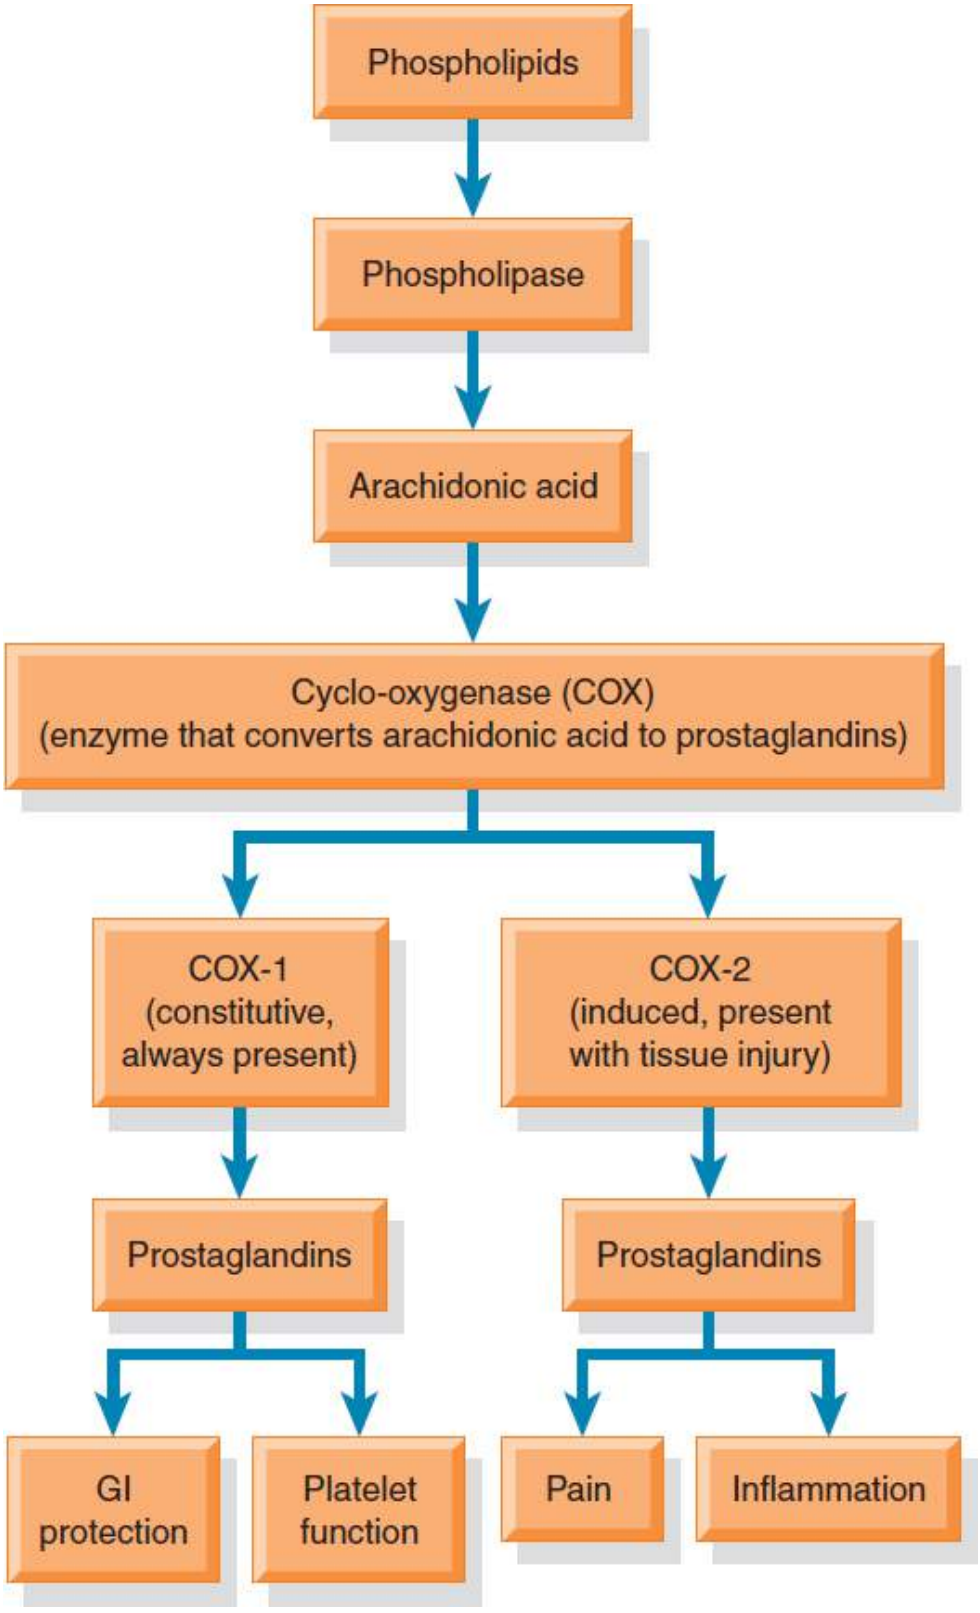

Figure 9-2 • Enzyme pathway: COX-1 and COX-2. Redrawn from Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacologic management* (p. 6). St. Louis, MO: Mosby-Elsevier. Copyright 2004, Pasero, C., & McCaffery, M. Used with permission.

Other analgesic agents work at the site of transduction by affecting the flux of ions. For example, sodium channels are closed and inactive at rest but undergo changes in response to nerve membrane depolarization. Transient channel opening leads to an influx of sodium that results in nerve conduction (Nouri, Osuagwu, Boyette-Davis, et al., 2018). Local anesthetics reduce nerve conduction by blocking sodium channels. The calcium channel blocking anticonvulsants that are used to treat neuropathic pain facilitate analgesia by reducing the flux of calcium ions and limiting glutamate, norepinephrine, and substance P release (Peterson, Benson, & Hurley, 2018).

Transmission

Transmission is another process involved in nociception. Effective transduction generates an action potential that is transmitted along the lightly myelinated rapid conducting A-delta fibers and the unmyelinated slower impulse conducting C fibers (Ellison, 2017) (see Fig. 9-1B). The endings of A-delta fibers detect thermal and mechanical injury, allow relatively quick localization of pain, and are responsible for a rapid reflex withdrawal from the painful stimulus. Unmyelinated C fibers respond to mechanical, thermal, and chemical stimuli. They produce poorly localized and often aching or burning pain. A-beta (β) fibers are the largest of the fibers and respond to touch, movement, and vibration but do not normally transmit pain (Ellison, 2017; Vardeh & Naranjo, 2017).

The action potential impulse with the noxious information passes through the dorsal root ganglia, then synapses in the dorsal horn of the spinal cord, and then ascends up to the spinal cord and transmits the information to the brain, where pain is perceived (Ellison, 2017; Ringkamp et al., 2018) (see Fig. 9-1B). Extensive modulation occurs in the dorsal horn via complex neurochemical mechanisms (see Fig. 9-1B inset). The primary A-delta fibers release glutamate and C fibers release substance P and other neuropeptides (Schliessbach & Maurer, 2017). Glutamate is a key neurotransmitter because it binds to the *N*-methyl-*D*-aspartate (NMDA) receptor and promotes pain transmission (Zhou, 2017).

Perception

An additional process involved in nociception is perception, which is the result of the neural activity associated with transmission of noxious stimuli (Ringkamp et al., 2018). It requires activation of higher brain structures for the occurrence of awareness, emotions, and impulses associated with pain (see Fig. 9-1C). Although the physiology of pain perception continues to be studied, it can be targeted by nonpharmacologic therapies, such as distraction, which are based on the belief that innate brain processes can strongly influence pain perception (Chayadi & McConnell, 2019).

Modulation

Modulation is another process involved in nociception. Modulation of the information generated in response to noxious stimuli occurs at every level from the periphery to the cortex and involves many different neurochemicals (Damien, Colloca, Bellei-Rodriguez, et al., 2018) (see Fig. 9-1D). For example, serotonin and norepinephrine are inhibitory neurotransmitters that are released in the spinal cord and the brain stem by the descending (efferent) fibers of the modulatory system (Nouri et al., 2018). Some antidepressants provide pain relief by blocking the body's reuptake (resorption) of serotonin and norepinephrine, extending their availability to fight pain (Martin et al., 2017). Endogenous opioids are located throughout the peripheral and central nervous systems, and like exogenous opioids, they bind to opioid receptors in the descending system and inhibit pain transmission (Nouri et al., 2018).

Neuropathic Pain

Neuropathic pain is caused by either a lesion or a disease involving the somatosensory nervous system (Bouhassira, 2019). Injuries to peripheral nerves can either be traumatic or nontraumatic, such as diabetic or compression neuropathies (Osborne, Anastakis, & Davis, 2018). Although specific causes may vary based on the underlying pathology, it is theorized that there are changes in the ion channels; imbalance of the stimuli processing between excitatory and inhibitory somatosensory signals; activity of glial cells; or potential differences in modulation of pain that occur with neuropathic pain (Colloca, Ludman, Bouhassira, et al., 2017; Liu, Zhu, Ju, et al., 2019) (Fig. 9-3). Recent research findings suggest that dysfunction in autophagy (i.e., cellular degradation of unnecessary materials) is involved with neuropathic pain (Liu et al., 2019). Research is ongoing to better define the peripheral and central mechanisms that initiate and maintain neuropathic pain (García, Gutiérrez-Lara, Centurión, et al., 2019; Kwiatkowski & Mika, 2018; Liu et al., 2019; Nishimura, Kawasaki, Suzuki, et al., 2019).

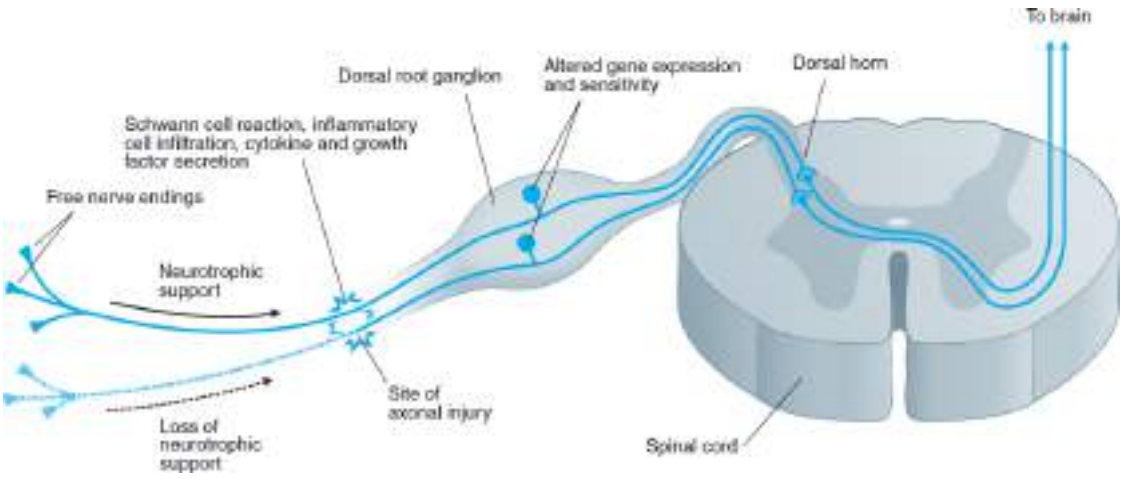

Figure 9-3 • Neuropathic pain. Nociceptive injury or inflammation may result in an altered physiologic response within the nociceptive system. These changes cause release of inflammatory cytokines that may alter gene expression and sensitivity in nociceptive fibers. In turn, these alter nociceptive activity, causing neuropathic pain. Used with permission from Golan, D. E., Tashjian, A. H., & Armstrong, E. J. (2017). *Principles of pharmacology: The pathophysiologic basis of drug therapy* (4th ed.). Baltimore, MD: Wolters Kluwer Health | Lippincott Williams & Wilkins.

Peripheral Mechanisms

At any point from the periphery to the CNS, the potential exists for the development of neuropathic pain. Nerve endings in the periphery can become damaged, leading to abnormal reorganization in the nervous system called maladaptive **neuroplasticity,** an underlying mechanism of some neuropathic pain states (Osborne et al., 2018). Changes in ion channels can occur, such as increased sodium channel activity in sensory nerves resulting in heightened excitability, increased transduction, and release of neurotransmitters (Colloca et al., 2017). These and many other processes lead to a phenomenon called **peripheral sensitization,** which is thought to contribute to the maintenance of neuropathic pain and is thought to be reflected in allodynia and hyperalgesia (Osborne et al., 2018). **Allodynia,** or pain from a normally non-noxious stimulus (e.g., touch), is one such type of abnormal sensation and a common feature of neuropathic pain (Chekka & Benzon, 2018; Osborne et al., 2018). In patients with allodynia, the mere weight of clothing or bedsheets on the skin can be excruciatingly painful. **Hyperalgesia** is an increased response of pain sensation from a stimulus which at a usual pain threshold produces a less intense pain response.

Central Mechanisms

Central mechanisms also play a role in the establishment of neuropathic pain. **Central sensitization** is defined as abnormal hyperexcitability of central

neurons in the spinal cord, which results from complex changes induced by incoming afferent barrages of nociceptors, which also can result in allodynia and hyperalgesia (Osborne et al., 2018). Extensive release and binding of excitatory neurotransmitters, such as glutamate, activate the NMDA receptor and cause an increase in intracellular calcium levels into the neuron, resulting in pain (Yan, Li, Zhou, et al., 2017). Similar to what happens in the peripheral nervous system, an increase in the influx of sodium is thought to lower the threshold for nerve activation, increase response to stimuli, and enlarge the receptive field served by the affected neuron (Osborne et al., 2018; Yan et al., 2017).

As in the peripheral nervous system, anatomic changes can occur in the CNS. For example, when the NMDA receptor cells are continuously activated, reorganization in the dorsal horn of the spinal cord can occur (Nouri et al., 2018). Nerve fibers can invade other locations and create abnormal sensations, such as allodynia, in the area of the body served by the injured nerve.

Pain Assessment

The highly subjective nature of pain causes challenges in assessment and management; however, the patient's self-report is the undisputed standard for assessing the existence and intensity of pain (APS, 2016; Herr, Coyne, McCaffery, et al., 2011; McCaffery, Herr, & Pasero, 2011). Self-report is considered the most reliable measure of the existence and intensity of the patient's pain and is recommended by The Joint Commission (Baker, 2017). Accepting and acting on the patient's report of pain are sometimes difficult. Because pain cannot be proven, clinicians may feel vulnerable to inaccurate or untruthful reports of pain. Although clinicians are entitled to their personal opinions, those thoughts cannot interfere with appropriate patient care. Chart 9-1 provides strategies to use when the patient's report of pain is not accepted.

Chart 9-1

Strategies to Use When the Patient's Report of Pain Is Not Accepted

- Acknowledge that everyone is entitled to a personal opinion, but personal opinion does not form the basis for professional practice.
- Clarify that the sensation of pain is subjective and cannot be proved or disproved.
- Quote recommendations from clinical practice guidelines, especially those published by the American Pain Society.
- Ask, "Why is it so difficult to believe that this person hurts?"

Quality and Safety Nursing Alert

Although accepting and responding to the report of pain may result in administering analgesic agents to an occasional patient who does not have pain, doing so helps to ensure that everyone who does have pain receives appropriate care. Health care professionals do not have the right to deprive any patient of appropriate assessment and treatment simply because they believe a patient is not being truthful. Pain is an extremely personal experience manifested uniquely by each person. It is important to carefully assess and reassess pain when administering analgesic medications.

Performing the Comprehensive Pain Assessment: Patient Interview

A comprehensive pain assessment should be conducted during the admission assessment or initial interview with the patient, with each new report of pain, and whenever indicated by changes in the patient's condition or treatment plan. It serves as the foundation for developing and evaluating the effectiveness of the pain treatment plan. The following are components of a comprehensive pain assessment and tips on how to elicit the information from the patient:

- *Location(s) of pain:* Ask the patient to state or point to the area(s) of pain on the body. Sometimes allowing patients to make marks on a body diagram is helpful in gaining this information.
- *Intensity:* Ask the patient to rate the severity of the pain using a reliable and valid pain assessment tool. Chart 9-2 provides guidance for educating patients and their families on how to use a pain rating scale. Various scales translated in several languages have been

evaluated and made available for use in clinical practice and for educational practice. The most common include the following:

Chart 9-2 **PATIENT EDUCATION**

Educating Patients and Their Families How to Use a Pain Rating Scale[a]

Step 1. Show the pain rating scale to the patient and the family and explain its primary purpose.

Example: "This is a pain rating scale that many of our patients use to help us understand their pain and to set goals for pain relief. We will ask you regularly about pain, but any time you have pain you must let us know. We do not always know when you hurt."

Step 2. Explain the parts of the pain rating scale. If the patient does not like it or understand it, switch to another scale (e.g., vertical presentation, VDS, or faces).

Example: "On this pain rating scale, 0 means no pain and 10 means the worst possible pain. The middle of the scale, around 5, means moderate pain. A 2 or 3 would be mild pain, but 7 or higher means severe pain."

Step 3. Discuss pain as a broad concept that is not restricted to a severe and intolerable sensation.

Example: "Pain refers to any kind of discomfort anywhere in your body. Pain also means aching and hurting. Pain can include pulling, tightness, burning, knifelike feelings, and other unpleasant sensations."

Step 4. Verify that the patient understands the broad concept of pain. Ask the patient to mention two examples of pain they have experienced. If the patient is already in pain that requires treatment, use the present situation as the example.

Example: "I want to be sure that I have explained this clearly, so would you give me two examples of pain you have had recently?" If the patient's examples include various parts of the body and various pain characteristics, that indicates that they understand pain as a fairly broad concept. An example of what a patient might say is "I have a mild, sort of throbbing headache now, and yesterday my back was aching."

Step 5. Ask the patient to practice using the pain rating scale with the present pain or select one of the examples mentioned.

Example: "Using the scale, what is your pain right now? What is it at its worst?" OR "Using the pain rating scale and one of your examples of pain, what is that pain usually? What is it at its worst?"

Step 6. Set goals for comfort and function/recovery/quality of life. Ask patients what pain rating would be acceptable or satisfactory, considering the activities required for recovery or for maintaining a satisfactory quality of life.

Example for a surgical patient: "I have explained the importance of coughing and deep breathing to prevent pneumonia and other complications. Now we need to determine the pain rating that will not interfere with this so that you may recover quickly."

Example for patient with chronic pain or terminal illness: "What do you want to do that pain keeps you from doing? What pain rating would allow you to do this?"

[a]When a patient is obviously in pain or not focused enough to learn to use a pain rating scale, pain treatment should proceed without pain ratings. Education can be undertaken when pain is reduced to a level that facilitates understanding how to use a pain scale.

VDS, verbal descriptor scale.

Copyright 2011, Pasero, C., & McCaffery, M. Used with permission from Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacologic management*. St. Louis, MO: Mosby-Elsevier.

- *Numeric Rating Scale (NRS):* The NRS is most often presented as a horizontal 0- to 10-point scale, with word anchors of "no pain" at one end of the scale, "moderate pain" in the middle of the scale, and "worst possible pain" at the end of the scale. It may also be put on a vertical axis, which may be helpful for patients who read from right to left.
- *Wong–Baker FACES Pain Rating Scale:* The FACES scale consists of six cartoon faces with word descriptors, ranging from a smiling face on the left for "no pain (or hurt)" to a frowning, tearful face on the right for "worst pain (or hurt)." Patients are asked to choose the face that best reflects their pain. The faces are most commonly numbered using a 0, 2, 4, 6, 8, 10 metric, although 0 to 5 can also be used. Patients are asked to choose the face that best describes their pain. The FACES scale is used in adults and children as young as 3 years (McCaffery et al., 2011). It is important to appreciate that FACES scales are self-report tools; clinicians should not attempt to match a face shown on a scale to the patient's facial expression to determine pain intensity. Patients may be able to understand the tool better if it is displayed vertically with no pain as the anchor at the bottom.
- *Faces Pain Scale—Revised (FPS-R):* The FPS-R has six faces to make it consistent with other scales using the 0 to 10 metric. The faces range from a neutral facial expression to one of intense pain and are numbered 0, 2, 4, 6, 8, and 10. As with the Wong–Baker FACES scale, patients are asked to choose the face that best reflects their pain. Faces scales have been shown to be reliable and valid measures in children as young as 3 years of age; however, the ability to optimally quantify pain (identify a number) is not acquired until approximately 8 years of age (Spagrud, Piira, & Von Baeyer, 2003). Ongoing research suggests that the FPS-R is preferred by both patients who are cognitively intact and older adults who are cognitively impaired, and by minority populations (Kang & Demiris, 2018).

- *Verbal descriptor scale (VDS):* A VDS uses different words or phrases to describe the intensity of pain, such as "no pain, mild pain, moderate pain, severe pain, very severe pain, and worst possible pain." The patient is asked to select the phrase that best describes pain intensity.
- *Visual Analogue Scale (VAS):* The VAS is a horizontal (sometimes vertical) 10-cm line with word anchors at the extremes, such as "no pain" on one end and "pain as bad as it could be" or "worst possible pain" on the other end. Patients are asked to make a mark on the line to indicate intensity of pain, and the length of the mark from "no pain" is measured and recorded in centimeters or millimeters. Although often used in research, the VAS is impractical for use in daily clinical practice and rarely used in that setting.
- *Quality:* Ask the patient to describe how the pain feels. Descriptors such as "sharp," "shooting," or "burning" may help identify the presence of neuropathic pain.
- *Onset and duration:* Ask the patient when the pain started and whether it is constant or intermittent.
- *Aggravating and relieving factors:* Ask the patient what makes the pain worse and what makes it better.
- *Effect of pain on function and quality of life:* The effect of pain on the ability to perform recovery activities should be regularly evaluated in the patient with acute pain. It is particularly important to ask patients with persistent pain about how pain has affected their lives, what they could do before the pain began that they can no longer do, or what they would like to do but cannot do because of the pain.
- ***Comfort–function goal*** (pain intensity): For patients with acute pain, identify short-term functional goals and reinforce to the patient that good pain control will more likely lead to successful achievement of the goals. For example, surgical patients are told that they will be expected to ambulate or participate in physical therapy postoperatively. Patients with chronic pain can be asked to identify their unique functional or quality-of-life goals, such as being able to work or walk the dog. Success is measured by progress toward meeting those functional goals (Topham & Drew, 2017).
- *Other information:* The patient's culture, past pain experiences, and pertinent medical history such as comorbidities, laboratory tests, and diagnostic studies are considered when establishing a treatment plan.

Patients who are unable to report their pain are at higher risk for undertreated pain than those who can report (Horgas, 2017; McCaffery et al., 2011). In the adult population, this includes patients who are cognitively impaired, critically ill (intubated, unresponsive), comatose, or imminently dying. Patients who are receiving neuromuscular blocking agents or are sedated from anesthesia and other medications given during surgery are also among this at-risk population.

The Hierarchy of Pain Measures is recommended as a framework for assessing pain in patients who are nonverbal (Herr et al., 2011; McCaffery et al., 2011). The key components of the hierarchy require the nurse to (1) attempt to obtain self-report, (2) consider underlying pathology or conditions and procedures that might be painful (e.g., surgery), (3) observe behaviors, (4) evaluate physiologic indicators, and (5) conduct an analgesic trial. Chart 9-3 provides detailed information on each component of the Hierarchy of Pain Measures.

When patients cannot self-report their pain, some observational tools may be used to help with clinical decision making. Some of these assign a score by observing behaviors that tend to be associated with pain. These observational scores are not considered equivalent to a patient's self-reported pain intensity score, however.

It is imperative to remember that behaviors can indicate the presence of pain, but the absence of behavior does not indicate the absence of pain. Patients who are not moving or making any sounds may still be experiencing intense pain. For instance, older adults with moderate and severe dementia frequently have comorbid disorders that may cause pain (Mueller, Schumacher, Holzer, et al., 2017). Accurately assessing and treating their pain can be difficult to achieve (see Chart 9-4 Nursing Research Profile: Evaluation of a Tool to Assess Pain in Older Adults with Dementia). The following tools are examples of validated measures that are appropriate for different populations of patients unable to self-report their pain (Fry & Elliott, 2018; Kochman, Howell, Sheridan, et al., 2017; Rijkenberg, Stilma, Bosman, et al., 2017; Schofield & Abdulla, 2018).

Chart 9-3

Hierarchy of Pain Measures

1. Attempt to obtain the patient's self-report, the single most reliable indicator of pain. Do not assume that a patient cannot provide a report of pain; many patients who are cognitively impaired are able to use a self-report tool if simple actions are taken.
   - Try using standard pain assessment tools (see text).
   - Increase the size of the font and other features of the scale.
   - Present the tool in vertical format (rather than the frequently used horizontal).
   - Try using alternative words, such as "ache," "hurt," and "sore," when discussing pain.
   - Ensure eyeglasses and hearing aids are functioning.
   - Ask about pain in the present.
   - Repeat instructions and questions more than once.
   - Allow ample time to respond.
   - Remember that head nodding and eye blinking or squeezing the eyes tightly can also be used to signal presence of pain and sometimes used to rate intensity.
   - Ask patients who are intubated and who are awake and oriented to point to a number on the numerical scale if they are able.
   - Repeat instructions and show the scale each time pain is assessed.
2. Consider the patient's condition or exposure to a procedure that is thought to be painful. If appropriate, assume pain is present and document as such when approved by institution policy and procedure. As an example, pain should be assumed to be present in a patient who is unresponsive, mechanically ventilated, and critically ill due to trauma.
3. Observe behavioral signs, for example, facial expressions, crying, restlessness, and changes in activity. A pain behavior in one patient may not be in another. Try to identify pain behaviors that are unique to the patient ("pain signature"). Many behavioral pain assessment tools are available that will yield a pain behavior score and may help determine whether pain is present. However, it is important to remember that a behavioral score is not the same as a pain intensity score. Behavioral tools are used to help identify the presence of pain, but the pain intensity is unknown if the patient is unable to provide it.
   - A surrogate who knows the patient well (e.g., parent, spouse, or caregiver) may be able to provide information about underlying painful pathology or behaviors that may indicate pain.
4. Evaluate physiologic indicators with the understanding that they are the *least* sensitive indicators of pain and may signal the existence of conditions other than pain or a lack of it (e.g., hypovolemia, blood loss). Patients quickly adapt physiologically despite pain and may have normal or below normal vital signs in the presence of severe pain. The overriding principle

is that the absence of an elevated blood pressure or heart rate does not mean the absence of pain.

5. Conduct an analgesic trial to confirm the presence of pain and to establish a basis for developing a treatment plan if pain is thought to be present. An analgesic trial involves the administration of a low dose of nonopioid or opioid and observing patient response. The initial low dose may not be enough to elicit a change in behavior and should be increased if the previous dose was tolerated, or another analgesic agent may be added. If behaviors continue despite optimal analgesic doses, other possible causes should be investigated. In patients who are completely unresponsive, no change in behavior will be evident and the optimized dose of the analgesic agent should be continued.

Chart 9-4 NURSING RESEARCH PROFILE

Evaluation of a Tool to Assess Pain in Older Adults with Dementia

Mueller, G., Schumacher, P., Holzer, E., et al. (2017). The inter-rater reliability of the observation instrument for assessing pain in elderly with dementia: An investigation in the long-term care setting. *Journal of Nursing Measurement, 25*(3), E173–E184.

Purpose

The aim of this study was to examine the interrater reliability of the German version of the observation instrument for assessing pain in older adults with dementia called the BISAD for the German (Beobachtungsinstrument für das Schmerzassessment bei alten Menschen mit Demenz). This is a tool that is commonly used to assess pain among older adults with moderate and severe dementia who reside in long-term care facilities in both Germany and Austria; however, interrater reliability was not previously done to ensure its validity.

Design

This study used a quantitative multicenter-descriptive cross-sectional design with a convenience sample of 71 participants who resided in one of three nursing homes in Austria. The nursing participants consisted of 46 registered nurses who had been working at one of the same three nursing homes for at least 2 y. Nurse participants were paired to independently evaluate a resident participant within the same hour using the eight-item BISAD observational pain assessment tool.

Findings

Although modest agreement between raters was noted, the absolute concordance of the total was only 25.32%. The analysis of interrater reliability was low and did not support reliability of the items in the BISAD. There was agreement that pain was greater with movement than when the participant residents were at rest.

Nursing Implications

Findings of this study are important since they indicate the items used in the BISAD tool are not reliable for assessing pain in older adult residents with moderate and severe dementia in nursing homes in Austria, although it is commonly used. This is an important finding since use of this tool with that population could yield inaccurate data upon which nurses could base pain management care. One interesting aspect of this study was that behaviors did demonstrate greater pain with activity than when at rest. Finally, the authors note that there may be cultural and language issues that affected the results and encourage a translated version of the tool be assessed in long-term care facilities where English is the primary language.

- FLACC: indicated for use in young children. Scores are assigned after assessing *F*acial expression, *L*eg movement, *A*ctivity, *C*rying, and *C*onsolability, with each of these five categories assigned scores from 0 to 2, yielding a total composite score of 0 to 10. Scores of "0" are interpreted as reflecting that the patient is relaxed and comfortable, scores of "1" to "3" are interpreted as consistent with mild discomfort, scores from "4" to "6" are considered consistent with moderate pain, and scores from "7" to "10" are considered consistent with severe discomfort or pain.
- PAINAD (*P*ain *A*ssessment *IN A*dvanced *D*ementia): indicated for use in adults with advanced dementia who are not able to verbalize their needs. Patterned after the FLACC, this tool was developed by the U.S. Department of Veterans Affairs for patients who have dementia.
- CPOT (*C*ritical Care *P*ain *O*bservation *T*ool): indicated for use in patients in critical-care units who cannot self-report pain, whether or not they may be intubated. It is also patterned after the FLACC.

Reassessing Pain

Following initiation of the pain management plan, pain is reassessed and documented on a regular basis to evaluate the effectiveness of treatment. At a minimum, pain should be reassessed with each new report of pain and before and after the administration of analgesic agents (McCaffery et al., 2011). The frequency of reassessment depends on the stability of the patient and the timing of peak effect of the medication administered, which is generally between 15 and 30 minutes following parenteral administration and between 1 and 2 hours following oral administration (Chou, Gordon, de Leon-Casasola, et al., 2016). For example, in the postanesthesia care unit (PACU), reassessment may be necessary as often as every 10 minutes when pain is unstable during intravenous (IV) opioid **titration** but may be done an hour following administration of oral medication in patients with satisfactory and stable pain control the day following surgery.

Veterans Considerations

Nurses should be aware that research has demonstrated a high prevalence of pain associated disorders, including arthritis, fibromyalgia, headaches and generalized abdominal, back, and joint pain in veteran populations (Nahin, 2017). In addition, reports of severe pain are more common in military veterans compared to nonveterans, especially in those who served, more recently, in conflicts in Iraq and Afghanistan (Nahin, 2017). In particular, younger veterans (18 to 39 years of age) and male veterans report significantly

higher levels of pain compared to matched age groups and men in the general public (Nahin, 2017). As a result, it is important for the nurse to determine during assessment if a patient has served in the U.S. military, to recognize that this group may have unique needs related to their service, and to advocate for multimodal and multidisciplinary approaches to help veterans better cope with pain. For example, Groessi, Liu, Change, and colleagues (2017) found that yoga was a safe and beneficial intervention in helping veterans to reduce pain and disability, while taking fewer opioid medications.

Pain Management

Achieving optimal pain relief is best viewed on a continuum, with the primary objective being to provide both effective and safe analgesia (Pozek, De Ruyter, & Khan, 2018). The quality of pain control should be addressed whenever patient care is passed on from one clinician to another, such as at change of shift and transfer from one clinical area to another. Optimal pain relief is the responsibility of *every* member of the health care team and begins with titration of the analgesic agent, followed by continued prompt assessment, analgesic agent administration, and nonpharmacologic interventions during the course of care to safely achieve pain intensities that allow patients to meet their functional goals with relative ease.

Although it may not always be possible to achieve a patient's pain intensity goal within the short time the patient is in an area like the PACU or emergency department, this goal provides direction for ongoing analgesic care. Important information to provide during transfer report is the patient's comfort–function goal, how close the patient is to achieving it, what has been done thus far to achieve it (analgesic agents and doses and/or nonpharmacologic interventions), and how well the patient has tolerated administration of the analgesic agent (adverse effects). There is growing interest among both clinicians and researchers in linking pain management to functional goals. One effort in this work is the Clinically Aligned Pain Assessment (CAPA) Tool, which is used to assess various degrees of comfort, pain control, function, and sleep (Topham & Drew, 2017). Pain management interventions should improve and not inhibit progress toward healing and rehabilitation.

Pharmacologic Management of Pain: Multimodal Analgesia

Pain is a complex phenomenon involving multiple underlying mechanisms that requires more than one analgesic agent to manage it safely and effectively. The recommended approach for the treatment of all types of pain in all age groups is called **multimodal analgesia or multimodal pain management.** A

multimodal regimen intentionally and simultaneously combines medications with different underlying mechanisms, along with nonpharmacologic interventions, which allows for lower doses of each of the medications in the treatment plan, reducing the potential for adverse effects. Furthermore, multimodal analgesia can result in comparable or greater pain relief with fewer adverse effects than can be achieved with any single analgesic agent (Beverly, Kaye, Ljungqvist, et al., 2017; Blackburn, 2018).

Routes of Administration

Oral is the preferred route of analgesic administration and should be used whenever feasible (Chou et al., 2016). Medications administered via the oral route are generally best tolerated, easiest to administer, and most cost-effective. When the oral route is not possible, such as when patients cannot swallow, are NPO (nothing by mouth), or nauseated, other routes of administration are used. For example, patients with cancer pain who are unable to swallow may take analgesic agents by the transdermal, rectal, or subcutaneous route of administration (Burchum & Rosenthal, 2019).

In the immediate postoperative period, the IV route is most often the first-line route of administration for analgesic delivery, and patients are transitioned to the oral route as tolerated (see Chapter 16 for the management of postoperative pain).

The rectal route of analgesic administration is an alternative route when oral or IV analgesic agents are not an option (e.g., for palliative purposes during end-of-life care). The rectum allows passive diffusion of medications and absorption into the systemic circulation. This route can be less expensive and does not involve the skill and expertise required of the parenteral route of administration. Limitations are that medication absorption can be unreliable and depends on many factors including rectal tissue health and administrator technique. Some patients may be resistant to or fearful of rectal administration. The rectal route is contraindicated in patients who are neutropenic or thrombocytopenic because of potential rectal bleeding. Diarrhea, perianal abscess or fistula, and abdominoperineal resection are also relative contraindications (Burchum & Rosenthal, 2019).

The topical route of administration is used for both acute and chronic pain. For example, the nonopioid diclofenac is available in patch and gel formulations for application directly over painful areas. Local anesthetic creams, such as eutectic mixture or emulsion of local anesthetics and lidocaine cream 4%, can be applied directly over the injection site prior to painful needle stick procedures; the lidocaine patch 5% is often used for well-localized types of neuropathic pain, such as postherpetic neuralgia. It is important to distinguish between topical and transdermal medication delivery. Although both routes require the medication to cross the stratum corneum to produce analgesia, transdermal delivery requires absorption into the systemic

circulation to achieve effects, whereas topical agents produce effects in the tissues immediately under the site of application (referred to as targeted peripheral analgesia). Compounding pharmacies may be consulted to custom blend antispasmodic agents, such as topical morphine or gabapentin, for topical application at the painful site.

A more invasive method used to manage pain is accomplished using **neuraxial** analgesia, which involves administering medication in the epidural or subarachnoid space (American Society of Regional Anesthesia and Pain Medicine, 2016). Delivery of analgesic agents by the neuraxial route is accomplished by inserting a needle into the subarachnoid space (for intrathecal [spinal] analgesia) or the epidural space, and either injecting the analgesic medication directly, or threading a catheter through the needle to enable bolus dosing or continuous administration (Conlin, Grant, & Wu, 2018; Hernandez, Grant, & Wu, 2018). Intrathecal catheters for acute pain management are used most often for providing anesthesia or a single bolus dose of an analgesic agent. Implanted intrathecal pumps deliver very small amounts of medication in a constant infusion for treatment of end-of-life pain or persistent pain (Jamison, Cohen, & Rosenow, 2018). Temporary epidural catheters for acute pain management are removed after 2 to 4 days. Epidural analgesia is administered by clinician-given bolus, continuous infusion (basal rate), and patient-controlled epidural analgesia (PCEA). The most common opioids given intraspinally are morphine, fentanyl, and hydromorphone. These are often combined with a local anesthetic, most often ropivacaine or bupivacaine (Jamison et al., 2018). The multimodal use of local anesthetics with opioids improves analgesia and produces an **opioid dose–sparing effect.**

A pain management technique that involves the use of an indwelling catheter is the continuous peripheral nerve block (also called *perineural anesthesia*), whereby an initial local anesthetic block is established and followed by the placement of a catheter or catheters through which an infusion of local anesthetic, usually ropivacaine or bupivacaine, is infused continuously to the targeted site of innervation. The effect of local anesthetic is dose dependent: at lower doses, the smaller sensory nerve fibers are affected before the larger motor fibers. Patients thus medicated are able to walk but have well controlled pain (Burchum & Rosenthal, 2019; Ilfeld & Mariano, 2018).

Dosing Regimen

Achieving, then maintaining, optimal pain management that is safe, effective, and progresses toward realistic functional goals requires patient education with continuing reassessment of analgesic effect and development of any untoward effects (Chou et al., 2016). Accomplishing these goals may require the mainstay analgesic agent to be given on a scheduled around-the-clock (ATC) basis, rather than PRN (as needed) to maintain stable analgesic blood levels when pain is continuous (Eksterowicz & DiMaggio, 2018). ATC dosing

regimens are designed to control pain for patients who report pain being present 12 hours or more during a 24-hour period. PRN dosing of analgesic agents is appropriate for intermittent pain, such as prior to painful procedures and for BTP (pain that "breaks through" the pain being managed by the mainstay analgesic agent), for which supplemental doses of analgesia are provided (Palat, 2018).

Patient-Controlled Analgesia

Patient-controlled analgesia (PCA) is an interactive method of pain management that allows patients to treat their pain by self-administering doses of analgesic agents (Burchum & Rosenthal, 2019). It is used to manage all types of pain by multiple routes of administration, including oral, IV, subcutaneous, epidural, and perineural (Fernandes, Hernandes, de Almeida, et al., 2017). Current guidelines from the APS, the American Society of Regional Anesthesia and Pain Medicine, and the American Society of Anesthesiologists strongly recommended IV PCA for postoperative pain management when it is necessary to use the parenteral route to deliver analgesic medications (Chou et al., 2016). A PCA infusion device is programmed so that the patient can press a button (pendant) to self-administer a dose of an analgesic agent (PCA dose) at a set time interval (demand or lockout) as needed. Patients who use PCAs must be able to understand the relationships among pain, pushing the PCA button or taking the analgesic agent, and pain relief, and must be cognitively and physically able to use any equipment that is necessary to administer the therapy (ECRI Institute Patient Safety Organization, 2017).

A basal rate (continuous infusion) may be used for patients who are opioid tolerant, and when PCEA is used. It is discouraged for patients who are opioid naïve and receiving IV PCA due to the risk of oversedation with subsequent respiratory depression (Chou et al., 2016; ECRI Institute Patient Safety Organization, 2017). Essential to the safe use of a basal rate with PCA is close monitoring by nurses of sedation and respiratory status and prompt decreases in opioid dose (e.g., discontinue basal rate) if increased sedation is detected (Pasero, Quinn, Portenoy, et al., 2011).

The primary benefit of PCA is that it recognizes that only the patient can feel the pain and only the patient knows how much analgesic will relieve it. This reinforces that PCA is for patient use only and that unauthorized activation of the PCA device by anyone other than the patient (PCA by proxy) should be discouraged (Burchum & Rosenthal, 2019).

Quality and Safety Nursing Alert

Staff, family, and other visitors should be instructed to contact the nurse if they have concerns about pain control rather than activating the PCA device for the patient.

However, for some patients who are candidates for PCA but unable to use the PCA equipment, the nurse or a capable family member may be authorized to manage the patient's pain using PCA equipment. This is referred to as Authorized Agent Controlled Analgesia; guidelines are available for the safe administration of this therapy (Cooney, Czarnecki, Dunwoody, et al., 2013).

Analgesic Medications

Analgesic medications are categorized into three main groups: (1) nonopioid antispasmodic agents, which include acetaminophen and NSAIDs; (2) opioid antispasmodic agents, which include, among others, morphine, hydromorphone, fentanyl, and oxycodone; and (3) co-analgesic agents (also referred to as **adjuvant analgesic agents).** The co-analgesic agents comprise the largest group and include various agents with unique and widely differing mechanisms of action. Examples are local anesthetics, some anticonvulsants, and some antidepressants (APS, 2016).

Nonopioid Analgesic Agents

Acetaminophen and NSAIDs comprise the group of nonopioid analgesic agents (refer to earlier discussion of the two categories of NSAIDs; see Fig. 9-2).

Indications and Administration

Nonopioid medications are analgesic agents used for a wide variety of painful conditions. They are appropriate alone for mild to some moderate nociceptive pain (e.g., from surgery, trauma, or osteoarthritis) and are added to opioids, local anesthetics, and/or anticonvulsants as part of a multimodal analgesic regimen for more severe nociceptive pain (APS, 2016; Chou et al., 2016; Comerford & Durkin, 2020). Since acetaminophen and NSAIDs have different mechanisms of action, they may be administered concomitantly (Chou et al., 2016). Although there is no research supporting staggering the two medications, it may be helpful for some patients. Unless contraindicated, surgical patients should routinely be given acetaminophen and an NSAID in scheduled doses throughout the postoperative course, which can be initiated preoperatively (Chou et al., 2016).

Nonopioids are often combined in a single tablet with opioids, such as oxycodone or hydrocodone, and are very popular for the treatment of mild to moderate acute pain. They are traditionally a common choice after invasive pain management therapies are discontinued and for pain treatment after

hospital discharge and dental surgery when an opioid is prescribed. Many people with persistent pain also take a combination nonopioid–opioid analgesic agent; however, it is important to remember that these combination medications are not appropriate for severe pain of any type because the maximum daily dose of the nonopioid limits the escalation of the opioid dose (Burchum & Rosenthal, 2019; Comerford & Durkin, 2020).

Acetaminophen is versatile in that it can be given by multiple routes of administration, including oral, rectal, and IV. Oral acetaminophen has a long history of safety in recommended doses in all age groups. It is a useful addition to multimodal treatment plans for postoperative pain (Wick, Grant, & Wu, 2017). Findings from one research study suggest that patients who receive scheduled acetaminophen with PRN opioids will use less opioids than if they receive PRN acetaminophen plus opioids (Valentine, Carvalho, Lazo, et al., 2015). These results were supported in a more recent study evaluating opioid use among women who underwent Cesarean deliveries (Holland, Bateman, Cole, et al., 2019).

IV acetaminophen is approved for the treatment of pain and fever and is given by a 15-minute infusion in single or repeated doses. It may be given alone for mild to moderate pain or in combination with opioid analgesic agents for more severe pain. The results of several research studies have been inconsistent regarding the opioid sparing effects of IV acetaminophen (Nelson & Wu, 2018). Recommended dosing is 1000 mg every 6 hours for a maximum of 4000 mg in adult patients (Comerford & Durkin, 2020).

A benefit of the NSAID group is the availability of a wide variety of agents for administration via noninvasive routes. Ibuprofen, naproxen, and celecoxib are the most widely used oral NSAIDs in the United States. When rectal formulations are unavailable, an intact oral tablet or a crushed tablet in a gelatin capsule may be inserted into the rectum. The rectal route may require higher doses than the oral route to achieve similar analgesic effects (Pasero et al., 2011). Diclofenac can be prescribed in patch and gel form for topical administration, and an intranasal patient-controlled formulation of ketorolac has been approved for the treatment of postoperative pain.

IV formulations of ketorolac and ibuprofen are available for acute pain treatment. Both have been shown to produce excellent analgesia alone for moderate nociceptive pain, and significant opioid dose–sparing effects when given as part of a multimodal analgesia plan for more severe nociceptive pain (Comerford & Durkin, 2020; Williams, 2018).

Adverse Effects of Nonopioid Analgesic Agents

Acetaminophen is widely considered one of the safest, best tolerated, and most cost effective of the analgesic agents (APS, 2016; Williams, 2018). Its most serious complication is hepatotoxicity (liver damage) as a result of overdose. In the healthy adult, a maximum daily dose below 4000 mg is rarely associated

with liver toxicity. Nevertheless, one manufacturer of oral acetaminophen voluntarily changed its dosing recommendations in 2011, calling for a maximum daily dose of 3000 mg (Shiffman, Battista, Kelly, et al., 2018). In 2014, the U.S. Food and Drug Administration (FDA) recommended that health care professionals stop prescribing and pharmacists stop dispensing prescription combination medication products that contain more than 325 mg of acetaminophen per tablet, capsule, or other dosage unit in order to reduce the risk of hepatotoxicity (FDA, 2014). Acetaminophen does not increase bleeding time and has a low incidence of gastrointestinal (GI) adverse effects, making it the analgesic agent of choice in many individuals with comorbidities. There are two potential interactions with acetaminophen that warrant caution. Acetaminophen should be avoided when consuming alcohol because the combination can result in serious liver damage; acetaminophen also should be avoided when warfarin is prescribed because it can inhibit metabolism of warfarin resulting in toxicity with bleeding risk (Burchum & Rosenthal, 2019).

NSAIDs have considerably more adverse effects than acetaminophen, with gastric toxicity and ulceration being the most common (Comerford & Durkin, 2020). The primary underlying mechanism of NSAID-induced gastric ulceration is the inhibition of COX-1, which leads to a reduction in GI-protective prostaglandins (see Fig. 9-2). This is a systemic (rather than local) effect and can occur regardless of the route of administration of the NSAID. Risk factors include advanced age (older than 60 years), presence of prior ulcer disease, and cardiovascular (CV) disease and other comorbidities (Williams, 2018). In patients with elevated risks, the use of a COX-2 selective NSAID (e.g., celecoxib) or the least ulcerogenic nonselective NSAID (e.g., ibuprofen) plus a proton pump inhibitor is recommended; however, there are risks with proton pump inhibitors as well (Gwee, Goh, Lima, et al., 2018). Proton pump inhibitors may decrease the absorption of some other medications such as itraconazole and rilpivirine (Burchum & Rosenthal, 2019). As with all medications, it is important to frequently reassess the need for continued use and to discontinue when appropriate. GI adverse effects are also related to the dose and duration of NSAID therapy; the higher the NSAID dose and the longer the duration of NSAID use, the higher the risk of GI toxicity (Williams, 2018). A principle of nonopioid analgesic use is to administer the lowest dose for the shortest time necessary (Pasero, Portenoy, & McCaffery, 2011).

All NSAIDs carry a risk of CV adverse effects through prostaglandin inhibition, and the risk is increased with COX-2 inhibition, whether it is produced by a COX-2 selective NSAID (e.g., celecoxib) or by NSAIDs that are nonselective inhibitors of both COX-1 and COX-2 (e.g., ibuprofen, naproxen, and ketorolac). Findings from a recent meta-analysis suggest that the risk of acute myocardial infarction is greatest during the first month of treatment with NSAIDs, with this risk developing during the first week of

treatment (Bally, Dendukuri, Rich, et al., 2017). All patients prescribed NSAIDs should receive the lowest effective dose for the shortest time period to decrease risks.

NSAIDs can negatively impact renal function, and are associated with diminished renal prostaglandin formation, interstitial nephritis, reduced secretion of renin, and greater reabsorption of water and sodium (APS, 2016). NSAID-induced renal toxicity can occur, but is relatively rare in otherwise healthy adults who are given NSAIDs for short-term pain management (e.g., in the perioperative period); however, individuals with acute or chronic volume depletion or hypotension rely on prostaglandin synthesis to maintain adequate renal blood flow, and NSAID inhibition of prostaglandin synthesis in such patients can cause acute kidney injury (Burchum & Rosenthal, 2019). Attention to adequate hydration is essential when administering NSAIDs to prevent this complication (Pasero et al., 2011).

Most nonselective NSAIDs increase bleeding time through inhibition of COX-1. This is both medication and dose related, so the lowest dose of nonopioids with minimal or no effect on bleeding time should be used in patients having procedures with high risk for bleeding. Options include acetaminophen, celecoxib, choline magnesium trisalicylate, salsalate, and nabumetone (APS, 2016; Burchum & Rosenthal, 2019).

Opioid Analgesic Agents

Although it is often used, the term *narcotic* is inaccurate and considered obsolete when discussing the use of **opioids** for pain management, in part because it is a term used loosely by law enforcement and the media to refer to various substances of potential abuse, which include opioids as well as cocaine and other illicit substances. Legally, controlled substances classified as narcotics include opioids, cocaine, and others. The accurate term, when discussing these agents in the context of pain management, is *opioid analgesics* (Burchum & Rosenthal, 2019).

Opioid analgesic agents are divided into two major groups: (1) **mu agonist** opioids (also called *morphinelike medications*) and (2) **agonist–antagonist** opioids. The mu agonist opioids comprise the larger of the two groups and include morphine, hydromorphone, hydrocodone, fentanyl, oxycodone, and methadone, among others. The agonist–antagonist opioids include buprenorphine, nalbuphine, and butorphanol (APS, 2016).

Opioid analgesic agents exert their effects by interacting with opioid receptor sites located throughout the body, including in the peripheral tissues, GI system, and CNS; they are abundant in the dorsal horn of the spinal cord. There are three major classes of opioid receptor sites involved in analgesia: the mu, delta, and kappa. The pharmacologic differences in the various opioids are the result of their interaction with these opioid receptor types (Burchum & Rosenthal, 2019; Sheth, Holtsman, & Mahajan, 2018). When an opioid binds

to the opioid receptor sites, it produces analgesia as well as unwanted effects, such as constipation, nausea, sedation, and respiratory depression (Arthur & Hui, 2018).

The opioid analgesic agents that are designated as first line (e.g., morphine, hydromorphone, fentanyl, and oxycodone) belong to the mu opioid agonist class because they bind primarily to the mu-type opioid receptors. The agonist–antagonist opioids are designated as "mixed" because they bind to more than one opioid receptor site. They bind as **agonists**, producing analgesia, at the kappa opioid receptor sites, and as weak antagonists at the mu opioid receptor sites. Their propensity to antagonize the effects of mu opioid analgesic agents limits their usefulness in pain management (Burchum & Rosenthal, 2019). They should be avoided in patients receiving long-term mu opioid therapy because their use may trigger severe pain and opioid **withdrawal** syndrome characterized by rhinitis, abdominal cramping, nausea, agitation, and restlessness.

Antagonists (e.g., naloxone, naltrexone, naloxegol) are medications that also bind to opioid receptors but produce no analgesia. If an antagonist is present, it competes with opioid molecules for binding sites on the opioid receptors and has the potential to block analgesia and other effects. Antagonists are used most often to reverse adverse effects, such as respiratory depression (Burchum & Rosenthal, 2019). Antagonists have been incorporated in the manufacture of some opioids in an effort to deter abuse of the opioid (Li, 2019)

Administration

Safe and effective use of opioid analgesic agents requires the development of an individualized treatment plan based on a comprehensive pain assessment, which includes clarifying the goals of treatment and discussing options with the patient and the family when appropriate (Chou et al., 2016; Sheth et al., 2018). Goals are periodically reevaluated, and changes made depending on patient response and in some cases disease progression.

Many factors are considered when determining the appropriate opioid analgesic agent for the patient with pain. These include the unique characteristics of the various opioids and patient factors, such as pain intensity, age, coexisting disease, current medication regimen and potential medication interactions, prior treatment outcomes, and patient preference (APS, 2016; Sheth et al., 2018). In all cases, a multimodal approach that may rely on the selection of appropriate analgesic agents from the nonopioid, opioid, and co-analgesic agent groups is recommended to manage all types of pain (APS, 2016; Li, 2019). Chart 9-5 lists the key considerations when developing an opioid pain treatment plan.

Titration of the opioid dose is usually required at the start and throughout the course of treatment when opioids are given. Whereas patients with cancer

pain most often are titrated upward over time for progressive pain, patients with acute pain, particularly postoperative pain, are eventually titrated downward and discontinued as pain resolves (Chou et al., 2016; FDA, 2017; Sheth et al., 2018). The dose and analgesic effect of mu agonist opioids have no **ceiling effect,** although the dose may be limited by adverse effects. The absolute dose given is based on a balance between pain relief and tolerability of adverse effects. The goal of titration is to use the smallest dose that provides satisfactory pain relief with the fewest adverse effects (Sheth et al., 2018). The time at which the dose can be increased is determined by the onset and peak effects of the opioid and its formulation.

Chart 9-5

Use of Opioids

- Perform a comprehensive assessment that addresses pain, comorbidities, and functional status.
- Develop an individualized treatment plan that includes specific goals related to pain intensity, activities (function/quality of life), and adverse effects (e.g., pain intensity rating of 3 on a 0–10 numerical rating scale to ambulate accompanied by minimal or no sedation).
- Use multimodal analgesia (e.g., add acetaminophen and NSAID; anticonvulsant in patients at risk for persistent postsurgical pain).
- Assess for presence preoperatively of underlying persistent pain in surgical patients and optimize its treatment.
- Consider **preemptive analgesic agents** before surgery, particularly for those at risk for severe postoperative pain or a persistent postsurgical pain syndrome.
- Provide analgesic agents prior to all painful procedures.
- Medication selection
  - Consider diagnosis, condition, or surgical procedure, current or expected pain intensity, age, presence of major organ dysfunction or failure, and presence of coexisting disease.
  - Consider pharmacologic issues (e.g., accumulation of metabolites and effects of concurrent medications).
  - Consider prior treatment outcomes and patient preference.
  - Be aware of available routes of administration (oral, transdermal, rectal, intranasal, IV subcutaneous, perineural, intraspinal) and formulations (e.g., short acting, modified release).
  - Be aware of cost differences.
- Route of administration selection
  - Use least invasive route possible.
  - Consider convenience and patient's ability to adhere to the regimen.
  - Consider staff's (or patient's or caregiver's) ability to monitor and provide care required.
- Dosing and titration
  - Consider previous dosing requirement and relative analgesic potencies when initiating therapy.
  - Use equianalgesic dose chart (Table 9-3) to determine starting dose with consideration of patient's current status (e.g., sedation and respiratory status) and comorbidities (e.g., medical frailty), and then titrate until adequate analgesia is achieved or dose-limiting adverse effects are encountered.
  - Use appropriate dosing schedule (e.g., around-the-clock for continuous pain; PRN for intermittent pain).
  - When dose is safe but additional analgesia is desired, titrate upward as prescribed by 25% for slight increase, 50% for moderate

increase, and 100% for considerable increase in analgesia.
    - Provide supplemental doses for breakthrough pain; consider PCA if appropriate.
- Treatment of adverse effects
    - Be aware of the prevalence and impact of opioid adverse effects.
    - Remember that most opioid adverse effects are dose dependent; always consider decreasing the opioid dose as a method of treating or eliminating an adverse effect; adding nonopioid analgesic agents for additive analgesia facilitates this approach.
    - Use a preventive approach in the management of constipation, including for patients receiving short-term opioid treatment.
    - Prevent respiratory depression by monitoring sedation levels and respiratory status frequently and decreasing the opioid dose as soon as increased sedation is detected.
- Monitoring
    - Continually and consistently evaluate the plan on the basis of the specific goals identified at the outset and assess pain intensity, adverse effects, and activity levels.
    - Make necessary modifications to treatment plan to maintain efficacy and safety.
- Tapering and cessation of treatment
    - If a decrease in dose or cessation of treatment is appropriate, do so in accordance with decreased pain intensity and after evaluation of functional outcomes.
    - Be aware of the potential for withdrawal syndrome (rhinitis, abdominal cramping, diarrhea, restlessness, agitation) and need for tapering schedule in patients who have been receiving opioid therapy for more than a few days.

IV, intravenous; NSAID, nonsteroidal anti-inflammatory drug; PCA, patient-controlled analgesia; PRN, as needed.

Equianalgesia. The term *equianalgesia* means approximately "equal analgesia." An equianalgesic chart provides a list of doses of analgesic agents, both oral and parenteral (IV, subcutaneous, and intramuscular), that are approximately equal to each other in ability to provide pain relief. Equianalgesic conversion of doses is developed from the ratio representing the difference in the potency of the two medications (Treillet, Laurent, & Hadjiat, 2018). The information is used to help ensure that patients are not overdosed or underdosed when they are switched from one opioid or route of administration to another. It requires a series of calculations based on the daily dose of the current opioid to determine the equianalgesic dose of the opioid to

which the patient is to be switched. Several excellent guidelines are available to assist in calculating equianalgesic doses (Burchum & Rosenthal, 2019) (see Table 9-3). Equianalgesic tools available in electronic health records enable all clinicians at any facility to easily convert analgesic dosages (APS, 2016).

TABLE 9-3 Equianalgesic Dose Chart for Common mu Opioid Analgesic Agents

- *Equianalgesic* means approximately the same pain relief.
- The equianalgesic chart is a guideline for selecting doses for patients who are opioid-naïve. Doses and intervals between doses are titrated according to individuals' responses.
- The equianalgesic chart is helpful when switching from one medication or route of administration to another.

Opioid	Oral	Parenteral	Comments
Morphine	30 mg	10 mg	Standard for comparison; first-line opioid via multiple routes of administration; once- and twice-daily oral formulations; clinically significant metabolites
Fentanyl	No formulation	100 mcg IV 100 mcg/h of transdermal fentanyl is approximately equal to 4 mg/h of IV morphine; 1 mcg/h of transdermal fentanyl is approximately equal to 2 mg/24 h of oral morphine	First-line opioid via IV, transdermal, and intraspinal routes; available in oral transmucosal and buccal formulations for breakthrough pain in patients who are opioid-tolerant; no clinically relevant metabolites
Hydrocodone	30 mg (not recommended)	No formulation	Available only in combination with acetaminophen and as such is appropriate only for mild to some moderate pain
Hydromorphone	7.5 mg	1.5 mg	First-line opioid via multiple routes of administration; once-daily oral formulation; clinically significant metabolites noted with long-term and high-dose infusion
Oxycodone	20 mg	No formulation in the United States	Short-acting and twice-daily oral formulations
Oxymorphone	10 mg	1 mg	Parenteral and short-acting and twice-daily oral formulations

IV, intravenous.

Formulation terminology. The terms *short acting, immediate release,* and *normal release* have been used interchangeably to describe oral opioids that have an onset of action of approximately 30 minutes and a relatively short duration of 3 to 4 hours. The term *immediate release* is misleading because none of the oral analgesic agents have an immediate onset of analgesia; *short acting* is preferred. The terms *modified release, extended release, sustained release, controlled release,* and *long acting* are used to describe opioids that are formulated to release over a prolonged period of time. For the purposes of this chapter, the term *modified release* will be used when discussing these opioid formulations.

Substance Use Disorder, Physical Dependence, and Tolerance

In 2013 the American Psychological Association (APA) renamed *addiction* as *substance use disorder* (SUD) (Lo Coco, Melchiori, Oiendi, et al., 2019). SUD includes a number of subcategories, including *opioid use disorder.* The terms *physical dependence* and *tolerance* often are confused with *substance use disorder*, previously understood as *addiction*; thus, clarification of definitions is important (Burchum & Rosenthal, 2019).

- **Physical dependence** is a normal response that occurs with repeated administration of the opioid, with intensity and duration dependent upon the half-life of the medication and how long it has been used. It is manifested by the occurrence of withdrawal symptoms when the opioid is suddenly stopped or rapidly reduced, or an antagonist such as naloxone is given. Withdrawal symptoms may be suppressed by the natural, gradual reduction of the opioid as pain decreases or by gradual, systematic reduction, referred to as tapering (Burchum & Rosenthal, 2019). Withdrawal occurs with prolonged use of opioids, regardless of whether the use of opioids is prescribed for pain management or because of SUD (Sheth et al., 2018).
- **Tolerance** is also a normal physiologic response that can occur with regular administration of an opioid and consists of a decrease in one or more effects of the opioid (e.g., decreased analgesia, sedation, or respiratory depression). Although it may occur in conjunction with SUD, it cannot be equated with SUD. It may be treated with increases in dose to attain the previous effect. With the exception of constipation, tolerance to the opioid adverse effects develops with regular daily dosing of opioids over several days (Burchum & Rosenthal, 2019; Sheth et al., 2018).

- **Substance Use Disorder (SUD)** was historically known as addiction or addictive disease, and defined as a chronic, relapsing, treatable neurologic disease. The APA has since described SUD as the impaired use of a substance, such as opioids, even while experiencing major problems, characterized by impaired control over use, compulsive use, continued use despite harm, and craving for the substance. With SUD, use of the opioid is for nontherapeutic reasons and is thus independent of pain relief. The development and characteristics of SUD are influenced by genetic, psychosocial, and environmental factors (Auriacombe, Serre, Denis, et al., 2019; Lo Coco et al., 2019; Sheth et al., 2018).
- **Withdrawal** occurs when a medication or substance to which the body has become dependent is abruptly reduced or discontinued. This is true of prescribed medications as well as illicitly obtained substances. Withdrawal is exhibited by a cascade of unpleasant symptoms including anxiety, nausea, vomiting, rhinitis, sneezing, chills, hot flashes, abdominal cramping, tremors, diaphoresis, hyperreflexia, diarrhea, piloerection, and/or insomnia (APS, 2016; Burchum & Rosenthal, 2019; Sheth et al., 2018).
- *Pseudoaddiction* is a mistaken diagnosis of substance use disorder that occurs when a patient's pain is not well controlled; the patient may begin to manifest symptoms suggestive of SUD. In an effort to obtain adequate pain relief, the patient may respond with demanding behavior, escalating demands for more or different medications, and repeated requests for opioids on time or before the prescribed interval between doses has elapsed. Pain relief typically eliminates these behaviors and is often accomplished by increasing opioid doses or decreasing intervals between doses (Sheth et al., 2018; Weissman & Haddox, 1989).

Pain management specialists have increasingly come to realize that the progression from prescribed opioid use to the disease of opioid SUD is poorly understood and complex. The National Institute on Drug Abuse (2014) estimated that the rates of SUD among patients with chronic pain vary widely, from 3% to 40%. A government effort to address the issue of SUD is the *Comprehensive Addiction and Recovery Act of 2016* which provides prevention, treatment, and rehabilitative support (Burchum & Rosenthal, 2019). There is real concern for adequately treating the 2 million Americans who are living with opioid SUD and the 50 million people who are living with chronic pain (National Institutes of Health [NIH], 2019). The patients in both groups need and deserve to receive informed, evidence-based, compassionate nursing care.

Opioid naïve versus opioid tolerant. Patients are often characterized as being either *opioid naïve* or *opioid tolerant.* Whereas an **opioid naïve** person

has not recently taken enough opioid on a regular basis to become tolerant to the effects of an opioid, an **opioid tolerant** person has taken an opioid long enough at doses high enough to develop tolerance to many of the effects, including analgesia and sedation. There is no set time for the development of tolerance, and there is great individual variation, with some not developing tolerance at all. By convention, most clinicians consider a patient who has taken opioids regularly for approximately 7 or more days to be opioid tolerant (Pasero et al., 2011).

Opioid-Induced Hyperalgesia

Opioid-induced hyperalgesia (OIH) is a paradoxical situation in which increasing doses of an opioid result in increasing sensitivity to pain. The incidence of clinically significant OIH has not been determined; however, it is a serious consequence of opioid administration. At this time, it is not possible to predict who will develop OIH as a result of opioid exposure, and the mechanisms underlying OIH are largely unknown. In general, OIH is thought to be the result of changes in the central and peripheral nervous systems that produce increased transmission of nociceptive signals (APS, 2016; Higgins, Smith, & Matthews, 2018; Ringkamp et al., 2018; Spofford & Hurley, 2018).

Some experts characterize OIH and analgesic tolerance as "opposite sides of the coin" (Pasero et al., 2011). In tolerance, increasing doses of opioid are needed to provide the same level of pain relief because opioid exposure induces neurophysiologic changes that reverse analgesia; in OIH, opioid exposure induces neurophysiologic changes that produce pain or increase sensitivity to noxious input (APS, 2016). In other words, tolerance may be inferred clinically when opioid treatment leads to decreased sensitivity to opioid analgesia over time (in the absence of another process that would explain this), whereas OIH may be inferred clinically when opioid treatment leads to increased pain or sensitivity to pain. Patients with OIH may report an increase in pain that increases with increased dosing of opioids (APS, 2016). Recent research findings have reported the onset of postoperative OIH following intraoperative administration of opioids (Spofford & Hurley, 2018). OIH is an area in which additional research is much needed.

Select Opioid Analgesic Agents

Morphine is the standard against which all other opioid medications are compared. It is used worldwide, particularly for cancer pain, and its use is established by extensive research and clinical experience. It is available in a wide variety of short-acting and modified-release oral formulations and is given by multiple routes of administration. It was the first medication to be given intraspinally and remains a first-line choice for long-term **intraspinal** analgesia. It is the only opioid uniquely formulated to produce analgesia for up to 48 hours following epidural administration for acute pain management (extended-release epidural morphine). Morphine is a **hydrophilic** medication

(readily absorbed in aqueous solution), which accounts for its slow onset and long duration of action when compared with other opioid analgesic agents (Tables 9-3 and 9-4). It has two principal, clinically significant **metabolites:** morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G). M6G may be responsible for some of the analgesic effect of morphine; accumulation of M3G can produce neurotoxicity, which necessitates switching the patient to a different opioid (Burchum & Rosenthal, 2019; Conlin et al., 2018; Howard & Brant, 2019; Sheth et al., 2018).

TABLE 9-4 Characteristics of Select First-Line Opioid Analgesic Agents[a]

Opioid	Onset (Minutes)	Peak (Minutes)	Duration (Hours)
Morphine	30 (PO) 5 (IV)	60–120 (PO) 20 (IV)	4–12 (PO) 4–5 (IV)
Fentanyl	5–15 (OT) 1–2 (IV)	20–30 (OT) 3–5 (IV)	2–5 (OT) 1/2–1 (IV)
Hydromorphone	15–30 (PO) 10–15 (IV)	30–60 (PO) 15–30 (IV)	4–5 (PO) 2–3 (IV)

[a]Characteristics do not apply to modified-release formulations.

IV, intravenous; OT, oral transmucosal; PO, oral.

Adapted from Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer; Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacologic management*. St. Louis, MO: Mosby-Elsevier.

Fentanyl, in contrast to morphine, is a **lipophilic** (readily absorbed in fatty tissues) opioid and as such has a fast onset and short duration of action (see Tables 9-3 and 9-4). These characteristics make it the most commonly used IV opioid when rapid analgesia is desired, such as for the treatment of severe, escalating acute pain, and for procedural pain when a short duration of action is desirable. This medication is a good choice for patients with end-organ failure because it has no clinically relevant metabolites. It also produces minimal hemodynamic adverse effects; thus, fentanyl is often preferred in patients who are hemodynamically unstable, such as the critically ill (Chou et al., 2016; Conlin et al., 2018; Howard & Brant, 2019).

Its lipophilicity makes fentanyl ideal for medication delivery by transdermal patch for long-term opioid administration and by the oral transmucosal and buccal routes for BTP treatment in patients who are opioid tolerant. Following application of the transdermal patch, a subcutaneous depot of fentanyl is established in the skin near the patch. After absorption from the depot into the systemic circulation, the medication distributes to fat and muscle. When the first patch is applied, 12 to 18 hours are required for clinically significant analgesia to be obtained; attention must be paid to providing adequate supplemental analgesia during that time. Conversely, when the patch is removed, the serum levels of fentanyl remain for a minimum of 16 hours, so it

is important to not administer additional long-acting opioids during that time. Another important caution is that heat (e.g., heating pads, hot water blankets, hot tubs, fever) may increase the rate of absorption leading to serious adverse events. The patch is changed every 48 to 72 hours depending on patient response. It is important to note that the patch is not appropriate for treating acute pain or rapidly changing pain (Burchum & Rosenthal, 2019; Howard & Brant, 2019; Sheth et al., 2018).

Hydromorphone is less hydrophilic than morphine but less lipophilic than fentanyl, which contributes to an onset and duration of action that is intermediate between morphine and fentanyl (see Tables 9-3 and 9-4). This medication is often used as an alternative to morphine, especially for acute pain because the two medications produce similar analgesia and have comparable adverse effect profiles. It is a first- or second-choice opioid (after morphine) for postoperative pain management via IV PCA and is available in a once-daily modified-release oral formulation for chronic pain management. Accumulation of its neuroexcitatory metabolite hydromorphone-3-glucuronide (H3G) may occur with high-dose, long-term infusion therapy, which would necessitate a switch to another opioid (Burchum & Rosenthal, 2019; Sheth et al., 2018).

Oxycodone is available in the United States for administration by the oral route only and is used to treat all types of pain. Single-entity short-acting and modified-release oxycodone formulations are used most often for moderate to severe cancer pain and in some patients with moderate to severe noncancer pain (see Table 9-3). When it is combined with acetaminophen, the dose of oxycodone is limited by the acetaminophen dose to avoid exceeding the maximum daily dose of that agent. Oxycodone has been used successfully as part of a multimodal treatment plan for postoperative pain as well (Burchum & Rosenthal, 2019; Sheth et al., 2018).

Oxymorphone has been available for many years in parenteral formulation and more recently in short-acting and modified-release oral tablets for the treatment of moderate to severe chronic pain (see Table 9-3). It must be taken on an empty stomach (1 hour before or 2 hours after a meal), and coingestion of alcohol at the time of dosing must be avoided because food and alcohol can increase the serum concentration of the medication up to 300% (Burchum & Rosenthal, 2019; Comerford & Durkin, 2020; Sheth et al., 2018).

Hydrocodone is commercially available only in combination with nonopioids (e.g., with acetaminophen or ibuprofen), which limits its use to the treatment of mild to some moderate pain (see Table 9-3). It is one of the more commonly prescribed analgesic agents in the United States; however, its prescription for the treatment of persistent pain (except for breakthrough dosing) should be carefully evaluated because of its ceiling on **efficacy** and safety concerns inherent in the nonopioid constituent. In the rare situation when a patient can only tolerate hydrocodone and needs a dose higher than is

possible with the acetaminophen or ibuprofen combination, hydrocodone alone can be obtained from a compounding pharmacy with a prescription. In 2014, the U.S. Drug Enforcement Agency changed hydrocodone from a schedule III to the more restrictive schedule II classification to reduce abuse of this pain medication (Federal Register, 2014). It is now also available as two extended-release products (Burchum & Rosenthal, 2019; Comerford & Durkin, 2020).

Methadone is a unique synthetic opioid analgesic medication that may have advantages over other opioids in carefully selected patients. In addition to being a mu opioid, it is an antagonist at the NMDA receptor site and thus has the potential to produce analgesic effects as a second- or third-line option for some neuropathic pain states. It may be used as an alternative when it is necessary to switch a patient to a new opioid because of inadequate analgesia or unacceptable adverse effects. The use of conventional equianalgesic dose conversion is not recommended when switching patients to and from methadone. Extensive guidelines on how to safely accomplish this are available elsewhere. In 2014, the APS, in conjunction with the Heart Rhythm Society and the College on Problems of Drug Dependence, issued clinical practice guidelines to encourage safe use of methadone (APS, 2016).

Methadone is usually given orally but has also been given by virtually every other route of administration. Although it has no active metabolites, methadone has a very long and highly variable **half-life** (5 to 100-plus hours; average is 20 hours), which makes it a good choice for the treatment of SUD; patients must be watched closely for excessive sedation, a sign of medication accumulation during this time period. (The medication is described as "long acting" because of its exceptionally long half-life.) When methadone is used to treat opioid use disorder, it is dosed once daily and is not intended to manage pain; acute pain management with other analgesic medications is needed in addition to daily methadone dosing. Other limitations are its propensity to interact with a large number of medications and prolong the QTc interval on the electrocardiogram (ECG). Some medications (e.g., clarithromycin and some antifungal medications) that inhibit CYP3A4, the enzyme that metabolizes methadone, should be avoided as they can inadvertently increase methadone levels in the blood. Despite these characteristics, methadone can be an effective and safe medication when prescribed by providers who have an appreciation of the unique characteristics of the medication and who are experienced in prescribing it (APS, 2016; Burchum & Rosenthal, 2019; Comerford & Durkin, 2020; Sheth et al., 2018).

Dual-Mechanism Analgesic Agents

The dual-mechanism analgesic agents tramadol and tapentadol bind weakly to the mu opioid receptor site and block the reuptake (resorption) of the inhibitory neurotransmitters serotonin and norepinephrine at central synapses in the spinal cord and brain stem of the modulatory descending pain pathway

(APS, 2016; Holtsman & Hale, 2018). This makes these neurotransmitters more available to counteract pain. Dual-mechanism analgesic agents have been described as providing automatic "built-in" multimodal analgesia because a single tablet produces an effect on more than one analgesic action site (Varrassi, Hanna, Macheras, et al., 2017). The underlying mechanisms of tapentadol and tramadol differ in that tramadol blocks the reuptake of both serotonin and norepinephrine, but tapentadol blocks the reuptake of only norepinephrine. This is pertinent because norepinephrine may play a more significant role than serotonin in the endogenous analgesia pathways. Serotonin may be the more powerful mediator of depression; low serotonin levels are associated with depression. This helps explain why selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine and paroxetine, which block only serotonin, are effective for the treatment of depression but not pain (APS, 2016; Burchum & Rosenthal, 2019; Comerford & Durkin, 2020; Holtsman & Hale, 2018).

Tramadol is used for both acute and chronic pain and is available in oral short-acting and modified-release formulations, including a short-acting tablet in combination with acetaminophen. It has demonstrated good efficacy for the treatment of neuropathic pain (Comerford & Durkin, 2020). The medication can lower seizure threshold and interact with other medications that block the reuptake of serotonin, such as the SSRIs, putting the patient at risk for serotonin syndrome, characterized by agitation, diarrhea, heart and blood pressure changes, and loss of coordination (Holtsman & Hale, 2018).

Tapentadol is available in short-acting and modified-release oral formulations. This medication has been shown to produce dose-dependent analgesia comparable to oxycodone. Major benefits are that it has no active metabolites and a significantly more favorable adverse effect profile (particularly GI) compared with opioid analgesic agents. These characteristics make tapentadol an attractive alternative to traditional oral opioid analgesic agents for many patients with pain (Comerford & Durkin, 2020; Holtsman & Hale, 2018).

Opioids to Avoid

Codeine is a prodrug, which means it is pharmacologically inactive when given. It must be metabolized to morphine for the patient to experience pain relief. It is estimated that 5% to 10% of patients lack the enzymatic ability to convert codeine to morphine via the CYP2D6 metabolic pathway, meaning that in this population of patients, codeine is an ineffective analgesic agent. In contrast, codeine has been associated with overdoses in some children due to rapid metabolism of the medication to morphine.

Meperidine has either been removed from or severely restricted on hospital formularies for the treatment of pain in an effort to improve patient safety. However, it is an accepted practice to use it in low doses (12.5 to 25 mg IV) to

treat *rigors* (shivering) associated with general anesthesia. A major limitation to the use of meperidine is its active metabolite, normeperidine, which is a CNS stimulant and can cause delirium, irritability, tremors, myoclonus, and generalized seizures. Concern for meperidine's neurotoxicity risks has dramatically reduced its use (APS, 2016; Burchum & Rosenthal, 2019; Comerford & Durkin, 2020; Sheth et al., 2018).

Adverse Effects of Opioid Analgesic Agents

The most common adverse effects of opioids are constipation, nausea, vomiting, pruritus, hypotension, and sedation. Respiratory depression, while less common, is the most serious and feared of the opioid adverse effects (Pasero, 2009). The risk of respiratory depression is increased when other medications that have depressive effects on the CNS, such as benzodiazepines (e.g., diazepam), alcohol, and barbiturates, are used concurrently with opioids. In surgical patients, postoperative ileus can become a major complication as well (Burchum & Rosenthal, 2019; Comerford & Durkin, 2020; Sheth et al., 2018). Morphine lowers blood pressure by dilating peripheral arterioles and veins. In the presence of dehydration or with concomitant use of hypotensive medications, orthostatic hypotension may result (Burchum & Rosenthal, 2019). Long-term use of opioids may result in opioid-induced androgen deficiency and sleep disordered breathing (Chowdhuri & Javaheri, 2017; Hsieh, DiGiorgio, Fakunle, et al., 2018; Nagappa, Weingarten, Montandon, et al., 2017).

Opioids can result in delayed gastric emptying, slowed bowel motility, and decreased peristalsis, all of which result in slow-moving, hard stool that is difficult to pass. Risk is elevated with advanced age, and immobility; however, it is an almost universal opioid adverse effect (i.e., tolerance rarely develops). Constipation is a primary reason people stop taking their pain medication, which underscores the importance of taking a preventive approach and aggressive management if symptoms are detected. Prevention includes reminding patients to take a daily stool softener plus mild peristaltic stimulant for as long as they are taking opioids (APS, 2016; Burchum & Rosenthal, 2019).

Postoperative nausea and vomiting (PONV) occur following opioid administration due to medulla chemoreceptor trigger zone stimulation. PONV are among the most unpleasant of the adverse effects associated with surgery, and can have a negative impact on patient outcomes, and increase the need for nursing intervention. Guidelines from the American Society of PeriAnesthesia Nurses (ASPAN) recommend that all patients be evaluated for PONV risk, risk factors be reduced if possible, multimodal analgesia be provided (so that no opioid or the lowest effective opioid dose can be given), and prophylactic treatment (e.g., dexamethasone and a serotonin receptor antagonist, such as ondansetron, at the end of surgery) be given to patients with moderate risk

(APS, 2016; ASPAN, 2006; Gan, Diemunsch, Habib, et al., 2014). More aggressive interventions should be utilized in patients with high risk (Pasero et al., 2011). (See Chapter 16 for further discussion of PONV.)

Pruritus is an adverse effect of opioids, not an allergic reaction to them. Although antihistamines such as diphenhydramine are commonly used, and patients may report being less bothered by itching after taking an antihistamine, this may be the result of sedating effects. Any additional coadministered sedating medication can be problematic in people already at risk for excessive sedation, such as postoperative patients, because this can lead to life-threatening respiratory depression (APS, 2016). Loratadine and cetirizine are considered nonsedating histamines and might be selected. Often the most effective, safest, and least expensive treatment of pruritus is opioid dose reduction. In fact, simply decreasing the opioid dose is sufficient to eliminate or make most of the adverse effects tolerable for many patients. Opioid rotation is another possible treatment. Nonsedating analgesic agents can be added to facilitate this approach. Parenteral low dose nalbuphine, an agonist–antagonist opioid, has been reported to be superior to placebo, control, antihistamines, and naloxone in the treatment of pruritus caused by neuraxial opioids (APS, 2016).

In addition to dose reduction strategies, most opioid pain treatment plans include prescriptions for medications that can be used to treat adverse effects should they occur. Recent research with animals demonstrated successful prevention of opioid induced pruritis through administration of capsaicin (Melo, Basso, Iftinca, et al., 2018). Nonpharmacologic interventions may also be effective, such as the application of a cool damp cloth over affected areas to help relieve the discomfort of pruritus.

With the exception of constipation, as patients become opioid tolerant, an accompanying tolerance to the opioid adverse effects develops. It is reassuring for patients receiving long-term opioid therapy to know that most of the adverse effects will subside with regular daily doses of opioids over several days.

Sedation and respiratory depression. Most patients experience sedation at the beginning of opioid therapy and whenever the opioid dose is increased significantly. If left untreated, excessive sedation can progress to clinically significant respiratory depression. Like other opioid adverse effects, sedation and respiratory depression are dose related. In most cases (exceptions may apply at the end of life), nurses should promptly reduce opioid doses or stop titration whenever advancing sedation is detected to prevent respiratory depression (Pasero, 2009; Pasero et al., 2011). In some patients (e.g., those with obstructive sleep apnea, pulmonary dysfunction), monitoring with capnography is warranted (Jarzyna, Junquist, Pasero, et al., 2011). When supplemental oxygen is needed to maintain the patient's oxygen saturation, pulse oximetry may not detect hypoventilation. Patients receiving opioid

therapy and supplemental oxygen can benefit from capnography, which reflects the adequacy of ventilation and airflow, in conjunction with monitoring of sedation and respiratory function (Gupta & Edwards, 2018).

Quality and Safety Nursing Alert

Opioid-induced respiratory depression is dose related and preceded by increasing sedation. Prevention of clinically significant opioid-induced respiratory depression begins with the administration of the lowest effective opioid dose, careful titration, close monitoring of sedation and respiratory function and status (i.e., rate, depth, regularity, excursion) throughout therapy, and prompt dose reduction when advancing sedation is detected (Nagappa et al., 2017).

The knowledge that excessive sedation precedes opioid-induced respiratory depression reinforces that systematic sedation assessment is an essential aspect of the care of patients receiving opioid therapy (Gupta & Edwards, 2018; Pasero, 2009). Nursing assessment of sedation is convenient, inexpensive, and takes minimal time to perform. A simple, easy-to-understand sedation scale, developed for the assessment of *unintended* sedation, which includes what should be done at each level of sedation, is recommended to enhance accuracy and consistency of assessment, better monitor trends, and improve communication among members of the health care team (Garcia & McMullan, 2019; Jarzyna et al., 2011; Pasero, 2009; Pasero et al., 2011; Quinlan-Colwell, Thear, Miller-Baldwin, et al., 2017). Chart 9-6 presents a widely used sedation scale.

Chart 9-6

Pasero Opioid-Induced Sedation Scale with Interventions

Each level of sedation is followed by the appropriate action in italics.

S = Sleep, easy to arouse
Acceptable; no action necessary; may increase opioid dose if needed

1 = Awake and alert
Acceptable; no action necessary; may increase opioid dose if needed

2 = Slightly drowsy, easily aroused
Acceptable; no action necessary; may increase opioid dose if needed

3 = Frequently drowsy, arousable, drifts off to sleep during conversation
Unacceptable; monitor respiratory status and sedation level closely until sedation level is stable at less than 3 and respiratory status is satisfactory; decrease opioid dose 25–50%[1] or notify primary[2] or anesthesia provider for orders; consider administering a nonsedating, opioid-sparing nonopioid, such as acetaminophen or an NSAID, if not contraindicated; ask patient to take deep breaths every 15–30 min.

4 = Somnolent, minimal, or no response to verbal and physical stimulation
Unacceptable; stop opioid; consider administering naloxone[3,4]; call Rapid Response Team (Code Blue); stay with patient, stimulate, and support respiration as indicated by patient status; notify primary[2] or anesthesia provider; monitor respiratory status and sedation level closely until sedation level is stable at less than 3 and respiratory status is satisfactory.

[1]Opioid analgesic agent prescriptions or a hospital protocol should include the expectation that a nurse will decrease the opioid dose if a patient is excessively sedated.

[2]For example, the primary provider, nurse practitioner, advanced practice nurse, or physician assistant responsible for the pain management prescription.

[3]For adults experiencing respiratory depression, mix 0.4 mg of naloxone and 10 mL of normal saline in syringe and administer this dilute solution very slowly (0.5 mL over 2 min) while observing the patient's response (titrate to effect).

[4]Hospital protocols should include the expectation that a nurse will administer naloxone to any patient suspected of having life-threatening opioid-induced sedation and respiratory depression.

Copyright 1994, Pasero, C. Used with permission from Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacologic management*. St. Louis, MO: Mosby-Elsevier.

Respiratory depression is assessed on the basis of what is normal for a particular person and is usually described as clinically significant when there is a decrease in the rate, depth, and regularity of respirations from baseline, rather than just by a specific number of respirations per minute (Pasero et al., 2011). There are many risk factors for opioid-induced respiratory depression, including older age (65 years of age or older), obesity, obstructive sleep apnea, and preexisting pulmonary dysfunction, or other comorbidities (APS, 2016;

Jarzyna et al., 2011). Risk is elevated during the first 24 hours following surgery and in patients who require a high dose of opioid in a short period of time (e.g., more than 10 mg of IV morphine or equivalent in the PACU). Patients who receive regularly scheduled opioids often develop tolerance to this effect in approximately 1 week (APS, 2016; Nagappa et al., 2017).

A comprehensive respiratory assessment constitutes more than counting a patient's respiratory rate (Pasero, 2009). A proper assessment requires watching the rise and fall of the patient's chest to determine rate, depth, and regularity of respirations. Listening to the sound of the patient's respirations is critical as well—snoring indicates airway obstruction and must be attended to promptly with repositioning and, depending on severity, a request for respiratory therapy consultation and further evaluation (Pasero, 2009; Pasero et al., 2011).

In most cases (exceptions may apply at the end of life), the opioid antagonist naloxone is promptly given IV to reverse clinically significant opioid-induced respiratory depression (Burchum & Rosenthal, 2019). The goal is to reverse only the sedation and respiratory depressant effects of the opioid. To this end, it should be diluted and titrated very slowly to prevent severe pain and other adverse effects, which can include hypertension, tachycardia, ventricular arrhythmias, pulmonary edema, and cardiac arrest (APS, 2016) (see Chart 9-6, footnote 3, for correct technique). Sometimes more than one dose of naloxone is necessary, because naloxone has a shorter duration of action (1 hour in most patients) than most opioids. In particular, this is true with transdermal fentanyl for which reversal requires repeated doses or an infusion of naloxone to insure appropriate reversal (Burchum & Rosenthal, 2019).

Co-Analgesic Medications

The **co-analgesic agents** comprise the largest group of analgesic agents, which offers many options. Medication selection and dosing is based on both experience and evidence-based guideline recommendations. There is considerable variability among individuals in their response to co-analgesic agents, including to agents within the same class; often a "trial and error" strategy is used in the outpatient setting. Treatment in the outpatient setting often is primarily for patients who have a neuropathic component of pain and involves the use of low initial doses and gradual dose escalation to allow tolerance to the adverse effects. Patients must be forewarned in this setting that the onset of analgesia is likely to require time to achieve analgesic benefit (Pasero, Polomano, Portenoy, et al., 2011). Following is a brief overview of the most commonly used co-analgesic agents.

Local Anesthetics

Local anesthetics have a long history of safe and effective use for all types of pain management. Local anesthetics are sodium channel blockers that affect

the formation and propagation of action potentials. They are given by various routes of administration and are generally well tolerated by most individuals (Pasero et al., 2011). Injectable and topical local anesthetics are commonly used for procedural pain treatment. Local anesthetics are added to opioid analgesic agents and other agents to be given intraspinally for the treatment of both acute and chronic pain. They are also infused for continuous peripheral nerve blocks, primarily after surgery (Chou et al., 2016).

The lidocaine patch 5% is placed directly over or adjacent to the painful area for absorption into the tissues directly below. This medication produces minimal systemic absorption and adverse effects. The patch is left in place for 12 hours and then removed for as long as 12 hours (12 hours on, 12 hours off regimen). This application process is repeated as needed for continuous analgesia (Burchum & Rosenthal, 2019). The medication is FDA approved for the neuropathic pain syndrome and postherpetic neuralgia; however, research suggests that it is effective and safe for a variety of other painful neuropathic conditions (APS, 2016). Lidocaine is also available in topical preparations as cream, gel, solution, ointment, and aerosol (APS, 2016; Burchum & Rosenthal, 2019). More recent liposomal formulations of local anesthetics such as bupivacaine, which can be instilled in a surgical wound, are reported to have longer duration of action, supporting improved analgesia (Shah, Votta-Velis, & Borgeat, 2018).

Allergy to local anesthetics is rare. Cardiac and CNS adverse effects are dose related (Burchum & Rosenthal, 2019). CNS signs of systemic toxicity include ringing in the ears, metallic taste, irritability, and seizures. Signs of cardiotoxicity include circumoral tingling and numbness, bradycardia, cardiac arrhythmias, and CV collapse (Pasero et al., 2011).

Membrane Stabilizer Anticonvulsant Medications

The anticonvulsant calcium channel blockers gabapentin and pregabalin are first-line analgesic agents for neuropathic pain (Peterson et al., 2018). They are increasingly being added to postoperative pain treatment plans to address the neuropathic component of surgical pain and can be considered as part of a multimodal approach for postoperative analgesia (Chou et al., 2016). Although further research is needed, their addition has been shown to improve analgesia, allow lower doses of other analgesic agents, and help prevent persistent neuropathic postsurgical pain syndromes, such as phantom limb, post thoracotomy, posthernia, and postmastectomy pain. They may be effective in improving the acute pain associated with burn injuries and as treatment for the neuropathic pain and pruritis following major burn injuries (Griggs, Goverman, Bittner, et al., 2017; Kaul, Amin, Rosenberg, et al., 2018; Wang, Beekman, Hew, et al., 2018). Analgesic anticonvulsant therapy is initiated with low doses and titrated according to patient response. Initial doses of gabapentin may not provide analgesia; titration to effective dosing may take up

to 2 months. Pregabalin has a more rapid onset of action with expected maximum effect typically reached in 2 weeks. Primary adverse effects of anticonvulsants are sedation and dizziness, which are usually transient and most notable during the titration phase of treatment (Peterson et al., 2018).

Antidepressant Medications

From an analgesic perspective, antidepressant co-analgesic medications are divided into two major groups: the tricyclic antidepressants (TCAs) and the serotonin and norepinephrine reuptake inhibitors (SNRIs). Evidence-based guidelines recommend the TCAs desipramine and nortriptyline and the SNRIs duloxetine and venlafaxine as first-line options for neuropathic pain treatment (Cruccu & Truini, 2017). Their delayed onset of action makes them inappropriate for acute pain treatment. Analgesic antidepressant therapy is initiated with low doses and titrated according to patient response (Comerford & Durkin, 2020; Issa, Marshall, & Wasan, 2018).

Primary adverse effects of TCAs are dry mouth, sedation, dizziness, mental clouding, weight gain, and constipation. Orthostatic hypotension is a potentially serious TCA adverse effect. The most serious adverse effect is cardiotoxicity, and patients with significant heart disease are at high risk. SNRIs are thought to have a more favorable adverse effect profile and to be better tolerated than the TCAs. Due to the side effects, including delirium and confusion, amitriptyline is not indicated for use in older adults (Aguiar, Costa, da Costa, et al., 2019; Burchum & Rosenthal, 2019). The 2015 Beers Criteria® identified amitriptyline as potentially inappropriate for prescription among older adults (Fick, Semla, Steinman, et al., 2019) (see Chapter 8 for further information on the Beers Criteria). The most common SNRI adverse effects are nausea, headache, sedation, insomnia, weight gain, impaired memory, sweating, and tremors (Comerford & Durkin, 2020).

Ketamine

Ketamine is a dissociative anesthetic with dose-dependent analgesic, sedative, and amnestic properties (Burchum & Rosenthal, 2019). As an NMDA antagonist, it blocks the binding of glutamate at the NMDA receptors and thus prevents the transmission of pain to the brain via the ascending pathway (see Fig. 9-1B, inset). At high doses, this medication can produce psychomimetic effects (e.g., hallucinations, dreamlike feelings); however, these are minimized when low doses are given. A benefit of the medication is that it does not produce respiratory depression. Ketamine is given most often by the IV route but can also be given by the oral, rectal, intranasal, and subcutaneous routes. In addition to intraoperative and procedural use, ketamine has been used for the treatment of persistent neuropathic pain, but its adverse effect profile makes it less favorable than other analgesic agents for long-term therapy. It is, however, increasingly used as a third-line analgesic agent for **refractory** acute pain among patients who are very opioid-tolerant or for patients who are not able to

be treated with opioids. It does have a potential for abuse (APS, 2016; Burchum & Rosenthal, 2019).

Gerontologic Considerations

Older adults often live with chronic pain, yet physiologic changes and comorbidities make management more complicated among them (HHS, 2019). Older adults are often sensitive to the effects of co-analgesic agents that produce sedation and other CNS effects, such as antidepressants and anticonvulsants. Since they are also at risk for undertreatment of pain, therapy should be initiated with low doses, and titration should proceed slowly with systematic assessment of patient response (Burchum & Rosenthal, 2019).

Older adults are also at increased risk for NSAID-induced GI toxicity. Acetaminophen should be used for mild pain and is recommended as first line for musculoskeletal pain (e.g., osteoarthritis). If an NSAID is needed for inflammatory pain, it is recommended that a COX-2 selective NSAID (if not contraindicated by an increased CV risk) or the nonselective NSAID least likely to cause a peptic ulcer should be used. The addition of a proton pump inhibitor to NSAID therapy, or opioid analgesic agents rather than an NSAID, is recommended for high-risk patients. The American Geriatric Society (AGS) recommends using extreme caution when prescribing NSAIDs among older adults (Jones, Ehrhardt, Ripoll, et al., 2016). NSAIDs are safest when used for short-term pain flares that may occur during transient worsening in severity of chronic diseases or conditions (e.g., osteoarthritis, fibromyalgia, low back pain). A number of NSAIDs are available in topical formulations which may be preferred for older adults (Burchum & Rosenthal, 2019; Horgas, 2017; HSS, 2019; Sowa, Weiner, & Camacho-Soto, 2018).

Age is considered an important factor to consider when selecting an opioid dose. The starting opioid dose should be reduced by 25% to 50% in adults older than 70 years because they are more sensitive to opioid adverse effects than younger adults; the number of subsequent doses is based on patient response (American Geriatrics Society [AGS], 2009; Burchum & Rosenthal, 2019).

Use of Placebos

A **placebo** is "any sham medication or procedure designed to be void of any known therapeutic value" (Lang, Christopher, Emmott, et al., 2018, p. 55). A saline injection is one example of a placebo. Administration of a medication at a known subtherapeutic dose (e.g., 0.10 mg of morphine in an adult) is also considered a placebo.

Placebos only are appropriately used as controls in research evaluating the effects of a new medication. The new substance or treatment is compared with the effects of a placebo and must show more favorable effects than placebos to

warrant further investigation or marketing of the substance or treatment (Enck, Klosterhalfen, & Weimer, 2017). When a person responds to a placebo in accordance with its intent, it is called a *positive placebo response* (Arnstein, Broglio, Wuhrman, et al., 2011). Individuals who participate in placebo-controlled research must be able to give informed consent or have a guardian who can provide informed consent.

TABLE 9-5 Nonpharmacologic Methods of Pain Management

Type	Examples	Nursing Considerations
Physical modalities	Proper body alignment; application of heat and/or cold; massage; transcutaneous electrical nerve stimulation (TENS); acupuncture; physical therapy; and aqua therapy	Be aware that some of these methods require a prescription in the inpatient setting, as inappropriate use can cause harm (e.g., burns or frostbite from extreme temperatures and prolonged thermal application).
Cognitive and behavioral methods	Relaxation breathing; distraction; listening, singing, or rhythmic tapping to music; imagery; humor; pet therapy; prayer; meditation; hypnosis	Prior to use, evaluate patient's cognitive ability to learn and perform necessary activities.
Movement therapy	Yoga, T'ai chi	Prior to use, evaluate patient's physical ability to perform necessary activities.
Biologically based therapies	Taking herbs, vitamins, and proteins; aromatherapy; diet modifications	Evaluate use to identify potential adverse effects.
Energy therapies	Therapeutic touch, Reiki, and healing touch	Obtain patient's permission before using intervention.

Chart 9-7

Considerations in Selecting and Using Nonpharmacologic Methods

- Do the patient, family, and health care team understand the relationship between nonpharmacologic pain management and antispasmodic agents? Patients who have been taking analgesic agents may mistakenly assume that when clinicians suggest a nonpharmacologic method, the purpose is to reduce the use or dose of analgesic agents. All involved must understand that nonpharmacologic methods are used to complement—not replace—pharmacologic methods.
- Does the patient understand the limitations of nonpharmacologic methods? Nonpharmacologic methods are valuable as comfort measures; however, not all such measures relieve pain and should not be promoted as such.
- Is the patient interested in using a nonmedication method, and have any been tried previously? If so, what happened? Is the patient using nonmedication methods because of unfounded fears about analgesic agents? Willingness and interest are important for successful use of nonpharmacologic methods; however, patients may fear taking analgesic agents that clearly are indicated for their pain, such as nonsteroidal anti-inflammatory drugs (NSAIDs) for an inflammatory painful condition. Such fears should be explored, and accurate information and appropriate treatment provided. Alternately, the reasons a patient refuses to use a nonpharmacologic method also should be explored, but the patient's right to refuse must be respected.
- What are the patient's preferences and coping styles? Encouraging patients to choose from a variety of techniques allows them to match the technique to their individual and cultural preferences. If none of the choices appeal to the patient, the patient's right to refuse use should be respected.
- Does the patient have the physical and cognitive abilities necessary for using the nonpharmacologic method? Does the patient have sufficient energy to learn and perform any tasks involved? For example, physical and mental fatigue can interfere with the use of distraction and relaxation imagery techniques. Does the patient want to dedicate the necessary time required for the nonpharmacologic method? For example, those who do not find a 20-min self-sustained relaxation technique appealing may be more suited for passive application of cold or heat.
- Do others (e.g., family, friends) want to be involved in helping the patient? Is the method a potential vehicle for improving relationships between the patient and others? For example, a method that patients cannot do for themselves, such as massage, may be a burden to some caregivers in the home, whereas others may welcome that opportunity to be physically close to a loved one.

- Are support materials and patient education resources available? Whenever possible, verbal, written, and in some cases, online or video education should be provided.

Adapted from McCaffery, M. (2002). What is the role of nondrug methods in the nursing care of patients with acute pain? *Pain Management Nursing, 3*(3), 77–80; McCaffery, M., & Pasero, C. (1999). *Pain: Clinical manual*. St. Louis, MO: Mosby.

Placebos should never be used clinically in a deceitful manner and without informed consent. It is disrespectful and harmful to use them. Pain relief resulting from a placebo is mistakenly believed to invalidate a patient's report of pain. This typically results in the patient being deprived of pain-relief measures, despite research showing that many patients who have obvious physical stimuli for pain (e.g., abdominal surgery) report pain relief after placebo administration. The reason for this is a mystery, but it is one of the many reasons that pain guidelines, position papers, nurse practice acts, and hospital policies nationwide agree that there are no individuals for whom and no condition for which placebos are the recommended treatment. The deceptive use of placebos has both ethical and legal implications, violates the nurse–patient relationship, and inevitably deprives patients of appropriate assessment and treatment (Arnstein et al., 2011; Enck et al., 2017; Lang et al., 2018).

Nonpharmacologic Methods of Pain Management

Most individuals use self-management strategies to deal with their health issues and promote well-being. According to national health information, it is estimated that American adults spent $30.2 billion on complementary health practices to treat painful conditions (O'Conner-Von, Heck, & Peltier, 2018). Nonpharmacologic complementary and alternative interventions include using natural products (e.g., herbs or botanicals, vitamins, probiotics) or using mind and body practices (e.g., acupuncture, behavior-based therapies, chiropractic manipulation, massage therapy, spirituality, yoga, T'ai chi) (HHS, 2019). Table 9-5 lists examples of select complementary and alternative therapies.

Nonpharmacologic therapies are usually effective alone for mild to some moderate-intensity pain. They should not be a replacement or alternative but complement pharmacologic therapies as part of a multimodal approach for more severe pain. The effectiveness of nonpharmacologic methods can be unpredictable, and although not all will relieve pain, they offer many benefits to patients with pain. For example, research suggests that nonpharmacologic methods can facilitate relaxation and reduce anxiety and stress. Many patients find that the use of nonpharmacologic methods helps them cope better with

their pain and feel greater control over the pain experience (HHS, 2019; O'Conner-Von et al., 2018).

Several nonpharmacologic methods can be used in the clinical setting to provide comfort and pain relief for all types of pain; however, time is often limited in this setting for implementation of these methods. Nurses play an important role in providing them and educating patients about their use. Many of the methods are relatively easy for nurses to incorporate into daily clinical practice and may be used individually or in combination with other nonpharmacologic therapies to facilitate patient-centered care utilizing a multimodal approach (HHS, 2019; O'Conner-Von et al., 2018). Chart 9-7 provides points for nurses to consider before using nonpharmacologic methods.

Unfolding Patient Stories: Stan Checketts • Part 1

Stan Checketts, a 52-year-old man, is in the emergency department with severe abdominal pain. The provider has prescribed buprenorphine 0.3-mg IV push for pain. Explain the assessments performed by the nurse prior to, during, and following the administration of the medication. Also consider nonpharmacologic interventions the nurse can incorporate to assist with his pain relief. (Stan Checketts' story continues in Chapter 41.)

Care for Stan and other patients in a realistic virtual environment: *vSim* (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Nursing Implications of Pain Management

The provision of optimal pain management requires a collaborative approach between patients with pain, their families, and members of the health care team. Everyone involved must share common goals, a common knowledge base, and a common language with regard to the antispasmodic agents and nonpharmacologic methods used to manage pain. Whether nurses provide care in the home, hospital, or any other setting, they are in a unique position to coordinate a comprehensive, evidence-based approach to meet the needs of people with pain. Chart 9-8 provides a plan of nursing care for the patient with pain.

Chart 9-8 PLAN OF NURSING CARE

Care of the Patient with Acute Pain

NURSING DIAGNOSIS: Acute Pain
GOAL: Achievement and maintenance of patient's comfort–function goal

Nursing Intervention	Rationale	Expected Outcomes
1. Perform and document a comprehensive pain assessment. a. Use a reliable and valid tool to determine pain intensity. b. Accept the patient's report of pain. c. Assist the patient in establishing a comfort–function goal. d. Apply the Hierarchy of Pain Measures in patients who are unable to report their pain. 2. Administer analgesic agents as prescribed. 3. Offer and educate patient how to use appropriate nonpharmacologic interventions. 4. Reassess for degree of pain relief and presence of adverse effects at peak effect time of intervention. 5. Obtain additional prescriptions as needed. 6. Prevent and treat adverse effects.	1. The comprehensive pain assessment is the foundation of the pain treatment plan; documentation ensures communication between team members. a. The use of valid and reliable tools helps ensure accuracy and consistency in assessment. b. Accepting the patient's report of pain is the undisputed standard of pain assessment. c. The comfort–function goal links function to pain control and provides direction for necessary adjustments in the treatment plan to maximize function. d. The use of the Hierarchy of Pain Measures provides a process to ensure pain	• If able, provides information about the pain • Expresses understanding of the link between function and pain control and establishes a realistic comfort–function goal • Reports a pain intensity that allows participation in important functional activities • If not able to report pain, demonstrates behaviors that indicate pain relief and participation in important functional activities • Expresses satisfaction with the use of nonpharmacologic methods • Tolerates pharmacologic and nonpharmacologic interventions without adverse effects

7. Educate patient and family about the effects of analgesic agents and the goals of care; explain how adverse effects will be prevented and treated; address fears of substance use disorder.	treatment in the patient who cannot report pain. 2. Pharmacologic interventions are the cornerstone of pain management. 3. Nonpharmacologic methods are used to supplement pharmacologic interventions. 4. Reassessment permits evaluation of both the effectiveness and safety of interventions. 5. Prescriptions for additional analgesic agents or adjustment in dose are often needed to maximize pain control. 6. Adverse effects are prevented whenever possible and promptly treated to reduce patient discomfort and prevent harm. 7. An understanding of the treatment plan and goals of care educates patients and their families how to partner with the health care team to optimize pain control.	• Demonstrates an understanding of the treatment plan and goals of care

CRITICAL THINKING EXERCISES

1 ebp An 88-year-old woman arrives in the emergency department following a motor vehicle crash in which she was the restrained front seat passenger. She repeatedly says "owie" and her daughter reports that this is her mom's way of expressing pain. Her daughter also reports that her mother was recently diagnosed with dementia after family members began noticing increasing forgetfulness and confusion at home. When asked to rate the intensity of her pain, the patient replies "owie, yes" but she is not able to easily assign a number to her pain. What pain assessment tool would be most helpful in assessing this patient's pain and in evaluating the effectiveness of interventions? What is the strength of the evidence supporting the assessment tool you selected?

2 pq A 62-year-old woman who has chronic abdominal pain following multiple surgeries resulting from an abusive domestic situation is admitted to the medical floor for reports of worsening pain at home. She reports pain and nausea but denies diarrhea or vomiting. In addition to the 50-mcg fentanyl transdermal patch she has used to control pain at home for the last 2 years, the primary provider has prescribed: 1 mg intravenous hydromorphone every 2 hours PRN pain; promethazine 25 mg IV every 4 hours PRN nausea; lorazepam 0.5 mg IV every 6 hours PRN anxiety; and zolpidem 1.75 mg sublingual nightly prior to sleep. The patient asks you to give her all her medications at the same time so that she can sleep. She asserts that "the nurses always give me the medication that way when I am in the hospital." You are concerned that all these medications are central nervous system depressants and that given together, they could lead to oversedation and possibly result in respiratory depression. How would you prioritize administering the medications that she is requesting and your ongoing assessments to ensure adequate symptom relief while maintaining patient safety and minimizing the risks of adverse outcomes?

3 ipc A 28-year-old man is hospitalized with a diagnosis of an epidural abscess. He reports a 5-year history of daily intravenous self-administration of heroin. He tells you that the oxycodone his primary provider prescribed is "not doing anything" and his pain "is 100/10." How will you collaborate with other members of the interprofessional health care team to manage his pain? Using a multimodal approach for analgesia, what other interventions, both pharmacologic and nonpharmacologic, can the team incorporate into his plan of care to better manage his severe pain?

10 Fluid and Electrolytes

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Differentiate between osmosis, diffusion, filtration, and active transport.
2. Describe the role of the kidneys, lungs, and endocrine glands in regulating the body's fluid composition and volume.
3. Plan effective care of patients with the following imbalances: fluid volume deficit and fluid volume excess, sodium deficit (hyponatremia) and sodium excess (hypernatremia), and potassium deficit (hypokalemia) and potassium excess (hyperkalemia).
4. Describe the cause, clinical manifestations, management, and nursing interventions for the following imbalances: calcium deficit (hypocalcemia) and calcium excess (hypercalcemia), magnesium deficit (hypomagnesemia) and magnesium excess (hypermagnesemia), phosphorus deficit (hypophosphatemia) and phosphorus excess (hyperphosphatemia), and chloride deficit (hypochloremia) and chloride excess (hyperchloremia).
5. Explain the roles of the lungs, kidneys, and chemical buffers in maintaining acid–base balance; and compare metabolic as well as respiratory acidosis and alkalosis with regard to causes, clinical manifestations, diagnosis, and management.
6. Interpret arterial blood gas measurements.

NURSING CONCEPTS

Acid–Base
Cellullar Regulation
Fluids and Electrolytes
Metabolism

GLOSSARY

acidosis: an acid–base imbalance characterized by an increase in H^+ concentration (decreased blood pH) (A low arterial pH due to increased H^+ concentration or reduced bicarbonate concentration is called *metabolic acidosis;* a low arterial pH due to increased PCO_2 is called *respiratory acidosis.*)

active transport: physiologic pump that uses energy to move fluid or electrolytes from one region to another

alkalosis: an acid–base imbalance characterized by a reduction in H^+ concentration or increase in bicarbonate concentration (increased blood pH) (A high arterial pH with either decreased H^+ ion concentration or increased bicarbonate concentration is called *metabolic alkalosis;* a high arterial pH due to reduced PCO_2 is called *respiratory alkalosis.*)

colloid: a fluid containing particles that are nonsoluble and evenly distributed throughout the solution

colloid oncotic pressure: osmotic pressure created by the protein (mainly albumin) in the bloodstream (*synonym:* colloidal osmotic pressure)

crystalloid: a fluid containing soluble mineral ions and water in solution

diffusion: the process by which solutes move from an area of higher concentration to one of lower concentration; does not require expenditure of energy

homeostasis: maintenance of a constant internal equilibrium in a biologic system

hydrostatic pressure: the pressure created by the weight of fluid against the wall that contains it. In the body, hydrostatic pressure in blood vessels results from the weight of fluid itself and the force resulting from cardiac contraction (*synonym:* hydraulic pressure)

hypertonic solution: a solution with an osmolality higher than that of serum

hypotonic solution: a solution with an osmolality lower than that of serum

isotonic solution: a solution with the same osmolality as blood

osmolality: the number of milliosmoles (the standard unit of osmotic pressure) per kilogram of solvent; expressed as milliosmoles per kilogram (mOsm/kg). (The term *osmolality* is used more often than *osmolarity* to evaluate serum and urine.)

osmolarity: the number of milliosmoles (the standard unit of osmotic pressure) per liter of solution; expressed as milliosmoles per liter (mOsm/L); describes the concentration of solutes or dissolved particles

osmosis: the process by which fluid moves across a semipermeable membrane from an area of low solute concentration to an area of high solute concentration; the process continues until the solute concentrations are equal on both sides of the membrane

tonicity: fluid tension or the effect that osmotic pressure of a solution with impermeable solutes exerts on cell size because of water movement across the cell membrane

Fluid and electrolyte balance are dependent on dynamic processes that are crucial for life and **homeostasis** (the maintenance of a constant internal equilibrium in a biologic system). Potential and actual disorders of fluid and electrolyte balance occur in every setting, with every disorder, and with a variety of changes that affect healthy people as well as those who are ill.

Nurses need to understand the physiology of fluid and electrolyte balance and acid–base balance to anticipate, identify, and respond to imbalances. Maintaining the balance of fluid and electrolytes is crucial to the care of patients of every age and in every clinical setting.

Fundamental Concepts

Basic concepts of chemistry are involved in fluid and electrolyte balance and imbalance. A solution is a mixture of solvent, which is a fluid medium, and solutes, which are particles. Blood is composed of blood cells that are suspended in plasma. The blood cells include erythrocytes, leukocytes, and platelets. Plasma is composed of 92% water, which is a solvent that contains solutes including proteins (mainly albumin), glucose, lipoproteins, and mineral ions, termed electrolytes.

Amount and Composition of Body Fluids

Approximately 60% of a typical adult's weight consists of fluid (water and electrolytes) (Fig. 10-1). Factors that influence the amount of body fluid are age, gender, and body fat. In general, younger people have a higher percentage of body fluid than older adults, and men have proportionately more body fluid than women. The skeleton has low water content. Muscle, skin, and blood contain the highest amounts of water (Norris, 2019).

Body fluid is located in two fluid compartments: the intracellular space (fluid in the cells) and the extracellular space (fluid outside the cells). Approximately two thirds of body fluid is in the intracellular fluid (ICF) compartment. Approximately one third is in the extracellular fluid (ECF) compartment (Norris, 2019).

The ECF compartment is further divided into the intravascular (blood), interstitial, and transcellular fluid spaces:

- The intravascular space (the fluid within the blood vessels) contains plasma, the effective circulating volume. Approximately 3 L of the average 6 L of blood volume in adults is made up of plasma. The remaining 3 L is made up of the blood cells: erythrocytes, leukocytes, and thrombocytes (platelets).
- The interstitial space contains the fluid that surrounds the cell and totals about 11 to 12 L in an adult. Lymph is an interstitial fluid.
- The transcellular space is the smallest division of the ECF compartment and contains approximately 1 L. Examples of transcellular fluids include cerebrospinal, pericardial, synovial, intraocular, and pleural fluids, sweat, and digestive secretions.

As the next section describes, the ECF transports electrolytes; it also carries other substances, such as enzymes and hormones.

Body fluid normally moves between the two major compartments (i.e., ICF and ECF) in an effort to maintain equilibrium between the spaces. A semipermeable membrane surrounding each of the cells allows certain fluids and electrolytes to move between the ICF and ECF. Loss of fluid from the ICF or ECF can disrupt equilibrium. The body constantly works to keep fluid and electrolytes in a homeostatic balance. If too much fluid moves from ICF to ECF, cellular dehydration can occur. If too much fluid moves from ECF to ICF, cell swelling can occur (Papadakis, McPhee, & Rabow, 2019).

Sometimes fluid is not lost from the body but is unavailable for use by either the ICF or ECF. Loss of ECF into a space that does not contribute to equilibrium between the ICF and the ECF is referred to as a third-space fluid shift, or third spacing. Third-space fluid accumulates within membrane-bound spaces in the body such as the peritoneal cavity and pleural space. Examples of third-spaced fluid include ascites, pleural effusion, pericardial effusion, and angioedema (Papadakis et al., 2019).

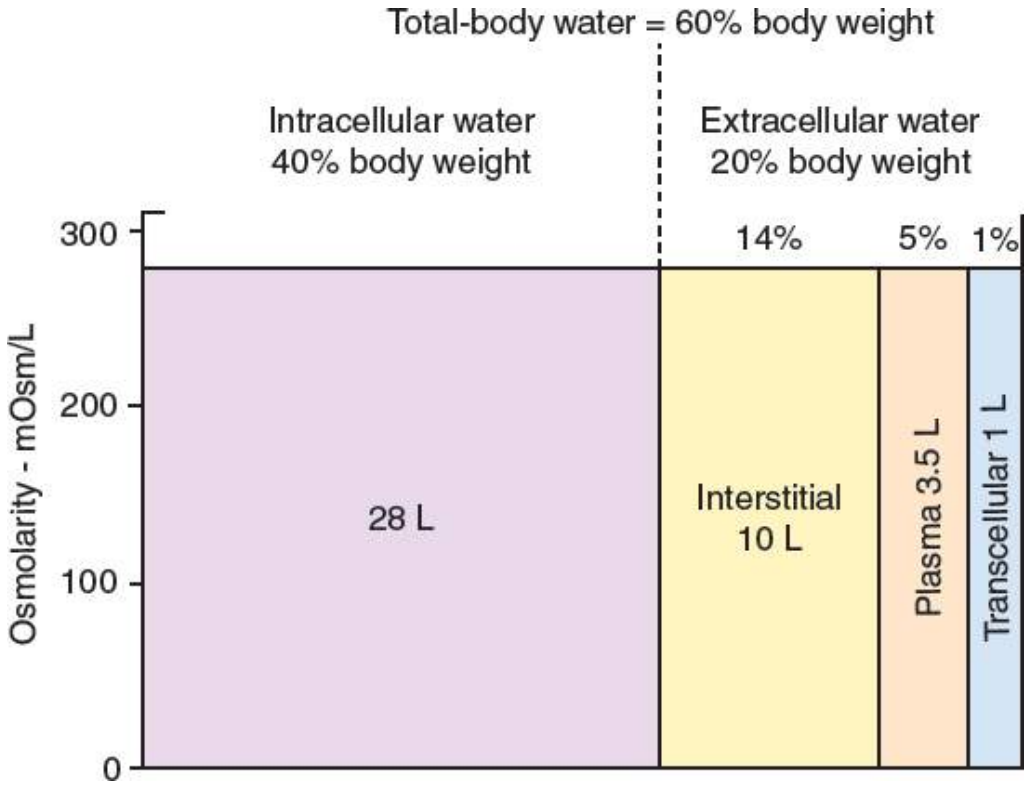

Figure 10-1 • Approximate sizes of body compartments in a 70-kg adult. Reprinted with permission from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed., Fig. 8-4, p. 162). Philadelphia, PA: Wolters Kluwer.

Early evidence of a third-space fluid shift is a decrease in urine output despite adequate fluid intake. Urine output decreases because fluid shifts out of the intravascular space; the kidneys then receive less blood and attempt to compensate by decreasing urine output. Other signs and symptoms of third spacing that indicate an intravascular fluid volume deficit (FVD) include increased heart rate, decreased blood pressure, decreased central venous pressure, edema, increased body weight, and imbalances in fluid intake and output (I&O). Third-space fluid is reabsorbed back into the bloodstream over a period of a few days to a few weeks. However, the acute volume depletion must be restored to prevent further complications (Sterns, 2017a).

Electrolytes

Electrolytes in body fluids are active chemicals (cations that carry positive charges and anions that carry negative charges). The major cations in body fluid are sodium, potassium, calcium, magnesium, and hydrogen ions. The major anions are chloride, bicarbonate, phosphate, sulfate, and negatively charged protein ions.

These chemicals unite in varying combinations. Therefore, electrolyte concentration in the body is expressed in terms of milliequivalents (mEq) per

liter, a measure of chemical activity, rather than in terms of milligrams (mg), and a unit of weight. More specifically, a milliequivalent is defined as being equivalent to the electrochemical activity of 1 mg of hydrogen. In a solution, cations and anions are equal in milliequivalents per liter.

Electrolyte concentrations in the ICF differ from those in the ECF, as reflected in Table 10-1. Because special techniques are required to measure electrolyte concentrations in the ICF, it is customary to measure the electrolytes in the most accessible portion of the ECF—namely, the plasma (Norris, 2019).

Sodium ions, which are positively charged, far outnumber the other cations in the ECF. Because sodium concentration affects the overall concentration of the ECF, sodium is important in regulating the volume of body fluid. Water follows movement of sodium in the body fluids. Retention of sodium is associated with fluid retention, and excessive loss of sodium is usually associated with decreased volume of body fluid.

As shown in Table 10-1, one of the major electrolytes in the ICF is potassium. The ECF has a low concentration of potassium, and patients can tolerate only small changes in potassium concentration. Changes in potassium within the ECF can cause cardiac rhythm disturbances and hyperkalemia can cause cardiac arrest. Therefore, the release of large stores of intracellular potassium, typically caused by trauma to the cells and tissues, can be extremely dangerous.

The body expends a great deal of energy maintaining the high extracellular concentration of sodium and the high intracellular concentration of potassium. It does so by means of a cell membrane pump that exchanges sodium and potassium ions, termed the sodium–potassium pump (see discussion later in this chapter).

Osmosis, Osmolality, and Osmolarity

When two different solutions are separated by a membrane that is semi-permeable; fluid shifts from the region of less concentrated solution to a more concentrated solution, until the solutions are of equal concentration. This diffusion of water caused by fluid and solute concentration gradients is known as **osmosis** (Fig. 10-2). Osmolality and osmolarity are terms that describe the concentration of solutes or dissolved particles in a solution. **Osmolality** is the number of milliosmoles of solute (the standard unit of osmotic pressure) per kilogram of solvent; it is expressed as milliosmoles per kilogram (mOsm/kg). **Osmolarity** is the number of milliosmoles (the standard unit of osmotic pressure) per liter of solution; it is expressed as milliosmoles per liter (mOsm/L). The term *osmolality* is used more often than *osmolarity* to evaluate the solutes in the blood or urine (Emmett & Palmer, 2018a).

Regulation of Fluid within the Body Compartments

Normal movement of fluids through the capillary wall into the tissues depends on Starling's Laws of Capillary Forces. Capillary forces are the two forces at every capillary membrane: hydrostatic pressure (also called hydraulic pressure) and osmotic pressure. **Hydrostatic pressure** is the pressure exerted by fluid on the walls of the blood vessel, and osmotic pressure is the pressure exerted by the solutes within the plasma. Hydrostatic pressure pushes fluid out of the capillary toward the ICF. Osmotic pressure pulls fluid into the capillary from the ICF. These forces oppose each other at every capillary membrane and balance each other out in healthy (homeostatic) conditions. The direction of fluid movement depends on the differences in the two opposing forces of hydrostatic and osmotic pressure (Fig. 10-3). If hydrostatic pressure is greater than osmotic pressure, then the movement of fluid is from ECF toward the ICF.

TABLE 10-1 Concentrations of Extracellular and Intracellular Electrolytes in Adults

Electrolyte	Extracellular Concentration*		Intracellular Concentration*	
	Conventional Units	SI Units (mmol/L)	Conventional Units	SI Units (mmol/L)
Sodium	135–145 mEq/L	135–145	10–14 mEq/L	10–14
Potassium	3.5–5.0 mEq/L	3.5–5.0	140–150 mEq/L	140–150
Chloride	98–106 mEq/L	98–106	3–4 mEq/L	3–4
Bicarbonate	24–31 mEq/L	24–31	7–10 mEq/L	7–10
Calcium	8.8–10.5 mg/dL	2.2–2.6	<1 mEq/L	<0.25
Phosphorus	2.5–4.5 mg/dL	0.8–1.45	Variable	Variable
Magnesium	1.8–3.6 mg/dL	0.75–1.07	40 mEq/kg†	20

*Values may vary among laboratories, depending on the method of analysis used.
†Values vary among various tissues and with nutritional status.

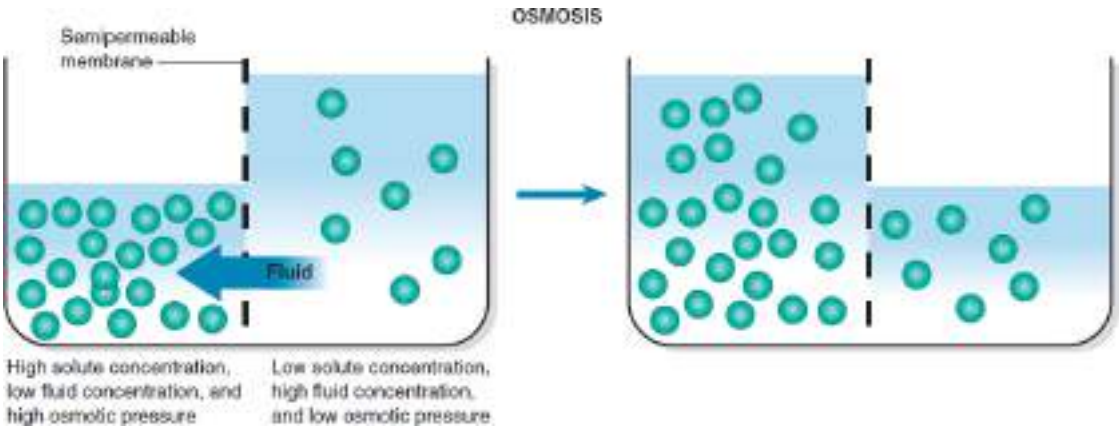

Figure 10-2 • Osmosis: when two different solutions are separated by a semi-permeable fluid shifts from the region of less concentrated solution to a more concentrated solution, until the solutions are of equal concentration.

Oncotic Pressure

Osmotic pressure specifically exerted by the albumin within the bloodstream is termed **colloid oncotic pressure** or **colloid osmotic pressure.** A **colloid** is fluid consisting of nonsoluble substances that are evenly distributed within a solvent. Blood is an example of a colloid solution. It is a mixture of blood cells and plasma which contains water, proteins, enzymes, and other solutes.

Crystalloid versus Colloid Solutions

Fluid replacement in the body depends on what type of fluid is lost. If a large amount of blood is lost, for example, the preferred treatment is replacement with matching blood (commonly packed red blood cells). However, crystalloid or colloid solutions can be used to temporarily replace blood or replenish fluid losses from the body. **Crystalloid** solutions are mineral ions dissolved in water. Examples include normal saline (0.9% NaCl), half normal saline (0.45% NaCl), and lactated Ringer's solution (Plasma-Lyte). Crystalloid solutions are commonly used to replace fluid in hypovolemia. Examples of colloid solutions include albumin solutions, hyperoncotic starch, and dextran. Colloid solutions are commonly used as temporary blood replacement until the correct type of blood is available for infusion (Mandel & Palevsky, 2019).

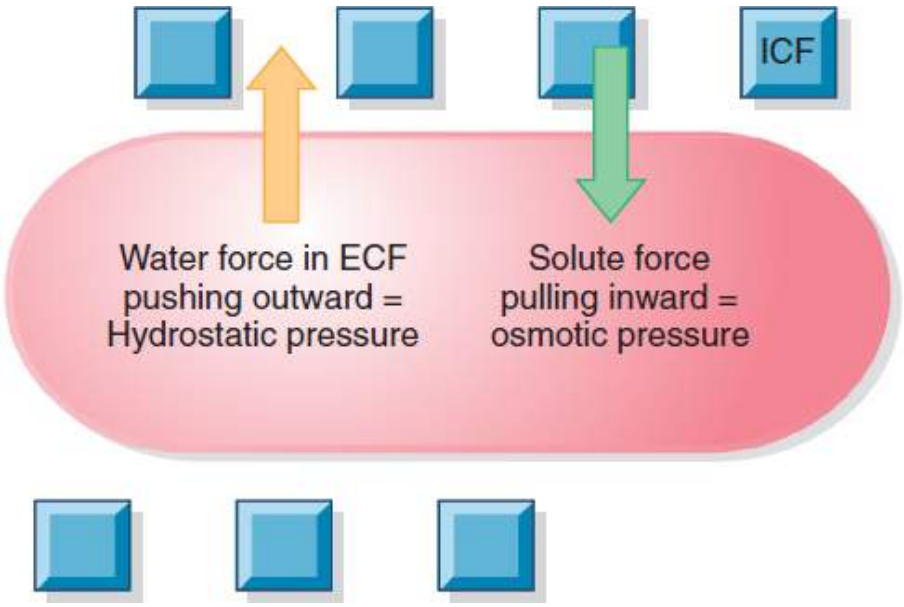

Figure 10-3 • The forces of osmotic and hydrostatic pressure constantly oppose each other. ECF, extracellular fluid; ICF, intracellular fluid.

Tonicity

Tonicity is the ability of solutes to cause an osmotic driving force that promotes water movement from one compartment to another. Movement of water is either from ICF to ECF or ECF to ICF. The tonicity of a solution can be used to drive water movement between compartments to change the state of cellular hydration and cell size. Tonicity most commonly refers to the NaCl content of the solution. The tonicity of a solution is determined by how it compares to physiologic fluid which is 0.9% NaCl (Sterns, 2017b). Fluids can be isotonic, hypotonic, or hypertonic compared to physiologic fluid of 0.9% NaCl.

Tonicity commonly pertains to intravenous (IV) solutions. IV solutions of different tonicities can be infused into the bloodstream to produce movement of water from one compartment to the other.

Isotonic solutions are composed of 0.9% NaCl; the same sodium and chloride concentration as the bloodstream and the same water concentration as the bloodstream. Isotonic solutions do not provoke water movement between ICF or ECF compartments. Isotonic solutions expand the plasma volume of the blood (Sterns, 2017b).

Hypotonic solutions are composed of less sodium chloride concentration compared to the blood; for example, 0.45% NaCl or 0.225% NaCl. Hypotonic solutions contain less solute but more water than the bloodstream. IV hypotonic solution infusions can be used to move water from the ECF into the ICF. IV hypotonic solutions can be used to hydrate a patient as they contain high water concentration (Sterns, 2017b).

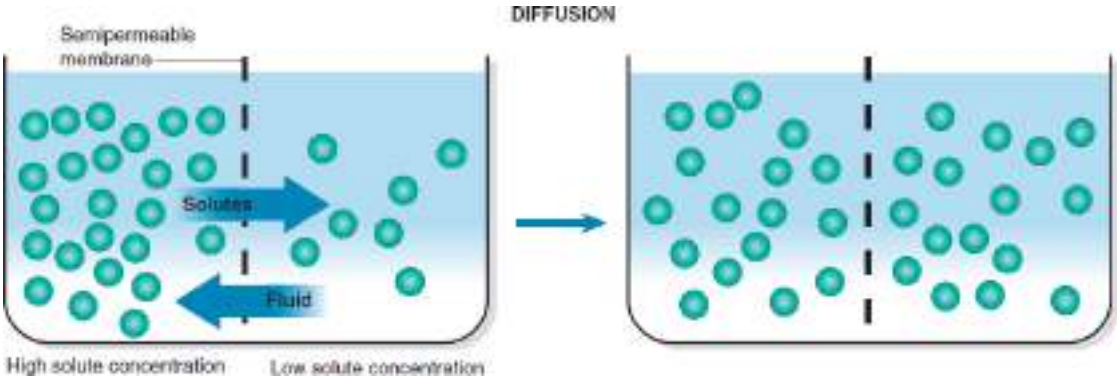

Figure 10-4 • Diffusion: movement of solutes from an area of greater concentration to an area of lesser concentration, leading ultimately to equalization of the solute concentrations.

Hypertonic solutions are composed of greater concentration of NaCl compared to blood (e.g., 3% NaCl). Hypertonic solutions contain more solute concentration and less water than the bloodstream. IV hypertonic solution can be infused into the bloodstream to pull water from the ICF into the ECF. The movement of water from ICF to ECF will cause dehydration of the cells. This is useful in disorders of severe edema; particularly cerebral edema, which requires immediate treatment. Sodium, glucose, and mannitol are examples of solutes capable of affecting water movement from ICF to ECF. Mannitol, a nonresorbable sugar alcohol, in water is an IV solution that can be used to move water from ICF to ECF rapidly. IV mannitol can induce a condition termed osmotic diuresis; it is most commonly used to decrease cerebral edema (Brater & Ellison, 2019). (See discussion of parenteral therapy later in this chapter.)

Osmotic diuresis is the increase in urine output caused by the excretion of solutes, such as glucose or mannitol. In high concentrations, glucose or mannitol can act as solutes within the bloodstream. These solutes exert a force that pulls water out of the ICF and brings it into the ECF (bloodstream). The water then is filtered out of the bloodstream at the kidneys and excreted into the urine. The urine contains extra water that is derived from the ICF; this increased urine volume is called diuresis (Brater & Ellison, 2019).

Diffusion

Diffusion is the natural tendency of a substance to move from an area of higher concentration to one of lower concentration (Fig. 10-4). It occurs through the random movement of ions and molecules. Examples of diffusion are the exchange of oxygen (O_2) and carbon dioxide (CO_2) between the pulmonary capillaries and alveoli and the tendency of sodium to move from the ECF compartment, where the sodium concentration is high, to the ICF, where its concentration is low (Hall, 2016).

Filtration

Hydrostatic pressure in the capillaries tends to filter fluid out of the intravascular compartment into the interstitial fluid. Movement of water and solutes occurs from an area of high hydrostatic pressure to an area of low hydrostatic pressure. The kidneys filter approximately 180 L of plasma per day. Another example of filtration is the passage of water and electrolytes from the capillary bed to the interstitial fluid; in this instance, the hydrostatic pressure results from the pumping action of the heart (Hall, 2016).

Sodium–Potassium Pump

The sodium concentration is greater in the ECF than in the ICF; because of this, sodium tends to enter the cell by diffusion. To maintain cellular function, more potassium needs to be inside the cell and more sodium needs to be outside the cell. The sodium–potassium pump maintains the electrolyte gradient of high extracellular Na^+ compared to low intracellular Na^+, and high intracellular K^+ compared to low extracellular K^+. The pump maintains the different concentrations of cations Na^+ and K^+ in and out of the cell. For every 3 Na^+ pumped out of the cell, 2 K^+ ions are pumped into the cell (Pirahanchi & Aeddula, 2019).

The sodium–potassium pump uses energy to maintain this electrolyte gradient and is powered by the enzyme termed Na^+K^+-ATPase. The sodium–potassium pump performs **active transport** which actively moves sodium from the ICF into the ECF and actively moves potassium from the ECF to the ICF. Active transport is the use of energy to create movement against a concentration gradient (Hall, 2016; Norris, 2019).

Systemic Routes of Gains and Losses

Water and electrolytes are gained in various ways. Healthy people gain fluids by drinking and eating, and their daily average intake and output (I & O) of water are approximately equal (Table 10-2).

TABLE 10-2 Sources of Body Water Gains and Losses in the Adult

Intake (mL)		Output (mL)	
Oral intake		Urine	1500
As water	1000	Insensible losses	
In food	1300	Lungs	300
Water of oxidation	200	Skin	500
		Feces	200
Total gain[a]	2500	Total loss[a]	2500

[a]Approximate volumes.

Kidneys

The daily urine volume excreted by the adult varies according to hydration status. A well-hydrated person excretes 1 to 2 L urine per day. A general rule is that the output is approximately 1 mL of urine per kilogram of body weight per hour (1 mL/kg/h) in all age groups (Sterns, 2017a). For example, a 70-kg adult will excrete 70 mL/h; over 24 hours this equals approximately 1680 mL of urine.

Skin

Perspiration is visible water and electrolyte loss through the skin (sweating). The chief solutes in sweat are sodium, chloride, and potassium. Actual sweat losses can vary from 0 to 1000 mL or more every hour, depending on factors such as the environmental and body temperature. Continuous water loss by evaporation through the skin (approximately 500 mL/day) occurs through perspiration, referred to as insensible water loss (Norris, 2019). Fever, high environmental temperature, and exercise greatly increase insensible water loss through the skin. Burn injury, which causes the loss of the natural skin barrier, also causes a large water loss (Sterns, 2017b).

Lungs

The lungs normally eliminate water vapor, also referred to as insensible water loss, at a rate of approximately 300 mL daily (Norris, 2019). The loss is much greater with increased respiratory rate or depth, or in a dry climate. Similar to water loss through the skin, fever, high environmental temperature, and exercise all increase insensible water loss through the lungs.

Gastrointestinal Tract

Loss of fluid from the gastrointestinal (GI) tract is about 100 to 200 mL daily. Approximately 8 L of fluid circulates through the GI system every 24 hours.

However, most of the fluid is reabsorbed into the bloodstream from the small intestine. Diarrhea and fistulas of the intestine can cause large losses of fluids (Sterns, 2018a).

Quality and Safety Nursing Alert

When fluid balance is critical, all routes of systemic gain and loss must be recorded and all volumes compared. Organs of fluid loss include the kidneys, skin, lungs, and GI tract.

Laboratory Tests for Evaluating Fluid Status

Serum osmolality primarily reflects the concentration of sodium, although blood urea nitrogen (BUN) and glucose also play a major role in determining serum osmolality. Urine osmolality is determined by urea, creatinine, and uric acid. When measured with serum osmolality, urine osmolality is the most reliable indicator of urine concentration. In healthy adults, normal serum osmolality is 275 to 290 mOsm/kg (Emmett & Palmer, 2018a). The value of osmolarity is usually within 10 mOsm of the value of osmolality (Emmett & Palmer, 2018a). Factors that increase and decrease serum and urine osmolality are identified in Table 10-3. Serum osmolality may be measured directly through laboratory tests or estimated at the bedside by doubling the serum sodium level or by using the following formula:

$$Na^{+} \times 2 = \frac{\text{Glucose}}{18} + \frac{\text{BUN}}{3} = \text{Approximate value of serum osmolality}$$

Urine specific gravity measures the density of urine compared to water. It is a measure of the concentration of solutes in the urine. It is one way to assess the kidneys' ability to excrete or conserve water. The specific gravity of urine is compared to that of distilled water, which has a specific gravity of 1.000. The normal range of urine specific gravity is 1.005 to 1.030 (Van Leeuwen & Bladh, 2017). Urine with a specific gravity of 1.005 is very dilute or high in water content, whereas urine with a specific gravity of 1.030 is very concentrated or low in water content. Under normal conditions, a well-hydrated person excretes urine with a low specific gravity, whereas a dehydrated person excretes urine with high specific gravity. Urine specific gravity can be measured by sending approximately 20 mL of urine to the laboratory for urinalysis testing or assessed using a urine dipstick test. Specific gravity is a less reliable indicator of urine concentration than urine osmolality; increased glucose or protein in urine can cause a falsely elevated specific

gravity. Factors that increase or decrease urine osmolality are the same as those for urine specific gravity (Sterns, 2017a).

TABLE 10-3 Factors Affecting Serum and Urine Osmolality

Fluid	Factors Increasing Osmolality	Factors Decreasing Osmolality
Serum (275–290 mOsm/kg water)	Severe dehydration Free water loss Diabetes insipidus Hypernatremia Hyperglycemia Stroke or head injury Acute tubular necrosis Consumption of methanol or ethylene glycol (antifreeze) High ion gap metabolic acidosis Mannitol therapy Advanced liver disease Alcoholism Burns	Fluid volume excess Syndrome of inappropriate antidiuretic hormone (SIADH) Acute kidney injury Diuretic use Adrenal insufficiency Hyponatremia Overhydration Paraneoplastic syndrome associated with lung cancer
Urine (200–800 mOsm/kg water)	Fluid volume deficit SIADH Congestive heart failure Acidosis Prerenal kidney injury	Fluid volume excess Diabetes insipidus Hyponatremia Aldosteronism Pyelonephritis Acute tubular necrosis

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer.

BUN is a laboratory value that measures the amount of urea in the bloodstream. The normal range of BUN is 10 to 20 mg/dL (3.6 to 7.2 mmol/L). BUN level can vary with renal function, amount of cellular breakdown, protein intake, and hydration status. If urine output decreases, as occurs in renal dysfunction, then urea is not excreted and accumulates in the bloodstream causing an increase. Increased BUN can also occur if water content in the bloodstream decreases due to dehydration. If a person is consuming a high protein diet, there is an increased amino acid content in the bloodstream, which in turn increases nitrogen content of the blood, thereby increasing BUN (Inker & Perrone, 2018).

Additional factors that increase BUN include GI bleeding, fever, and sepsis. Factors that decrease BUN include end-stage liver disease, a low protein diet, starvation (due to low protein), and any condition that results in expanded fluid volume which dilutes urea in the blood (e.g., pregnancy). Because of all these variables, BUN is not an optimal gauge of kidney function (Inker & Perrone, 2018).

Creatinine is a breakdown product of muscle metabolism that is almost totally cleared from the bloodstream and excreted by the kidney. It is a better indicator of renal function than BUN because it does not vary with protein intake or hydration status. The normal serum creatinine is approximately 0.7 to 1.4 mg/dL (62 to 124 mmol/L); however, its concentration depends on lean body mass and varies from person to person. Serum creatinine levels increase when renal function decreases in most people and is an accurate gauge of kidney function (Norris, 2019).

Hematocrit measures the percentage of red blood cells (RBCs) (erythrocytes) in a volume of whole blood and normally ranges from 42% to 52% in men and 35% to 47% in women. Conditions that increase the hematocrit value are dehydration and polycythemia. Dehydration causes decreased water content of the blood which concentrates the RBCs in the bloodstream. Polycythemia is a disorder in which there is an abnormally high number of RBCs made by the bone marrow, which in turn increases the number of RBCs in the bloodstream. Conversely, over hydration (which increases the volume of water within the bloodstream) will decrease the hematocrit. Anemia (which is a lack of sufficient production of RBCs by the bone marrow) causes decreased hematocrit (Schrier, 2018).

Urine sodium values change with sodium intake and the status of fluid volume: As sodium intake increases, excretion increases; as the circulating fluid volume decreases, sodium is conserved. Normal urine sodium levels range from 75 to 200 mEq/24 h (75 to 200 mmol/24 h). A random specimen usually contains more than 40 mEq/L of sodium. Urine sodium levels are used to assess volume status and are useful in the diagnosis of hyponatremia and acute kidney injury (Sterns, 2017a).

Homeostatic Mechanisms

The body is equipped with remarkable homeostatic mechanisms to keep the composition and volume of body fluid within narrow limits of normal. Organs involved in homeostasis include the kidneys, heart, lungs, pituitary gland, adrenal glands, and parathyroid glands (Norris, 2019).

Kidney Functions

Vital to the regulation of fluid and electrolyte balance, the kidneys normally filter 180 L of plasma every day in the adult and excrete 1 to 2 L of urine (Inker & Perrone, 2018). They act both autonomously and in response to hormones, such as aldosterone and antidiuretic hormone (ADH) (Norris, 2019). Major functions of the kidneys in maintaining normal fluid balance include the following:

- Regulation of ECF volume and osmolality by selective retention and excretion of body fluids

- Regulation of normal electrolyte levels in the ECF by selective electrolyte retention and excretion of hydrogen ions
- Regulation of pH of the ECF by retention and excretion of hydrogen ions
- Excretion of metabolic wastes and toxic substances (Inker & Perrone, 2018)

Given these functions, failure of the kidneys results in multiple fluid and electrolyte abnormalities.

Heart and Blood Vessel Functions

The pumping action of the heart circulates blood through the kidneys under sufficient pressure to allow for urine formation. Failure of this pumping action interferes with renal perfusion and thus with water and electrolyte regulation.

Lung Functions

The lungs are also vital in maintaining homeostasis. Through exhalation, the lungs remove approximately 300 mL of water daily in the normal adult as insensible water loss (Sterns, 2017a). Abnormal conditions, such as hyperventilation (abnormally deep respiration) or continuous coughing, increase this water loss. The lungs also play a major role in acid–base balance. Because the lungs regulate carbon dioxide (CO_2), which directly influences acid content of the bloodstream, they influence acid–base balance. When the lungs have a decrease in breathing rate, CO_2 is retained in the alveoli and bloodstream, which increases acid content of the blood. When the lungs have an increase in breathing rate, CO_2 is blown off, lost from the bloodstream, which decreases acid content of the blood (Norris, 2019).

Pituitary Functions

The hypothalamus manufactures ADH, which is stored in the posterior pituitary gland and released as needed to conserve water. ADH is secreted by the pituitary gland in reaction to dehydration or blood loss and acts at the nephrons. At the collecting duct of the nephron, ADH causes increased reabsorption of water from the tubules into the bloodstream (Norris, 2019). This increases the water content of the bloodstream (Fig. 10-5).

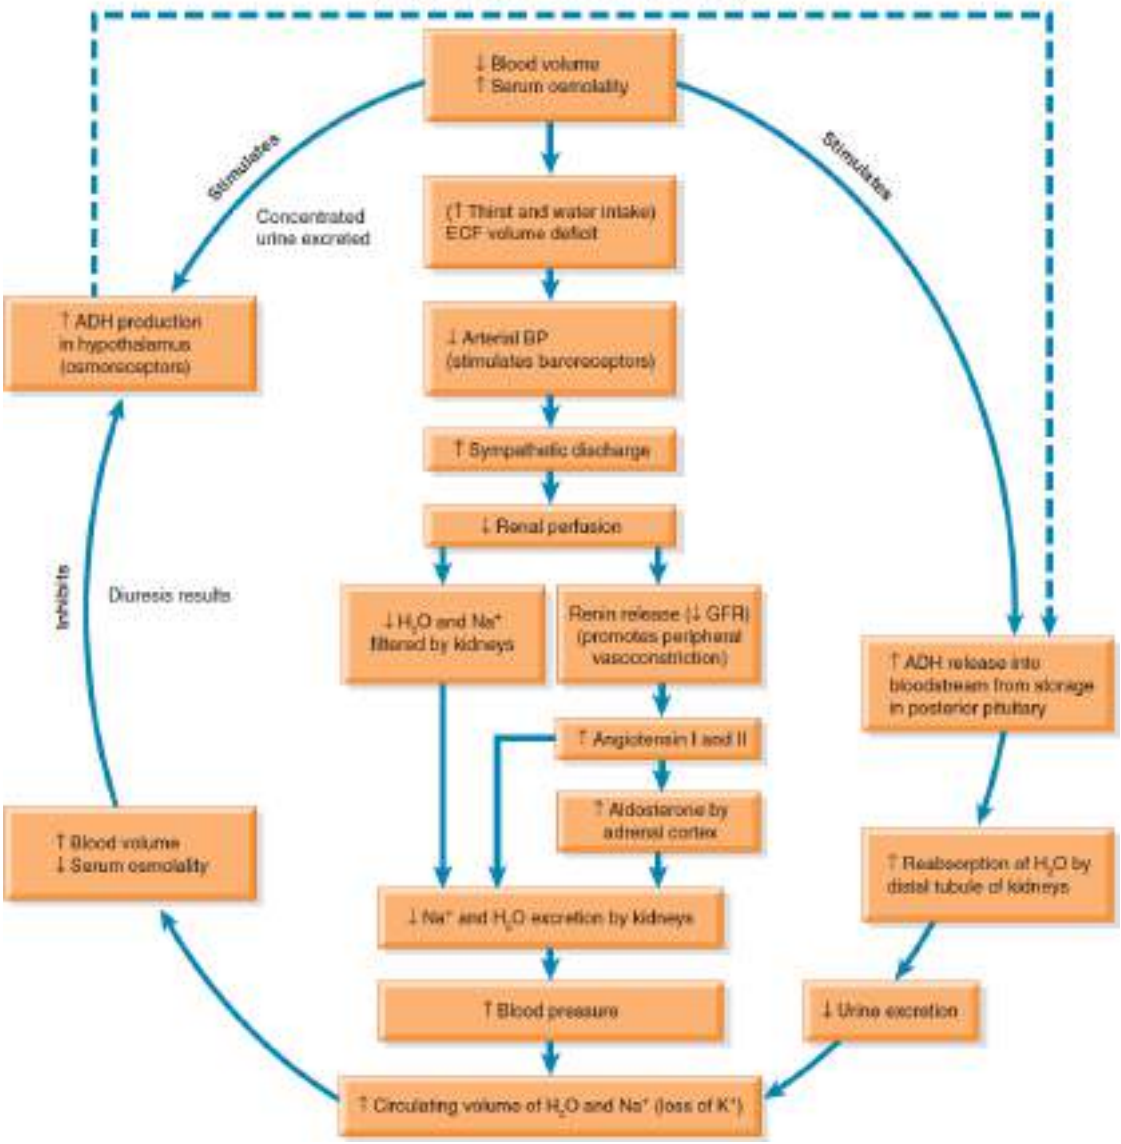

Figure 10-5 • Fluid regulation cycle. ADH, antidiuretic hormone; BP, blood pressure; ECF, extracellular fluid; GFR, glomerular filtration rate.

Adrenal Functions

Aldosterone, a mineralocorticoid secreted by the zona glomerulosa (outer zone) of the adrenal cortex, has a profound effect on fluid balance. Increased secretion of aldosterone causes sodium retention (and thus water retention) and potassium loss. Conversely, decreased secretion of aldosterone causes sodium and water loss and potassium retention.

Cortisol, another adrenocortical hormone, has less mineralocorticoid action. However, when secreted in large quantities (or administered as corticosteroid therapy), it can also produce sodium and fluid retention (Norris, 2019).

Parathyroid Functions

The parathyroid glands, embedded in the thyroid gland, regulate calcium and phosphate balance by means of parathyroid hormone (PTH). PTH influences reabsorption of calcium from the bones into the bloodstream, calcium absorption from the intestine, and calcium reabsorption into the bloodstream from the renal tubules (Norris, 2019).

Baroreceptors

The baroreceptors are located in the left atrium and the carotid and aortic arches. These receptors respond to changes in the circulating blood volume and regulate sympathetic and parasympathetic neural activity as well as endocrine activities.

As arterial pressure decreases, baroreceptors transmit fewer impulses from the carotid and the aortic arches to the vasomotor center. A decrease in impulses stimulates the sympathetic nervous system, which stimulates the sinoatrial (SA) node in the heart. The outcome is an increase in heart rate, conduction, and contractility and an increase in blood pressure. Sympathetic stimulation constricts renal arterioles, which in turn triggers renin release and stimulation of the renin–angiotensin–aldosterone system (see next section for further discussion) (Hall, 2016).

Renin–Angiotensin–Aldosterone System

When the kidneys sense low perfusion or diminished blood pressure, they secrete renin from the juxtaglomerular apparatus, which triggers the renin–angiotensin–aldosterone system. This system is one of the body's most important compensatory mechanisms in maintaining fluid balance. Renin circulates to the liver and converts angiotensinogen, a protein synthesized by the liver, into angiotensin I. Angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II. Angiotensin II stimulates potent peripheral arterial vasoconstriction which increases arterial blood pressure. Angiotensin II also stimulates the adrenal gland to secrete aldosterone. Aldosterone increases sodium and water reabsorption at the nephron into the bloodstream. This raises blood volume and blood pressure. Aldosterone also stimulates secretion of potassium into the nephron tubules, which in turn causes potassium excretion by the kidney (Norris, 2019).

Antidiuretic Hormone and Thirst

ADH and the thirst mechanism have important roles in maintaining sodium concentration and oral intake of fluids. Oral intake is controlled by the thirst center located in the hypothalamus. As serum concentration or osmolality increases or blood volume decreases, neurons in the hypothalamus are stimulated by intracellular dehydration; thirst then occurs, and the person

increases their intake of oral fluids. When increased osmolality is sensed by the brain, the posterior pituitary is stimulated to release ADH. ADH acts at the kidney nephrons to increase water reabsorption into the bloodstream. ADH raises blood volume and decreases urine output (Hall, 2016; Norris, 2019).

Osmoreceptors

Located on the surface of the hypothalamus, osmoreceptors sense changes in sodium concentration. As osmotic pressure increases, the neurons become dehydrated and quickly release impulses to the posterior pituitary, which increases the release of ADH, which then travels in the blood to the kidneys, where it alters permeability to water, causing increased reabsorption of water and decreased urine output. The retained water dilutes the ECF and returns its concentration to normal. Restoration of normal osmotic pressure provides feedback to the osmoreceptors to inhibit further ADH release (Hall, 2016) (see Fig. 10-5).

Natriuretic Peptides

Natriuretic peptide hormones affect fluid volume and cardiovascular function through natriuresis (the excretion of sodium), direct vasodilation, and the opposition of the renin–angiotensin–aldosterone system. The most common natriuretic peptides include atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and *N*-terminal fragment of pro-brain natriuretic peptide (NT-pro BNP) (Chen & Colucci, 2017). ANP is synthesized, stored, and released by muscle cells of the atria of the heart. BNP and NT-pro BNP are released mainly by ventricular muscle cells of the heart. BNP and NT-pro BNP levels are often measured in the clinical diagnosis and management of heart failure (see Chapter 25). NT-pro BNP has a longer half-life than BNP, so its level remains elevated in the bloodstream for a longer period of time than BNP. Natriuretic peptides are also secreted in other disorders including renal failure, coronary heart disease, valvular heart disease, constrictive pericarditis, pulmonary hypertension, and sepsis. Natriuretic peptides decrease water and sodium in the circulatory system which in turn decreases blood pressure. Their action is directly opposite that of the renin–angiotensin–aldosterone system (Fig. 10-6).

There are two other natriuretic peptides that are not usually measured clinically. C-type natriuretic peptide (CNP) is distributed within the brain, ovary, uterus, testis, and epididymis. D-type natriuretic peptide (DNP) has structural similarities to ANP, BNP, and CNP.

Gerontologic Considerations

Normal physiologic changes of aging include reduced cardiac, renal, and respiratory function. Body fat changes, body water content decreases, and muscle mass decreases. These changes of aging may alter the older adult's responses to fluid and electrolyte changes and acid–base disturbances. Decreased respiratory function and renal function can cause impaired acid–base balance in older adults with major illness or trauma. Decreased renal function that occurs with age can also cause slightly elevated serum creatinine. Decreased muscle mass that occurs with aging leads to decreased daily breakdown of muscle, which reduces serum creatinine. Therefore, high–normal and minimally elevated serum creatinine values may indicate substantially reduced renal function in older adults (Cash & Glass, 2018).

In addition, the use of multiple medications by older adults can affect renal and cardiac function and body water content, thereby increasing susceptibility to fluid and electrolyte disturbances. Routine procedures, such as the vigorous administration of laxatives or enemas before colon x-ray studies, may produce a serious FVD, necessitating the use of IV fluids to prevent hypotension and other effects of hypovolemia.

Alterations in fluid and electrolyte balance that may produce minor changes in young and middle-aged adults may produce profound changes in older adults. In many older patients, the clinical manifestations of fluid and electrolyte disturbances may be subtle or atypical. For example, fluid deficit may not trigger thirst sensation and can lead to delirium in the older adult (see Chapter 8). Rapid infusion of an excessive volume of IV fluids can cause fluid overload and cardiac failure in older patients. These reactions are likely to occur more quickly and with the administration of smaller volumes of fluid than in healthy young and middle-aged adults because of the decreased cardiac reserve and reduced renal function that accompany aging (Cash & Glass, 2018).

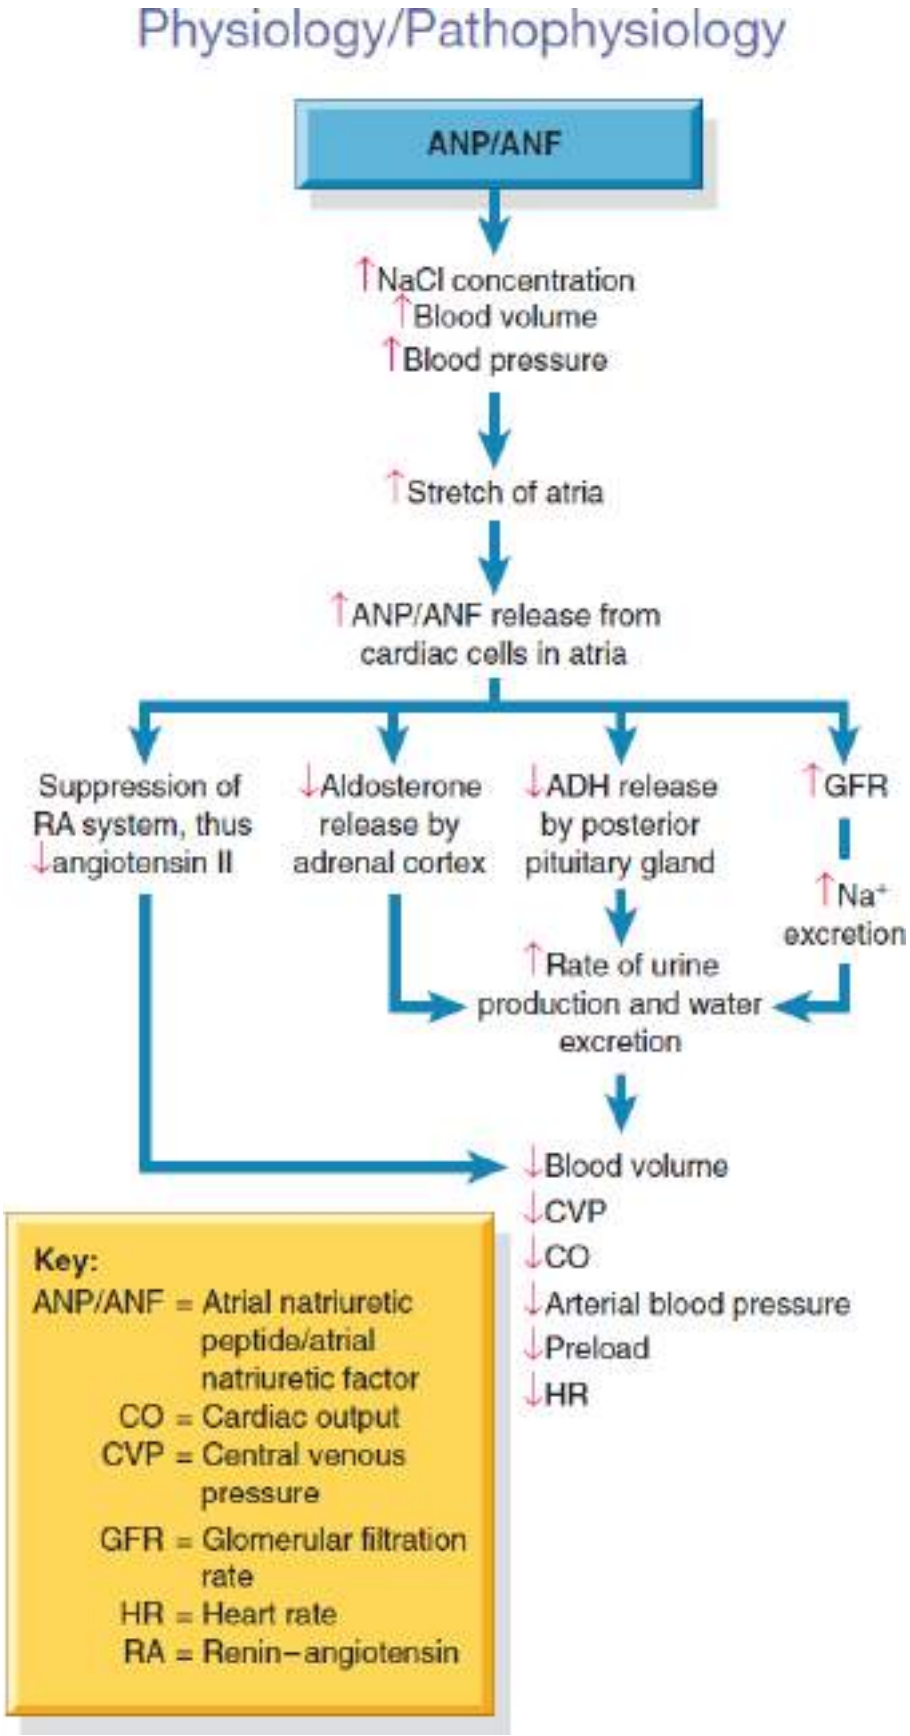

Figure 10-6 • Role of atrial natriuretic peptide in maintenance of fluid balance.

Dehydration is the rapid loss of body weight due to the loss of either water or sodium. This results in an elevated sodium concentration (Sterns, 2017c). Dehydration in older adults is common because of decreased kidney mass, decreased glomerular filtration rate, decreased renal blood flow, decreased ability to concentrate urine, inability to conserve sodium, decreased excretion of potassium, and a decrease of total-body water. Loss of subcutaneous tissue and resultant thinning of the skin occurs with aging; the dermis is dehydrated and loses strength and elasticity.

FLUID VOLUME DISTURBANCES

Hypovolemia

FVD, or hypovolemia, occurs when loss of ECF volume exceeds the intake of fluid. It occurs when water and electrolytes are lost in the same proportion as they exist in normal body fluids; thus, the ratio of serum electrolytes to water remains the same. FVD should not be confused with dehydration, which refers to loss of water alone, with increased serum sodium levels. FVD may occur alone or in combination with other imbalances. Serum electrolyte concentrations can remain normal, increase, or increase in FVD (Sterns, 2017a).

Pathophysiology

FVD results from loss of body fluids and occurs more rapidly when coupled with decreased fluid intake. FVD can also develop with a prolonged period of inadequate intake. Causes of FVD include abnormal fluid losses, such as those resulting from vomiting, diarrhea, GI suctioning, and sweating; decreased intake, as in nausea or lack of access to fluids; and third-space fluid shifts, or the movement of fluid from the vascular system to other body spaces (e.g., with edema formation in burns, ascites with liver dysfunction). Additional causes include diabetes insipidus (a decreased ability to concentrate urine due to either a deficit of ADH or nephron resistance to ADH), adrenal insufficiency, osmotic diuresis, hemorrhage, and coma (Sterns, 2017a).

Clinical Manifestations

FVD can develop rapidly, and its severity depends on the degree of fluid loss. Clinical signs and symptoms and laboratory findings are presented in Table 10-4.

Assessment and Diagnostic Findings

Laboratory data used to evaluate fluid volume status include BUN and its relation to serum creatinine concentration. Normal BUN to serum creatinine concentration ratio is 10:1. A volume-depleted patient has a BUN elevated out of proportion to the serum creatinine (ratio greater than 20:1) because urea becomes concentrated in FVD (Sterns, 2017a).

The presence and cause of hypovolemia may be determined through the health history and physical examination. In addition, the hematocrit level is greater than normal because there is a decreased plasma volume, which concentrates the volume of RBCs.

Serum electrolyte changes may also exist. Potassium and sodium levels can be reduced (hypokalemia, hyponatremia) or elevated (hyperkalemia, hypernatremia).

- Hypokalemia can occur with GI and renal losses as these organs are major regulators of potassium.
- Hyperkalemia can occur with adrenal insufficiency due to aldosterone deficiency which causes lack of potassium excretion.
- Hyponatremia can occur with increased thirst and ADH release, which increases water content of the bloodstream.
- Hypernatremia can result from increased insensible water losses and diabetes insipidus.

TABLE 10-4 Fluid Volume Disturbances

Imbalance	Contributing Factors	Signs/Symptoms and Laboratory Findings
Fluid volume deficit (hypovolemia)	Loss of water and electrolytes, as in vomiting, diarrhea, fistulas, fever, excess sweating, burns, blood loss, gastrointestinal suction, and third-space fluid shifts; and decreased intake, as in anorexia, nausea, and inability to gain access to fluid. Diabetes insipidus and uncontrolled diabetes both contribute to a depletion of extracellular fluid volume.	Acute weight loss, ↓ skin turgor, oliguria, concentrated urine, capillary filling time prolonged, low CVP, ↓ BP, flattened neck veins, dizziness, weakness, thirst and confusion, ↑ pulse, muscle cramps, sunken eyes, nausea, increased temperature; cool, clammy, pale skin *Labs indicate:* ↑ hemoglobin and hematocrit, ↑ serum and urine osmolality and specific gravity, ↓ urine sodium, ↑ BUN and creatinine, ↑ urine specific gravity and osmolality
Fluid volume excess (hypervolemia)	Compromised regulatory mechanisms, such as kidney injury, heart failure, and cirrhosis; overzealous administration of sodium-containing fluids; and fluid shifts (i.e., treatment of burns). Prolonged corticosteroid therapy, severe stress, and hyperaldosteronism augment fluid volume excess.	Acute weight gain, peripheral edema and ascites, distended jugular veins, crackles, elevated CVP, shortness of breath, ↑ BP, bounding pulse and cough, ↑ respiratory rate, ↑ urine output *Labs indicate:* ↓ hemoglobin and hematocrit, ↓ serum and urine osmolality, ↓ urine sodium and specific gravity

BP, blood pressure; BUN, blood urea nitrogen; CVP, central venous pressure; ↓, decreased; ↑, increased.

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Oliguria, the excretion of less than 400 mL urine per day in the adult, may or may not be present in hypovolemia. Urine specific gravity will change in relation to the kidneys' attempt to conserve water. If the kidney does not reabsorb water, urine contains more water, and urine specific gravity is low. If the kidney does reabsorb water, urine will be concentrated and specific gravity increases. Due to lack of ADH in diabetes insipidus, urine water content increases, which decreases urine specific gravity. Aldosterone is secreted when fluid volume is low, causing reabsorption of sodium and chloride and resulting in decreased urinary sodium and chloride. When the kidneys conserve water, urine osmolality can increase to greater than 450 mOsm/kg and urine specific gravity increases (Sterns, 2017a). Normal values for laboratory data are listed in Appendix A on thePoint.

Gerontologic Considerations

Increased sensitivity to fluid and electrolyte changes in older patients requires careful physical assessment, measurement of I&O of fluids from all sources, assessment of daily weight, careful monitoring of side effects and interactions of medications, and prompt reporting and management of disturbances. In most adult patients, it is useful to monitor skin turgor to detect subtle changes. However, assessment of skin turgor is not as valid in older adults because the skin has lost elasticity; therefore, other assessment measures (e.g., slowness in filling of veins of the hands and feet) become more useful in detecting FVD (Cash & Glass, 2018; Weber & Kelley, 2018).

The nurse also performs a functional assessment of the older patient's ability to determine fluid and food needs and to obtain adequate intake in addition to assessments discussed earlier in this chapter. For example, the nurse assesses whether or not the patient is cognitively intact, able to ambulate and to use both arms and hands to reach fluids and foods, and able to swallow with an intact gag reflex. Results of this functional assessment have a direct bearing on how the patient will be able to meet their own need for fluids and foods (Weber & Kelley, 2018). During an older patient's hospital stay, the nurse provides fluids if the patient is unable to carry out self-care activities.

The nurse should also recognize that some older patients deliberately restrict their fluid intake to avoid episodes of urinary incontinence. In this situation, the nurse should identify interventions to deal with the incontinence, such as encouraging the patient to wear protective clothing or devices, to carry a urinal in the car, or to pace fluid intake to allow access to toilet facilities during the day. Older adults without cardiovascular or renal dysfunction should be reminded to drink adequate fluids, particularly in very warm or humid weather (Cash & Glass, 2018).

Medical Management

When planning the correction of fluid loss for the patient with FVD, the primary provider considers the patient's maintenance requirements and other factors (e.g., fever) that can influence fluid needs. If the deficit is not severe, the oral route is preferred, provided the patient can drink. However, if fluid losses are acute or severe, the IV route is required. Isotonic electrolyte crystalloid solutions (e.g., lactated Ringer's solution or 0.9% sodium chloride) are frequently the first-line choice to treat the hypotensive patient with FVD because they expand plasma volume. As soon as the patient becomes normotensive, a hypotonic electrolyte solution (e.g., 0.45% sodium chloride) is often used to provide both electrolytes and water for renal excretion of metabolic wastes (Sterns, 2017a; Sterns, 2017b). These and additional fluids are listed in Table 10-5.

Accurate and frequent assessments of I&O, weight, vital signs, central venous pressure, level of consciousness, breath sounds, and skin color are monitored to determine when therapy should be slowed to avoid volume overload. The rate of fluid administration is based on the severity of loss and the patient's hemodynamic response to volume replacement (Sterns, 2017a; Sterns, 2017b).

If the patient with severe FVD is not excreting enough urine and is therefore oliguric, the primary provider needs to determine whether the depressed renal function is caused by reduced renal blood flow secondary to FVD (prerenal azotemia) or, more seriously, by acute tubular necrosis (intrarenal azotemia) from prolonged FVD (Norris, 2019). The test used in this situation is referred to as a fluid challenge test. During a fluid challenge test, volumes of fluid are given at specific rates and intervals while the patient's hemodynamic response to this treatment is monitored (i.e., vital signs, breath sounds, orientation status, central venous pressure, urine output) (Sterns, 2017b).

TABLE 10-5 Select Water and Electrolyte Solutions

Solution	Considerations
Isotonic Solutions	
0.9% NaCl (isotonic, also called *normal saline* [NS]) Na^+ 154 mEq/L Cl^- 154 mEq/L (308 mOsm/L) Also available with varying concentrations of dextrose (a 5% dextrose concentration is commonly used)	• An isotonic solution that expands the extracellular fluid (ECF) volume; used in hypovolemic states, resuscitative efforts, shock, diabetic ketoacidosis, metabolic alkalosis, hypercalcemia, mild Na^+ deficit • Supplies an excess of Na^+ and Cl^-; can cause fluid volume excess and hyperchloremic acidosis if used in excessive volumes, particularly in patients with compromised renal function, heart failure, or edema • When mixed with 5% dextrose, the resulting solution becomes temporarily hypertonic in relation to plasma and, in addition to the previously described electrolytes, provides 170 cal/L. After dextrose is metabolized it leaves an isotonic solution. • Only solution that may be given with blood products • Tonicity similar to plasma
Lactated Ringer's solution Na^+ 130 mEq/L K^+ 4 mEq/L Ca^{++} 3 mEq/L Cl^- 109 mEq/L Lactate (metabolized to bicarbonate) 28 mEq/L (274 mOsm/L) Also available with varying concentrations of dextrose (the most common is 5% dextrose)	• An isotonic solution that contains multiple electrolytes in roughly the same concentration as found in plasma (note that solution is lacking in Mg^{++}); provides 9 cal/L • Used in the treatment of hypovolemia, burns, fluid lost as bile or diarrhea, and for acute blood loss replacement • Lactate is rapidly metabolized into HCO_3^- in the body. Lactated Ringer's solution should not be used in lactic acidosis because the ability to convert lactate into HCO_3^- is impaired in this disorder • Not to be given with a pH >7.5 because bicarbonate is formed as lactate breaks down, causing alkalosis • Should not be used in kidney injury because it contains potassium and can cause hyperkalemia • Tonicity similar to plasma
5% dextrose in water (D_5W) No electrolytes 50 g of dextrose	• An isotonic solution that supplies 170 cal/L and free water to aid in renal excretion of solutes • Used in treatment of hypernatremia, fluid loss, and dehydration • Should not be used in excessive volumes in the early postoperative period (when antidiuretic hormone secretion is increased due to stress reaction) • Should not be used solely in treatment of fluid volume deficit because it dilutes plasma electrolyte concentrations • Contraindicated in head injury because it may cause increased intracranial pressure

	• Should not be used for fluid resuscitation because it can cause hyperglycemia • Should be used with caution in patients with renal or cardiac disease because of risk of fluid overload • Electrolyte-free solutions may cause peripheral circulatory collapse, anuria in patients with sodium deficiency, and increased body fluid loss • Converts to hypotonic solution as dextrose is metabolized by body. Over time, D_5W without NaCl can cause water intoxication (intracellular fluid volume excess [FVE]) because the solution is hypotonic • Fluid therapy for an extended period of time without electrolytes may result in hypokalemia
Hypotonic Solutions 0.45% NaCl (half-strength saline) Na^+ 77 mEq/L Cl^- 77 mEq/L (154 mOsm/L) Also available with varying concentrations of dextrose (the most common is a 5% concentration)	• Provides Na^+, Cl^-, and free water • Free water is desirable to aid the kidneys in elimination of solute • Lacking in electrolytes other than Na^+ and Cl^- • When mixed with 5% dextrose, the solution becomes slightly hypertonic to plasma temporarily until dextrose is metabolized. It leaves a hypotonic solution after dextrose metabolism. Provides 170 cal/L • Used to treat hypertonic dehydration, Na^+ and Cl^- depletion, and gastric fluid loss • Not indicated for third-space fluid shifts or increased intracranial pressure • Administer cautiously, because hypotonic solution can cause fluid shifts from vascular system into cells, resulting in cardiovascular collapse and increased intracranial pressure
Hypertonic Solutions 3% NaCl (hypertonic saline) Na^+ 513 mEq/L Cl^- 513 mEq/L (1026 mOsm/L) 5% NaCL (hypertonic solution) Na^+ 855 mEq/L Cl^- 855 mEq/L (1710 mOsm/L) IV Mannitol 5–25% (hypertonic solution) (1372 mOsm/L contained in 25% solution)	• Used to increase ECF volume, decrease cellular swelling • Highly hypertonic solution used only in critical situations to treat hyponatremia • Must be given slowly and cautiously, because it can cause intravascular volume overload and pulmonary edema • Assists in removing intracellular fluid excess • Highly hypertonic solution used to treat symptomatic hyponatremia • Administer slowly and cautiously because it can cause intravascular volume overload and pulmonary edema • Supplies no calories

Colloid Solutions	
Dextran in NS or D_5W Available in low-molecular-weight (Dextran 40) and high-molecular-weight (Dextran 70) forms	• Colloid solution used as volume/plasma expander for intravascular part of ECF • Affects clotting by coating platelets and decreasing ability to clot • Remains in circulatory system up to 24 h • Used to treat hypovolemia in early shock to increase pulse pressure, cardiac output, and arterial blood pressure • Improves microcirculation by decreasing red blood cell aggregation • Contraindicated in hemorrhage, thrombocytopenia, renal disease, and severe dehydration • Not a substitute for blood or blood products

An example of a typical fluid challenge test involves administering 100 to 200 mL of normal saline solution over 15 minutes. The goal is to provide fluids rapidly enough to attain adequate tissue perfusion without compromising the cardiovascular system. The response by a patient with FVD but normal renal function is increased urine output and an increase in blood pressure and central venous pressure.

Shock can occur when the volume of fluid lost exceeds 25% of the intravascular volume or when fluid loss is rapid (Mandel & Palevsky, 2019). (Shock and its causes and treatment are discussed in detail in Chapter 11.)

Nursing Management

To assess for FVD, the nurse monitors and measures fluid I&O at least every 8 hours, and sometimes hourly. Maintaining an accurate I&O is a particular challenge with patients in critical-care settings. As FVD develops, body fluid losses exceed fluid intake through excessive urination (polyuria), diarrhea, vomiting, or other mechanisms. Once FVD has developed, the kidneys attempt to conserve body fluids, leading to a urine output of less than 1 mL/kg/h in an adult. Urine in this instance is concentrated and represents a healthy renal response.

Vital signs should be closely monitored in FVD.

Quality and Safety Nursing Alert

The nurse observes for a weak, rapid pulse and orthostatic hypotension (i.e., a decrease in systolic pressure exceeding 20 mm Hg when the patient moves from a lying to a sitting position).

A decrease in body temperature often accompanies FVD, unless there is a concurrent infection.

Skin and tongue turgor are monitored on a regular basis. In a healthy person, pinched skin immediately returns to its normal position when released (Weber & Kelley, 2018). This elastic property, referred to as turgor, is partially dependent on interstitial fluid volume. In a person with FVD, the skin flattens more slowly after the pinch is released. In a person with severe FVD, the skin may remain elevated for many seconds. Tissue turgor is best measured by pinching the skin over the sternum, dorsal surface of the hand, inner aspects of the thighs, or forehead. It is important to recognize skin turgor is normally diminished in old age. Tongue turgor is not affected by age, and evaluating this may be more valid than evaluating skin turgor (Sterns, 2017a). In a normal person, the tongue has one longitudinal furrow. In the person with FVD, there are additional longitudinal furrows and the tongue is smaller because of fluid loss. The degree of oral mucous membrane moisture is also assessed; a dry mouth may indicate either FVD or mouth breathing.

Quality and Safety Nursing Alert

It is useful to monitor daily body weight when monitoring fluid volume; an acute loss of 0.5 kg (1.1 lb) represents a fluid loss of approximately 500 mL. One liter (1000 mL) of fluid weighs approximately 1 kg, or 2.2 lb. A weight loss or gain of 1–2 lb/day is mainly due to water loss or gain.

Urine concentration is monitored by measuring the urine specific gravity. In a volume-depleted patient, the urine specific gravity should be greater than 1.020, indicating healthy renal conservation of fluid. Dark amber-colored urine is highly concentrated; whereas, clear yellow urine indicates a dilute urine.

Mental function is eventually affected, resulting in confusion, lack of cognition, and delirium in severe FVD as a result of decreasing cerebral perfusion. Behavioral changes are particularly evident in older adults with FVD. Decreased peripheral perfusion can result in cold extremities. In patients with relatively normal cardiopulmonary function, a low central venous pressure is indicative of hypovolemia (Sterns, 2017a). Patients with acute cardiopulmonary decompensation require more extensive hemodynamic monitoring of pressures in both sides of the heart to determine whether hypovolemia exists. Hemodynamic monitoring is particularly important in critically ill patients (Mandel & Palevsky, 2019) (see Chapters 11 and 21).

Preventing Hypovolemia

To prevent FVD, the nurse identifies patients at risk and takes measures to minimize fluid losses. For example, if the patient has diarrhea, measures should be implemented to control diarrhea and replacement fluids given. This includes administering antidiarrheal medications and small volumes of oral fluids at frequent intervals.

Correcting Hypovolemia

When possible, oral fluids are given to help correct FVD, with consideration given to the patient's likes and dislikes. The type of fluid the patient has lost is also considered, and fluids most likely to replace the lost electrolytes are appropriate. If the patient is reluctant to drink because of oral discomfort, the nurse assists with frequent mouth care and provides nonirritating fluids. The patient may be offered small volumes of oral rehydration solutions (e.g., Rehydralyte, Elete, and Cytomax). These solutions provide fluid, glucose, and electrolytes in concentrations that are easily absorbed. If nausea is present, an antiemetic may be needed before oral fluid replacement can be tolerated (Sterns, 2017a; Sterns, 2017b).

If the deficit cannot be corrected by oral fluids, therapy may need to be initiated by an alternative route (enteral or parenteral) until adequate circulating blood volume and renal perfusion are achieved. Isotonic fluids are prescribed to increase ECF volume (Sterns, 2017b).

Hypervolemia

Fluid volume excess (FVE), or hypervolemia, refers to an expansion of the ECF caused by the abnormal retention of water and sodium in approximately the same proportions in which they normally exist in the ECF. It is most often secondary to an increase in the total-body sodium content, which, in turn, leads to an increase in total-body water. This can be referred to as an isotonic accumulation of fluids. Because there is isotonic retention of body substances, the serum sodium concentration remains essentially normal.

Pathophysiology

FVE may be related to simple fluid overload or diminished function of the homeostatic mechanisms responsible for regulating fluid balance. Contributing factors can include heart failure, kidney dysfunction, and cirrhosis of the liver. Another contributing factor is consumption of excessive amounts of table or other sodium salts. Excessive administration of sodium-containing fluids in a patient with impaired regulatory mechanisms may predispose them to a serious FVE as well (Sterns, 2018a).

Clinical Manifestations

Clinical manifestations of FVE result from expansion of the ECF and may include edema, distended jugular veins, and crackles (abnormal lung sounds due to interstitial pulmonary fluid). In patients who are ambulatory, edema is most evident in the ankles; in patients who are supine, edema occurs over the sacrum (Weber & Kelley, 2018). Further discussion of clinical signs and symptoms and laboratory findings can be found in Table 10-4.

Assessment and Diagnostic Findings

Laboratory data useful in diagnosing FVE include BUN and hematocrit levels. In FVE, both of these values may be decreased because of plasma dilution. In chronic kidney disease, both serum osmolality and the sodium level are decreased due to excessive retention of water. The urine sodium level is increased if the kidneys are attempting to excrete excess volume. A chest x-ray may reveal pulmonary congestion in FVE. Hypervolemia occurs when aldosterone is chronically stimulated—for example, in conditions such as cirrhosis, heart failure, and nephrotic syndrome. Aldosterone increases both sodium and water reabsorption into the bloodstream from the nephron; therefore, the urine sodium level is normal in these conditions (Emmett & Palmer, 2019; Sterns, 2018a).

Medical Management

Management of FVE is directed at the causes, and if related to excessive administration of sodium-containing fluids, discontinuing the infusion may be all that is needed. Symptomatic treatment consists of administering diuretics and restricting fluids and sodium. Diuretics are medications that reduce sodium and water reabsorption at the nephron and thereby enhance water loss via the kidneys (Brater & Ellison, 2019).

Pharmacologic Therapy

Diuretics are prescribed when dietary restriction of sodium alone is insufficient to reduce edema. The choice of diuretic is based on the severity of the hypervolemic state, the degree of impairment of renal function, and the potency of the diuretic. Thiazide diuretics block sodium and water reabsorption into the bloodstream at the distal tubule of the nephron, where 5% to 10% of sodium is normally reabsorbed. This leads to a small amount of sodium and water loss via the urine. Loop diuretics, such as furosemide, bumetanide, or torsemide, can cause a greater loss of both sodium and water because they block sodium reabsorption in the ascending limb of the loop of Henle, where 20% to 30% of filtered sodium is normally reabsorbed.

Generally, thiazide diuretics, such as hydrochlorothiazide, are prescribed for mild to moderate hypervolemia and loop diuretics for severe hypervolemia (Brater & Ellison, 2019).

Electrolyte imbalances may result from side effects of diuretics. Hypokalemia can occur with all diuretics except those that inhibit aldosterone. Potassium supplements can be prescribed with diuretics to avoid this complication. Hyperkalemia can occur with diuretics that inhibit aldosterone (e.g., spironolactone, a potassium-sparing diuretic), especially in patients with decreased renal function. Hyponatremia occurs with diuresis due to increased release of ADH secondary to reduction in circulating volume. Decreased magnesium levels occur with administration of loop and thiazide diuretics due to decreased reabsorption and increased excretion of magnesium by the kidney (Brater & Ellison, 2019; Vallerand & Sanoski, 2019).

Azotemia (increased nitrogen levels in the blood) can occur with FVE when urea and creatinine are not excreted due to decreased perfusion by the kidneys and decreased excretion of waste, as occurs in renal failure. High uric acid levels (hyperuricemia) can also occur from increased reabsorption and decreased excretion of uric acid by the kidneys.

Dialysis

If renal function is so severely impaired that pharmacologic agents cannot act efficiently, other modalities are considered to remove sodium and fluid from the body. Hemodialysis or peritoneal dialysis may be used to remove nitrogenous wastes and control potassium and acid–base balance, and to remove sodium and fluid. Continuous renal replacement therapy may also be required (see Chapter 48 for a discussion of these treatment modalities).

Nutritional Therapy

Treatment of FVE usually involves dietary restriction of sodium. An average daily diet not restricted in sodium contains 6 to 15 g of salt, whereas low sodium diets can range from a mild restriction (less than 2000 mg/day) to as little as 250 mg of sodium per day, depending on the patient's needs. A mild sodium-restricted diet allows only light salting of food (about half the usual amount) in cooking and at the table, and no addition of salt to commercially prepared foods that are already seasoned. Foods high in sodium must be avoided. It is the sodium salt (sodium chloride) rather than sodium itself that contributes to edema. Therefore, patients are instructed to read food labels carefully to determine salt content (Olendzki, 2017).

Because about half of ingested sodium is in the form of seasoning, seasoning substitutes can play a major role in decreasing sodium intake. Lemon juice, onions, and garlic are excellent substitute flavorings, although some patients prefer salt substitutes. Most salt substitutes contain potassium

and must therefore be used cautiously by patients taking potassium-sparing diuretics (e.g., spironolactone, triamterene, amiloride). These substitutes should not be used in conditions associated with potassium retention, such as advanced kidney disease. Salt substitutes containing ammonium chloride can be harmful to patients with liver damage (Olendzki, 2017; Vallerand & Sanoski, 2019).

In some communities, drinking water may contain too much sodium for a sodium-restricted diet. Depending on its source, water may contain as little as 1 mg or more than 1500 mg of sodium per quart. Patients may need to use distilled water if the local water supply is very high in sodium. Bottled water can have a sodium content that ranges from 0 to 1200 mg/L; therefore, if sodium is restricted, the label must be carefully examined for sodium content before purchasing and drinking bottled water. Also, patients on sodium-restricted diets should be cautioned to avoid water softeners that add sodium to water in exchange for other ions, such as calcium. Protein intake may be increased in patients who are malnourished or who have low serum protein levels in an effort to increase capillary oncotic pressure. Increasing oncotic pressure in the bloodstream will pull fluid out of the tissues into vessels for excretion by the kidneys (Sterns, 2018a).

Nursing Management

To assess for FVE, the nurse measures I&O at regular intervals to identify excessive fluid retention. The patient is weighed daily, and rapid weight gain is noted. Breath sounds are assessed at regular intervals in at-risk patients, particularly if parenteral fluids are being given. The nurse monitors the degree of edema in the most dependent parts of the body, such as the feet and ankles in ambulatory patients and the sacral region in patients confined to bed. Pitting edema is assessed by pressing a finger into the affected part, creating a pit or indentation that is evaluated on a scale of 1+ (minimal) to 4+ (severe) (see Chapter 25, Fig. 25-2). Peripheral edema is monitored by measuring the circumference of the extremity with a tape measure marked in millimeters (Weber & Kelley, 2018).

Quality and Safety Nursing Alert

An acute weight gain of 1 kg (2.2 lb) is equivalent to a gain of approximately 1 L of fluid.

Preventing Hypervolemia

Specific interventions vary with the underlying condition and the degree of FVE. However, most patients require sodium-restricted diets in some form,

and adherence to the prescribed diet is encouraged. Patients are instructed to avoid over-the-counter (OTC) medications without first checking with a health care provider, because they may contain sodium (e.g., Alka-Seltzer). If fluid retention persists despite adherence to a prescribed diet, hidden sources of sodium, such as the water supply or use of water softeners, should be considered.

Detecting and Controlling Hypervolemia

It is important to detect FVE before the condition becomes severe. Interventions include promoting rest, restricting sodium intake, monitoring parenteral fluid therapy, and administering appropriate medications.

Regular rest periods may be beneficial, because bed rest favors diuresis of fluid. The mechanism is related to diminished venous pooling and the subsequent increase in effective circulating blood volume and renal perfusion. Sodium and fluid restriction should be instituted as indicated. Because most patients with FVE require diuretics, the patient's response to these agents is monitored. The rate of parenteral fluids and the patient's response to these fluids are also closely monitored (Frandsen & Pennington, 2018). If dyspnea or orthopnea is present, the patient is placed in a semi-Fowler position to promote lung expansion. The patient is turned and repositioned at regular intervals because edematous tissue is more prone to skin breakdown than normal tissue. Because conditions predisposing to FVE are likely to be chronic, patients are taught to monitor their response to therapy by documenting fluid I&O and body weight changes. The importance of adhering to the treatment regimen is emphasized.

Educating Patients About Edema

Because edema is a common manifestation of FVE, patients need to recognize its symptoms and understand its importance. The nurse gives special attention to edema when instructing the patient with FVE. Edema can occur as a result of increased capillary fluid pressure, decreased capillary oncotic pressure, or increased interstitial oncotic pressure, causing expansion of the interstitial fluid compartment (Hall, 2016). Edema can be localized (e.g., in the ankle, as in rheumatoid arthritis) or generalized (as in cardiac failure and kidney injury) (Sterns, 2018b). Severe generalized edema is called *anasarca.*

Edema occurs when there is a change in the capillary membrane, increasing the formation of interstitial fluid or decreasing the removal of interstitial fluid. Sodium retention is a frequent cause of the increased ECF volume. Burns and infection are examples of conditions associated with increased interstitial fluid volume. Obstruction to lymphatic outflow, a plasma albumin level less than 1.5 to 2 g/dL, or a decrease in plasma oncotic pressure contributes to increased

interstitial fluid volume. If there is decreased cardiac output as in heart failure, the kidneys sense low perfusion and secrete renin which triggers the renin–angiotensin–aldosterone system that increases sodium and water retention (Sterns, 2018b). A thorough medication history is necessary to identify any medications that could cause edema, such as nonsteroidal anti-inflammatory drugs (NSAIDs), estrogens, corticosteroids, and antihypertensive agents (Vallerand & Sanoski, 2019).

Ascites is a type of edema in which fluid accumulates in the peritoneal cavity; it results from heart failure, nephrotic syndrome, cirrhosis, and some malignant tumors. The patient commonly reports shortness of breath and a sense of pressure because of pressure on the diaphragm.

The goal of treatment is to preserve or restore the circulating intravascular fluid volume. Thus, in addition to treating the cause of the edema, other treatments may include diuretic therapy, restriction of fluids and sodium, elevation of the extremities, application of anti-embolic stockings, paracentesis (pulling fluid out of the peritoneal cavity using a needle and syringe), dialysis, and continuous renal replacement therapy in cases of kidney injury or life-threatening fluid volume overload (Sterns, 2018b).

ELECTROLYTE IMBALANCES

Disturbances in electrolyte balances are common in clinical practice and may need to be corrected based on history, physical examination findings, and laboratory values (with comparison to previous values).

Sodium Imbalances

Sodium (Na^+) is the most abundant electrolyte in the ECF; its concentration ranges from 135 to 145 mEq/L (135 to 145 mmol/L), and it is the primary determinant of ECF volume and osmolality. Sodium has a major role in controlling water distribution throughout the body, because it does not easily cross the plasma membrane and because of its abundance and high concentration in the body. Sodium is regulated by ADH, thirst, and the renin–angiotensin–aldosterone system. A loss or gain of sodium is usually accompanied by a loss or gain of water. Sodium also functions in establishing the electrochemical state necessary for muscle contraction and the transmission of nerve impulses (Hall, 2016).

The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) may be associated with sodium imbalance. When there is a decrease in the circulating plasma osmolality, blood volume, or blood pressure, ADH (also

called arginine vasopressin [AVP]) is released from the posterior pituitary. Oversecretion of ADH can cause SIADH. Patients at risk for SIADH include older adults; those who have had brain surgery or have a brain tumor, pulmonary malignancy, or acquired immune deficiency syndrome (AIDS); those on mechanical ventilation; and those taking selective serotonin reuptake inhibitors (SSRIs) (Sterns, 2017d). (SIADH is discussed in more detail in Chapter 45.)

Sodium imbalance can develop under simple or complex circumstances. The two most common sodium imbalances are sodium deficit and sodium excess (Table 10-6).

TABLE 10-6 Sodium Imbalances

Imbalance	Contributing Factors	Signs/Symptoms and Laboratory Findings
Sodium deficit (hyponatremia) Serum sodium <135 mEq/L	Loss of sodium, as in use of diuretics, loss of GI fluids, renal disease, and adrenal insufficiency. Gain of water, as in excessive administration of D_5W and water supplements for patients receiving hypotonic tube feedings; disease states associated with SIADH, such as head trauma and oat-cell lung tumor; medications associated with water retention (oxytocin and certain tranquilizers); and psychogenic polydipsia. Hyperglycemia and heart failure cause a loss of sodium.	Anorexia, nausea and vomiting, headache, lethargy, dizziness, confusion, muscle cramps and weakness, muscular twitching, seizures, papilledema, dry skin, ↑ pulse, ↓ BP, weight gain, edema *Labs indicate:* ↓ serum and urine sodium, ↓ urine specific gravity and osmolality
Sodium excess (hypernatremia) Serum sodium >145 mEq/L	Fluid deprivation in patients who cannot respond to thirst, hypertonic tube feedings without adequate water supplements, diabetes insipidus, heatstroke, hyperventilation, watery diarrhea, burns, and diaphoresis. Excess corticosteroid, sodium bicarbonate, and sodium chloride administration, and saltwater nonfatal drowning victims.	Thirst, elevated body temperature, swollen dry tongue and sticky mucous membranes, hallucinations, lethargy, restlessness, irritability, simple partial or tonic–clonic seizures, pulmonary edema, hyperreflexia, twitching, nausea, vomiting, anorexia, ↑ pulse, and ↑ BP *Labs indicate:* ↑ serum sodium, ↓ urine sodium, ↑ urine specific gravity and osmolality, ↓ CVP

BP, blood pressure; CVP, central venous pressure; ↓, decreased; D_5W, dextrose 5% in water; GI, gastrointestinal; ↑, increased; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

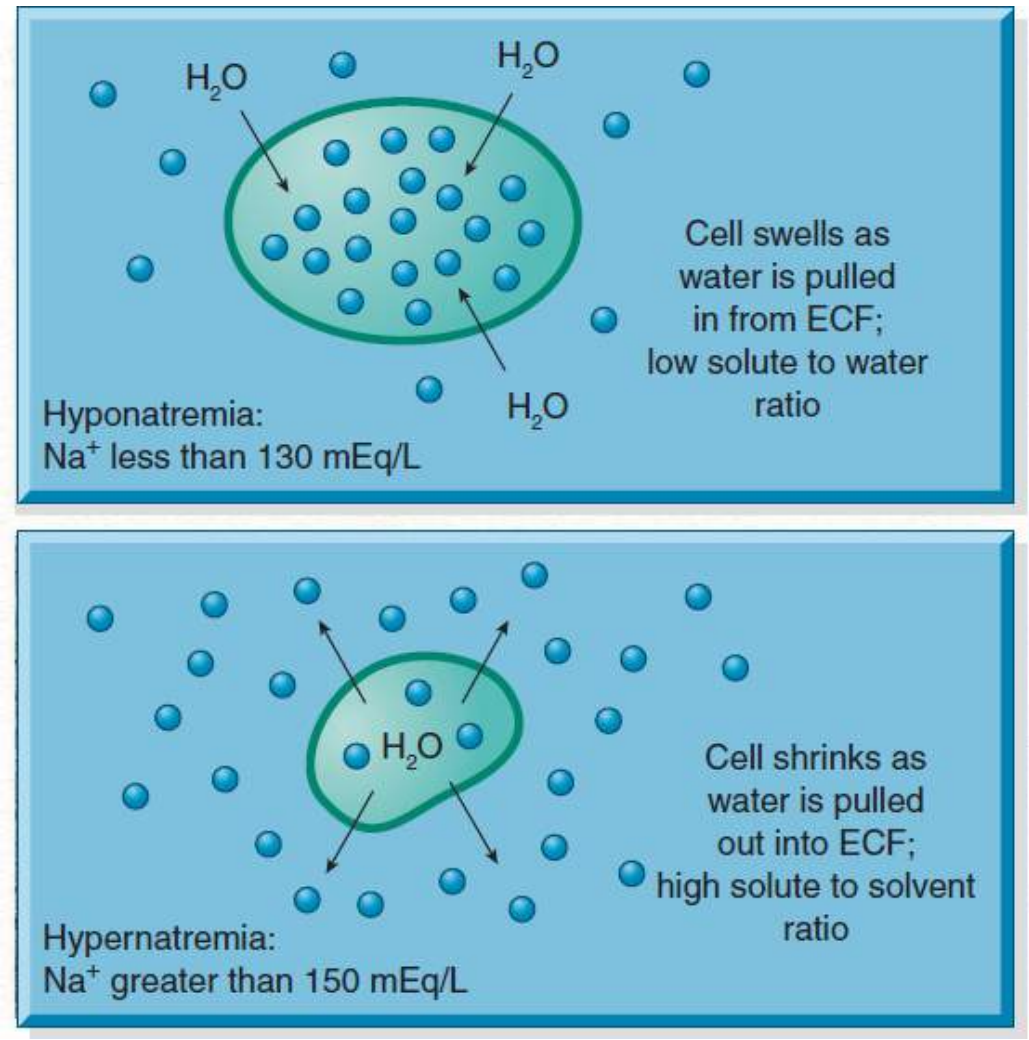

Figure 10-7 • Effect of extracellular sodium level on cell size.

Sodium Deficit (Hyponatremia)

Hyponatremia refers to a serum sodium level that is less than 135 mEq/L (135 mmol/L) (Sterns, 2017e). Hyponatremia can present as an acute or chronic form. Acute hyponatremia is commonly the result of a fluid overload in a surgical patient. This is a dilutional hyponatremia because the excess water dilutes the sodium in the bloodstream. Chronic hyponatremia is seen more frequently in patients outside the hospital setting, has a longer duration, and has less serious neurologic sequelae. Another type of hyponatremia is exercised-associated hyponatremia, which is more frequently found in women and those of smaller stature. It can occur during extreme temperatures, because of excessive fluid intake before exercise, or prolonged exercise that results in excess loss of sodium through perspiration (Apostu, 2014; McDermott, Anderson, Armstrong, et al., 2017).

Pathophysiology

Hyponatremia primarily occurs due to an imbalance of water rather than sodium. Checking the urine sodium value can assist in differentiating renal from nonrenal causes of hyponatremia. Low sodium in the urine occurs as the nephrons of the kidney retain sodium to compensate for nonrenal fluid loss (i.e., vomiting, diarrhea, sweating). High sodium concentration in the urine is associated with renal salt wasting that occurs in renal dysfunction or diuretic use. In dilutional hyponatremia, the ECF volume has excess water but there is no edema, and the excess water dilutes the sodium (Sterns, 2017e).

A deficiency of aldosterone, as occurs in adrenal insufficiency, also predisposes to sodium deficiency. Lack of aldosterone causes lack of sodium and water reabsorption into the bloodstream at the nephrons. In addition, the use of certain medications, such as anticonvulsants (e.g., carbamazepine, oxcarbazepine, levetiracetam), SSRIs (e.g., fluoxetine, sertraline, paroxetine), or desmopressin acetate, have side effects that increase the risk of hyponatremia (Liamis, Megapanou, Elisaf, et al., 2019).

Clinical Manifestations

Clinical manifestations of hyponatremia depend on the cause, magnitude, and speed with which the deficit occurs. Poor skin turgor, dry mucosa, headache, decreased saliva production, orthostatic fall in blood pressure, nausea, vomiting, and abdominal cramping can occur. Neurologic changes, including altered mental status, status epilepticus, and coma, are related to the cellular swelling and cerebral edema associated with hyponatremia. As the extracellular sodium level decreases, the cellular fluid becomes relatively more concentrated and pulls water into the cells (Fig. 10-7). In general, patients with an acute decrease in serum sodium levels have more cerebral edema and higher mortality rates than do those with more slowly developing hyponatremia. Acute decreases in sodium, developing in less than 48 hours, may be associated with cerebral edema. Cerebral edema can lead to compression of brain stem structures and brain herniation. Chronic decreases in sodium, developing over 48 hours or more, can occur in status epilepticus and other neurologic conditions (Sterns, 2017e).

Clinical features of hyponatremia associated with sodium loss and water gain include anorexia, muscle cramps, and a feeling of exhaustion. The severity of symptoms increases with the degree of hyponatremia and the speed with which it develops. When the serum sodium level decreases to less than 115 mEq/L (115 mmol/L), signs of increasing intracranial pressure, such as lethargy, confusion, muscle twitching, focal weakness, hemiparesis, papilledema, seizures, and death, may occur (Sterns, 2017e).

Assessment and Diagnostic Findings

Targeted assessment includes the history and physical examination with a focused neurologic examination; evaluation of signs and symptoms as well as laboratory test results; identification of current IV fluids, if applicable; and a review of all medications the patient is taking. Regardless of the cause of hyponatremia, the serum sodium level is less than 135 mEq/L; in SIADH, it may be lower than 100 mEq/L (100 mmol/L). Serum osmolality is usually decreased. When hyponatremia is due to lack of sodium ingestion, the urinary sodium content is less than 20 mEq/L (20 mmol/L) and the specific gravity is low (1.002 to 1.004). However, when hyponatremia is due to SIADH, the urinary sodium content is greater than 20 mEq/L, and the urine specific gravity is usually greater than 1.012. Although the patient with SIADH retains water abnormally there is no peripheral edema; instead, fluid accumulates inside the cells. This phenomenon sometimes manifests as pitting edema (Sterns, 2017d).

Medical Management

The key to treating hyponatremia is an assessment that focuses on the clinical symptoms of the patient and signs of hyponatremia (including laboratory values). As a general rule, treating the underlying condition will bring the sodium level back to normal.

Sodium Replacement

The most common treatment for hyponatremia is careful administration of sodium by mouth, nasogastric tube, or a parenteral route. For patients who can eat and drink, sodium is easily replaced, because sodium is consumed abundantly in a normal diet. For those who cannot consume sodium, lactated Ringer's solution or isotonic saline (0.9% sodium chloride) solution may be prescribed. Serum sodium must not be increased by more than 12 mEq/L in 24 hours to avoid neurologic damage due to demyelination (Jain, Phadke, Chauhan, et al., 2018). This condition may occur when the serum sodium concentration is overcorrected (exceeding 140 mEq/L) too rapidly or in the presence of hypoxia or anoxia. It may produce lesions that show symmetric myelin destruction affecting all fiber tracts that can present with altered cognition and decreased alertness, ataxia, paraparesis, dysarthria, horizontal gaze paralysis, pseudobulbar palsy, and coma. The usual daily sodium requirement in adults is approximately 100 mEq, provided there are not excessive losses (Sterns, 2020). Select water and electrolyte solutions are described in Table 10-5.

In SIADH, the administration of hypertonic saline solution alone cannot change the plasma sodium concentration. Excess sodium would be excreted rapidly in highly concentrated urine. With the addition of the diuretic furosemide, urine is not concentrated and isotonic urine is excreted to effect a change in water balance. In patients with SIADH, in whom water restriction is

difficult, lithium can antagonize the osmotic effect of ADH on the nephrons' collecting ducts (Sterns, 2017d).

Water Restriction

In patients with normal or excess fluid volume, hyponatremia is usually treated effectively by restricting fluid. However, if neurologic symptoms are severe (e.g., seizures, delirium, coma), or in patients with traumatic brain injury, it may be necessary to administer small volumes of a hypertonic sodium solution with the goal of alleviating cerebral edema. Incorrect use of these fluids is extremely dangerous, because 1 L of 3% sodium chloride solution contains 513 mEq of sodium and 1 L of 5% sodium chloride solution contains 855 mEq of sodium. The recommendation for hypertonic saline administration in patients with craniocerebral trauma is 3% saline between 0.10 and 1.0 mL/kg of body weight per hour (Sterns, 2017d).

Quality and Safety Nursing Alert

In patients with hyponatremia, highly hypertonic sodium solutions (2–23% sodium chloride) should be administered slowly. The patient needs close monitoring, because only small volumes are needed to elevate the serum sodium concentration.

Pharmacologic Therapy

AVP receptor antagonists (also called ADH receptor antagonists) are pharmacologic agents that treat hyponatremia by blocking the effect of ADH at the nephron, which in turn allows diuresis to occur and leads to water excretion. Use of IV conivaptan HCl, an AVP receptor antagonist, is limited to the treatment of hospitalized patients. It may be a useful therapy for those patients with moderate to severe symptomatic hyponatremia but is contraindicated in patients with seizures, delirium, or coma, which warrants the use of hypertonic saline. Tolvaptan is an oral medication indicated for clinically significant hypervolemic and euvolemic hyponatremia that must be initiated and monitored in the hospital setting (Frandsen & Pennington, 2018; Vallerand & Sanoski, 2019).

Nursing Management

The nurse needs to identify and monitor patients at risk for hyponatremia. The nurse monitors I&O as well as daily body weight. I&O can be used to identify excess water input or lack of sufficient water output.

The nurse needs to get a thorough history to identify if the patient is a performance athlete. Performance athletes (i.e., marathon runners) may use

salt tablets to compensate for loss of sodium with sweating, hoping to decrease sodium loss during prolonged exercise; however, there is no evidence that this practice works and it is not recommended (Hew-Butler, Loi, Pani, et al., 2017).

Hyponatremia is a frequently overlooked cause of confusion in older patients, who are at increased risk because of decreased renal function and subsequent inability to excrete excess fluids. Administration of prescribed and OTC medications that cause sodium loss or water retention is often the predisposing factor. A diminished sense of thirst or decreased ability to access food or fluids may also contribute to the problem (Cash & Glass, 2018).

Detecting and Controlling Hyponatremia

Early detection and treatment of hyponatremia are necessary to prevent serious consequences. For patients at risk, the nurse closely monitors fluid I&O as well as daily body weight. It is also necessary to monitor laboratory values (i.e., sodium) and be alert for GI manifestations such as anorexia, nausea, vomiting, and abdominal cramping. The nurse must be alert for central nervous system changes, such as lethargy, confusion, muscle twitching, and seizures. Neurologic signs are associated with very low sodium levels that have fallen rapidly because of fluid overloading. Serum sodium is monitored very closely in patients who are at risk for hyponatremia; when indicated, urine sodium and specific gravity are also monitored.

For a patient with abnormal losses of sodium who can consume a general diet, the nurse encourages foods and fluids with high sodium content to control hyponatremia. For example, broth made with one beef cube contains approximately 900 mg of sodium; 8 oz of tomato juice contains approximately 700 mg of sodium. The nurse also needs to be familiar with the sodium content of parenteral fluids (see Table 10-5).

If the primary cause of hyponatremia is water retention, it is safer to restrict fluid intake than to administer sodium. In normovolemia or hypervolemia, administration of sodium predisposes a patient to fluid volume overload. In severe hyponatremia, the aim of therapy is to elevate the serum sodium level only enough to alleviate neurologic signs and symptoms. It is generally recommended that the serum sodium concentration be increased to no greater than 125 mEq/L (125 mmol/L) with a hypertonic saline solution (Sterns, 2020).

Quality and Safety Nursing Alert

When administering fluids to patients with cardiovascular disease, the nurse assesses for hemodynamic signs of circulatory overload (e.g., cough, dyspnea, jugular venous distention, dependent edema, 1–2 lb weight gain in 24 h). The lungs should be auscultated for crackles as this can indicate pulmonary edema.

For the patient taking lithium, the nurse observes for lithium toxicity, particularly when sodium is lost. In such instances, supplemental salt and fluid are given. Because diuretics promote sodium loss, the patient taking lithium is instructed not to use diuretics without close medical supervision. For all patients on lithium therapy, normal salt and oral fluid intake (approximately 6- to 15-g sodium and 2.5- to 3.0-L fluid/day) should be encouraged and a sodium restricted diet should be avoided (Frandsen & Pennington, 2018; Vallerand & Sanoski, 2019).

Excess water supplements are avoided in patients receiving isotonic or hypotonic enteral feedings, particularly if abnormal sodium loss occurs or water is being abnormally retained (as in SIADH). Actual fluid needs are determined by evaluating fluid I&O, urine specific gravity, and serum sodium levels.

Sodium Excess (Hypernatremia)

Hypernatremia is a serum sodium level higher than 145 mEq/L (145 mmol/L). It can be caused by a gain of sodium in excess of water or by a loss of water in excess of sodium. It can occur in patients with normal fluid volume or in those with FVD or FVE. With water loss, the patient loses more water than sodium; as a result, the serum sodium concentration increases and the increased concentration pulls fluid out of the cell. This is both an extracellular and an intracellular FVD. In sodium excess, the patient ingests or retains more sodium than water (Mushin & Mount, 2018; Sterns, 2017e).

Chart 10-1

Dysnatremia

Dysnatremia is lack of normal sodium level in the bloodstream; either hypernatremia or hyponatremia. In performance athletes who lose excessive water via perspiration, sodium can become concentrated in the bloodstream causing hypernatremia. This can lead to the following life-threatening conditions:

- Encephalopathy
- Confusion
- Disorientation
- Stupor

In performance athletes who lose excess sodium via perspiration during exercise, this can lead to excess sodium depletion from the bloodstream causing hyponatremia. This can also manifest as the following:

- Confusion
- Disorientation
- Stupor

Testing of the blood and urine can differentiate hyponatremia from hypernatremia, determine the severity of the dysnatremia, and guide appropriate therapy.

A strategy for maintaining fluid and electrolyte balance in aerobic effort. *Procedia—Social and Behavioral Sciences, 117*(2014), 323—328; Hew-Butler, T., Loi, V., Pani, A., et al. (2017). Exercise-induced hyponatremia: 2017 update. *Frontiers in Medicine (Lausanne), 4*, 21.

Pathophysiology

A common cause of hypernatremia is fluid deprivation in patients who do not respond to thirst. Most often affected are patients who are very old, very young, or cognitively impaired. Administration of hypertonic enteral feedings without adequate water supplements leads to hypernatremia, as does watery diarrhea and greatly increased insensible water loss through the lungs or skin (e.g., hyperventilation, burns). In addition, diabetes insipidus, which is a lack of ADH due to posterior pituitary dysfunction, can lead to lack of adequate reabsorption of water into the bloodstream at the level of the nephron. This leads to inadequate water volume in the bloodstream which leads to hypernatremia if the patient does not respond to thirst, or if fluids are excessively restricted (Sterns, 2017c).

Less common causes of hypernatremia are heatstroke, nonfatal drowning in seawater (which contains a sodium concentration of approximately 500 mEq/L), and malfunction of hemodialysis or peritoneal dialysis systems. IV

administration of hypertonic saline or excessive use of sodium bicarbonate also causes hypernatremia. Exertional dysnatremia can occur in performance athletes (Apostu, 2014) (Chart 10-1).

Clinical Manifestations

The clinical manifestations of hypernatremia are due to increased plasma osmolality caused by an increase in plasma sodium concentration. Water moves out of the cell into the ECF, resulting in cellular dehydration (Norris, 2019) (see Fig. 10-7). Clinical signs and symptoms as well as laboratory findings can be found in Table 10-6. Dehydration (resulting in hypernatremia) is often overlooked as the cause of mental status and behavioral changes in older patients (Cash & Glass, 2018). Body temperature may increase mildly, but it returns to normal after the hypernatremia is corrected.

A primary characteristic of hypernatremia is thirst. Thirst is a strong defender of normal serum sodium levels in healthy people. Because of thirst, hypernatremia does not occur unless the person is unconscious or cannot access water. However, those who are ill and older adults may have an impaired thirst mechanism (Cash & Glass, 2018).

Assessment and Diagnostic Findings

In hypernatremia, the serum sodium level exceeds 145 mEq/L (145 mmol/L) and the serum osmolality exceeds 300 mOsm/kg (300 mmol/L). The urine specific gravity and urine osmolality are increased as the kidneys attempt to conserve water (provided the water loss is from a route other than the kidneys). Patients with diabetes insipidus do not reabsorb water into the bloodstream at the nephron. These patients consequently develop excess urine output, dehydration, and hypernatremia. Without ADH, these patients excrete very dilute urine with a urine osmolality less than 250 mOsm/kg (Emmett & Palmer, 2018a).

Medical Management

Treatment of hypernatremia consists of a gradual lowering of the serum sodium level by the infusion of a hypotonic solution (e.g., 0.45% sodium chloride) or an isotonic nonsaline solution (e.g., dextrose 5% in water [D_5W]). D_5W can be used when water needs to be replaced without sodium. However, hypotonic sodium chloride solution (0.45% NaCl) is thought to be safer than D_5W because it allows a gradual reduction in the serum sodium level. Gradual reduction in serum sodium decreases the risk of cerebral edema. Hypotonic sodium chloride solution (0.45% NaCl) is the IV solution of choice in severe hyperglycemia with hypernatremia. A rapid reduction in the serum sodium

level that occurs with D_5W temporarily decreases the plasma osmolality below that of the fluid in the brain tissue, causing dangerous cerebral edema. Alternatively in hypernatremia, diuretics can be prescribed to treat the excess sodium (Sterns & Hoorn, 2019).

There is no consensus about the exact rate at which serum sodium levels should be reduced. As a general rule, the serum sodium level is reduced at a rate no faster than 0.5 to 1 mEq/L/h to allow sufficient time for readjustment through diffusion across fluid compartments. Desmopressin acetate, a synthetic ADH, may be prescribed to treat diabetes insipidus if it is the cause of hypernatremia (Bichet, 2017; Mushin & Mount, 2018).

Nursing Management

Fluid losses and gains are carefully monitored in patients who are at risk for hypernatremia. The nurse should assess for abnormal losses of water or low water intake and for large gains of sodium, as might occur with ingestion of OTC medications that have a high sodium content (e.g., Alka-Seltzer). In addition, the nurse obtains a medication history, because some prescription medications have a high sodium content. The nurse also notes the patient's thirst or elevated body temperature and evaluates it in relation to other clinical signs and symptoms. The patient is monitored closely for changes in behavior, such as restlessness, disorientation, and lethargy (Sterns, 2017c; Sterns & Hoorn, 2019).

Preventing Hypernatremia

The nurse attempts to prevent hypernatremia by providing oral fluids at regular intervals, particularly in patients who are unable to perceive or respond to thirst. If fluid intake remains inadequate or the patient is unconscious, the nurse consults with the primary provider to plan an alternative route for intake, either by enteral feedings or by the parenteral route. If enteral feedings are used, sufficient water should be given to keep the serum sodium and BUN within normal limits. As a rule, the higher the osmolality of the enteral feeding, the greater is the need for water supplementation (Emmett & Palmer, 2018a; Sterns & Hoorn, 2019). Some herbal medications can also increase serum sodium levels.

For patients with diabetes insipidus, adequate water intake must be ensured. If the patient is alert and has an intact thirst mechanism, merely providing access to water may be sufficient. If the patient has a decreased level of consciousness or other disability interfering with adequate fluid intake, parenteral fluid replacement may be prescribed. This therapy can be anticipated in patients with neurologic disorders, particularly in the early postoperative period (Bichet, 2017).

Correcting Hypernatremia

When parenteral fluids are necessary for managing hypernatremia, the nurse monitors the patient's response to the infusion of fluids by reviewing serial serum sodium levels and by observing for changes in neurologic status, such as confusion, disorientation, and possible decreased level of consciousness (Mushin & Mount, 2018). With a gradual decrease in the serum sodium level, neurologic status should improve. However, too rapid reduction in the serum sodium level renders the plasma temporarily hypoosmotic compared to the intracellular fluid within the brain cells. This can cause fluid in the plasma to shift into the brain cells which can produce the dangerous state of cerebral edema (Hutto & French, 2017).

Potassium Imbalances

Potassium (K^+) is the major intracellular electrolyte; in fact, 98% of the body's potassium is inside the cells. The remaining 2% is in the ECF and is important to neuromuscular and cardiac function. Potassium influences both skeletal and cardiac muscle activity. For example, alterations in K^+ concentration can change myocardial irritability and rhythm. Under the influence of the sodium–potassium pump, potassium is constantly being pumped into the cells. The normal serum potassium concentration ranges from 3.5 to 5 mEq/L (3.5 to 5 mmol/L), and even minor variations are significant (Norris, 2019). Potassium imbalances are commonly associated with various diseases, injuries, medications (e.g., NSAIDs and ACE inhibitors), and acid–base imbalances (Mount, 2017a). The two types of potassium imbalances are potassium deficit and potassium excess (Table 10-7).

TABLE 10-7 Potassium Imbalances

Imbalance	Contributing Factors	Signs/Symptoms
Potassium deficit (hypokalemia) Serum potassium <3.5 mEq/L	Diarrhea, vomiting, gastric suction, corticosteroid administration, hyperaldosteronism, carbenicillin, amphotericin B, bulimia, osmotic diuresis, alkalosis, starvation, diuretics, and digoxin toxicity	Fatigue, anorexia, nausea and vomiting, muscle weakness, polyuria, decreased bowel motility, ventricular asystole or fibrillation, paresthesias, leg cramps, ↓ BP, ileus, abdominal distention, hypoactive reflexes. *ECG:* flattened T waves, prominent U waves, ST depression, prolonged PR interval
Potassium excess (hyperkalemia) Serum potassium >5.0 mEq/L	Pseudohyperkalemia, oliguric kidney injury, use of potassium-conserving diuretics in patients with renal insufficiency, metabolic acidosis, Addison disease, crush injury, burns, stored bank blood transfusions, rapid IV administration of potassium, and certain medications such as ACE inhibitors, NSAIDs, cyclosporine	Muscle weakness, tachycardia → bradycardia, arrhythmias, flaccid paralysis, paresthesias, intestinal colic, cramps, abdominal distention, irritability, anxiety. *ECG:* tall tented T waves, prolonged PR interval and QRS duration, absent P waves, ST depression

ACE, angiotensin-converting enzyme; BP, blood pressure; ↓, decreased; ECG, electrocardiogram; →, followed by; IV, intravenous; NSAIDs, nonsteroidal anti-inflammatory drugs.

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health state* (10th ed.). Philadelphia, PA: Wolters Kluwer.

To maintain potassium balance, the renal system must function, because 80% of the potassium excreted daily leaves the body by way of the kidneys; the other 20% is lost through the bowel and in sweat. The kidneys regulate potassium balance by adjusting the amount of potassium that is excreted in the urine. As serum potassium levels increase, so does the potassium level in the renal tubular cell. A concentration gradient occurs, favoring the movement of potassium into the renal tubule and excretion of potassium in the urine. Aldosterone also increases the excretion of potassium by the kidney. Because the kidneys do not conserve potassium as well as they conserve sodium, potassium may still be lost in urine in the presence of a potassium deficit (Norris, 2019).

Potassium Deficit (Hypokalemia)

Hypokalemia (serum potassium level below 3.5 mEq/L [3.5 mmol/L]) usually indicates a deficit in total potassium stores. However, it may occur in patients

with normal potassium stores: When **alkalosis** (high blood pH) is present, a temporary shift of serum potassium into the cells occurs (see later discussion).

Pathophysiology

Potassium-losing diuretics, such as the thiazides and loop diuretics, can induce hypokalemia. Other medications that can lead to hypokalemia include corticosteroids, sodium penicillin, and amphotericin B (Vallerand & Sanoski, 2019). GI loss of potassium is another common cause of potassium depletion. Vomiting and gastric suction frequently lead to hypokalemia, because potassium is lost when gastric fluid is lost and because potassium is lost through the kidneys in response to metabolic alkalosis. Because relatively large amounts of potassium are contained in intestinal fluids, potassium deficit occurs frequently with diarrhea, which may contain as much potassium as 30 mEq/L. Potassium deficit also occurs from prolonged intestinal suctioning, recent ileostomy, and villous adenoma (a tumor of the intestinal tract characterized by excretion of potassium-rich mucus) (Mount, 2017b).

Alterations in acid–base balance have a significant effect on potassium distribution due to shifts of hydrogen and potassium ions between the cells and the ECF. Respiratory or metabolic alkalosis promotes the transcellular shift of potassium and can have a variable and unpredictable effect on serum potassium. For example, hydrogen ions move out of the cells into the bloodstream in alkalotic states to help correct the high pH, and potassium ions move into the cells to maintain an electrically neutral state (Mount, 2017c) (see later discussion of acid–base balance).

Aldosterone from the adrenal gland acts on the nephron to increase sodium and water reabsorption into the bloodstream. It simultaneously secretes potassium into the renal tubules which in turn is excreted in the urine. In hyperaldosteronism, potassium is constantly secreted into the nephron tubule fluid which leads to loss of potassium into the urine. Hyperaldosteronism causes renal potassium wasting and can lead to severe potassium depletion. Primary hyperaldosteronism is seen in patients with adrenal adenomas (tumors). Secondary hyperaldosteronism occurs in patients with cirrhosis, nephrotic syndrome, heart failure, or malignant hypertension (Dick, Queiroz, Bernardi, et al., 2018).

Insulin promotes the entry of potassium into cells from the bloodstream; therefore, patients with persistent insulin hypersecretion may experience hypokalemia. Patients receiving high carbohydrate parenteral nutrition will have increased secretion of insulin. This will cause the shift of potassium into the cells from the bloodstream, causing hypokalemia. In diabetic ketoacidosis (DKA), potassium moves out of the cell since H^+ ions are high; during this acute phase it seems as though the patient has hyperkalemia. With insulin

treatment of DKA, potassium moves back into the cells, causing hypokalemia (Palmer & Clegg, 2016a).

Patients who are not able to eat a normal diet for a prolonged period are at risk for hypokalemia. This may occur in debilitated older adults and in patients with alcoholism or anorexia nervosa. In addition to poor intake, people with bulimia frequently experience increased potassium loss through self-induced vomiting and overuse of laxatives, diuretics, and enemas. These patients may also be deficient in magnesium. Magnesium depletion also causes renal potassium loss and must be corrected first; otherwise, urine loss of potassium will continue (Mount, 2017d).

Clinical Manifestations

Potassium deficiency can result in widespread derangements in physiologic function. Severe hypokalemia can cause death through cardiac or respiratory arrest. Clinical signs develop when the potassium level decreases to less than 3 mEq/L (3 mmol/L) (Mount, 2017b). Clinical signs and symptoms can be found in Table 10-7. If prolonged, hypokalemia can lead to an inability of the kidneys to concentrate urine, causing dilute urine (resulting in polyuria, nocturia) and excessive thirst. Potassium depletion suppresses the release of insulin and results in glucose intolerance (Palmer & Clegg, 2016a).

Assessment and Diagnostic Findings

In hypokalemia, the serum potassium concentration is less than the lower limit of normal, which is 3.5 mEq/L. Electrocardiographic (ECG) changes can include flat T waves or inverted T waves or both, suggesting ischemia, and depressed ST segments (Fig. 10-8). An elevated U wave is specific to hypokalemia.

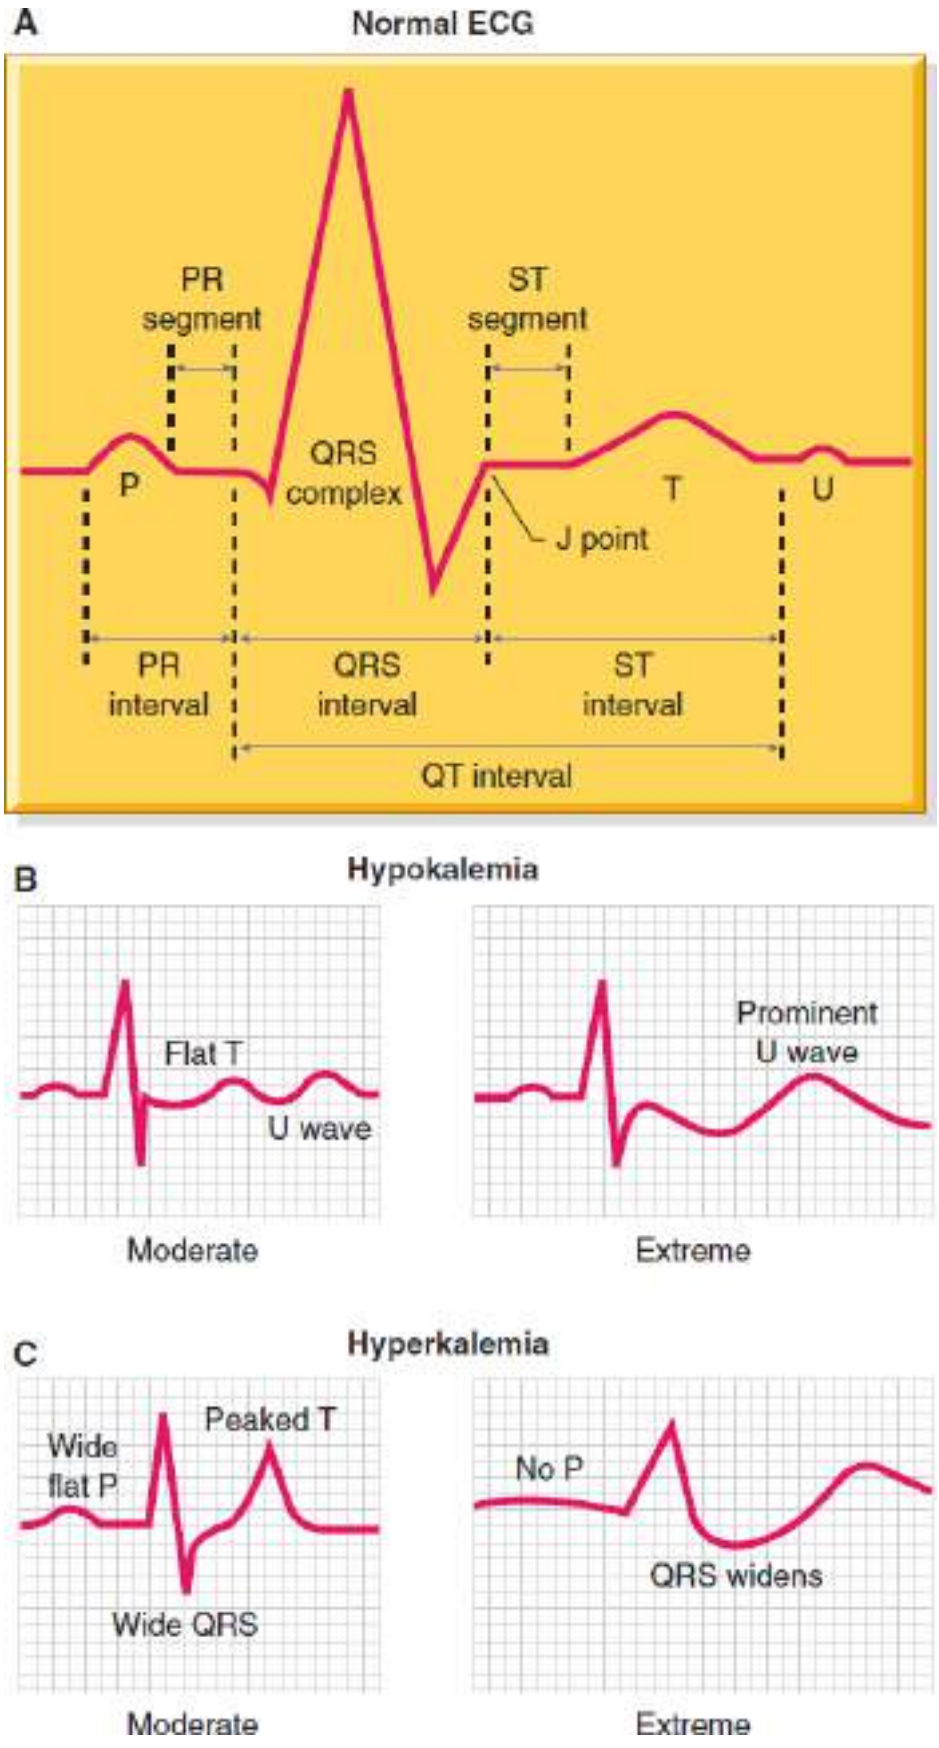

Figure 10-8 • Effect of potassium on the electrocardiogram (ECG). **A.** Normal tracing. **B.** Hypokalemia: serum potassium level below

normal. **Left:** Flattening of the T wave and the appearance of a U wave. **Right:** Further flattening with prominent U wave. **C.** Hyperkalemia: serum potassium level above normal. **Left:** Moderate elevation with wide, flat P wave; wide QRS complex; and peaked T wave. **Right:** ECG changes seen with extreme potassium elevation: widening of QRS complex and absence of P wave.

Quality and Safety Nursing Alert

Hypokalemia increases sensitivity to digitalis, predisposing the patient to digitalis toxicity at lower digitalis levels.

Metabolic alkalosis is commonly associated with hypokalemia. This is discussed further in the section on acid–base disturbances in this chapter.

The source of the potassium loss is usually evident from a careful history. However, if the cause of the loss is unclear, a 24-hour urinary potassium excretion test can be performed to distinguish between renal and extrarenal loss. Urinary potassium excretion exceeding 20 mEq/day with hypokalemia suggests that renal potassium loss is the cause.

Medical Management

If hypokalemia cannot be prevented by conventional measures such as increased intake in the daily diet or by oral potassium supplements for deficiencies, then it is treated cautiously with IV replacement therapy (Mount, 2017b). Potassium loss must be corrected daily; administration of 40 to 60 mEq/day of potassium is adequate in the adult if there are no abnormal losses of potassium.

For patients who are at risk for hypokalemia, a diet containing sufficient potassium should be provided. Dietary intake of potassium in the average adult is 50 to 100 mEq/day. Foods high in potassium include most fruits and vegetables, legumes, whole grains, milk, and meat (Palmer & Clegg, 2016b).

When dietary intake is inadequate for any reason, oral or IV potassium supplements may be prescribed. Many salt substitutes contain 50 to 60 mEq of potassium per teaspoon and may be sufficient to prevent hypokalemia. If oral administration of potassium is not feasible, the IV route is indicated. The IV route is mandatory for patients with severe hypokalemia (e.g., serum level of 2 mEq/L). Although potassium chloride (KCl) is usually used to correct potassium deficits, potassium acetate or potassium phosphate may be prescribed (Mount, 2017e; Vallerand & Sanoski, 2019).

Nursing Management

Because hypokalemia can be life-threatening, the nurse needs to monitor for its early presence in patients at risk. Fatigue, anorexia, muscle weakness, decreased bowel motility, paresthesias, and arrhythmias are signals that warrant assessing the serum potassium concentration. When available, the ECG may provide useful information (Mount, 2017b). For example, patients receiving digitalis who are at risk for potassium deficiency should be monitored closely for signs of digitalis toxicity, because hypokalemia potentiates the action of digitalis.

Preventing Hypokalemia

The nurse helps prevent hypokalemia by encouraging patients at risk to eat foods rich in potassium (when the diet allows). Consumption of foods high in potassium should be encouraged; examples include bananas, melon, citrus fruits, fresh and frozen vegetables (avoid canned vegetables), lean meats, milk, and whole grains. If the hypokalemia is caused by abuse of laxatives or diuretics, patient education may help alleviate the problem. Part of the health history and assessment should be directed at identifying problems that are amenable to prevention through education. Careful monitoring of fluid I&O is necessary, because 40 mEq of potassium is lost for every liter of urine output. The ECG is monitored for changes, and arterial blood gas (ABG) values are checked for elevated bicarbonate and pH levels.

Correcting Hypokalemia

The oral route is ideal to treat mild to moderate hypokalemia because oral potassium supplements are well absorbed. Care should be exercised when administering potassium, particularly in older adults, who have lower lean body mass and total-body potassium levels and therefore lower potassium requirements. In addition, because of the physiologic loss of renal function with advancing years, potassium may be retained more readily in older than in younger people (Cash & Glass, 2018).

Quality and Safety Nursing Alert

Oral potassium supplements can produce small bowel lesions; therefore, the patient must be assessed for and cautioned about abdominal distention, pain, or GI bleeding.

Administering Intravenous Potassium

Potassium should be given only after adequate urine output has been established. A decrease in urine volume to less than 20 mL/h for 2 consecutive hours is an indication to stop the potassium infusion and notify the primary

provider. Potassium is primarily excreted by the kidneys; when oliguria occurs, potassium administration can cause the serum potassium concentration to rise to dangerous levels (Mount, 2017e).

Quality and Safety Nursing Alert

Potassium is never given by IV push or intramuscularly to avoid replacing potassium too quickly. Potassium is extremely irritating to tissues. IV potassium must be given using an infusion pump.

Each health care facility has its own policy for the administration of potassium, which must be consulted. Administration of IV potassium is done with extreme caution using an infusion pump with the patient monitored by continuous ECG. Caution must be used when selecting a premixed solution of IV fluid containing KCl, as the concentrations range from 10 to 40 mEq/100 mL. Renal function should be monitored through BUN and serum creatinine levels and urine output if the patient is receiving potassium replacement. During replacement therapy, the patient should be monitored for signs of worsening hypokalemia as well as hyperkalemia.

Potassium Excess (Hyperkalemia)

Hyperkalemia (serum potassium level greater than 5 mEq/L [5 mmol/L]) seldom occurs in patients with normal renal function. In older adults, there is an increased risk of hyperkalemia due to decreases in renin and aldosterone as well as an increased number of comorbid cardiac conditions. Like hypokalemia, hyperkalemia is often caused by iatrogenic (treatment-induced) causes. Although hyperkalemia is less common than hypokalemia, it is usually more dangerous because cardiac arrest is more frequently associated with high serum potassium levels (Mount, 2017a).

Pathophysiology

Major causes of hyperkalemia are decreased renal excretion of potassium, rapid administration of potassium, and movement of potassium from the ICF compartment to the ECF compartment. Hyperkalemia is commonly seen in patients with untreated kidney injury, particularly those in whom potassium levels increase as a result of infection or excessive intake of potassium in food or medications (Mount, 2017a). Patients with hypoaldosteronism or Addison disease are at risk for hyperkalemia because of a lack of aldosterone. Lack of aldosterone activity at the nephron causes inadequate sodium and water reabsorption into the bloodstream and inadequate excretion of potassium in the

urine. Therefore, deficient adrenal hormones lead to sodium loss and potassium retention (Norris, 2019).

Medications have been identified as a probable contributing factor in more than 60% of hyperkalemic episodes. Medications commonly implicated are KCl, heparin, ACE inhibitors, NSAIDs, beta-blockers, cyclosporine, tacrolimus, and potassium-sparing diuretics (Comerford & Durkin, 2020). Potassium regulation is compromised in acute and chronic kidney disease, with a glomerular filtration rate less than 10% to 20% of normal (Mount, 2017c).

Improper use of potassium supplements predisposes all patients to hyperkalemia, especially if salt substitutes are used. Not all patients receiving potassium-losing diuretics require potassium supplements, and patients receiving potassium-conserving diuretics should not receive supplements.

Quality and Safety Nursing Alert

Potassium supplements are extremely dangerous for patients who have impaired renal function and thus decreased ability to excrete potassium. Even more dangerous is the IV administration of potassium to such patients, because serum levels can rise very quickly. It is possible to exceed the renal tolerance of any patient with rapid IV potassium administration, as well as when large amounts of oral potassium supplements are ingested.

In **acidosis** (low blood pH), potassium moves out of the cells and into the ECF. This occurs as hydrogen ions enter the cells to buffer the pH of the ECF (see later discussion).

An elevated ECF potassium level should be anticipated when extensive tissue trauma has occurred, as in burns, crushing injuries, or severe infections. Similarly, it can occur with lysis of malignant cells after chemotherapy (i.e., tumor lysis syndrome). Any disorder that causes high amounts of cellular lysis or deterioration can cause hyperkalemia (Mount, 2017a).

Pseudohyperkalemia (a false hyperkalemia) has several causes, including the improper collection or transport of a blood sample, a traumatic venipuncture, and use of a tight tourniquet around an exercising extremity while drawing a blood sample, producing hemolysis of the sample before analysis. Other causes include marked leukocytosis (white blood cell count exceeding 200,000/mm^3) and thrombocytosis (platelet count exceeding 1 million/mm^3); drawing blood above a site where potassium is infusing; and familial pseudohyperkalemia, in which potassium leaks out of the RBCs while the blood is awaiting analysis. Lack of awareness of these causes of pseudohyperkalemia can lead to aggressive treatment of a nonexistent

hyperkalemia, resulting in serious lowering of serum potassium levels. Therefore, measurements of grossly elevated levels of potassium in the absence of clinical manifestations (e.g., normal ECG) should be verified by retesting (Mount, 2017a).

Clinical Manifestations

Clinical signs and symptoms can be found in Table 10-7. The most important consequence of hyperkalemia is its effect on the myocardium. Cardiac effects of elevated serum potassium are usually not significant when the level is less than 7 mEq/L (7 mmol/L); however, they are almost always present when the level is 8 mEq/L (8 mmol/L) or greater. As the plasma potassium level rises, disturbances in cardiac conduction occur. The earliest changes, often occurring at a serum potassium level greater than 6 mEq/L (6 mmol/L), are peaked, narrow T waves; ST-segment depression; and a shortened QT interval. If the serum potassium level continues to increase, the PR interval becomes prolonged and is followed by disappearance of the P waves. Finally, there is decomposition and widening of the QRS complex (see Fig. 10-7). Ventricular arrhythmias and cardiac arrest may occur (Mount, 2017a).

Assessment and Diagnostic Findings

Serum potassium levels and ECG changes are crucial to the diagnosis of hyperkalemia, as discussed previously. ABG analysis may reveal either a metabolic or a respiratory acidosis. These are discussed further in the section on acid–base disturbances in this chapter. Correcting the acidosis helps correct the hyperkalemia.

Medical Management

In disorders involving potassium level changes, an ECG should be obtained immediately. Shortened repolarization and peaked T waves are seen initially in hyperkalemia. To verify results, a repeat serum potassium level should be obtained from a vein that is not concomitantly infusing an IV solution containing potassium (Mount, 2017e).

In nonacute situations, restriction of dietary potassium and potassium-containing medications may correct the imbalance. For example, eliminating the use of potassium-containing salt substitutes in a patient who is taking a potassium-conserving diuretic may be all that is needed to deal with mild hyperkalemia.

Administration, either orally or by retention enema, of cation exchange resins (e.g., sodium polystyrene sulfonate) may be necessary. The use of cation exchange resins requires normal bowel function. For instance, cation exchange

resins cannot be used if the patient has a paralytic ileus (i.e., absence of peristalsis in the intestine), because intestinal perforation can occur. Sodium polystyrene sulfonate binds with potassium and then is eliminated in the feces. Other cations in the GI tract can also be depleted which can cause hypomagnesemia and hypocalcemia. Sodium polystyrene sulfonate may also cause sodium retention and fluid overload and should be used with caution in patients with heart failure (Frandsen & Pennington, 2018; Mount, 2017e).

Patiromer sorbitex calcium is another oral agent that is a potassium-removing resin used to treat hyperkalemia. It exchanges calcium for potassium in the lower intestine, thereby increasing fecal excretion of potassium. Side effects include GI intolerance, hypomagnesemia, and edema (Depret, Peacock, Liu, et al., 2019).

Emergency Pharmacologic Therapy

If serum potassium levels are dangerously elevated, it may be necessary to administer IV calcium gluconate. Within minutes after administration, calcium antagonizes the action of hyperkalemia on the heart but does not reduce the serum potassium concentration. Calcium chloride and calcium gluconate are not interchangeable; calcium gluconate contains 4.5 mEq of calcium, and calcium chloride contains 13.6 mEq of calcium. Therefore, caution is required when using calcium preparations to reduce potassium levels (Ashurst, Sergent, & Sergent, 2016).

Monitoring the blood pressure is essential to detect hypotension, which may result from the rapid IV administration of calcium gluconate. The ECG should be continuously monitored during administration; the appearance of bradycardia is an indication to stop the infusion. The myocardial protective effects of calcium last about 30 minutes. Extra caution is required if the patient has received an accelerated dose of a digitalis-based cardiac glycoside to reach a desired serum digitalis level rapidly as parenteral administration of calcium sensitizes the heart to digitalis and may precipitate digitalis toxicity (Ashurst et al., 2016).

IV administration of sodium bicarbonate may be necessary in severe metabolic acidosis to alkalinize the plasma, shift potassium into the cells, and furnish sodium to antagonize the cardiac effects of potassium. Effects of this therapy begin within 30 to 60 minutes and may persist for hours; however, they are temporary. Circulatory overload and hypernatremia can occur when large amounts of hypertonic sodium bicarbonate are given. Bicarbonate therapy should be guided by the bicarbonate concentration or calculated base deficit obtained from blood gas analysis or laboratory measurement (Mount, 2017c).

IV administration of regular insulin and a hypertonic dextrose solution causes a temporary shift of potassium into the cells. Glucose and insulin therapy have an onset of action within 30 minutes and lasts for several hours.

Loop diuretics, such as furosemide, increase excretion of water by inhibiting sodium, potassium, and chloride reabsorption in the ascending loop of Henle and distal renal tubule (Ashurst et al., 2016).

Beta-2 agonists, such as albuterol, are highly effective in decreasing potassium; however, their use is not without risk as they can cause tachycardia and chest discomfort (Depret et al., 2019; Long, Warix, & Koyfman, 2018). Beta-2 agonists, administered intravenously or via nebulizer, move potassium into the cells and may be used in the absence of ischemic cardiac disease. Their use is a stopgap measure that only temporarily protects the patient from hyperkalemia.

If the hyperkalemic condition is not transient, removal of potassium from the body can also be done through peritoneal dialysis, hemodialysis, or other forms of renal replacement therapy.

Nursing Management

Patients at risk for potassium excess (e.g., those with kidney disease) need to be identified and closely monitored for signs of hyperkalemia. The nurse monitors I&O and observes for signs of muscle weakness and arrhythmias. When measuring vital signs, an apical pulse should be taken. The presence of paresthesias and GI symptoms such as nausea and intestinal cramping should be noted. Serum potassium levels, as well as BUN, serum creatinine, serum glucose, and ABG values, should be monitored for patients at risk for developing hyperkalemia.

Preventing Hyperkalemia

Measures should be taken to prevent hyperkalemia in patients at risk, when possible, by encouraging the patient to adhere to the prescribed potassium restriction. Potassium-rich foods to be avoided include many fruits and vegetables, legumes, whole-grain breads, lean meat, milk, eggs, coffee, tea, and cocoa. Conversely, foods with minimal potassium content include butter, margarine, cranberry juice or sauce, ginger ale, gumdrops or jelly beans, hard candy, root beer, sugar, and honey. Labels of cola beverages must be checked carefully because some are high in potassium and some are not (McDonough & Youn, 2017).

Correcting Hyperkalemia

It is possible to exceed the tolerance for potassium if given rapidly by the IV route. Therefore, careful monitoring is necessary when administering potassium solutions. Particular attention is paid to the solution's concentration and rate of administration. IV administration should only be via an infusion pump (Mount, 2017e).

The nurse must caution patients to use salt substitutes sparingly if they are taking other supplementary forms of potassium or potassium-conserving diuretics. In addition, potassium-conserving diuretics, potassium supplements, and salt substitutes should not be given to patients with kidney injury (Mount, 2017e).

Calcium Imbalances

More than 99% of the body's calcium (Ca^{++}) is located in the skeletal system; it is a major component of bones and teeth. About 1% of skeletal calcium is rapidly exchangeable with blood calcium, and the rest is more stable and only slowly exchanged. The small amount of calcium located outside the bone circulates in the serum, partly bound to protein and partly ionized. Calcium plays a major role in transmitting nerve impulses and helps regulate muscle contraction and relaxation, including cardiac muscle. Calcium is instrumental in activating enzymes that stimulate many essential chemical reactions in the body, and it also plays a role in blood coagulation. Because many factors affect calcium regulation, both hypocalcemia and hypercalcemia are relatively common disturbances (Norris, 2019) (Table 10-8).

The normal adult total serum calcium level is 8.8 to 10.4 mg/dL (2.2 to 2.6 mmol/L) (Fischbach & Fischbach, 2018). Calcium exists in plasma in three forms: ionized, bound, and complex. Approximately 50% of the serum calcium exists in a physiologically active ionized form that is important for neuromuscular activity and blood coagulation; this is the only physiologically and clinically significant form. The normal ionized serum calcium level is 4.5 to 5.1 mg/dL (1.1 to 1.3 mmol/L). Less than half of the plasma calcium is bound to serum proteins, primarily albumin. The remainder is combined with nonprotein anions: phosphate, citrate, and carbonate (Hogan & Goldfarb, 2018).

TABLE 10-8 Calcium Imbalances

Imbalance	Contributing Factors	Signs/Symptoms and Laboratory Findings
Calcium deficit (hypocalcemia) Serum calcium <8.8 mg/dL	Hypoparathyroidism (may follow thyroid surgery or radical neck dissection), malabsorption, pancreatitis, alkalosis, vitamin D deficiency, massive subcutaneous infection, generalized peritonitis, massive transfusion of citrated blood, chronic diarrhea, decreased parathyroid hormone, diuretic phase of acute kidney injury, ↑ PO_4, fistulas, burns, alcoholism	Numbness, tingling of fingers, toes, and circumoral region; positive Trousseau sign and Chvostek sign; seizures, carpopedal spasms, hyperactive deep tendon reflexes, irritability, bronchospasm, anxiety, impaired clotting time, ↓ prothrombin, diarrhea, ↓ BP. *ECG:* prolonged QT interval and lengthened ST *Labs indicate:* ↓ Mg^{++}
Calcium excess (hypercalcemia) Serum calcium >10.4 mg/dL	Hyperparathyroidism, malignant neoplastic disease, prolonged immobilization, overuse of calcium supplements, vitamin D excess, oliguric phase of acute kidney injury acidosis, corticosteroid therapy, thiazide diuretic use, increased parathyroid hormone, and digoxin toxicity	Muscular weakness, constipation, anorexia, nausea and vomiting, polyuria and polydipsia, dehydration, hypoactive deep tendon reflexes, lethargy, deep bone pain, pathologic fractures, flank pain, calcium stones, hypertension. *ECG:* shortened ST segment and QT interval, bradycardia, heart blocks

BP, blood pressure; ↓, decreased; ECG, electrocardiogram; ↑, increased.
Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health state* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Calcium is absorbed from foods in the presence of normal gastric acidity and vitamin D. It is excreted primarily in the feces, with the remainder excreted in the urine. The serum calcium level is controlled by PTH and calcitonin. As ionized serum calcium decreases in the bloodstream, the parathyroid glands secrete PTH. This, in turn, increases calcium absorption from the GI tract, increases calcium reabsorption from the renal tubule, and releases calcium from the bone. The resultant increase in calcium ion concentration in the bloodstream then suppresses PTH secretion. When calcium increases excessively, the thyroid gland secretes calcitonin, which inhibits calcium reabsorption from bone and decreases the serum calcium concentration (Norris, 2019).

Calcium Deficit (Hypocalcemia)

Hypocalcemia (serum calcium value lower than 8.8 mg/dL [2.20 mmol/L]) occurs in a variety of clinical situations. A patient may have a total-body calcium deficit (as in osteoporosis) but a normal serum calcium level. Older adults and those with disability have an increased risk of hypocalcemia because immobility, particularly lack of weight-bearing activity, increases bone resorption (Cash & Glass, 2018; Goltzman, 2017).

Pathophysiology

The parathyroid glands are instrumental in regulating blood and body calcium levels. Several factors can cause hypocalcemia, including primary hypoparathyroidism and surgical hypoparathyroidism. Surgical hypoparathyroidism is more common as a result of unintentional trauma or devascularization of the parathyroid glands (Kazaure & Sosa, 2018). Not only is hypocalcemia associated with thyroid and parathyroid surgery, but it can also occur after radical neck dissection and is most likely in the first 24 to 48 hours after surgery. Transient hypocalcemia can occur with massive administration of citrated blood (i.e., massive hemorrhage and shock), because citrate can combine with ionized calcium and temporarily remove it from the circulation (Goltzman, 2017).

Inflammation of the pancreas causes the breakdown of proteins and lipids. It is thought that calcium ions combine with the fatty acids released by lipolysis, forming soaplike compounds. As a result of this process, hypocalcemia occurs and is common in pancreatitis. Hypocalcemia may also be related to excessive secretion of glucagon from the inflamed pancreas, which results in increased secretion of calcitonin from the thyroid gland.

Hypocalcemia is common in patients with acute kidney injury, because these patients frequently have elevated serum phosphate levels. Hyperphosphatemia usually causes a reciprocal drop in the serum calcium level. Other causes of hypocalcemia include inadequate vitamin D consumption, magnesium deficiency, medullary thyroid carcinoma, low serum albumin levels, alkalosis, and alcohol abuse. Medications predisposing to hypocalcemia include aluminum-containing antacids, aminoglycosides, caffeine, cisplatin, corticosteroids, mithramycin, phosphates, isoniazid, loop diuretics, and proton pump inhibitors (Goltzman, 2017).

Clinical Manifestations

Tetany, the most characteristic manifestation of hypocalcemia and hypomagnesemia, refers to the entire symptom complex induced by increased neural excitability. Clinical signs and symptoms are caused by spontaneous discharges of both sensory and motor fibers in peripheral nerves and are outlined in Table 10-8.

Chvostek sign (Fig. 10-9A) consists of twitching of muscles innervated by the facial nerve in response to tapping of the muscle just below the zygomatic arch. Trousseau sign (Fig. 10-9B) can be elicited by inflating a blood pressure cuff on the upper arm to about 20 mm Hg above systolic pressure; within 2 to 5 minutes, carpal spasm will occur as ischemia of the ulnar nerve develops (Goltzman, 2019a).

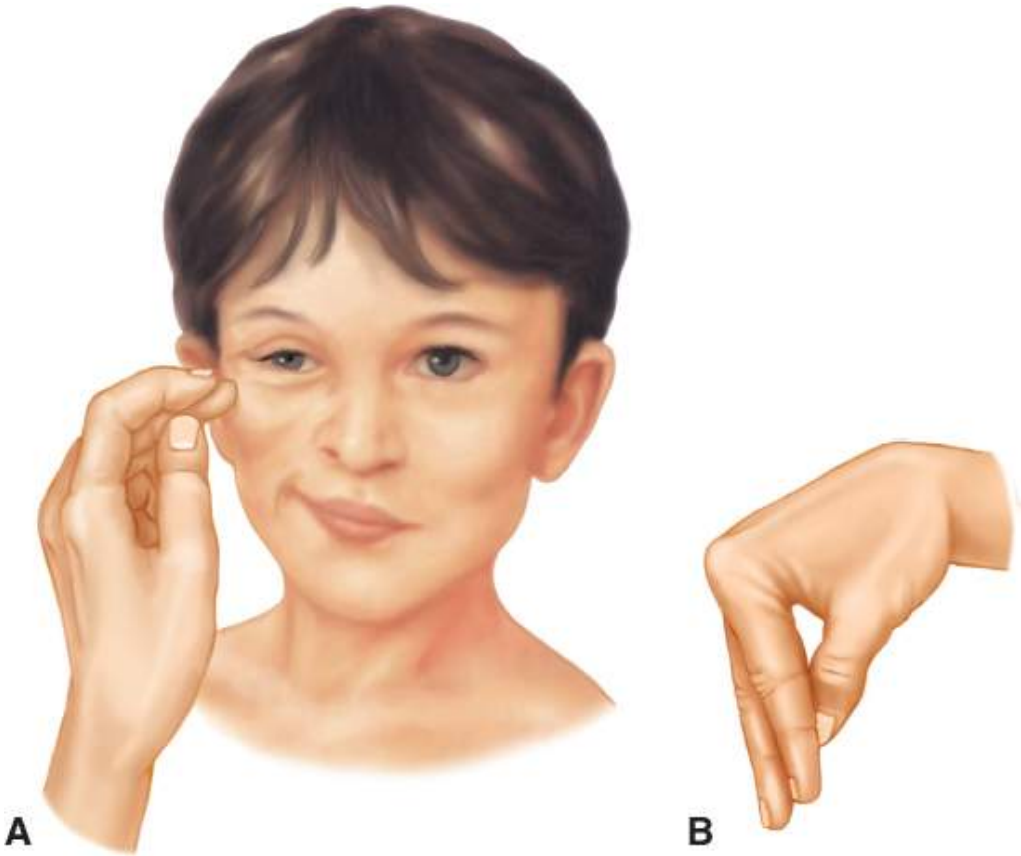

Figure 10-9 • **A.** Chvostek sign: a contraction of the facial muscles elicited in response to light tap over the facial nerve in front of the ear. **B.** Trousseau sign: a carpopedal spasm induced by inflating a blood pressure cuff above systolic blood pressure. Adapted from Bullock, B. A., & Henze, R. J. (2000). *Focus on pathophysiology* (p. 173). Philadelphia, PA: Lippincott Williams & Wilkins.

Hypocalcemia can cause seizures because low calcium levels increase irritability of the central and peripheral nervous systems. Other changes associated with hypocalcemia include mental changes such as depression, impaired memory, confusion, delirium, and hallucinations. A prolonged QT interval is seen on the ECG due to prolongation of the ST segment, and torsades de pointes, a type of ventricular tachycardia, may occur. Respiratory effects with decreasing calcium include dyspnea and laryngospasm. Signs and symptoms of chronic hypocalcemia include hyperactive bowel sounds, dry and brittle hair and nails, and abnormal clotting (Goltzman, 2019a).

Osteoporosis is associated with prolonged low intake of calcium and represents a total-body calcium deficit, even though serum calcium levels are usually normal. This disorder occurs in millions of Americans and is most common in postmenopausal women. It is characterized by loss of bone mass, which causes bones to become porous and brittle and therefore susceptible to fracture (Black & Rosen, 2016) (see Chapter 36 for further discussion of osteoporosis).

Assessment and Diagnostic Findings

When evaluating serum calcium levels, the serum albumin level and the arterial pH must also be considered. Because abnormalities in serum albumin levels may affect interpretation of the serum calcium level, it may be necessary to calculate the corrected serum calcium if the serum albumin level is abnormal. For every decrease in serum albumin of 1 g/dL below 4 g/dL, the total serum calcium level is underestimated by approximately 0.8 mg/dL (Hogan & Goldfarb, 2018). Chart 10-2 displays a quick method that nurses can use to calculate the corrected serum calcium level.

Clinicians often discount a low serum calcium level in the presence of a similarly low serum albumin level. The ionized calcium level is usually normal in patients with reduced total serum calcium levels and concomitant hypoalbuminemia. When the arterial pH increases (alkalosis), more calcium becomes bound to protein. As a result, the ionized portion decreases. Symptoms of hypocalcemia may occur with alkalosis. Acidosis has the opposite effect—that is, less calcium is bound to protein and therefore more exists in the ionized form. However, relatively small changes in serum calcium levels occur in these acid–base abnormalities (Yu & Stubbs, 2019).

Chart 10-2

Calculating Corrected Serum Calcium Level

Abnormalities in serum albumin levels may affect interpretation of the serum calcium level. Below is a method for calculating the corrected serum calcium level if the serum albumin level is abnormal.

Quick Calculation Method

$$\text{Measured total serum } Ca^{++} \text{ level (mg/dL)} + 0.8 \times (4.0 - \text{Measured albumin level [g/dL]}) = \text{Corrected total calcium concentration (mg/dL)}$$

Example Calculation

A patient's reported serum albumin level is 2.5 g/dL; the reported serum calcium level is 10.5 mg/dL. First, the decrease in serum albumin level from normal (i.e., the difference from the normal albumin concentration of 4 g/dL) is calculated: 4 g/dL − 2.5 g/dL = 1.5 g/dL. Next, the following ratio is calculated:

$$0.8 \text{ mg/dL}:1 \text{ g/dL} = X \text{ mg/dL}:1.5 \text{ mg/dL}$$
$$X = 0.8 \times 1.5 \text{ mg/dL}$$
$$X = 1.2 \text{ mg/dL calcium}$$

Finally, 1.2 mg/dL is added to 10.5 mg/dL (the reported serum calcium level) to obtain the corrected total serum calcium level: 1.2 mg/dL + 10.5 mg/dL = 11.7 mg/dL.

Ideally, the ionized level of calcium should be measured in the laboratory. However, in many laboratories, only the total calcium level is reported; therefore, the concentration of the ionized fraction must be estimated by simultaneous measurement of the serum albumin level. Magnesium and phosphorus levels need to be assessed to identify possible causes of decreased calcium (Yu & Stubbs, 2019).

Medical Management

Emergency Pharmacologic Therapy

Acute symptomatic hypocalcemia is life-threatening and requires prompt treatment with IV administration of a calcium salt. Parenteral calcium salts include calcium gluconate and calcium chloride (Duval, Bach, Masson, et al., 2018; Goltzman, 2019b). Although calcium chloride produces a significantly higher ionized calcium level than calcium gluconate does, it is not used as often because it is more irritating and can cause sloughing of tissue if it infiltrates.

IV administration of calcium is particularly dangerous in patients receiving digitalis-derived medications, because calcium ions exert an effect similar to that of digitalis and can cause digitalis toxicity, with adverse cardiac effects. The IV site that delivers calcium must be observed often for any evidence of infiltration because of the risk of extravasation and resultant cellulitis or necrosis. A 0.9% sodium chloride solution should not be used with calcium because it increases renal calcium loss. Solutions containing phosphates or bicarbonate should not be used with calcium because they cause precipitation when calcium is added. The nurse must clarify with the primary provider and pharmacist which calcium salt to administer, because calcium gluconate yields 4.5 mEq of calcium and calcium chloride provides 13.6 mEq of calcium. Calcium replacement can cause orthostatic hypotension; therefore, the patient should remain in bed during IV infusion, and blood pressure is monitored (Duval et al., 2018).

Quality and Safety Nursing Alert

Too rapid IV administration of calcium can cause cardiac arrest, preceded by bradycardia. Therefore, calcium should be diluted in D_5W and given as a slow IV bolus or a slow IV infusion using an infusion pump. A 0.9% sodium chloride solution should not be used when administering calcium.

Nutritional Therapy

Vitamin D therapy may be instituted to increase calcium absorption from the GI tract; otherwise, the amount of calcium absorbed may not satisfy the body's calcium requirement. In addition, aluminum hydroxide, calcium acetate, or calcium carbonate antacids may be prescribed to decrease elevated phosphorus levels before treating hypocalcemia in the patient with chronic kidney disease. Increasing the dietary intake of calcium to at least 1000 to 1500 mg/day in the adult is recommended. Calcium supplements must be given in divided doses of no higher than 500 mg to promote calcium absorption. Calcium-containing foods include milk products; green, leafy vegetables; canned salmon; canned sardines; and fresh oysters. Hypomagnesemia can also cause tetany; if the tetany responds to IV calcium, then a low magnesium level is considered as a possible cause in chronic kidney dysfunction (Goltzman, 2019b; Rosen & Drezner, 2019).

Nursing Management

It is important to assess for hypocalcemia in at-risk patients. Seizure precautions are initiated if hypocalcemia is severe. The status of the airway is

closely monitored because laryngospasm can occur. Safety precautions are taken, as indicated, if confusion is present (Duval et al., 2018).

The nurse must educate the patient with hypocalcemia about foods that are rich in calcium. The nurse must also advise the patient to consider calcium supplements if sufficient calcium is not consumed in the diet. Such supplements should be taken in divided doses with meals. Alcohol and caffeine in high doses inhibit calcium absorption, and moderate cigarette smoking increases urinary calcium excretion. The patient is also cautioned to avoid the overuse of laxatives and antacids that contain phosphorus, because their use decreases calcium absorption (Rosen & Drezner, 2019).

Calcium Excess (Hypercalcemia)

Hypercalcemia (serum calcium value greater than 10.4 mg/dL [2.6 mmol/L]) can affect many organ systems. Symptoms depend on the degree of hypercalcemia and the rate of rise of calcium in the bloodstream. Mild hypercalcemia usually causes no apparent symptoms if the rise in calcium level is chronic over a long period of time. Moderate hypercalcemia can also be well tolerated. Marked symptoms occur when rise in calcium level is acute (Shane, 2019b).

Pathophysiology

The most common causes of hypercalcemia are malignancies and hyperparathyroidism. Malignant tumors can produce hypercalcemia by various mechanisms. The most common malignancies that are associated with hypercalcemia are breast, lung, renal, and multiple myeloma. In hyperparathyroidism, excessive PTH secretion causes increased release of calcium from the bones and increased intestinal and renal absorption of calcium. Calcifications of soft tissue occur when the calcium–phosphorus product (serum calcium × serum phosphorus) exceeds 70 mg/dL. Calcium levels are inversely related to phosphorus levels (Shane, 2019a).

Bone calcium is lost during immobilization, and sometimes this causes elevation of total (and especially ionized) calcium in the bloodstream. However, symptomatic hypercalcemia from immobilization is rare; when it does occur, it is limited to people with high calcium turnover rates (e.g., adolescents during a growth spurt). Most cases of hypercalcemia secondary to immobility occur after severe or multiple fractures or spinal cord injury (Shane, 2019a).

Thiazide diuretics can cause a slight elevation in serum calcium levels because they potentiate the action of PTH on the kidneys, reducing urinary calcium excretion. Vitamin A and D intoxication, as well as chronic lithium use and theophylline toxicity, can cause calcium excess.

Hypercalcemia reduces neuromuscular excitability because it suppresses activity at the myoneural junction. Decreased tone in smooth and striated muscle may cause symptoms such as muscle weakness, incoordination, anorexia, and constipation. Lethal arrhythmias (e.g., ventricular fibrillation) can occur when the serum calcium level is about 18 mg/dL (4.5 mmol/L). Calcium enhances the inotropic effect of digitalis; therefore, hypercalcemia aggravates digitalis toxicity (Shane, 2019a).

Clinical Manifestations

Clinical signs and symptoms can be found in Table 10-8. The symptoms of hypercalcemia are proportional to the degree of elevation of the serum calcium level. The more severe symptoms tend to appear when the serum calcium level climbs rapidly and may be as high as 16 mg/dL (4 mmol/L) or higher. However, some patients become profoundly disturbed with serum calcium levels of only 12 mg/dL (3 mmol/L). These symptoms resolve as serum calcium levels return to normal after treatment (Shane, 2019b).

Hypercalcemic crisis refers to an acute rise in the serum calcium level. Severe thirst and polyuria are often present. Other findings may include muscle weakness, intractable nausea, abdominal cramps, severe constipation, diarrhea, peptic ulcer symptoms, and bone pain. Lethargy, confusion, and coma may also occur. This condition is dangerous and may result in cardiac arrest. Emergency treatment with calcitonin is indicated (Shane & Berenson, 2019) (see later discussion under Pharmacologic Therapy).

Assessment and Diagnostic Findings

In hypercalcemia, the serum calcium level is greater than 10.4 mg/dL (2.6 mmol/L). Cardiovascular changes may include a variety of arrhythmias (e.g., heart blocks) and shortening of the QT interval and ST segment. The PR interval is sometimes prolonged. The double-antibody PTH test may be used to differentiate between primary hyperparathyroidism and malignancy as a cause of hypercalcemia: PTH levels are increased in primary or secondary hyperparathyroidism and suppressed in malignancy. X-rays may reveal bone changes if the patient has hypercalcemia secondary to a malignancy, bone cavitations, or urinary calculi. Urine calcium can be normal or elevated in hyperparathyroidism and hypercalcemia caused by malignancy (Shane, 2019b).

Medical Management

Therapeutic aims include decreasing the serum calcium level and reversing the process causing the hypercalcemia. Treating the underlying cause (e.g.,

chemotherapy for a malignancy, partial parathyroidectomy for hyperparathyroidism) is essential.

Pharmacologic Therapy

To treat hypercalcemia, measures include administering fluids to dilute serum calcium and promote its excretion by the kidneys, mobilizing the patient, and restricting dietary calcium intake. IV administration of 0.9% sodium chloride solution temporarily dilutes the serum calcium level and increases urinary calcium excretion by inhibiting tubular reabsorption of calcium. Administering IV phosphate can cause a reciprocal drop in serum calcium. Furosemide is often used in conjunction with administration of a saline solution; in addition to causing diuresis, furosemide increases calcium excretion. Although often overlooked, fluids and medications that contain calcium and dietary sources of calcium should be halted (Shane & Berenson, 2019).

Calcitonin can be used to lower the serum calcium level and is particularly useful for patients with heart disease or acute kidney injury who cannot tolerate large sodium loads. Calcitonin reduces bone resorption, increases the deposition of calcium and phosphorus in the bones, and increases urinary excretion of calcium and phosphorus. Although several forms are available, calcitonin derived from salmon is commonly used. Skin testing for allergy to salmon calcitonin may be necessary before the hormone is given. Systemic allergic reactions are possible because this hormone is a protein; resistance to the medication may develop later because of antibody formation. Calcitonin is administered by intramuscular injection or intranasal spray rather than subcutaneously, because patients with hypercalcemia have poor perfusion of subcutaneous tissue (Shane & Berenson, 2019).

For patients with cancer, treatment is directed at controlling the condition by surgery, chemotherapy, or radiation therapy. Corticosteroids may be used to decrease bone turnover and tubular reabsorption for patients with sarcoidosis, myelomas, lymphomas, and leukemias; patients with solid tumors are less responsive. Some bisphosphonates (e.g., pamidronate disodium, ibandronate sodium) inhibit osteoclast activity. IV forms of bisphosphonates can cause fever, transient leukopenia, eye inflammation, nephrotic syndrome, and jaw osteonecrosis (Shane & Berenson, 2019).

Mithramycin, a cytotoxic antibiotic, inhibits bone resorption and thus lowers the serum calcium level. This agent must be used cautiously because it has significant side effects, including thrombocytopenia, nephrotoxicity, rebound hypercalcemia when discontinued, and hepatotoxicity. Inorganic phosphate salts can be given orally or by nasogastric tube (in the form of Phospho-Soda or Neutra-Phos), rectally (as retention enemas), or IV. IV phosphate therapy is used with extreme caution in the treatment of hypercalcemia, because it can cause severe calcification in various tissues,

hypotension, tetany, and acute kidney injury (Frandsen & Pennington, 2018; Vallerand & Sanoski, 2019).

Nursing Management

The nurse must monitor for hypercalcemia in at-risk patients. Interventions such as increasing patient mobility and encouraging fluids can help prevent hypercalcemia, or at least minimize its severity. Hospitalized patients at risk should be encouraged to ambulate as soon as possible. Those who are outpatients and receive home care are educated about the importance of frequent ambulation (Daly, 2017).

When encouraging oral fluids, the nurse considers the patient's likes and dislikes. Fluids containing sodium should be given unless contraindicated, because sodium assists with calcium excretion. Patients are encouraged to drink 2.8 to 3.8 L (3 to 4 quarts) of fluid daily (Sterns, 2017b). Adequate fiber in the diet is encouraged to offset the tendency for constipation. Safety precautions are implemented, as necessary, when altered mental status is present. The patient and family are informed that these mental changes are reversible with treatment. Increased calcium increases the effects of digitalis; therefore, the patient on digitalis should be frequently assessed for signs and symptoms of digitalis toxicity. Because ECG changes (premature ventricular contractions, paroxysmal atrial tachycardia, and heart block) can occur, the cardiac rate and rhythm are monitored for any abnormalities (Shane & Berenson, 2019; Vallerand & Sanoski, 2019).

Magnesium Imbalances

Magnesium (Mg^{++}) is an abundant intracellular cation. It acts as an activator for many intracellular enzyme systems and plays a role in both carbohydrate and protein metabolism. The normal serum magnesium level is 1.8 to 2.6 mg/dL (0.74 to 1.07 mmol/L) (Fischbach & Fischbach, 2018). Approximately one third of serum magnesium is bound to protein; the remaining two thirds exist as free cations—the active component (Mg^{++}). Magnesium balance is important in neuromuscular function. Because magnesium acts directly on the myoneural junction, variations in the serum level affect neuromuscular irritability and contractility. For example, an excess of magnesium diminishes the excitability of the muscle cells, whereas a deficit increases neuromuscular irritability and contractility. Magnesium produces its sedative effect at the neuromuscular junction, probably by inhibiting the release of the neurotransmitter acetylcholine. It also increases the stimulus threshold in nerve fibers. Magnesium imbalances are magnesium deficit and magnesium excess (Norris, 2019) (Table 10-9).

Magnesium also affects the cardiovascular system, acting peripherally to produce vasodilation and decreased peripheral resistance. Most magnesium in the body is stored within bone, whereas magnesium ions in the blood are bound to protein, such as albumin, or free as Mg^{++} ions (Yu, 2019a).

TABLE 10-9 Magnesium Imbalances

Imbalance	Contributing Factors	Signs/Symptoms
Magnesium deficit (hypomagnesemia) Serum magnesium <1.8 mg/dL	Chronic alcoholism, hyperparathyroidism, hyperaldosteronism, diuretic phase of acute kidney injury, malabsorptive disorders, diabetic ketoacidosis, refeeding after starvation, parenteral nutrition, chronic laxative use, diarrhea, acute myocardial infarction, heart failure, decreased serum K^+ and Ca^{++} and certain pharmacologic agents (e.g., gentamicin, cisplatin, cyclosporine)	Neuromuscular irritability, positive Trousseau sign and Chvostek sign, insomnia, mood changes, anorexia, vomiting, increased tendon reflexes, and ↑ BP. *ECG:* PVCs, flat or inverted T waves, depressed ST segment, prolonged PR interval, and widened QRS
Magnesium excess (hypermagnesemia) Serum magnesium >2.6 mg/dL	Oliguric phase of acute kidney injury (particularly when magnesium-containing medications are given), adrenal insufficiency, excessive IV magnesium administration, diabetic ketoacidosis, and hypothyroidism	Flushing, hypotension, muscle weakness, drowsiness, hypoactive reflexes, depressed respirations, cardiac arrest and coma, diaphoresis. *ECG:* tachycardia → bradycardia, prolonged PR interval and QRS, peaked T waves

BP, blood pressure; ECG, electrocardiogram; →, followed by; ↑, increased; IV, intravenous; PVCs, premature ventricular contractions.

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health state* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Magnesium Deficit (Hypomagnesemia)

Hypomagnesemia refers to a below-normal serum magnesium concentration and is frequently associated with hypokalemia and hypocalcemia. Magnesium is similar to calcium in two aspects: (1) it is the ionized fraction of magnesium that is primarily involved in neuromuscular activity and other physiologic processes, and (2) magnesium levels should be evaluated in combination with albumin levels. Because about 30% of magnesium is protein bound, principally to albumin, a decreased serum albumin level can reduce the measured total magnesium concentration; however, it does not reduce the ionized plasma magnesium concentration. Magnesium is essential for the

function of the Na^+/K^+ pump, and low Mg^{++} levels have effects on intracellular influxes of K^+ and myocardial ion fluxes (Norris, 2019; Yu, 2019a).

Pathophysiology

An important route of magnesium loss is the GI tract; such loss can occur with nasogastric suction, diarrhea, or fistulas. Because fluid from the lower GI tract has a higher concentration of magnesium (10 to 14 mEq/L) than fluid from the upper tract (1 to 2 mEq/L), losses from diarrhea and intestinal fistulas are more likely to induce magnesium deficit than are those from gastric suction. Although magnesium losses are relatively small in nasogastric suction, hypomagnesemia occurs if losses are prolonged and magnesium is not replaced through IV infusion. Because the distal small bowel is the major site of magnesium absorption, any disruption in small bowel function (e.g., intestinal resection or inflammatory bowel disease) can lead to hypomagnesemia. Hypomagnesemia is a common yet often overlooked imbalance in acutely and critically ill patients. Studies suggest that up to 65% of patients in intensive care are magnesium deficient (Upala, Jaruvongvanich, Wijarnpreecha, et al., 2016). Hypomagnesemia may occur with withdrawal from alcohol and administration of tube feedings or parenteral nutrition (Yu, 2019a).

Chronic alcohol abuse is a major cause of symptomatic hypomagnesemia in the United States. The serum magnesium level should be measured at least every 2 or 3 days in patients undergoing withdrawal from alcohol. The level may be normal on admission but may decrease as a result of metabolic changes, such as the intracellular shift of magnesium associated with IV glucose administration (Yu, 2019a).

During nutritional replacement, the major cellular electrolytes move from the serum to intracellular compartments of newly synthesized cells. Therefore, if the enteral or parenteral feeding formula is deficient in magnesium content, serious hypomagnesemia can occur. Because of this, serum magnesium levels should be measured at regular intervals in patients who are receiving parenteral or enteral feedings, especially those who have undergone a period of starvation (Yu, 2019a).

Other causes of hypomagnesemia include the administration of aminoglycosides, cyclosporine, cisplatin, diuretics, digitalis, proton pump inhibitors, and amphotericin, as well as the rapid administration of citrated blood, especially to patients with renal or hepatic disease. Magnesium deficiency often occurs in DKA, secondary to increased renal excretion during osmotic diuresis and shifting of magnesium into the cells with insulin therapy (Yu, 2019a). A magnesium IV solution can be used to counteract seizures due to preeclampsia or eclampsia, the cardiac arrhythmia torsades de pointes, asthma, and hypertension (Vallerand & Sanoski, 2019).

Clinical Manifestations

Clinical signs and symptoms can be found in Table 10-9. Some clinical manifestations of hypomagnesemia are due directly to the low serum magnesium level; others are due to secondary changes in potassium and calcium metabolism. Symptoms do not usually occur until the serum magnesium level has dropped to less than 1.8 mEq/L (0.75 mmol/L). Chvostek and Trousseau signs (see earlier discussion) occur, in part, because of accompanying hypocalcemia (Norris, 2019).

Hypomagnesemia may be accompanied by marked alterations in psychological status. Apathy, depressed mood, apprehension, and extreme agitation have been noted, as well as ataxia, dizziness, insomnia, and confusion. At times, delirium, auditory or visual hallucinations, and frank psychoses may occur (Yu & Yarlagadda, 2019).

Magnesium deficiency can disturb the ECG by prolonging the QRS, depressing the ST segment, and predisposing to cardiac arrhythmias, such as premature ventricular contractions, supraventricular tachycardia, torsades de pointes, and ventricular fibrillation. Increased susceptibility to digitalis toxicity is associated with low serum magnesium levels. Patients receiving digoxin are also likely to be receiving diuretic therapy, predisposing them to renal loss of magnesium. Concurrent hypokalemia and hypocalcemia must be addressed in addition to hypomagnesemia. These electrolyte disturbances are difficult to correct until magnesium has been replenished. Additionally, hypocalcemia can be worsened by isolated treatment of hypomagnesemia with IV magnesium sulfate because sulfate binds ionized calcium (Yu & Yarlagadda, 2019).

Assessment and Diagnostic Findings

On laboratory analysis, the serum magnesium level is less than 1.8 mg/dL (0.74 mmol/L). Urine magnesium may help identify the cause of magnesium depletion, and levels are measured after a loading dose of magnesium sulfate is given. Additional diagnostic techniques (nuclear magnetic resonance spectroscopy and the ion-selective electrode) are sensitive and direct means of measuring ionized serum magnesium levels (Yu, 2019b).

Medical Management

Mild magnesium deficiency can be corrected by diet alone. Principal dietary sources of magnesium include green leafy vegetables, beans, lentils, white potatoes, wheat bran, dry roasted almonds, and peanut butter (National Institutes of Health [NIH], 2019).

If necessary, magnesium salts can be given orally in an oxide or gluconate form to replace continuous losses but can produce diarrhea. Patients receiving

parenteral nutrition require magnesium in the IV solution to prevent hypomagnesemia

Vital signs must be assessed frequently during magnesium administration to detect changes in cardiac rate or rhythm, hypotension, and respiratory distress. Monitoring urine output is essential before, during, and after magnesium administration as this is how Mg^{++} is excreted; the primary provider is notified if urine volume decreases to less than 100 mL over 4 hours. Calcium gluconate must be readily available to treat hypocalcemic tetany or hypermagnesemia.

Quality and Safety Nursing Alert

Inadvertent overdosage of IV magnesium can result in serious patient harm and death. Whenever a patient is prescribed IV magnesium, a second nurse should independently double check the IV magnesium prescription, including dose calculations, and check infusion pump settings. Milligrams (mg) and grams (g) are not equivalent to milliequivalent (mEq) dosages.

Nursing Management

The nurse should be aware of patients at risk for hypomagnesemia and observe them for its signs and symptoms. Patients receiving digitalis are monitored closely, because a deficit of magnesium can predispose them to digitalis toxicity. If hypomagnesemia is severe, seizure precautions are implemented. Other safety precautions are instituted, as indicated, if confusion is observed. Patients should be screened for dysphagia (difficulty in swallowing), as this may occur in those with magnesium depletion.

Patient education plays a major role in treating magnesium deficit. The patient is educated about sources of magnesium-rich foods, including green vegetables, nuts, legumes, bananas, and oranges.

Magnesium Excess (Hypermagnesemia)

Hypermagnesemia (serum magnesium level higher than 2.6 mg/dL [1.07 mmol/L]) is a rare electrolyte abnormality, because the kidneys efficiently excrete magnesium (Norris, 2019). A serum magnesium level can appear falsely elevated if blood specimens are allowed to hemolyze or are drawn from an extremity with a tourniquet that was applied too tightly.

Pathophysiology

The most common cause of hypermagnesemia is kidney injury (Yu & Gupta, 2019). In fact, most patients with advanced kidney injury have at least a slight elevation in serum magnesium levels. This condition is aggravated when such patients receive magnesium to control seizures.

Hypermagnesemia can occur in patients with untreated DKA when catabolism causes the release of cellular magnesium that cannot be excreted because of profound fluid volume depletion and resulting oliguria. A surplus of magnesium can also result from excessive magnesium given to treat hypertension of pregnancy or to treat hypomagnesemia. Increased serum magnesium levels can also occur in adrenocortical insufficiency, Addison disease, or hypothermia.

Excessive use of magnesium-based antacids or laxatives and medications that decrease GI motility, including opioids and anticholinergics, can also increase serum magnesium levels. Decreased elimination of magnesium or its increased absorption due to intestinal hypomotility from any cause can contribute to hypermagnesemia. Lithium intoxication can also cause an increase in serum magnesium levels. Extensive soft tissue injury or necrosis as with trauma, shock, sepsis, cardiac arrest, or severe burns can also result in hypermagnesemia (Yu & Gupta, 2019).

Clinical Manifestations

Acute elevation of the serum magnesium level depresses the central nervous system as well as the peripheral neuromuscular junction. Clinical signs and symptoms can be found in Table 10-9. The respiratory center is depressed when serum magnesium levels exceed 10 mEq/L (5 mmol/L). Coma, atrioventricular heart block, and cardiac arrest can occur when the serum magnesium level is greatly elevated and not treated. High levels of magnesium also result in platelet clumping and delayed thrombin formation (Yu & Gupta, 2019).

Assessment and Diagnostic Findings

In hypermagnesemia, the serum magnesium level is greater than 2.6 mg/dL (1.07 mmol/L). Increased potassium and calcium are present concurrently. As creatinine clearance decreases to less than 3.0 mL/min, the serum magnesium levels increase. ECG findings may include a prolonged PR interval, tall T waves, a widened QRS, and a prolonged QT interval, as well as an atrioventricular block (Norris, 2019).

Medical Management

Hypermagnesemia can be prevented by avoiding the administration of magnesium to patients with kidney injury and by carefully monitoring seriously ill patients who are receiving magnesium salts. In patients with severe hypermagnesemia, all parenteral and oral magnesium salts are discontinued. In emergencies, such as respiratory depression or defective cardiac conduction, ventilatory support and IV elemental calcium as a magnesium antagonist are indicated. In addition, hemodialysis with a magnesium-free dialysate can reduce the serum magnesium to a safe level within hours. Administration of loop diuretics (e.g., furosemide) and sodium chloride or lactated Ringer's IV solution enhances magnesium excretion in patients with adequate renal function. IV calcium antagonizes the cardiovascular and neuromuscular effects of magnesium (Yu & Gupta, 2019).

Nursing Management

Patients at risk for hypermagnesemia should be monitored closely. If hypermagnesemia is suspected, the nurse should monitor the vital signs, noting hypotension and shallow respirations. The nurse should be aware that arrhythmias, bradycardia, and heart block can occur. The nurse also observes for decreased deep tendon reflexes (DTRs), muscle weakness, and changes in the level of consciousness. Medications that contain magnesium are not given to patients with compromised renal function, and patients with kidney injury are cautioned to check with their primary providers before taking OTC supplements. Administration of fluids and diuretics are often used in treatment, and monitoring of I&O is important. Hemodialysis may be necessary in severe hypermagnesemia, particularly if cardiovascular or neurologic manifestations are present. Hemodialysis is also necessary in patients with severe hypermagnesemia and kidney injury (Yu & Gupta, 2019).

Phosphorus Imbalances

Phosphorus (HPO_4^-) is a critical constituent of all body tissues and is plentiful in the average diet of people living in developed countries. Intake of phosphorus usually exceeds body requirements and the kidney excretes the excess. Phosphorus is essential to the function of muscle and RBCs; the formation of adenosine triphosphate (ATP) and of 2,3-diphosphoglycerate, which facilitates the release of oxygen from hemoglobin; and the maintenance of acid–base balance, as well as the nervous system and the intermediary metabolism of carbohydrate, protein, and fat. It is a major component of the cell structure, phospholipids, nucleotides, and nucleic acids (DNA and RNA). It provides structural support to bones and teeth. Phosphorus is the primary anion of the ICF and requires active transport mechanisms to maintain its

presence inside the cells. Most intracellular phosphorus is bound to proteins and lipids. About 85% of phosphorus is located in bones and teeth, 14% in soft tissue, and less than 1% in the ECF (Norris, 2019).

TABLE 10-10 Phosphorus Imbalances

Imbalance	Contributing Factors	Signs/Symptoms
Phosphorus deficit (hypophosphatemia) Serum phosphorus <2.7 mg/dL	Refeeding after starvation, alcohol withdrawal, diabetic ketoacidosis, respiratory and metabolic alkalosis, ↓ magnesium, ↓ potassium, hyperparathyroidism, vomiting, diarrhea, hyperventilation, vitamin D deficiency associated with malabsorptive disorders, burns, acid–base disorders, parenteral nutrition, and diuretic and antacid use	Paresthesias, muscle weakness, bone pain and tenderness, chest pain, confusion, cardiomyopathy, respiratory failure, seizures, tissue hypoxia, and increased susceptibility to infection, nystagmus
Phosphorus excess (hyperphosphatemia) Serum phosphorus >4.5 mg/dL	Acute kidney injury and chronic kidney disease, excessive intake of phosphorus, vitamin D excess, respiratory and metabolic acidosis, hypoparathyroidism, volume depletion, leukemia/lymphoma treated with cytotoxic agents, increased tissue breakdown, rhabdomyolysis	Tetany, tachycardia, anorexia, nausea and vomiting, muscle weakness, signs and symptoms of hypocalcemia; hyperactive reflexes; soft tissue calcifications in lungs, heart, kidneys, and cornea

↓, decreased.

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health state* (10th ed.). Philadelphia, PA: Wolters Kluwer.

The normal serum phosphorus level is 2.7 to 4.5 mg/dL (0.87 to 1.45 mmol/L) in adults (Fischbach & Fischbach, 2018). Phosphorus homeostasis is maintained through absorption and secretion in the GI tract, filtration and absorption in the kidneys, and shifts into and out of bone. PTH and vitamin D assist in phosphate homeostasis by varying phosphate reabsorption in the proximal tubule of the kidney. PTH allows the shift of phosphate from bone to plasma. Phosphorus deficit and phosphorus excess are less common electrolyte imbalances (Table 10-10).

Phosphorus Deficit (Hypophosphatemia)

Hypophosphatemia is indicated by a value below 2.7 mg/dL (0.87 mmol/L). Although it often indicates phosphorus deficiency, hypophosphatemia may

occur under a variety of circumstances in which total-body phosphorus stores are normal. Phosphorus deficiency can also occur as an abnormally low content of phosphorus in lean tissues without evidence of low phosphate in the bloodstream. Hypophosphatemia can be due to lack of sufficient intake, excess excretion (renal phosphate wasting), shift of phosphorus from extracellular to intracellular spaces, or by decreased intestinal absorption of phosphorus (Yu & Stubbs, 2019).

Pathophysiology

Hypophosphatemia rarely occurs due to inadequate intake, as there are many dietary sources of phosphate (e.g., meats, dairy products, beans). However, phosphate can become depleted in GI malabsorption disorders such as chronic diarrhea, Crohn's disease, or celiac disease. Hypophosphatemia can also occur in anorexia, bulimia, and alcoholism. Vitamin D deficit can cause low phosphate levels in the bloodstream. Vitamin D regulates intestinal absorption of calcium and phosphate ion; therefore, a deficiency of vitamin D can cause both decreased calcium and phosphorus levels. These deficiencies can lead to osteomalacia (softened and brittle bones) in the adult (Norris, 2019).

Hypophosphatemia can occur if there is high intake of antacids—particularly those containing calcium, magnesium, or aluminum. Excess phosphorus binding by antacids may decrease the phosphorus available from the diet to an amount lower than required to maintain serum phosphorus balance. The degree of hypophosphatemia depends on the amount of phosphorus in the diet compared to the dose of antacid (Yu & Stubbs, 2019).

Hypophosphatemia can also occur during the administration of calories to patients who have had severe protein–calorie malnutrition. This syndrome can be induced in any person with severe malnutrition (e.g., patients with anorexia nervosa or alcoholism, older patients who are debilitated and unable to eat). Feeding a patient who is nutritionally deprived stimulates a large insulin release that can cause shift of phosphate from the extracellular to the intracellular compartment. Also, marked hypophosphatemia can develop in patients who are malnourished who receive parenteral nutrition that does not contain sufficient phosphorus (Aubry, Friedli, Schetz, et al., 2018).

Other causes of hypophosphatemia include heatstroke, prolonged intense hyperventilation, alcohol withdrawal, DKA, respiratory alkalosis, hepatic encephalopathy, and major thermal burns. Hyperparathyroidism can also cause increased urinary losses of phosphorus leading to hypophosphatemia. Loss of phosphorus through the kidneys also occurs with acute volume expansion, osmotic diuresis, the use of carbonic anhydrase inhibitors (acetazolamide), and some malignancies.

Respiratory alkalosis can cause a decrease in phosphorus in the bloodstream because of an intracellular shift of phosphorus. Respiratory alkalosis,

commonly caused by extreme hyperventilation, can reduce serum phosphate concentrations to very low levels and is a common cause of marked hypophosphatemia in patients who are hospitalized.

Some genetic disorders, such as Fanconi syndrome and X-linked hypophosphatemic rickets, cause renal phosphate wasting. Acquired oncogenic osteomalacia, a paraneoplastic syndrome that occurs with some types of cancer, can also cause low phosphate levels. Hypophosphatemia is also a frequent complication of renal transplantation (Yu & Stubbs, 2019).

Clinical Manifestations

Most of the signs and symptoms of phosphorus deficiency result from a deficiency of ATP, 2,3-diphosphoglycerate, or both (Yu & Stubbs, 2019). ATP deficiency impairs cellular energy resources; diphosphoglycerate deficiency impairs oxygen delivery to tissues, resulting in generalized weakness and neurologic manifestations. Clinical signs and symptoms can be found in Table 10-10.

Muscle damage may develop as the ATP level in the muscle tissue declines. Clinical manifestations are muscle weakness, which may be subtle or profound and may affect any muscle group; muscle pain; and at times acute rhabdomyolysis (breakdown of skeletal muscle). Weakness of the diaphragm and intercostal muscles may greatly impair ventilation. Bone pain, altered mental status, seizures, focal neurologic signs, and heart failure can occur with severe hypophosphatemia (Yu & Stubbs, 2019).

Assessment and Diagnostic Findings

On laboratory analysis, the serum phosphorus level is less than 2.7 mg/dL (0.87 mmol/L). When reviewing laboratory results, the nurse should keep in mind that glucose or insulin administration causes a decrease in the serum phosphorus level. Acute hypophosphatemia can occur during the treatment of DKA due to high doses of insulin. Elevated PTH levels that occur as a result of hyperparathyroidism can lower blood levels of phosphate. A 24-hour urine collection for phosphorus can be done if renal-phosphate wasting is suspected. Fanconi syndrome causes loss of glucose, amino acids, uric acid, and phosphate in the urine. X-rays and bone density studies may show skeletal changes of reduced bone mineralization caused by osteomalacia or rickets. A technetium (Tc99m) sestamibi scan of the neck can be done to check for hyperparathyroidism. CT scan, MRI, or indium-111 octreotide scan may show oncogenic osteomalacia (decreased bone density due to cancer) (Sharma & Castro, 2019).

Medical Management

Prevention of hypophosphatemia is the goal. In patients at risk for hypophosphatemia, serum phosphate levels should be closely monitored and correction initiated before deficits become severe. Adequate amounts of phosphorus should be added to parenteral solutions, and attention should be paid to the phosphorus levels in enteral feeding solutions.

Medical management of hypophosphatemia depends on the etiology, and treatment of the cause is essential. Severe hypophosphatemia is dangerous and requires prompt attention. Oral phosphate supplements are usually adequate for mild hypophosphatemia. Sources of phosphorus include dairy foods, meats, and beans. Oral supplements may be sufficient to treat renal-wasting disorders, malabsorption, or oncogenic osteomalacia until an exact etiology is found. Vitamin D may also be necessary to enhance absorption of phosphorus and calcium.

Aggressive IV phosphorus correction is usually limited to the patient whose serum phosphorus levels decrease to less than 1 mg/dL (0.3 mmol/L). Possible effects of IV administration of phosphorus include tetany from hypocalcemia and calcifications in tissues (blood vessels, heart, lung, kidney, eyes) from hyperphosphatemia.

Recently a monoclonal antibody-type drug, burosumab, has been approved for patients with renal phosphate wasting disorders and hypophosphatemic rickets. This drug has been found to normalize phosphate levels, improve bone mineralization, and heal fractures in rickets (Perwad & Portale, 2019).

If hyperparathyroidism is caused by parathyroid tumor, surgery may be necessary. A parathyroid tumor, termed an adenoma, can cause hyperparathyroidism with resulting demineralization of bone (osteomalacia). Patients with hyperparathyroidism can also be given calcimimetic medications, such as cinacalcet, which activate the calcium receptor in the gland and decrease PTH secretion (Wang & Yuan, 2019).

Patients with oncogenic osteomalacia should be treated for the cancer causing this syndrome. If malabsorption is the cause of hypophosphatemia, treatment of the GI disorder is necessary. Because patients with osteomalacia are at high risk for fracture, fall precautions should be observed. If hypophosphatemia is caused by an eating disorder, the patient should obtain behavioral counseling and nutritional therapy.

Nursing Management

The nurse should identify patients at risk for hypophosphatemia and monitor them. Because patients who are malnourished and receiving parenteral nutrition are at risk when calories are introduced too aggressively, preventive measures involve gradually introducing the solution to avoid rapid shifts of phosphorus into the cells. Vitamin D and calcium levels should also be monitored as phosphate levels are influenced by these levels. Vitamin D

supplementation may be needed to enhance calcium and phosphate absorption (Aubry et al., 2018).

In patients requiring correction of phosphorus losses, the nurse frequently monitors serum phosphorus levels and documents and reports early signs of hypophosphatemia (apprehension, confusion, change in level of consciousness). If the patient experiences mild hypophosphatemia, foods such as milk and milk products, organ meats, beans, nuts, fish, poultry, and whole grains should be encouraged. With moderate hypophosphatemia, supplements such as Neutra-Phos capsules, K-Phos, and Fleet Phospho-Soda may be prescribed (Vallerand & Sanoski, 2019; Yu & Stubbs, 2019).

For patients with severe hypophosphatemia, IV preparations of phosphorus are available as sodium or potassium phosphate. The rate of phosphorus administration should not exceed 3 mmol/h, and the site should be carefully monitored because tissue sloughing and necrosis can occur with infiltration. Serum calcium and phosphate blood levels should be monitored every 6 hours with IV therapy.

Phosphorus Excess (Hyperphosphatemia)

Hyperphosphatemia is a serum phosphorus level that exceeds 4.5 mg/dL (1.45 mmol/L). Abnormally high levels of phosphate in the bloodstream can arise from excessive intake of phosphorus, decreased excretion of phosphorus, or a disorder that shifts intracellular phosphate into the extracellular space.

Pathophysiology

Various conditions can lead to hyperphosphatemia; however, the most common is kidney injury, which diminishes urinary phosphate excretion (Stubbs & Yu, 2019). When renal insufficiency progresses to 40% to 50% of renal function, hyperphosphatemia can occur. Other causes include increased intake or a shift of phosphate from the intracellular to extracellular space. Conditions such as excessive vitamin D intake, administration of total parenteral nutrition, chemotherapy for neoplastic disease, hypoparathyroidism, pseudohypoparathyroidism, metabolic or respiratory acidosis, DKA, acute hemolysis, high phosphate intake, profound muscle necrosis, and increased phosphorus absorption may also lead to this phosphorus imbalance. Hypoparathyroidism causes hyperphosphatemia by failure of the kidneys to inhibit renal reabsorption of phosphate. The kidneys reabsorb excessive phosphate into the bloodstream. Pseudohypoparathyroidism is a disorder caused by end-organ resistance to PTH. Excessive use of phosphate-containing laxatives or enemas can also lead to hyperphosphatemia. False elevation of phosphate in the bloodstream can occur with elevated protein or bilirubin levels, dyslipidemia, or hemolysis. The primary complication of increased

phosphorus is metastatic calcification in the organs, soft tissues, joints, and arteries. Arterial calcification is a risk factor for myocardial infarction, stroke, and peripheral arterial disease (Norris, 2019; Stubbs & Yu, 2019).

Clinical Manifestations

Clinical signs and symptoms can be found in Table 10-10. Most symptoms result from decreased calcium levels and soft tissue calcifications. The most important short-term consequence is tetany (severe muscle cramping). Because of the reciprocal relationship between phosphorus and calcium, a high serum phosphorus level tends to cause a low serum calcium concentration. Hypocalcemia causes neuromuscular irritability and muscle spasms (Bove-Fenderson & Mannstadt, 2018).

The major long-term consequence is soft tissue calcification, which occurs mainly in patients with a reduced glomerular filtration rate. High serum levels of inorganic phosphorus promote precipitation of calcium phosphate in nonosseous sites, which can decrease urine output, impair vision, and produce palpitations. Skin and soft tissue deposits of calcium can cause pruritus (Marcucci, Cianferotti, & Brandi, 2018).

Assessment and Diagnostic Findings

On laboratory analysis, the serum phosphorus level exceeds 4.5 mg/dL (1.5 mmol/L). The serum calcium level is useful also for diagnosing the primary disorder and assessing the effects of treatments. X-rays may show skeletal changes with abnormal bone development. PTH levels are decreased in hypoparathyroidism. BUN and creatinine levels are used to assess renal function (Marcucci et al., 2018).

Medical Management

Phosphate intake should be reduced and phosphate binders can be given with meals to reduce hyperphosphatemia. When possible, treatment is directed at the underlying disorder. For example, hyperphosphatemia may be related to volume depletion or respiratory or metabolic acidosis. Correction of these disorders may normalize the blood level of phosphate.

Calcium carbonate or calcium citrate are phosphate binders that can be used to lower blood phosphate levels. However, careful monitoring of calcium is essential as hypercalcemia can result. Phosphate binding resins that do not contain calcium include sevelamer and lanthanum. Sucroferric oxyhydroxide can also be used particularly in patients who require iron supplementation. Forced diuresis with a loop diuretic or saline diuresis can be used in patients

with normal renal function. Hemodialysis can also lower phosphorus (Carfagna, Del Vecchio, Pontoriero, et al., 2018).

Nursing Management

The nurse monitors patients at risk for hyperphosphatemia. If a low phosphorus diet is prescribed, the patient is instructed to avoid phosphorus-rich foods, such as hard cheeses, cream, nuts, meats, whole-grain cereals, dried fruits, dried vegetables, kidneys, sardines, and dairy foods (Shimada, Shutto-Uchita, & Yamabe, 2019). When appropriate, the nurse instructs the patient to avoid phosphate-containing laxatives and enemas. When administering phosphate binders, calcium levels should be monitored as well. During diuresis the nurse monitors urine output. The nurse also educates the patient about recognizing the signs of hypocalcemia, such as muscle cramping (Goltzman, 2019a).

Chloride Imbalances

Chloride (Cl^-) is the major anion of the ECF compartment. It maintains cellular integrity by providing water balance and maintains acid–base balance. Sodium and chloride make up the electrolytes that exert osmotic pressure. Chloride is also contained in gastric and pancreatic juices, sweat, bile, and saliva. Chloride is produced in the stomach, where it combines with hydrogen to form hydrochloric acid. Chloride control depends on the intake of chloride and the excretion and reabsorption of its ions in the kidneys. A small amount of chloride is lost in the feces (Norris, 2019).

The normal serum chloride level is 97 to 107 mEq/L (97 to 107 mmol/L). Inside the cell, the chloride level is 4 mEq/L. The serum level of chloride reflects a change in dilution or concentration of the ECF and does so in direct proportion to the sodium concentration. Serum osmolality parallels chloride levels as well. Aldosterone secretion increases sodium reabsorption, thereby increasing chloride reabsorption (Hall, 2016).

The choroid plexus, which secretes cerebrospinal fluid in the brain, depends on sodium and chloride to attract water to form the fluid portion of the cerebrospinal fluid.

Bicarbonate has an inverse relationship with chloride. As chloride moves from plasma into the RBCs (called the *chloride shift*), bicarbonate moves back into the plasma. Hydrogen ions are formed, which then help release oxygen from hemoglobin (Emmett & Szerlip, 2017a). When the level of one of these three electrolytes (sodium, bicarbonate, or chloride) is disturbed, the other two are also affected. Chloride assists in maintaining acid–base balance and works as a buffer in the exchange of oxygen and CO_2 in RBCs (Fischbach &

Fischbach, 2018). Chloride is primarily obtained from the diet as table salt. The chloride imbalances are chloride deficit and chloride excess (Table 10-11).

Chloride Deficit (Hypochloremia)

Hypochloremia is a serum chloride level below 97 mEq/L (97 mmol/L).

Pathophysiology

Hypochloremia can occur with GI tube drainage, gastric suctioning, gastric surgery, and severe vomiting and diarrhea. Administration of chloride-deficient IV solutions, low sodium intake, decreased serum sodium levels, DKA, chronic respiratory acidosis, massive blood transfusions, diuretic therapy, excessive sweating, burns, SIADH, and fever may cause hypochloremia. Administration of aldosterone, ACTH, corticosteroids, bicarbonate, excess diuretics, or laxatives decreases serum chloride levels as well. As chloride decreases (usually because of volume depletion), sodium and bicarbonate ions are retained by the kidney to balance the loss. Bicarbonate accumulates in the ECF, which raises the pH and can lead to hypochloremic metabolic alkalosis (Emmett & Szerlip, 2017a).

Clinical Manifestations

The signs and symptoms of hypochloremia are outlined in Table 10-11. The signs and symptoms of hyponatremia, hypokalemia, and metabolic alkalosis may also be present. Metabolic alkalosis is a disorder that results in a high pH and a high serum bicarbonate level as a result of excess alkali intake or loss of hydrogen ions. With compensation, the partial pressure of CO_2 in arterial blood ($PaCO_2$) increases to 50 mm Hg. Hyperexcitability of muscles, tetany, hyperactive DTRs, weakness, twitching, and muscle cramps may result. Hypokalemia can cause hypochloremia, resulting in cardiac arrhythmias. In addition, because low chloride levels parallel low sodium levels, a water excess may occur. Hyponatremia can cause seizures and coma (Squiers, 2017).

TABLE 10-11 Chloride Imbalances

Imbalance	Contributing Factors	Signs/Symptoms and Laboratory Findings
Chloride deficit (hypochloremia) Serum chloride <96 mEq/L	Addison disease, reduced chloride intake or absorption, untreated diabetic ketoacidosis, chronic respiratory acidosis, excessive sweating, vomiting, gastric suction, diarrhea, sodium and potassium deficiency, metabolic alkalosis; loop, osmotic, or thiazide diuretic use; overuse of bicarbonate, rapid removal of ascitic fluid with a high sodium content, IV fluids that lack chloride (dextrose and water), draining fistulas and ileostomies, heart failure, cystic fibrosis	Agitation, irritability, tremors, muscle cramps, hyperactive deep tendon reflexes, hypertonicity, tetany, slow shallow respirations, seizures, arrhythmias, coma *Labs indicate:* ↓ serum chloride, ↓ serum sodium, ↑ pH, ↑ serum bicarbonate, ↑ total carbon dioxide content, ↓ urine chloride level, ↓ serum potassium
Chloride excess (hyperchloremia) Serum chloride >108 mEq/L	Excessive sodium chloride infusions with water loss, head injury (sodium retention), hypernatremia, kidney injury, corticosteroid use, dehydration, severe diarrhea (loss of bicarbonate), respiratory alkalosis, administration of diuretics, overdose of salicylates, sodium polystyrene sulfonate, acetazolamide, phenylbutazone and ammonium chloride use, hyperparathyroidism, metabolic acidosis	Tachypnea, lethargy, weakness, deep rapid respirations, decline in cognitive status, ↓ cardiac output, dyspnea, tachycardia, pitting edema, arrhythmias, coma *Labs indicate:* ↑ serum chloride, ↑ serum potassium and sodium, ↓ serum pH, ↓ serum bicarbonate, normal anion gap, ↑ urinary chloride level

↓, decreased; ↑, increased; IV, intravenous.

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health state* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Assessment and Diagnostic Findings

In addition to the chloride level, sodium and potassium levels are also evaluated, because these electrolytes are lost along with chloride. ABG analysis identifies the acid–base imbalance, which is usually metabolic alkalosis. The urine chloride level, which is also measured, decreases in hypochloremia.

Medical Management

Treatment involves correcting the cause of hypochloremia and the contributing electrolyte and acid–base imbalances. Normal saline (0.9% sodium chloride) or half-strength saline (0.45% sodium chloride) solution is given by IV to replace the chloride. If the patient is receiving a diuretic (loop, osmotic, or thiazide), it may be discontinued or another diuretic prescribed (Squiers, 2017).

Ammonium chloride, an acidifying IV agent, may be prescribed to treat metabolic alkalosis; the dosage depends on the patient's weight and serum chloride level. This agent is metabolized by the liver, and its effects last for about 3 days. Its use should be avoided in patients with impaired liver or renal function (Emmett & Szerlip, 2017b).

Nursing Management

The nurse monitors the patient's I&O, ABG values, and serum electrolyte levels. Changes in the patient's level of consciousness and muscle strength and movement are reported to the primary provider promptly. Vital signs are monitored, and respiratory assessment is carried out frequently. The nurse provides and educates the patient about foods with high chloride content, which include tomato juice, bananas, dates, eggs, cheese, milk, salty broth, canned vegetables, and processed meats. A person who drinks free water (water without electrolytes) or bottled water and excretes large amounts of chloride needs instruction to avoid drinking this kind of water (Squiers, 2017).

Chloride Excess (Hyperchloremia)

Hyperchloremia exists when the serum level of chloride exceeds 107 mEq/L (107 mmol/L). Hypernatremia, bicarbonate loss, and metabolic acidosis can occur with high chloride levels.

Pathophysiology

High serum chloride levels are almost exclusively a result of iatrogenically induced hyperchloremic metabolic acidosis, stemming from excessive

administration of chloride relative to sodium, most commonly as 0.9% normal saline solution, 0.45% normal saline solution, or lactated Ringer's solution. This condition can also be caused by the loss of bicarbonate ions via the kidney or the GI tract with a corresponding increase in chloride ions. Chloride ions in the form of acidifying salts accumulate, and acidosis occurs with a decrease in bicarbonate ions. Head trauma, increased perspiration, excess adrenocortical hormone production, and decreased glomerular filtration can lead to a high serum chloride level (Squiers, 2017).

Clinical Manifestations

The signs and symptoms of hyperchloremia are the same as those of metabolic acidosis: hypervolemia and hypernatremia. Tachypnea, weakness, lethargy, deep and rapid respirations, diminished cognitive ability, and hypertension occur. If untreated, hyperchloremia can lead to a decrease in cardiac output, arrhythmias, and coma. A high chloride level is accompanied by a high sodium level and fluid retention (Squiers, 2017).

Assessment and Diagnostic Findings

The serum chloride level is 108 mEq/L (108 mmol/L) or greater, the serum sodium level is greater than 145 mEq/L (145 mmol/L), the serum pH is less than 7.35, and the serum bicarbonate level is less than 22 mEq/L (22 mmol/L). Urine chloride levels are elevated.

Medical Management

Correcting the underlying cause of hyperchloremia and restoring electrolyte, fluid, and acid–base balance are essential. Hypotonic IV solutions may be given to restore balance. Lactated Ringer's solution may be prescribed to convert lactate to bicarbonate in the liver, which increases the bicarbonate level and corrects the acidosis. IV sodium bicarbonate may be given to increase bicarbonate levels, which leads to the renal excretion of chloride ions because bicarbonate and chloride compete for combination with sodium. Diuretics may be given to eliminate chloride as well. Sodium, chloride, and fluids are restricted (Squiers, 2017).

Nursing Management

Monitoring vital signs, ABG values, and I&O is important to assess the patient's status and the effectiveness of treatment. Assessment findings related to respiratory, neurologic, and cardiac systems are documented, and changes are discussed with the primary provider. The nurse educates the patient about

the diet that should be followed to manage hyperchloremia and maintain adequate hydration.

Acid–Base Disturbances

Acid–base disturbances are commonly encountered in clinical practice, especially in critical-care units. Identification of the specific acid–base imbalance is important in ascertaining the underlying cause of the disorder and determining appropriate treatment.

Plasma pH is an indicator of hydrogen ion (H^+) concentration and measures the acidity or alkalinity of the blood. Homeostatic mechanisms keep pH within a normal range (7.35 to 7.45). These mechanisms consist of buffer systems, the kidneys, and the lungs. The H^+ concentration is extremely important: The greater the concentration, the more acidic the solution and the lower the pH. The lower the H^+ concentration, the more alkaline the solution and the higher the pH (Larkin & Zimmanck, 2015; Norris, 2019).

Buffer systems prevent major changes in the pH of body fluids by removing or releasing H^+; they can act quickly to prevent excessive changes in H^+ concentration. Hydrogen ions are buffered by both intracellular and extracellular buffers. The body's major extracellular buffer system is the bicarbonate–carbonic acid buffer system, which is assessed when ABGs are measured. Normally, there are 20 parts of bicarbonate (HCO_3^-) to 1 part of carbonic acid (H_2CO_3). If this ratio is altered, the pH will change. It is the ratio of HCO_3^- to H_2CO_3 that is important in maintaining pH, not absolute values (Larkin & Zimmanck, 2015; Norris, 2019).

CO_2 is a potential acid; when dissolved in water, it becomes carbonic acid ($CO_2 + H_2O = H_2CO_3$). Therefore, when CO_2 is increased, the carbonic acid content is also increased. When the CO_2 level decreases, carbonic acid decreases. If either bicarbonate or carbonic acid is increased or decreased so that the 20:1 ratio is no longer maintained, acid–base imbalance results (Larkin & Zimmanck, 2015; Theodore, 2019).

Less important buffer systems in the ECF include the inorganic phosphates and the plasma proteins. Intracellular buffers include proteins, organic and inorganic phosphates, and, in RBCs, hemoglobin (Norris, 2019).

The kidneys regulate the bicarbonate level in the ECF; they can regenerate bicarbonate ions as well as reabsorb them from the renal tubular cells. In respiratory acidosis and most cases of metabolic acidosis, the kidneys excrete hydrogen ions and conserve bicarbonate ions to help restore balance. In respiratory and metabolic alkalosis, the kidneys retain hydrogen ions and excrete bicarbonate ions to help restore balance. The kidneys cannot

compensate for the metabolic acidosis created by kidney injury. Renal compensation for imbalances is relatively slow (a matter of hours or days) (Larkin & Zimmanck, 2015; Norris, 2019).

The lungs, under the control of the medulla, control the CO_2 and thus the carbonic acid content of the ECF. They do so by adjusting ventilation in response to the amount of CO_2 in the arterial blood. A rise in the partial pressure of CO_2 in arterial blood (designated $PaCO_2$) is a powerful stimulant to respiration. Of course, the partial pressure of oxygen in arterial blood (designated PaO_2) also influences respiration. However, its effect is not as marked as that produced by the $PaCO_2$ (Theodore, 2019).

In metabolic acidosis, the lungs compensate by raising respiratory rate, causing greater elimination of CO_2 (to reduce the acid load). In metabolic alkalosis, the lungs compensate by decreasing respiratory rate, causing CO_2 to be retained (to increase the acid load).

In order to understand acid–base imbalances, it is important to comprehend the chemical reaction that occurs in the bloodstream to maintain homeostasis. The bicarbonate buffer system is demonstrated by the following chemical equation:

$$CO_2 + H_2O \longleftrightarrow H_2CO_3 \longleftrightarrow H^+ \text{ and } HCO_3^-$$

TABLE 10-12 Normal Values for Arterial and Mixed Venous Bloods

Parameter	Arterial Blood	Mixed Venous Blood
pH	7.35–7.45	7.32–7.42
PCO_2	35–45 mm Hg	38–52 mm Hg
PO_2[a]	>80 mm Hg	24–48 mm Hg
HCO_3^-	22–26 mEq/L	19–25 mEq/L
Base excess/deficit	±2 mEq/L	±5 mEq/L
Oxygen saturation (SaO_2%)	>94%	65–75%

[a]At altitudes of 3000 feet and higher; age dependent.

Adapted from Fischbach, F., & Fischbach, M. (2018). *A manual of laboratory and diagnostic tests* (10th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

In this chemical equation, carbon dioxide (CO_2) and water form carbonic acid (H_2CO_3) which dissociates into H^+ and HCO_3^-. It is also important to recognize that the major organs that control acid–base balance are the lungs, in control of CO_2, and the kidneys, which can excrete or reabsorb the ions needed to balance the pH. ABGs are laboratory tests that can provide values of blood pH, $PaCO_2$, PaO_2, and HCO_3^-. ABGs are used to diagnose acid–base imbalances of the bloodstream. The saturation of Hgb with oxygen can also be

measured by pulse oximetry and designated as SaO_2. Normal range of SaO_2 is 95% to 100% (Theodore, 2019) (Table 10-12).

If the lungs slow down breathing rate, a condition termed hypoventilation, CO_2 will increase. Hypoventilation increases CO_2 retention. Normal $PaCO_2$ range is 35 to 45 mm Hg. Hypoventilation can increase the $PaCO_2$ greater than 45 mm Hg. Increased CO_2 will move the chemical equation to the right, which produces more H^+ ions and an acidotic bloodstream. The normal pH of the bloodstream is 7.35 to 7.45. An acidotic bloodstream has a pH less than 7.35 (Larkin & Zimmanck, 2015; Norris, 2019).

If the lungs increase breathing rate, a condition called hyperventilation, CO_2 is lost via the lungs. If CO_2 decreases it moves the equation to the left, pulling H^+ out of the bloodstream and creating an alkalotic bloodstream. An alkalotic bloodstream has a pH greater than 7.45 (Larkin & Zimmanck, 2015; Norris, 2019).

If H^+ ions increase in the bloodstream due to lactic acid accumulation, DKA, toxicity, or other source, it will push the equation to the left and increase CO_2 to be eliminated by the lungs. The lungs will increase breathing rate to rid the body of CO_2 in attempt to compensate for the high acid (Larkin & Zimmanck, 2015; Theodore, 2019).

If H^+ ions decrease in the bloodstream, it will pull the equation to the right using up some CO_2 to create more H^+. The lungs will slow breathing rate in an attempt to compensate by accumulating CO_2, which will produce H^+ (Larkin & Zimmanck, 2015; Theodore, 2019).

Acute and Chronic Metabolic Acidosis (Base Bicarbonate Deficit)

Metabolic acidosis is a common clinical disturbance characterized by a low pH due to an increased H^+ concentration and a low plasma bicarbonate concentration. Metabolic acidosis can occur by a gain of hydrogen ions or a loss of bicarbonate ions in the bloodstream. It can be divided clinically into two forms, according to the values of the serum anion gap: high anion gap metabolic acidosis and normal anion gap metabolic acidosis. The anion gap refers to the difference between the sum of all measured positively charged electrolytes (cations) and the sum of all negatively charged electrolytes (anions) in blood. Because the sum of measured cations is typically greater than the sum of measured anions in the bloodstream, there normally exists a disparity with predominance of cations; this is referred to as the anion gap. The anion gap reflects unmeasured anions (phosphates, sulfates, and proteins) in plasma that replace bicarbonate in metabolic acidosis. Measuring the anion

gap is necessary when analyzing conditions of metabolic acidosis as it can help determine the cause of the acidosis (Emmett & Szerlip, 2018).

The anion gap can be calculated by either of the following equations:

$$\text{Anion gap} = Na^+ + K^+ - (Cl^- + HCO_3^-)$$
$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-)$$

Potassium is often omitted from the equation because of its low level in the plasma; therefore, the second equation is used more often than the first (Theodore, 2019).

The normal value for an anion gap is 8 to 12 mEq/L (8 to 12 mmol/L) without potassium in the equation. If potassium is included in the equation, the normal value for the anion gap is 12 to 16 mEq/L (12 to 16 mmol/L). The unmeasured anions in the serum normally account for less than 16 mEq/L of the anion production. Metabolic acidotic conditions can be differentiated according to the anion gap; there is either a normal anion gap or high anion gap. A person diagnosed with metabolic acidosis is determined to have normal anion gap metabolic acidosis if the anion gap is within this normal range (8 to 12 mEq/L). An anion gap greater than 16 mEq (16 mmol/L) suggests excessive accumulation of unmeasured anions and would indicate high anion gap metabolic acidosis. An anion gap occurs because not all electrolytes are measured. More anions are left unmeasured than cations (Emmett & Szerlip, 2018).

Pathophysiology

Normal anion gap metabolic acidosis results from the direct loss of bicarbonate, as in diarrhea, lower intestinal fistulas, ureterostomies, use of diuretics, early renal insufficiency, excessive administration of chloride, and the administration of parenteral nutrition without bicarbonate or bicarbonate-producing solutes (e.g., lactate) (Emmett & Szerlip, 2018).

High anion gap metabolic acidosis occurs when there is an excessive accumulation of acids. High anion gap occurs in lactic acidosis, salicylate poisoning (acetylsalicylic acid), renal failure, methanol, ethylene or propylene glycol toxicity, DKA, and ketoacidosis that occurs with starvation. The high amount of hydrogen ions due to the acids present are neutralized and buffered by HCO_3^- causing the bicarbonate concentration to fall and become exhausted. Other anions in the bloodstream are called upon to neutralize the high acid in the blood. In all of these instances, abnormally high levels of anions are used to neutralize the H^+, which increases the anion gap above normal limits (high anion gap) (Emmett & Szerlip, 2019).

Concept Mastery Alert

Metabolic acidosis is characterized by a low pH and low plasma bicarbonate concentration. Nurses need to remember that an anion gap is calculated primarily to identify the cause (pathology) of metabolic acidosis.

	Reduced or Negative Anion Gap	Normal Anion Gap	High Anion Gap
Anion gap without potassium	<8	8–12 mEq/L	>12
Anion gap with potassium	<12	12–16 mEq/L	>16
Clinical significance	Hypoproteinemia	Normal anion gap metabolic acidosis	High anion gap metabolic acidosis

Clinical Manifestations

Signs and symptoms of metabolic acidosis vary with the severity of the acidosis but include headache, confusion, drowsiness, increased respiratory rate and depth, nausea, and vomiting. Peripheral vasodilation and decreased cardiac output occur when the pH drops to less than 7. Additional physical assessment findings include decreased blood pressure, cold and clammy skin, arrhythmias, and shock. Chronic metabolic acidosis is primarily caused by chronic kidney disease because dysfunctional kidneys do not excrete acid (Emmett & Szerlip, 2018; Kovesdy, 2018).

Assessment and Diagnostic Findings

ABG measurements are used in the diagnosis of acid–base imbalances such as metabolic acidosis. Expected ABG changes include a low bicarbonate level (less than 22 mEq/L) and a low blood pH (less than 7.35). The cardinal feature of metabolic acidosis is a decrease in the serum bicarbonate level. In conditions of acidosis there is elevated H^+ and the sodium–potassium cellular pump brings H^+ into the cells in place of K^+. Therefore, high K^+ accumulates in the bloodstream in metabolic acidosis as a result of the shift of potassium out of the cells (Theodore, 2019). Later, when the acidosis is corrected and pH normalized, the cellular pump causes potassium to move back into the cells and hypokalemia may occur. Blood levels of potassium need to be closely monitored. ECG monitoring is recommended as changes of potassium in the bloodstream can cause arrhythmias (Palmer & Clegg, 2016a).

In metabolic acidosis, the lungs compensate for the high H^+ through hyperventilation to decrease the CO_2 level, which in turn reduces H^+ (see

carbonic acid equation). Calculation of the anion gap is helpful in determining the cause of metabolic acidosis. There are certain conditions that cause high anion gap metabolic acidosis and others that cause normal anion gap metabolic acidosis (Table 10-13).

TABLE 10-13 Summary of Single Acid–Base Disturbances and Their Compensatory Responses

Acid–Base Imbalance	Primary Disturbance	Respiratory Compensation and Predicted Response[a]	Renal Compensation and Predicted Response[a,b]
Metabolic acidosis	↓ pH and HCO_3^- HCO_3^- <22 mEq/L	↑ ventilation and ↓ PCO_2 *1 mEq/L ↓ HCO_3^- → 1–1.2 mm Hg ↓ PCO_2*	↑ H^+ excretion and ↑ HCO_3^- reabsorption if no renal disease
Metabolic alkalosis	↑ pH and HCO_3^- HCO_3^- >26 mEq/L	↓ ventilation and ↑ PCO_2 *1 mEq/L ↑ HCO_3^- → 0.7 mm Hg ↑ PCO_2*	↓ H^+ excretion and ↓ HCO_3^- reabsorption if no renal disease
Respiratory acidosis	↓ pH and ↑ PCO_2 PCO_2 >45 mm Hg	None	↑ H^+ excretion and ↑ HCO_3^- reabsorption *Acute: 1 mm Hg ↑ PCO_2 → 0.1 mEq/L ↑ HCO_3^-* *Chronic: 1 mm Hg ↑ PCO_2 → 0.3 mEq/L ↑ HCO_3^-*
Respiratory alkalosis	↑ pH and ↓ PCO_2 PCO_2 <35 mm Hg	None	↓ H^+ excretion and ↓ HCO_3^- reabsorption *Acute: 1 mm Hg ↓ PCO_2 → 0.2 mEq/L ↓ HCO_3^-* *Chronic: 1 mm Hg ↓ PCO_2 → 0.4 mEq/L ↓ HCO_3^-*

Note: Predicted compensatory responses are in *italics.*

[a]If blood values are the same as predicted compensatory values, a single acid–base disorder is present; if values are different, a mixed acid–base disorder is present.

[b]Acute renal compensation refers to duration of minutes to several hours; chronic renal compensation refers to a duration of several days.

Medical Management

Treatment is directed at correcting the metabolic imbalance. If the problem results from excessive intake of chloride, treatment is aimed at eliminating the source of the chloride. When necessary, bicarbonate is given; however, the administration of sodium bicarbonate during cardiac arrest can result in

paradoxical intracellular acidosis. Hyperkalemia may occur with acidosis and hypokalemia with reversal of the acidosis and subsequent movement of potassium back into the cells. Therefore, the serum potassium level is monitored closely, and hypokalemia is corrected as acidosis is reversed (Mount, 2017c).

In chronic metabolic acidosis, low serum calcium levels are treated before the chronic metabolic acidosis is treated to avoid tetany resulting from an increase in pH and a decrease in ionized calcium. Alkalizing agents may be given. Treatment modalities may also include hemodialysis or peritoneal dialysis (Goltzman, 2019b).

Acute and Chronic Metabolic Alkalosis (Base Bicarbonate Excess)

Metabolic alkalosis is a clinical disturbance characterized by a high pH (decreased H^+ concentration) and a high plasma bicarbonate concentration. It is caused by a gain of bicarbonate or a loss of H^+ (Emmett & Szerlip, 2017a; Norris, 2019).

Pathophysiology

A common cause of metabolic alkalosis is severe vomiting or gastric suction that causes loss of stomach HCl (hydrogen and chloride ions). The disorder also occurs in pyloric stenosis, in which only gastric fluid is lost. Gastric fluid has an acid pH (usually 1 to 3), and loss of this highly acidic fluid pulls H^+ ions from the bloodstream to replenish the gastric acid. As a result, the bloodstream loses H^+ ions and becomes alkalotic. Other situations predisposing to metabolic alkalosis include those associated with loss of potassium, such as diuretic therapy that promotes excretion of potassium (e.g., thiazides, furosemide), and ACTH secretion (as in hyperaldosteronism and Cushing's syndrome) (Emmett & Szerlip, 2017a; Norris, 2019).

Hypokalemia produces alkalosis in two ways: (1) when the bloodstream is low in K^+, the nephrons reabsorb K^+ into the bloodstream and secrete H^+ into the tubule fluid which is excreted in the urine and (2) when the bloodstream is low in K^+, intracellular potassium moves out of the cells into the ECF, and as potassium ions leave the cells, hydrogen ions must enter to maintain electroneutrality (Mount, 2017c). Excessive alkali ingestion from antacids containing bicarbonate or from the use of sodium bicarbonate during cardiopulmonary resuscitation can also cause metabolic alkalosis (Emmett & Szerlip, 2017b).

Chronic metabolic alkalosis can occur with long-term diuretic therapy (thiazides or furosemide), villous adenoma in the GI tract, external drainage of gastric fluids, significant potassium depletion, cystic fibrosis, and the chronic ingestion of milk and calcium carbonate (Emmett & Szerlip, 2017b).

Clinical Manifestations

In alkalosis, H^+ ions are decreased in the bloodstream, leaving negatively charged proteins attracting other positive ions. Calcium (Ca^{++}) ions bind to these proteins. As calcium ions bind to proteins in the bloodstream, free Ca^{++} ions decrease in the bloodstream and hypocalcemia develops. Alkalosis is primarily manifested by symptoms related to hypocalcemia, such as tingling of the fingers and toes, dizziness, and tetany (cramping muscles). Because it is the ionized fraction of calcium that is diminished in metabolic alkalosis, neuromuscular symptoms due to hypocalcemia are often the predominant symptoms (Emmett & Szerlip, 2017c).

In metabolic alkalosis, the lungs attempt to compensate by slowing respiratory rate, which increases CO_2 retention, and in turn increases H^+ content of the blood (see carbonic acid equation). If the kidneys are functional, there is increased renal excretion of HCO_3^- and conservation of H^+ in an attempt to reduce the alkalinity of the bloodstream. As the pH of blood increases in metabolic alkalosis, H^+ ions are reabsorbed into the bloodstream to neutralize the blood. As the nephrons increase H^+ ion reabsorption, they excrete K^+, and hypokalemia develops (Larkin & Zimmanck, 2015). In hypokalemia a prominent U wave often develops on the ECG and ventricular rhythm disturbances, such as PVCs, may occur. Hypokalemia also can lead to decreased GI motility and paralytic ileus (Emmett & Szerlip, 2017c).

Assessment and Diagnostic Findings

In metabolic alkalosis, evaluation of ABGs reveals a pH greater than 7.45 and a serum bicarbonate concentration greater than 26 mEq/L (see Table 10-12 for normal values of ABGs). The $PaCO_2$ increases as the lungs attempt to compensate for the excess bicarbonate by retaining CO_2. This hypoventilation is more pronounced in patients who are semiconscious, unconscious, or debilitated than in patients who are alert. Because of hypoventilation the patient may develop hypoxemia (Emmett & Szerlip, 2017c).

Urine chloride levels may help identify the cause of metabolic alkalosis if the patient's history provides inadequate information. Metabolic alkalosis is the setting in which urine chloride concentration may be a more accurate estimate of fluid volume than the urine sodium concentration. Urine chloride concentrations can help to determine the source of the metabolic alkalosis. Urine chloride concentrations can be used to differentiate between vomiting, diuretic therapy, and excessive

adrenocorticosteroid secretion as the cause of the metabolic alkalosis. In patients with vomiting or cystic fibrosis, those receiving nutritional repletion, and those receiving diuretic therapy, hypovolemia and hypochloremia produce urine chloride concentrations lower than 25 mEq/L. Signs of hypovolemia are not present, and the urine chloride concentration exceeds 40 mEq/L in patients with mineralocorticoid excess or alkali loading; these patients usually have expanded fluid volume (Emmett & Palmer, 2019).

Medical Management

Treatment of both acute and chronic metabolic alkalosis is aimed at correcting the underlying acid–base disorder. Because volume depletion is commonly present with GI losses of H^+, the patient's I&O must be monitored carefully.

Treatment includes restoring normal fluid volume by administering normal saline because continued volume depletion perpetuates the alkalosis. In patients with hypokalemia, potassium is given as KCl to replace both K^+ and Cl^- losses. Proton pump inhibitors (e.g., omeprazole) are recommended to reduce the production of gastric hydrogen chloride (HCl). This decreased HCl will in turn decrease the loss of HCl with gastric suction in metabolic alkalosis. Carbonic anhydrase inhibitors (e.g., acetazolamide) are useful in treating metabolic alkalosis in patients who cannot tolerate rapid volume expansion (e.g., patients with heart failure). Carbonic anhydrase inhibitors act at the nephron to enhance bicarbonate excretion (Mehta & Emmett, 2018).

Acute and Chronic Respiratory Acidosis (Carbonic Acid Excess)

Respiratory acidosis is a clinical disorder in which the pH is less than 7.35 and the $PaCO_2$ is greater than 45 mm Hg. It may be either acute or chronic.

Pathophysiology

Respiratory acidosis is due to inadequate excretion of CO_2 with inadequate ventilation, resulting in elevated plasma CO_2 concentrations

and, consequently, increased levels of carbonic acid. In addition to an elevated $PaCO_2$, inadequate ventilation usually causes a decrease in PaO_2. Acute respiratory acidosis occurs in emergency situations, such as acute pulmonary edema, aspiration of a foreign object, atelectasis, pneumothorax, and overdose of sedatives, as well as in nonemergent situations, such as sleep apnea associated with severe obesity, severe pneumonia, and acute respiratory distress syndrome. Respiratory acidosis commonly occurs in patients with severe chronic obstructive pulmonary disease (COPD) when patients acutely decompensate due to respiratory infection or heart failure. Respiratory acidosis can also occur in diseases that impair respiratory muscle function and cause hypoventilation. These disorders include severe scoliosis, muscular dystrophy, multiple sclerosis, myasthenia gravis, and Guillain-Barré syndrome (Feller-Kopman & Schwartzstein, 2017).

Clinical Manifestations

Clinical signs in acute and chronic respiratory acidosis vary. Acute respiratory acidosis can occur due to sudden hypercapnia (elevated $PaCO_2$) that will increase pulse, blood pressure, and respiratory rate. The patient may complain of confusion, disorientation, or may exhibit diminished level of consciousness. An elevated $PaCO_2$, greater than 60 mm Hg causes reflexive cerebrovascular vasodilation and increased cerebral blood flow. Ventricular fibrillation may be the first sign of respiratory acidosis in anesthetized patients (Feller-Kopman & Schwartzstein, 2017).

If respiratory acidosis is severe, intracranial pressure may increase, resulting in papilledema and dilated conjunctival blood vessels. Acidosis can cause hyperkalemia as the hydrogen ion concentration overwhelms the compensatory mechanisms. Acidosis causes H^+ ion to move into the cells, causing a shift of potassium out of the cell. The bloodstream then gains increased potassium ions (i.e., hyperkalemia) (Mount, 2017c).

Chronic respiratory acidosis occurs with pulmonary diseases such as COPD, including emphysema and chronic bronchitis; obstructive sleep apnea; and obesity. As long as the $PaCO_2$ does not exceed the body's ability to compensate, the patient will be asymptomatic. However, if the $PaCO_2$ increases rapidly, reflexive cerebral vasodilation will increase intracranial pressure, and cyanosis and tachypnea will develop. Patients with slowly progressive COPD gradually accumulate CO_2 over a

prolonged period of time (months to years) and the body becomes used to high CO_2 levels. Patients with long-term COPD may not develop symptoms of hypercapnia because compensatory renal changes have had time to occur (Feller-Kopman & Schwartzstein, 2017).

Quality and Safety Nursing Alert

If the $PaCO_2$ is chronically greater than 50 mm Hg, the respiratory center becomes relatively insensitive to CO_2 as a respiratory stimulant, leaving hypoxemia as the major drive for respiration. Patients with long-term COPD breathe independently based on a hypoxic drive. High oxygen concentration administration can remove the stimulus of hypoxemia. The patient can lose the independent stimulus to breathe and incur respiratory failure. Therefore, oxygen is given with extreme caution in patients with long-term COPD.

Assessment and Diagnostic Findings

In respiratory acidosis, ABG analysis reveals a pH less than 7.35, a $PaCO_2$ greater than 45 mm Hg, and variation in the bicarbonate level, depending on the duration of the acute respiratory acidosis. When compensation occurs over a prolonged period and renal retention of bicarbonate has fully occurred, the bicarbonate neutralizes the acidosis. Arterial pH is within the lower limits of normal (e.g., pH 7.35). Depending on the cause of respiratory acidosis, other diagnostic measures include monitoring of serum electrolyte levels, chest x-ray for determining respiratory infection or other disease, and a drug screen if an overdose is suspected. ECG monitoring is recommended to identify any cardiac involvement as a result of COPD (Feller-Kopman & Schwartzstein, 2017).

Medical Management

Treatment is directed at improving ventilation in acute and chronic respiratory acidosis. Exact measures vary according to the cause of inadequate ventilation. Pharmacologic agents are commonly used. For example, bronchodilators help reduce bronchial spasm and increase ventilation, antibiotics are used for respiratory infections, and

thrombolytics or anticoagulants are used for pulmonary emboli (Stoller, 2019).

Pulmonary physiotherapy and nebulizer treatment can be used to clear the respiratory tract of mucus and purulent drainage. Adequate hydration (2 to 3 L/day) is indicated to keep the mucous membranes moist and decrease viscosity of mucous, thereby facilitating removal of secretions. Low concentration of supplemental oxygen is given as necessary (Aboussouan, 2018).

Mechanical ventilation, used appropriately, may be necessary to improve pulmonary ventilation. $PaCO_2$ should be reduced slowly and gradually using a mechanical ventilator. Mechanical ventilation can cause too rapid ventilatory loss of CO_2, which pulls H^+ out of the bloodstream too rapidly. If there is a rapid loss of H^+ the bloodstream becomes too alkalotic. The kidneys are unable to eliminate bicarbonate quickly enough to prevent alkalosis and seizures (Feller-Kopman & Schwartzstein, 2017).

Acute and Chronic Respiratory Alkalosis (Carbonic Acid Deficit)

Respiratory alkalosis is a clinical condition in which the arterial pH is greater than 7.45 and the $PaCO_2$ is less than 35 mm Hg. As with respiratory acidosis, acute and chronic conditions can cause this acid–base disturbance.

Pathophysiology

Respiratory alkalosis is caused by hyperventilation, which causes excessive loss or "blowing off" of CO_2 and, hence, there is a decrease in the plasma carbonic acid concentration (see carbonic acid equation). Causes include extreme anxiety such as panic disorder, hypoxemia, salicylate intoxication, gram-negative sepsis, and inappropriate ventilator settings.

Chronic respiratory alkalosis results from chronic hypocapnia which leads to decreased serum H^+ ion, resulting in alkalosis. Chronic hepatic insufficiency and cerebral tumors can cause chronic hyperventilation that leads to chronic respiratory alkalosis (Schwartzstein, Richards, Edlow, et al., 2018).

Clinical Manifestations

Clinical signs of respiratory alkalosis consist of lightheadedness and inability to concentrate due to cerebral artery vasoconstriction and decreased cerebral blood flow, numbness and tingling from decreased calcium ionization in the bloodstream, tinnitus, and sometimes loss of consciousness. Cardiac effects of respiratory alkalosis include tachycardia and ventricular and atrial arrhythmias (Schwartzstein et al., 2018).

Assessment and Diagnostic Findings

Analysis of ABGs assists in the diagnosis of both acute and chronic respiratory alkalosis. In the acute state, the pH is elevated above normal (greater than 7.45) as a result of a low $PaCO_2$ and a normal bicarbonate level. The kidneys take days to compensate for acid–base imbalances. Therefore, the kidneys cannot alter the bicarbonate level in the bloodstream quickly enough and medical intervention is necessary (Norris, 2019).

In the compensated state of chronic respiratory alkalosis, the kidneys have had sufficient time to lower the bicarbonate level to a near-normal level. Evaluation of serum electrolytes is indicated to identify any decrease in potassium, as hydrogen is pulled out of the cells in exchange for potassium. A decreased calcium level may occur as severe alkalosis inhibits calcium ionization, resulting in carpopedal spasms and tetany. A decreased phosphate level can occur due to alkalosis because there is increased uptake of phosphate by the cells. A toxicology screen should be performed to rule out salicylate intoxication due to aspirin poisoning (Schwartzstein et al., 2018).

Medical Management

Treatment depends on the exact underlying cause of respiratory alkalosis. If the cause is anxiety, the patient is instructed to breathe more slowly to allow CO_2 to accumulate or to breathe into a closed system (such as a paper bag or CO_2 rebreather mask). An antianxiety agent may be required to relieve hyperventilation in very anxious patients. Treatment of other causes of respiratory alkalosis is directed at correcting the underlying problem.

Mixed Acid–Base Disorders

Patients can simultaneously experience two or more independent acid–base disorders. A normal pH in the presence of changes in the $PaCO_2$ and plasma HCO_3^- concentration immediately suggests a mixed disorder. An example of a mixed disorder is the simultaneous occurrence of metabolic acidosis due to lactic acid accumulation and respiratory acidosis due to hypoventilation. Both of these disorders result in excessive acid accumulation in the bloodstream due to respiratory failure and cardiac arrest (Emmett & Palmer, 2018b).

Compensation

Generally, the pulmonary and renal systems compensate for each other to return the pH to normal. In a single acid–base disorder, the system not causing the problem tries to compensate by returning the ratio of bicarbonate to carbonic acid to the normal 20:1. The lungs compensate for metabolic disturbances by changing CO_2 excretion; hypoventilation accumulates CO_2, hyperventilation causes loss of CO_2. The kidneys compensate for respiratory disturbances by altering bicarbonate reabsorption and H^+ secretion (Norris, 2019; Theodore, 2019).

In respiratory acidosis, excess hydrogen in the blood is excreted in the urine in exchange for bicarbonate ions which are conserved. In respiratory alkalosis, the renal excretion of bicarbonate increases, and hydrogen ions are retained. In metabolic acidosis, the lungs compensate by increasing the ventilation rate and the kidneys retain bicarbonate. In metabolic alkalosis, the respiratory system compensates by decreasing ventilation to conserve CO_2 and increase the $PaCO_2$, which in turn increases carbonic acid. Because the lungs respond to acid–base disorders within minutes, compensation for metabolic imbalances occurs faster than renal compensation for respiratory imbalances (Norris, 2019; Theodore, 2019).

Table 10-13 summarizes compensation effects.

Blood Gas Analysis

Blood gas analysis is often used to identify the specific acid–base disturbance and the degree of compensation that has occurred. The analysis is usually based on an arterial blood sample; however, if an arterial sample cannot be obtained, a mixed venous sample may be used

(Theodore, 2019). Results of ABG analysis provide information about alveolar ventilation, oxygenation, and acid–base balance. It is necessary to evaluate the concentrations of serum electrolytes (e.g., sodium, potassium, chloride) along with ABG data because electrolytes are commonly affected by acid–base imbalances. The health history, physical examination, previous blood gas results, and serum electrolytes should always be part of the assessment used to determine the cause of the acid–base disorder (Larkin & Zimmanck, 2015). Responding to isolated sets of blood gas results without these data can lead to serious errors in interpretation. Treatment of the underlying condition usually corrects acid–base disorders (Chart 10-3).

PARENTERAL FLUID THERAPY

When patients cannot take oral fluid or oral feedings, their status is termed NPO (*nil per os*), meaning nothing by mouth. In patients who are NPO, **parenteral fluid therapy,** also termed IV fluid therapy, is used to administer fluids. IV fluid therapy can be initiated to replace fluids in various clinical settings such as hospitals, outpatient diagnostic and surgical settings, clinics, and home health care. IV fluids can also be used to administer medications and provide nutrients.

Purpose

The choice of an IV solution depends on the purpose of its administration. Generally, IV fluids are given to achieve one or more of the following goals:

- To provide water, electrolytes, and nutrients to meet daily requirements
- To replace water and correct electrolyte deficits
- To administer medications and blood products

IV solutions contain dextrose and/or electrolytes mixed in various proportions with water. Pure, electrolyte-free water can never be given by IV because it rapidly enters RBCs and causes them to rupture (Sterns, 2017b).

Types of Intravenous Solutions

IV solutions are categorized as isotonic, hypotonic, or hypertonic, according to whether their total osmolality is the same as, less than, or greater than that of blood, respectively (see earlier discussion of osmolality and tonicity). Electrolyte solutions are considered isotonic if the total electrolyte content (anions + cations) is between 250 and 375 mEq/L, hypotonic if the total electrolyte content is less than 250 mEq/L, and hypertonic if the total electrolyte content is greater than 375 mEq/L. The nurse must also consider a solution's osmolality, keeping in mind that the osmolality of plasma is approximately 300 mOsm/L (300 mmol/L). For example, a 10% dextrose solution has an osmolality of approximately 505 mOsm/L, which is greater than the osmolality of the bloodstream (Emmett & Palmer, 2018a).

Isotonic Fluids

Fluids that are classified as isotonic have a total osmolality close to that of the ECF and do not cause cells to shrink or swell. When isotonic fluids are administered they expand the ECF volume. One liter of isotonic fluid expands the ECF by 1 L; however, isotonic solution expands the plasma component of ECF by only 0.25 L. An isotonic solution is a crystalloid solution (water containing soluble mineral salts). Plasma is a colloidal solution. A colloidal solution is a mixture of fluid containing insoluble large particles, such as proteins. Colloidal solutions exert oncotic pressure; crystalloids do not exert oncotic pressure (Siparsky, 2019; Sterns, 2018a).

Quality and Safety Nursing Alert

It is important for the nurse to recognize that in blood loss, 3 L of isotonic fluid (crystalloid solution) is needed to replace 1 L of blood (colloidal solution).

Because isotonic fluids expand the water volume in the intravascular space, patients with heart failure or hypertension who receive isotonic solutions should be carefully monitored for signs of fluid overload (Siparsky, 2019).

Chart 10-3 ASSESSMENT

Assessing Arterial Blood Gases

The following steps are recommended to evaluate arterial blood gas values. They are based on the assumption that the average values are:

pH = 7.35–7.45

$PaCO_2$ = 35–45 mm Hg

HCO_3^- = 24 to 27 mEq/L

1. *First, note the pH.* It can be high, low, or normal, as follows:

   A normal pH may indicate perfectly normal blood gases, *or* it may indicate a *compensated* imbalance. A compensated imbalance is one in which the body has been able to correct the pH by either respiratory or metabolic changes (depending on the primary problem). For example, a patient with primary metabolic acidosis starts out with a low bicarbonate level but a normal CO_2 level. Soon afterward, the lungs try to compensate for the imbalance by exhaling large amounts of CO_2 (hyperventilation). As another example, a patient with primary respiratory acidosis starts out with a high CO_2 level; soon afterward, the kidneys attempt to compensate by retaining bicarbonate. If the compensatory mechanism is able to restore the bicarbonate to carbonic acid ratio back to 20:1, full compensation (and thus normal pH) will be achieved.

   pH > 7.45 (alkalosis)

   pH < 7.35 (acidosis)

   pH = 7.4 (normal)

2. The next step is to determine the primary cause of the disturbance. This is done by evaluating the $PaCO_2$ and HCO_3^- in relation to the pH.

   Example: pH > 7.45 (alkalosis)

   a. If the $PaCO_2$ is less than 35 mm Hg, the primary disturbance is respiratory alkalosis. (This situation occurs when a patient hyperventilates and "blows off" too much CO_2. Recall that CO_2 dissolved in water becomes carbonic acid, the acid side of the "carbonic acid–bicarbonate buffer system.")

   b. If the HCO_3^- is greater than 27 mEq/L, the primary disturbance is metabolic alkalosis. (This situation occurs when the body gains too much bicarbonate, an alkaline substance. Bicarbonate is the basic or alkaline side of the "carbonic acid–bicarbonate buffer system.")

   Example: pH < 7.35 (acidosis)

   c. If the $PaCO_2$ is greater than 40 mm Hg, the primary disturbance is respiratory acidosis. (This situation occurs when a patient

hypoventilates and thus retains too much CO_2, an acidic substance.)

d. If the HCO_3^- is less than 24 mEq/L, the primary disturbance is metabolic acidosis. (This situation occurs when the body's bicarbonate level drops, either because of direct bicarbonate loss or because of gains of acids such as lactic acid or ketones.)

3. The next step involves determining if compensation has begun. This is done by looking at the value other than the primary disorder. If it is moving in the same direction as the primary value, compensation is under way. Consider the following gases:

The first set (1) indicates acute respiratory acidosis without compensation (the $PaCO_2$ is high, the HCO_3^- is normal). The second set (2) indicates chronic respiratory acidosis. Note that compensation has taken place—that is, the HCO_3^- has elevated to an appropriate level to balance the high $PaCO_2$ and produce a normal pH.

	pH	$PaCO_2$	HCO_3^-
(1)	7.2	60 mm Hg	24 mEq/L
(2)	7.4	60 mm Hg	37 mEq/L

4. Two distinct acid–base disturbances may occur simultaneously. These can be identified when the pH does not explain one of the changes. When the $PaCO_2$ is ↑ and the HCO_3 is ↓, respiratory acidosis and metabolic acidosis coexist. When the $PaCO_2$ is ↓ and the HCO_3 is ↑, respiratory alkalosis and metabolic alkalosis coexist.

Example: Metabolic and respiratory acidosis

a. pH 7.2 decreased pH (indicates acidosis)

b. $PaCO_2$ 52 increased pH (indicates respiratory acidosis)

c. HCO_3 13 decreased HCO_3 (indicates metabolic acidosis)

5. If metabolic acidosis exists, then calculate the anion gap (AG) to determine the cause of the metabolic acidosis (AG vs. non-AG):

$AG = Na - (Cl^- + HCO_3^-)$

Normal AG = 10−14 mmol/L

6. Evaluate the patient to determine if the clinical signs and symptoms are compatible with the acid–base analysis.

Adapted from Fischbach, F., & Fischbach, M. (2018). *A manual of laboratory and diagnostic tests* (10th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

D_5W

A solution of D_5W is unique in that it may be both isotonic and hypotonic (Hoorn, 2017). Once given, the glucose is rapidly metabolized, and this initially isotonic solution (same osmolality as serum) then disperses as a hypotonic fluid—one third extracellular and two thirds intracellular. It is essential to consider this action of D_5W, especially if the patient is at risk for increased intracranial pressure. During fluid resuscitation, this solution should not be used because hyperglycemia can result. Therefore, D_5W is used mainly to supply water and to correct an increased serum osmolality. About 1 L of D_5W provides less than 170 kcal and is a minor source of the body's daily caloric requirements (Hoorn, 2017).

Normal Saline Solution

Normal saline (0.9% sodium chloride) solution contains water, sodium, and chloride. Because the osmolality is entirely contributed by electrolytes, the solution remains within the ECF and expands the intravascular volume. For this reason, normal saline solution is often used to correct an extracellular volume deficit but is not identical to ECF. It is used with administration of blood transfusions and to replace large sodium losses, such as in burn injuries. It should not be used in heart failure, pulmonary edema, renal impairment, or sodium retention. Normal saline does not supply calories (Hoorn, 2017).

Other Isotonic Solutions

Several other solutions contain ions in addition to sodium and chloride and are somewhat similar to the ECF in composition. Lactated Ringer's solution contains potassium and calcium in addition to sodium chloride. It is used to correct dehydration, blood loss, and sodium depletion and to replace GI losses.

Hypotonic Fluids

One purpose of hypotonic solution is to replace fluid, because it is hypotonic compared with plasma. Another purpose of hypotonic solution is to provide free water. At times, hypotonic sodium solutions are used to treat hypernatremia and other hyperosmolar conditions. Half-strength saline (0.45% sodium chloride) solution is frequently used.

Hypertonic Fluids

Hypertonic fluids include 3% NaCl and IV mannitol. If a patient is sodium depleted, a hypertonic sodium IV solution might be used. If a patient is experiencing acute cerebral edema, IV mannitol is often used. Hypertonic solutions pull water from the interstitial and intracellular compartments into the bloodstream. These solutions draw water out of intracellular compartments causing cellular dehydration (Hoorn, 2017). Normal saline and lactated Ringer's solution are considered isotonic solutions. When 5% dextrose (D_5W) is added to normal saline solution or lactated Ringer's solution, the total osmolality exceeds that of the ECF. With the added dextrose, these are then considered hypertonic solutions. However, the dextrose is quickly metabolized, and after the dextrose is depleted, only the isotonic solution remains. Therefore, any effect on the intracellular compartment is temporary. Similarly, with hypotonic electrolyte solutions containing 5% dextrose, once the dextrose is metabolized, these solutions disperse as hypotonic fluids. However, higher concentrations of dextrose, such as 50% dextrose ($D_{50}W$) in water, are strongly hypertonic. Hypertonic solutions should be administered into central veins so that they can be diluted by large amounts of rapid blood flow (Hoorn, 2017).

Saline solutions are also available in osmolar concentrations greater than that of the ECF. These solutions draw water from the ICF to the ECF and cause cells to shrink. If given rapidly or in large quantity, they may cause an extracellular volume excess and precipitate circulatory overload and dehydration. As a result, these solutions must be given cautiously and usually only when the serum osmolality has decreased to dangerously low levels. Hypertonic solutions exert an osmotic pressure greater than that of the ECF (Hoorn, 2017).

Other Intravenous Therapies

When the patient is unable to tolerate food, nutritional requirements are often met using the IV route. Solutions may include high concentrations of glucose (such as 50% dextrose in water), protein, or fat to meet nutritional requirements (see Chapter 41). The IV route may also be used to administer colloids, plasma expanders, and blood products (Hoorn, 2017). Examples of blood products include whole blood, packed RBCs, fresh-frozen plasma, albumin, and cryoprecipitate (these are discussed in more detail in Chapter 28).

Many medications are also delivered by the IV route, either by continuous infusion or by intermittent bolus directly into the vein. Because IV medications enter the circulation rapidly, administration by this route is potentially hazardous. All medications can produce adverse reactions; however, medications given by the IV route can cause these reactions quickly after administration, because the medications are delivered directly into the bloodstream. Administration rates and recommended dilutions for individual medications are available in specialized texts pertaining to IV medications and in manufacturers' package inserts; these should be consulted to ensure safe IV administration of medications (Institute for Safe Medication Practices [ISMP], 2019).

Quality and Safety Nursing Alert

The nurse must assess the patient for a history of allergic reactions to medications. Although obtaining drug allergy information is important when administering any medication, it is especially critical with IV administration, because the medication is delivered directly into the bloodstream. This can trigger an immediate hypersensitivity reaction.

Nursing Management of the Patient Receiving Intravenous Therapy

In many settings, the ability to perform venipuncture to gain access to the venous system for administering fluids and medication is an expected nursing skill. This responsibility includes selecting the appropriate venipuncture site and type of cannula and being proficient in the technique of vein entry. The nurse should demonstrate competency in and knowledge of IV catheter placement according to the Nurse Practice Act applicable in their state and should follow the rules and regulations, organizational policies and procedures, and practice guidelines of that state's board of nursing (Gorski, Hadaway, Hagle, et al., 2016).

Managing Systemic Complications

Fluid Overload

Overloading the circulatory system with excessive IV fluids causes increased blood pressure and central venous pressure. Signs and symptoms of fluid overload include moist crackles on auscultation of the lungs, cough, restlessness, distended neck veins, edema, weight gain, dyspnea, and rapid, shallow respirations. Possible causes include rapid infusion of an IV solution or hepatic, cardiac, or renal disease. The risk of fluid overload and subsequent pulmonary edema is especially increased in older patients with cardiac disease; this is referred to as circulatory overload. Its treatment includes decreasing the IV rate, monitoring vital signs frequently, assessing breath sounds, and placing the patient in a high Fowler position. The primary provider is contacted immediately. This complication can be avoided by using an infusion pump and by carefully monitoring all infusions. Complications of circulatory overload include heart failure and pulmonary edema (Connelly, 2018).

Air Embolism

The risk of air embolism is rare but ever-present. It is most often associated with cannulation of central veins and directly related to the size of the embolus and the rate of entry. Air entering into central veins gets to the right ventricle, where it lodges against the pulmonary valve and blocks the flow of blood from the ventricle into the pulmonary arteries. Manifestations of air embolism include palpitations, dyspnea, continued coughing, jugular venous distention, wheezing, and cyanosis; hypotension; weak, rapid pulse; altered mental status; and chest, shoulder, and low back pain. Treatment calls for immediately clamping the cannula and replacing a leaking or open infusion system, placing the patient on the left side in the Trendelenburg position, assessing vital signs and breath sounds, and administering oxygen. Air embolism can be prevented by using locking adapters on all lines, filling all tubing completely with solution, and using an air detection alarm on an IV infusion pump. Complications of air embolism include shock and death. The amount of air necessary to induce death in humans is not known; however, the rate of entry is probably as important as the actual volume of air (Malik, Claus, Illman, et al., 2017).

Infection

Pyogenic substances in either the infusion solution or the IV administration set can cause bloodstream infections. Signs and symptoms include an abrupt temperature elevation shortly after the infusion is started, backache, headache, increased pulse and respiratory rate, nausea and vomiting, diarrhea, chills and shaking, and general malaise. Additional symptoms include erythema, edema, and induration or drainage at the insertion site. In sepsis, vascular collapse and septic shock may occur (Connelly, 2018). (See Chapter 11 for a discussion of septic shock.)

Infection ranges in severity from local involvement of the insertion site to systemic dissemination of organisms through the bloodstream, as in sepsis. Measures to prevent infection are essential at the time the IV line is inserted and throughout the entire infusion (Hugill, 2017).

Managing Local Complications

Local complications of IV therapy include phlebitis, infiltration and extravasation, thrombophlebitis, hematoma, and clotting of the needle (Simin, Milutinović, Turkulov, et al., 2019). Chart 10-4 provides a Nursing Research Profile about complications of peripheral IVs.

Phlebitis

Phlebitis, or inflammation of a vein, can be categorized as chemical, mechanical, or bacterial; however, two or more of these types of irritation often occur simultaneously. Chemical phlebitis can be caused by an irritating medication or solution (increased pH or high osmolality of a solution), rapid infusion rates, and medication incompatibilities. Mechanical phlebitis results from long periods of cannulation, catheters in flexed areas, catheter gauges larger than the vein lumen, and poorly secured catheters. Bacterial phlebitis can develop from poor hand hygiene, lack of aseptic technique, failure to check all equipment before use, and failure to recognize early signs and symptoms of phlebitis. Other factors include poor venipuncture technique, catheter in place for a prolonged period, and failure to adequately secure the catheter (Hugill, 2017). Phlebitis is characterized by a reddened, warm area around the insertion site or along the path of the vein, pain or tenderness at the site or along the vein, and swelling. The incidence of phlebitis increases with the length of time the IV line is in place, the composition of the fluid or medication infused (especially its pH and tonicity), catheter material, emergency insertions, the size and site of the cannula inserted,

ineffective filtration, inadequate anchoring of the line, and the introduction of microorganisms at the time of insertion (Mihala, Ray-Barruel, Chopra, et al., 2018).

Chart 10-4 **NURSING RESEARCH PROFILE**

Complication Rates of Peripheral IVs

Simin, D., Milutinović, D., Turkulov, V., et al. (2019). Incidence, severity and risk factors of peripheral intravenous cannula-induced complications: An observational prospective study. *Journal of Clinical Nursing, 28*(9–10), 1585–1599.

Purpose

The incidence and severity of complications of peripheral IV insertion is not known. The purpose of this study was to determine the incidence, severity, and risk factors of peripheral IV cannula-induced complications in hospitalized adult patients.

Design

This was an observational prospective study. Observations were made of 1428 IV insertions among 368 adult patients hospitalized in a tertiary medical center.

Findings

Phlebitis was the most common complication, with a rate of 44%, followed by infiltration with a rate of 16%, while the incidence of occlusion and catheter dislodgement were 7.6% and 5.6%, respectively. The risk factors for phlebitis were identified as the presence of a comorbidity (i.e., diabetes), a current infection, and an indwelling urinary catheter. The frequency of infiltration increased with the age of the patient, the number of attempts at the IV insertion in the same anatomic site, and the number of medications and IV solutions administered per day.

Nursing Implications

Medical-surgical nurses assess for all complications following IV insertion but should be particularly alert for phlebitis, which is the most common. This study provides evidence that older patients are at higher risk of infiltration and that attempting multiple IV sticks in the same anatomic site may lead to higher complication rates. The nurse should also be aware that patients who have comorbidities (such as diabetes) and those who are receiving multiple medications and IV solutions are at higher risk for IV complications.

Chart 10-5 ASSESSMENT

Assessing for Phlebitis

Grade	Clinical Criteria
0	No clinical symptoms
1	Erythema at access site with or without pain
2	Pain at access site Erythema, edema, or both
3	Pain at access site Erythema, edema, or both Streak formation Palpable venous cord
4	Pain at access site with erythema Streak formation Palpable venous cord (longer than 1 inch) Purulent drainage

Adapted from Gorski, L. A., Hadaway, L., Hagle, M., et al. (2016). Infusion therapy standards of practice. *Journal of Infusion Nursing, 39*(1 Suppl), S1–S159.

The Infusion Nurses Society (INS) has identified specific standards for assessing phlebitis (Gorski et al., 2016); these appear in Chart 10-5. Phlebitis is graded according to the most severe presenting indication.

Treatment consists of discontinuing the IV line and restarting it in another site, and applying a warm, moist compress to the affected site (INS, 2016). Phlebitis can be prevented by using aseptic technique during insertion, using the appropriate-size cannula or needle for the vein, considering the composition of fluids and medications when selecting a site, observing the site hourly for any complications, anchoring the cannula or needle well, and changing the IV site according to agency policy and procedures (Mihala et al., 2018).

Infiltration and Extravasation

Infiltration is the unintentional administration of a nonvesicant solution or medication into surrounding tissue. This can occur when the IV cannula dislodges or perforates the wall of the vein. Infiltration is characterized by edema around the insertion site, leakage of IV fluid from the insertion site, discomfort and coolness in the area of infiltration, and a significant decrease in the flow rate. When the solution is particularly irritating, sloughing of tissue may result. Close monitoring

of the insertion site is necessary to detect infiltration before it becomes severe (Nickel, 2019; Simin et al., 2019).

Infiltration is usually easily recognized if the insertion area is larger than the same site of the opposite extremity but is not always so obvious. A common misconception is that a backflow of blood into the tubing proves that the catheter is properly placed within the vein. However, if the catheter tip has pierced the wall of the vessel, IV fluid will seep into tissues and flow into the vein. Although blood return occurs, infiltration may have occurred as well. A more reliable means of confirming infiltration is to apply a tourniquet above (or proximal to) the infusion site and tighten it enough to restrict venous flow. If the infusion continues to drip despite the venous obstruction, infiltration is present.

As soon as the nurse detects infiltration, the infusion should be stopped, the IV catheter removed, and a sterile dressing applied to the site after careful inspection to determine the extent of infiltration. The infiltration of any amount of blood product, irritant, or vesicant is considered the most severe (Brooks, 2018; Odom, Lowe, & Yates, 2018).

The IV infusion should be started in a new site or proximal to the infiltration site if the same extremity must be used again. A warm compress may be applied to the site if small volumes of noncaustic solutions have infiltrated over a long period, or if the solution was isotonic with a normal pH; the affected extremity should be elevated to promote the absorption of fluid. If the infiltration is recent and the solution was hypertonic or had an increased pH, a cold compress may be applied to the area (Gorski et al., 2016; Odom et al., 2018).

Infiltration can be detected and treated early by inspecting the site every hour for redness, pain, edema, blood return, coolness at the site, and IV fluid leaking from the IV site. Using the appropriate size and type of cannula for the vein prevents this complication. The use of electronic infusion devices (EIDs) does not cause an infiltration or extravasation; however, these devices will exacerbate the problem until the infusion is turned off. The Infusion Nursing Standards of Practice state that a standardized infiltration scale should be used to document the infiltration (Brooks, 2018; Gorski et al., 2016) (Chart 10-6).

Extravasation is similar to infiltration, with an inadvertent administration of vesicant or irritant solution or medication into the surrounding tissue. Medications such as vasopressors, potassium and calcium preparations, and chemotherapeutic agents can cause pain, burning, and redness at the site. Blistering, inflammation, and necrosis of tissues can occur. Older patients, comatose or anesthetized patients,

patients with diabetes, and patients with peripheral vascular or cardiovascular disease are at greater risk for extravasation; other risk factors include high pressure infusion pumps, palpable cording of vein, and fluid leakage from the insertion site. The extent of tissue damage is determined by the concentration of the medication, the quantity that extravasated, the location of the infusion site, the tissue response, and the duration of the process of extravasation (Gorski et al., 2016; Odom et al., 2018).

Chart 10-6 **ASSESSMENT**

Assessing for Infiltration

Grade	Clinical Criteria
0	No clinical symptoms
1	Skin blanched, edema less than 1 inch in any direction, cool to touch, with or without pain
2	Skin blanched, edema 1 to 6 inches in any direction, cool to touch, with or without pain
3	Skin blanched, translucent, gross edema greater than 6 inches in any direction, cool to touch, mild to moderate pain, possible numbness
4	Skin blanched, translucent, skin tight, leaking, skin discolored, bruised, swollen, gross edema greater than 6 inches in any direction, deep pitting tissue edema, circulatory impairment, moderate to severe pain, infiltration of any amount of blood products, irritant, or vesicant

Adapted from Gorski, L. A., Hadaway, L., Hagle, M., et al. (2016). Infusion therapy standards of practice. *Journal of Infusion Nursing, 39*(1 Suppl), S1–S159.

When extravasation occurs, the infusion must be stopped and the provider notified promptly. The agency's protocol to treat extravasation is initiated; the protocol may specify specific treatments, including antidotes specific to the medication that extravasated, and may indicate whether the IV line should remain in place or be removed before treatment. The protocol often specifies infiltration of the infusion site with an antidote prescribed after assessment by the provider, removal of the cannula, and application of warm compresses to sites of extravasation from alkaloids or cold compresses to sites of extravasation

from alkylating and antibiotic vesicants. The affected extremity should not be used for further cannula placement. Thorough neurovascular assessments of the affected extremity must be performed frequently (Gorski et al., 2016).

Reviewing the institution's IV policy and procedures and incompatibility charts and checking with the pharmacist before administering any IV medication, whether peripherally or centrally, are recommended to determine incompatibilities and vesicant potential to prevent extravasation. Careful, frequent monitoring of the IV site, avoiding insertion of IV devices in areas of flexion, securing the IV line, and using the smallest catheter possible that accommodates the vein help minimize the incidence and severity of this complication. In addition, when vesicant medication is given by IV push, it should be given through a side port of an infusing IV solution to dilute the medication and decrease the severity of tissue damage if extravasation occurs. Extravasation is rated as grade 4 on the infiltration scale. Complications of an extravasation may include blister formation, skin sloughing and tissue necrosis, functional or sensory loss in the injured area, and disfigurement or loss of limb (Gorski et al., 2016; Nickel, 2019).

Thrombophlebitis

Thrombophlebitis refers to the presence of a clot plus inflammation in the vein. It is evidenced by localized pain, redness, warmth, and swelling around the insertion site or along the path of the vein, immobility of the extremity because of discomfort and swelling, sluggish flow rate, fever, malaise, and leukocytosis (Brooks, 2018).

Treatment includes discontinuing the IV infusion; applying a cold compress first to decrease the flow of blood, followed by a warm compress; elevating the extremity; and restarting the line in the opposite extremity. If the patient has signs and symptoms of thrombophlebitis, the IV line should not be flushed (although flushing may be indicated in the absence of phlebitis to ensure cannula patency and to prevent mixing of incompatible medications and solutions). The catheter should be cultured after the skin around the catheter is cleaned with alcohol. If purulent drainage exists, the site is cultured before the skin is cleaned (Brooks, 2018; Hugill, 2017).

Thrombophlebitis can be prevented by avoiding trauma to the vein at the time the IV line is inserted, observing the site every hour, and checking medication additives for compatibility (Gorski et al., 2016).

Hematoma

Hematoma results when blood leaks into tissues surrounding the IV insertion site. Leakage can result if the vein wall is perforated during venipuncture, the needle slips out of the vein, a cannula is too large for the vessel, or insufficient pressure is applied to the site after removal of the needle or cannula. The signs of a hematoma include ecchymosis, immediate swelling at the site, and leakage of blood at the insertion site.

Treatment includes removing the needle or cannula and applying light pressure with a sterile, dry dressing; applying ice for 24 hours to the site to avoid extension of the hematoma; elevating the extremity to maximize venous return, if tolerated; assessing the extremity for any circulatory, neurologic, or motor dysfunction; and restarting the line in the other extremity if indicated. A hematoma can be prevented by carefully inserting the needle and by frequently monitoring patients who have a bleeding disorder, are taking anticoagulant medication, or have advanced liver disease (Nickel, 2019).

Clotting and Obstruction

Blood clots may form in the IV line as a result of kinked IV tubing, a very slow infusion rate, an empty IV bag, or failure to flush the IV line after intermittent medication or solution administrations. The signs are decreased flow rate and blood backflow into the IV tubing (Brooks, 2018).

If blood clots in the IV line, the infusion must be discontinued and restarted in another site with a new cannula and administration set. The tubing should not be irrigated or milked. Neither the infusion rate nor the solution container should be raised, and the clot should not be aspirated from the tubing. Clotting of the needle or cannula may be prevented by not allowing the IV solution bag to run dry, taping the tubing to prevent kinking and maintain patency, maintaining an adequate flow rate, and flushing the line after intermittent medication or other solution administration. In some cases, a specially trained nurse or primary provider may inject a thrombolytic agent into the catheter to clear an occlusion resulting from fibrin or clotted blood (Brooks, 2018; Gorski et al., 2016).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

At times, IV therapy must be given in the home setting, in which case much of the daily management rests with the patient and family. Education becomes essential to ensure that the patient and family can manage the IV fluid and infusion correctly and avoid complications. Written instructions as well as demonstration and return demonstration help reinforce the key points for all of these functions (Payne, 2019).

Continuing and Transitional Care

Home infusion therapies cover a wide range of treatments, including antibiotic, analgesic, and antineoplastic medications; blood or blood component therapy; and parenteral nutrition. When direct nursing care is necessary, arrangements are made to have an infusion nurse visit the home and administer the IV therapy as prescribed. In addition to implementing and monitoring the IV therapy, the nurse carries out a comprehensive assessment of the patient's condition and continues to educate the patient and family about the skills involved in overseeing the IV therapy setup. Any dietary changes that may be necessary because of fluid or electrolyte imbalances are explained or reinforced during such sessions (Payne, 2019).

Periodic laboratory testing may be necessary to assess the effects of IV therapy and the patient's progress. Blood specimens may be obtained by a laboratory near the patient's home, or a home visit may be arranged to obtain blood specimens for analysis (Payne, 2019).

The nurse collaborates with the case manager in assessing the patient, family, and home environment; developing a plan of care in accordance with the patient's treatment plan and level of ability; and arranging for appropriate referral and follow-up if necessary. Any necessary equipment may be provided by the agency or purchased by the patient, depending on the terms of the home care arrangements. Appropriate documentation is necessary to assist in obtaining third-party payment for the service provided.

CRITICAL THINKING EXERCISES

1 ebp A 34-year-old woman comes to the walk-in clinic where you work. She is going to run her first marathon and asks about using salt tablets to compensate for loss of sodium through sweat. What is the best evidence for the use of salt tablets in performance athletes? What is the strength of the evidence base guiding your recommendation?

2 ipe An 82-year-old man with hypovolemia has been admitted to the medical unit where you work. What nursing and interprofessional assessments are indicated during your initial interactions with him? What other interprofessional services might you try to engage?

3 pq A 55-year-old woman is sent to the emergency department by her primary provider. The patient has a history of congestive heart failure. The primary provider has requested laboratory tests. Blood gas results are as follows: pH 7.46; HCO_3^- 26; $PaCO_2$ 40 mm Hg. Blood chemistry results are as follows: potassium 4.5 mEq/L; sodium 140 mEq/L; glucose 110 mg/dL. Vital signs: BP 140/92, HR 90 bpm, RR 18 bpm. What is your priority for this patient? Give your rationale. What further diagnostic testing is indicated?

11 Shock, Sepsis, and Multiple Organ Dysfunction Syndrome

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the pathophysiology, clinical manifestations, and collaborative management of progressive stages of various types of shock, of sepsis, and of multiple organ dysfunction syndrome.
2. Compare and contrast the pathophysiology, clinical manifestations, and collaborative management of shock states in hypovolemic, cardiogenic, and distributive shock.
3. Identify medical and nursing management priorities in treating patients across the continuum of shock.
4. Describe medical and nursing management priorities in the treatment and prevention of sepsis and septic shock.
5. Discuss the role of nurses in providing psychosocial support to patients experiencing shock, sepsis, and multiple organ dysfunction syndrome, and their families.
6. Discuss the role of nurses in providing transitional care to patients and their families after having been managed in a critical-care unit for shock, sepsis, or multiple organ dysfunction syndrome.

NURSING CONCEPTS

Cellular Regulation
Fluids and Electrolytes
Infection
Medical Emergencies
Perfusion

GLOSSARY

anaphylactic shock: distributive shock state resulting from a severe allergic reaction producing an acute systemic vasodilation and relative hypovolemia

cardiogenic shock: shock state resulting from impairment or failure of the myocardium

colloids: intravenous solutions that contain molecules that are too large to pass through capillary membranes

crystalloids: intravenous electrolyte solutions that move freely between the intravascular compartment and interstitial spaces

cytokines: messenger substances that may be released by a cell to create an action at that site or may be carried by the bloodstream to a distant site before being activated; (*synonyms*: biochemical mediators, inflammatory mediators)

distributive shock: shock state resulting from displacement of intravascular volume creating a relative hypovolemia and inadequate delivery of oxygen to the cells

hypovolemic shock: shock state resulting from decreased intravascular volume due to fluid loss

multiple organ dysfunction syndrome: presence of altered function of two or more organs in an acutely ill patient such that interventions are necessary to support continued organ function

neurogenic shock: shock state resulting from loss of sympathetic tone causing relative hypovolemia

sepsis: life-threatening organ dysfunction caused by a dysregulated host response to infection

septic shock: a subset of sepsis in which underlying circulatory and cellular metabolic abnormalities are profound enough to substantially increase mortality

shock: life-threatening physiologic condition in which there is inadequate blood flow to tissues and cells of the body

systemic inflammatory response syndrome: a syndrome resulting from a clinical insult that initiates an inflammatory response that is systemic, rather than localized to the site of the insult; a type of cytokine release syndrome also referred to as cytokine storm

Shock is a life-threatening condition that results from inadequate tissue perfusion. Many conditions may cause shock; irrespective of the cause, tissue hypoperfusion prevents adequate oxygen delivery to cells, leading to cell dysfunction and death. The progression of shock is neither linear nor predictable, and shock states, especially septic shock (the most life-threatening form of sepsis), comprise an area of ongoing clinical research. Nurses caring

for patients with shock and those at risk for shock must understand the underlying mechanisms of the various shock states (i.e., hypovolemic, cardiogenic, obstructive [see Chapter 25], and distributive shock [i.e., septic, neurogenic, anaphylactic]) and recognize the subtle as well as more obvious signs of each of these states. If shock is not effectively treated, **multiple organ dysfunction syndrome (MODS)** which is the presence of altered function of two or more organs in an acutely ill patient such that interventions are necessary to support continued organ function may ensue, often resulting in patient death. MODS may be a complication of any form of shock but is most commonly seen in patients with sepsis. Rapid assessment with early recognition and response to shock states and sepsis is essential to the patient's recovery.

Overview of Shock

Shock can best be defined as a clinical syndrome that results from inadequate tissue perfusion, creating an imbalance between the delivery of oxygen and nutrients needed to support cellular function (Kislitsina, Rich, Wilcox, et al., 2019; Massaro, 2018). Adequate blood flow to the tissues and cells requires an effective cardiac pump, adequate vasculature or circulatory system, and sufficient blood volume. If one of these components is impaired, perfusion to the tissues is threatened or compromised. Without treatment, inadequate blood flow to the cells results in poor delivery of oxygen and nutrients, cellular hypoxia, and cell death that progresses to organ dysfunction and eventually death.

Shock affects all body systems. It may develop rapidly or slowly, depending on the underlying cause. During shock, the body struggles to survive, calling on all its homeostatic mechanisms to restore blood flow. Any insult to the body can create a cascade of events resulting in poor tissue perfusion. Therefore, any patient with any disease state may be at risk for developing shock. The primary underlying pathophysiologic process and underlying disorder are used to classify the shock state (e.g., hypovolemic shock, cardiogenic shock, obstructive shock [see Chapter 25], distributive shock [i.e., septic, neurogenic, anaphylactic]; all discussed later in the chapter).

Regardless of the initial cause of shock, certain physiologic responses are common to all types of shock. These physiologic responses include hypoperfusion of tissues, hypermetabolism, and activation of the inflammatory response. The body responds to shock states by activating the sympathetic nervous system and mounting a hypermetabolic and inflammatory response. Failure of compensatory mechanisms to effectively restore physiologic balance is the final pathway of all shock states and results in end-organ dysfunction and death (Massaro, 2018; Seymour & Angus, 2018).

Nursing care of patients with shock requires ongoing systematic assessment. Many of the interventions required in caring for patients with shock call for close collaboration with other members of the health care team and rapid implementation of prescribed therapies. Nurses are in key positions to identify early signs of shock and anticipate rapid therapy.

Normal Cellular Function

Energy metabolism occurs within the cell, where nutrients are chemically broken down and stored in the form of adenosine triphosphate (ATP). Cells use this stored energy to perform necessary functions, such as active transport, muscle contraction, and biochemical synthesis, as well as specialized cellular functions, such as the conduction of electrical impulses. ATP can be synthesized aerobically (in the presence of oxygen) or anaerobically (in the absence of oxygen). Aerobic metabolism yields far greater amounts of ATP per mole of glucose than does anaerobic metabolism; therefore, it is a more efficient and effective means of producing energy. In addition, anaerobic metabolism results in the accumulation of the toxic end product lactic acid, which must be removed from the cell and transported to the liver for conversion into glucose and glycogen.

Pathophysiology

The pathophysiology of shock involves cellular changes, vascular responses, and changes in blood pressure.

Cellular Changes

In shock, the cells lack an adequate blood supply and are deprived of oxygen and nutrients; therefore, they must produce energy through anaerobic metabolism. This results in low-energy yields from nutrients and an acidotic intracellular environment. Because of these changes, normal cell function ceases (Fig. 11-1). The cell swells and the cell membrane becomes more permeable, allowing electrolytes and fluids to seep out of and into the cell. The sodium–potassium pump becomes impaired; cell structures, primarily the mitochondria, are damaged, and death of the cell results.

Glucose is the primary substrate required for the production of cellular energy in the form of ATP. In stress states, catecholamines, cortisol, glucagon, and inflammatory **cytokines** (i.e., biochemical or inflammatory mediators) are released, causing hyperglycemia and insulin resistance to mobilize glucose for cellular metabolism. Activation of these substances promotes gluconeogenesis, which is the formation of glucose from noncarbohydrate sources such as proteins and fats. Glycogen that has been stored in the liver is converted to

glucose through glycogenolysis to meet metabolic needs, increasing the blood glucose concentration (i.e., hyperglycemia).

Continued activation of the stress response by shock states causes a depletion of glycogen stores, resulting in increased proteolysis and eventual organ failure (Massaro, 2018). The deficit of nutrients and oxygen for normal cellular metabolism causes a buildup of metabolic end products in the cells and interstitial spaces. The clotting cascade, also associated with the inflammatory process, becomes activated, which compounds this pathologic cycle. With significant cell injury or death caused by shock, the clotting cascade is overproductive, resulting in small clots lodging in microcirculation, further hampering cellular perfusion (Seymour & Angus, 2018). This upregulation of the clotting cascade further compromises microcirculation of tissues, exacerbating cellular hypoperfusion (Seymour & Angus, 2018). Cellular metabolism is impaired, and a self-perpetuating negative situation (i.e., a positive feedback loop) is initiated.

Vascular Responses

Local regulatory mechanisms, referred to as autoregulation, stimulate vasodilation or vasoconstriction in response to biochemical mediators released by the cell, communicating the need for oxygen and nutrients (Kislitsina et al., 2019). A cytokine is a substance released by a cell or immune cells such as macrophages; the substance triggers an action at a cell site or travels in the bloodstream to a distant site, where it triggers action. Researchers are learning more every day about the physiologic actions of numerous proinflammatory and anti-inflammatory biochemical mediators that are responsible for the complex clinical presentation of shock states (Honore, Hoste, Molnár, et al., 2019).

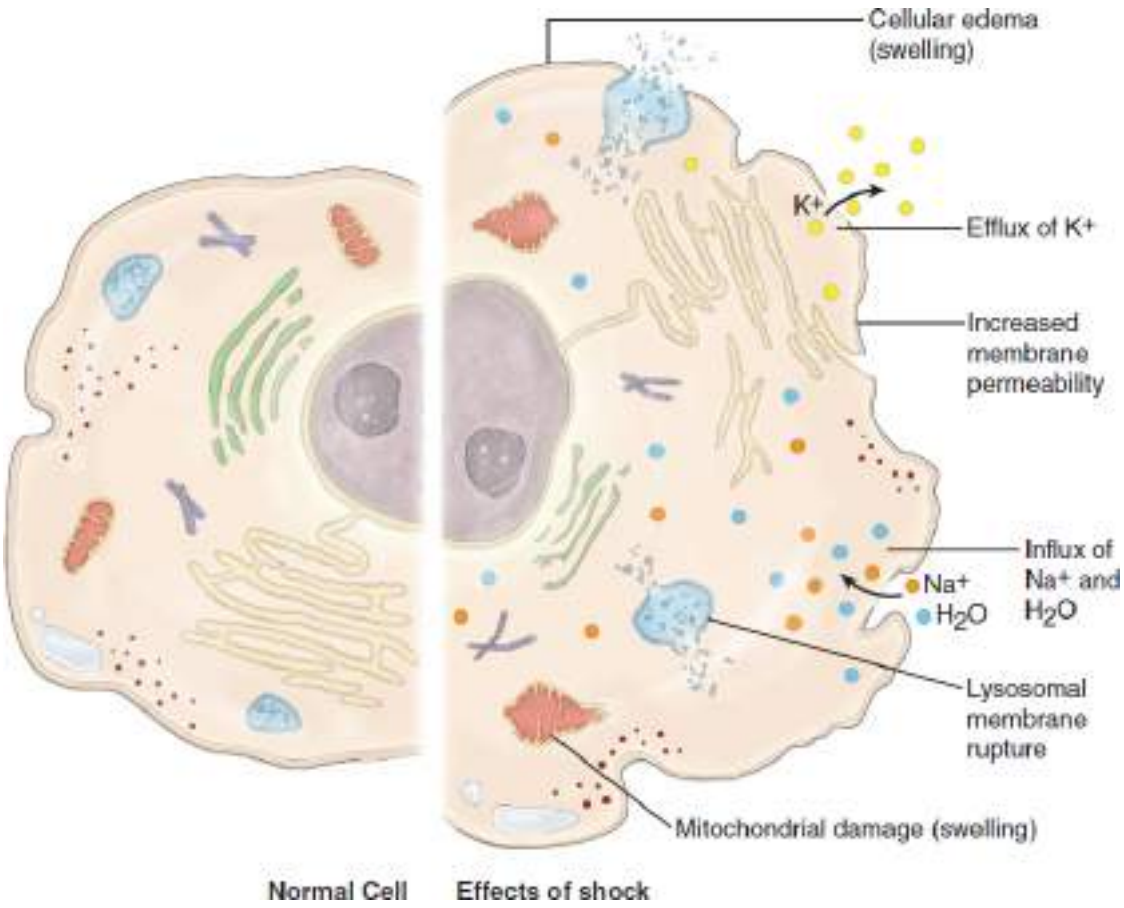

Figure 11-1 • Cellular effects of shock. The cell swells and the cell membrane becomes more permeable; fluids and electrolytes seep from and into the cell. Mitochondria and lysosomes are damaged and the cell dies.

Blood Pressure Regulation

Three major components of the circulatory system—blood volume, the cardiac pump, and the vasculature—must respond effectively to complex neural, chemical, and hormonal feedback systems to maintain an adequate blood pressure (BP) and perfuse body tissues. BP is regulated through a complex interaction of neural, chemical, and hormonal feedback systems affecting both cardiac output and peripheral resistance. This relationship is expressed in the following equation:

Mean arterial BP = Cardiac output × Peripheral resistance

Cardiac output is a product of the stroke volume (the amount of blood ejected from the left ventricle during systole) and heart rate. Peripheral resistance is primarily determined by the diameter of the arterioles.

Tissue perfusion and organ perfusion depend on mean arterial pressure (MAP), or the average pressure at which blood moves through the vasculature. MAP must exceed 65 mm Hg for cells to receive the oxygen and nutrients needed to metabolize energy in amounts sufficient to sustain life (Hallisey &

Greenwood, 2019). True MAP can be calculated only by complex methods; however, most digital BP machines provide a MAP reading to guide clinical decisions.

BP is regulated by baroreceptors (pressure receptors) located in the carotid sinus and aortic arch. These pressure receptors are responsible for monitoring the circulatory volume and regulating neural and endocrine activities (see Chapter 27 for further description). When BP drops, catecholamines (e.g., epinephrine, norepinephrine) are released from the adrenal medulla. These increase heart rate and cause vasoconstriction, restoring BP. Chemoreceptors, also located in the aortic arch and carotid arteries, regulate BP and respiratory rate using much the same mechanism in response to changes in oxygen and carbon dioxide (CO_2) concentrations in the blood. These primary regulatory mechanisms can respond to changes in BP on a moment-to-moment basis.

The kidneys regulate BP by releasing renin, an enzyme needed for the eventual conversion of angiotensin I to angiotensin II, a potent vasoconstrictor. This stimulation of the renin–angiotensin mechanism and the resulting vasoconstriction indirectly lead to the release of aldosterone from the adrenal cortex, which promotes the retention of sodium and water (i.e., hypernatremia). Hypernatremia then stimulates the release of antidiuretic hormone (ADH) by the pituitary gland. ADH causes the kidneys to retain water further in an effort to raise blood volume and BP. These secondary regulatory mechanisms may take hours or days to respond to changes in BP. The relationship between the initiation of shock and the responsiveness of primary and secondary regulatory mechanisms that compensate for deficits in blood volume, the pumping effectiveness of the heart, or vascular tone, which may result because of the shock state, is noted in Figure 11-2.

Stages of Shock

Shock progresses along a continuum and can be identified as early or late, depending on the signs and symptoms and the overall severity of organ dysfunction. A convenient way to understand the physiologic responses and subsequent clinical signs and symptoms of shock is to divide the continuum into separate stages: compensatory (stage 1), progressive (stage 2), and irreversible (stage 3). The earlier that interventions are initiated along this continuum, the greater the patient's chance of survival. Current research and evidence-based practice focuses on assessing patients at greatest risk for shock and implementing early and aggressive interventions to reverse tissue hypoxia (Zhang, Hong, Smischney, et al., 2017). Current evidence suggests that the window of opportunity that increases the likelihood of patient survival occurs when aggressive therapy begins within 3 hours of identifying a shock state,

especially septic shock (Rhodes, Evans, Alhazzani, et al., 2017; Singer, Deutschman, Seymour, et al., 2016).

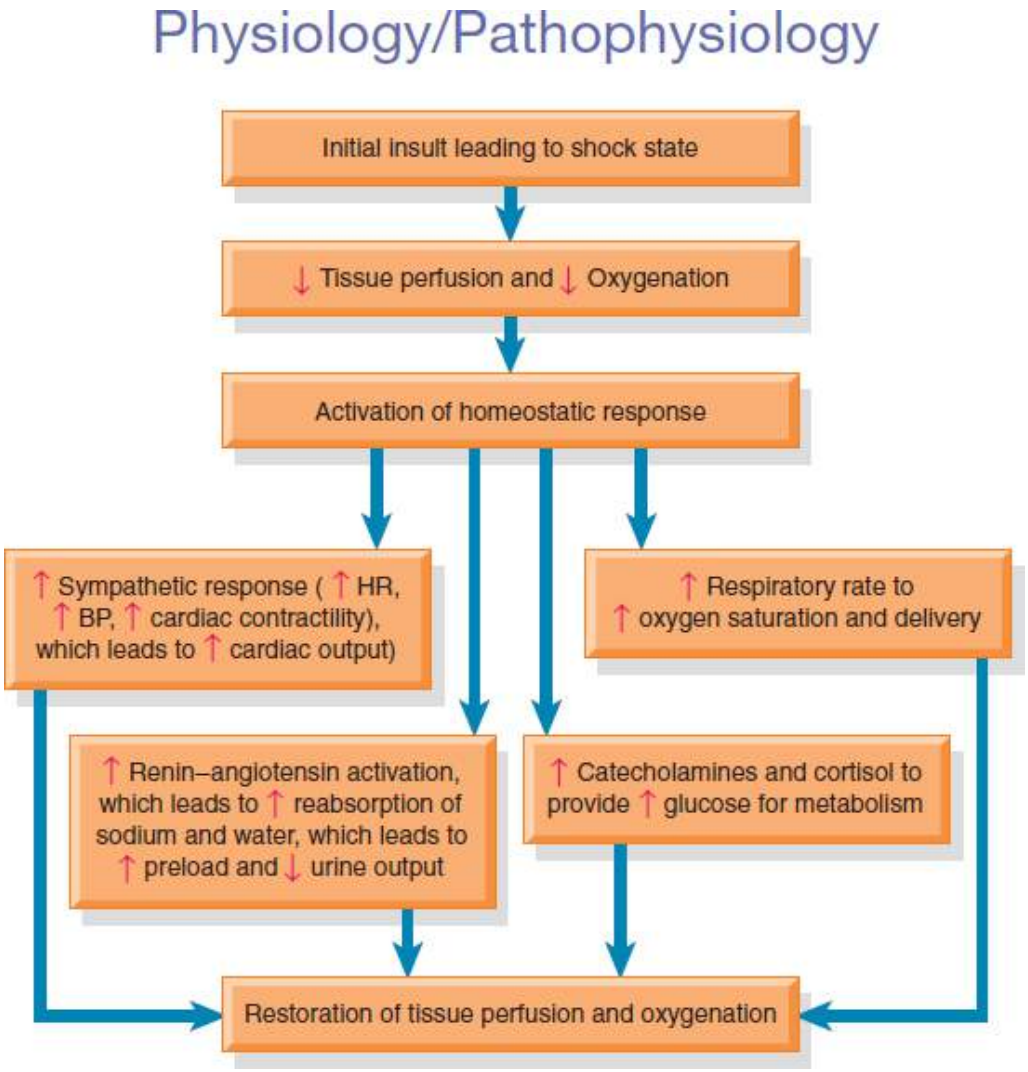

Figure 11-2 • Pathophysiologic sequence of regulatory mechanisms in shock.

Compensatory Stage

In the compensatory stage of shock, the BP remains within normal limits. Vasoconstriction, increased heart rate, and increased contractility of the heart contribute to maintaining adequate cardiac output. This results from stimulation of the sympathetic nervous system and subsequent release of catecholamines (e.g., epinephrine, norepinephrine). Patients display the often-described "fight-or-flight" response. The body shunts blood from organs such as the skin, kidneys, and gastrointestinal (GI) tract to the brain, heart, and lungs to ensure adequate blood supply to these vital organs. As a result, the skin may be cool and pale, bowel sounds are hypoactive, and urine output decreases in response to the release of aldosterone and ADH.

Clinical Manifestations

Despite a normal BP, the patient shows numerous clinical signs indicating inadequate organ perfusion (Table 11-1). The result of inadequate perfusion is anaerobic metabolism and a buildup of lactic acid, producing metabolic acidosis. The respiratory rate increases in response to the need to increase oxygen to the cells and in compensation for metabolic acidosis. This rapid respiratory rate facilitates removal of excess CO_2 but raises the blood pH and often causes a compensatory respiratory alkalosis. The patient may experience a change in effect, feel anxious, or be confused. If treatment begins in this stage of shock, the prognosis for the patient is better than in later stages.

TABLE 11-1 Clinical Findings in Stages of Shock

Finding	Stage: Compensatory	Progressive	Irreversible
Blood pressure	Normal	Systolic ≤100 mm Hg; MAP ≤65 mm Hg Requires fluids resuscitation to support blood pressure	Requires mechanical or pharmacologic support
Heart rate	>100 bpm	>150 bpm	Erratic
Respiratory status	≥22 breaths/min $PaCO_2$ <32 mm Hg	Rapid, shallow respirations; crackles PaO_2 <80 mm Hg $PaCO_2$ >45 mm Hg	Requires intubation and mechanical ventilation and oxygenation
Skin	Cold, clammy Capillary refill ≤3.5 s	Mottling, petechiae Capillary refill ≥3.5 s	Jaundice
Urinary output	Decreased	<0.5 mL/kg/h	Anuric; requires dialysis
Mentation	Confusion and/or agitation	Lethargy	Unconscious
Acid–base balance	Respiratory alkalosis	Metabolic acidosis	Profound acidosis

MAP, mean arterial pressure; $PaCO_2$, partial pressure of arterial carbon dioxide; PaO_2, partial pressure of arterial oxygen.

Managing sepsis and septic shock: Current guidelines and definitions. *American Journal of Nursing*, *118*(2), 34–39; Rhodes, A., Evans, L., Alhazzani, W., et al. (2017). Surviving Sepsis Campaign. (2017). Retrieved on 11/27/20 at: www.sccm.org/getattachment/SurvivingSepsisCampaign/Guidelines/Adult-Patients/SSC-Guidelines-FAQ.pdf?lang=en-US; Simmons, J., & Ventetuolo, C. E. (2017). Cardiopulmonary monitoring of shock. *Current Opinion*, *23*(3), 223–231.

Medical Management

Medical treatment is directed toward identifying the cause of the shock, correcting the underlying disorder so that shock does not progress, and supporting those physiologic processes that thus far have responded successfully to the threat. Because compensation cannot be maintained indefinitely, measures such as fluid replacement, supplemental oxygen, and

medication therapy must be initiated to maintain an adequate BP and reestablish and maintain adequate tissue perfusion (Makic & Bridges, 2018; Rhodes et al., 2017).

Nursing Management

Early intervention along the continuum of shock is the key to improving the patient's prognosis (Makic & Bridges, 2018; Rhodes et al., 2017). The nurse must systematically assess the patient at risk for shock, recognizing subtle clinical signs of the compensatory stage before the patient's BP drops. Early interventions include identifying the cause of shock, administering intravenous (IV) fluids and oxygen, and obtaining necessary laboratory tests to rule out and treat metabolic imbalances or infection. Special considerations related to recognizing early signs of shock in the older adult patient are discussed in Chart 11-1.

Monitoring Tissue Perfusion

In assessing tissue perfusion, the nurse observes for subtle changes in level of consciousness, vital signs (including pulse pressure), urinary output, skin (including assessment of capillary refill and signs of mottling), respiratory rate, and laboratory values (e.g., base deficit, lactic acid levels). In the compensatory stage of shock, serum sodium and blood glucose levels are elevated in response to the release of aldosterone and catecholamines. If infection is suspected, blood cultures should be obtained prior to administration of prescribed antibiotics; both of these interventions should be given priority in the care of the patient (Bridges, 2017; Levy, Evans, & Rhodes, 2018).

The nurse should monitor the patient's hemodynamic status and promptly report deviations to the primary provider, assist in identifying and treating the underlying disorder by continuous in-depth assessment of the patient, administer prescribed fluids and medications, and promote patient safety. Vital signs are key indicators of hemodynamic status, and BP is an indirect measure of tissue hypoxia. The nurse should report a systolic BP of 100 mm Hg or lower, or a drop in systolic BP of 40 mm Hg from baseline, or a MAP of 65 mm Hg or less (Hallisey & Greenwood, 2019; Rhodes et al., 2017). If the patient is concurrently diagnosed with an infection or if an infection is suspected, the nurse should promptly notify the primary provider if the patient exhibits any two of the three following signs (Singer et al., 2016) (see later discussion of Septic Shock):

- Respiratory rate greater than or equal to 22 breaths/min
- Altered mentation

- Systolic BP less than or equal to 100 mm Hg

Pulse pressure correlates well with stroke volume. Pulse pressure is calculated by subtracting the diastolic measurement from the systolic measurement; the difference is the pulse pressure. Normally, the pulse pressure is 30 to 40 mm Hg. Narrowing or decreased pulse pressure is an earlier indicator of shock than a drop in systolic BP (Simmons & Ventetuolo, 2017). Decreased or narrowing pulse pressure, an early indication of decreased stroke volume, is illustrated in the following example:

Chart 11-1

Recognizing Shock in Older Adults

The physiologic changes associated with aging, coupled with pathologic and chronic disease states, place older adults at increased risk for developing a state of shock and possibly multiple organ dysfunction syndrome. Older adults can recover from shock if it is detected and treated early with aggressive and supportive therapies. Nurses play an essential role in assessing and interpreting subtle changes in older adults' responses to illness.

- Medications such as beta-blocking agents (e.g., metoprolol) used to treat hypertension may mask tachycardia, a primary compensatory mechanism to increase cardiac output, during hypovolemic states.
- The aging immune system may not mount a truly febrile response (temperature greater than 38.3°C [101°F]); however, a lack of a febrile response (temperature less than 37°C [98.6°F]) or an increasing trend in body temperature should be addressed. The patient may also report increased fatigue and malaise in the absence of a febrile response.
- The heart does not function well in hypoxemic states, and the aging heart may respond to decreased myocardial oxygenation with arrhythmias that may be misinterpreted as a normal part of the aging process.
- There is a progressive decline in respiratory muscle strength, maximal ventilation, and response to hypoxia. Older adults have a decreased respiratory reserve and decompensate more quickly.
- Changes in mentation may be inappropriately misinterpreted as dementia. Older adults with a sudden change in mentation should be aggressively assessed for acute delirium (hypo- and hyperdelirium states) and treated for the presence of infection and organ hypoperfusion.

Surviving Sepsis Campaign: International guidelines for management of sepsis and septic shock: 2016. *Critical Care Medicine, 45*(3), 486–552; Rowe, T. A., & McKoy, J. M. (2017). Sepsis in older adults. *Infectious Disease Clinics of North America, 31*(4), 731–742.

Systolic BP − Diastolic BP = Pulse pressure

Normal pulse pressure:

120 mm Hg − 80 mm Hg = 40 mm Hg

Narrowing of pulse pressure:

90 mm Hg − 70 mm Hg = 20 mm Hg

Elevation of the diastolic BP with release of catecholamines and attempts to increase venous return through vasoconstriction is an early compensatory mechanism in response to decreased stroke volume, BP, and overall cardiac output.

Quality and Safety Nursing Alert

By the time BP drops, damage has already been occurring at the cellular and tissue levels. Therefore, the patient at risk for shock must be assessed and monitored closely before the BP falls.

Continuous central venous oximetry ($Sc\bar{v}O_2$) monitoring may be used to evaluate mixed venous blood oxygen saturation and severity of tissue hypoperfusion states. A central catheter is introduced into the superior vena cava (SVC), and a sensor on the catheter measures the oxygen saturation of the blood in the SVC as blood returns to the heart and pulmonary system for reoxygenation. A normal $Sc\bar{v}O_2$ value is 70% (Zhang et al., 2017). Body tissues use approximately 25% of the oxygen delivered to them during normal metabolism. During stressful events, such as shock, more oxygen is consumed and the $Sc\bar{v}O_2$ saturation is lower, indicating that the tissues are consuming more oxygen.

Interventions focus on decreasing tissue oxygen requirements and increasing perfusion to deliver more oxygen to the tissues. For instance, sedating agents may be given to lower metabolic demands, or the patient's pain may be treated with opioid, nonopioid, or sedating agents (e.g., propofol, dexmedetomidine, acetaminophen) to decrease metabolic demands for oxygen. Supplemental oxygen and mechanical ventilation may be required to increase the delivery of oxygen in the blood. Administration of IV fluids and medications supports BP and cardiac output, and the transfusion of packed red blood cells enhances oxygen transport. Monitoring tissue oxygen consumption with $Sc\bar{v}O_2$ is an invasive measure to more accurately assess tissue oxygenation in the compensatory stage of shock before changes in vital signs detect altered tissue perfusion (Rhodes et al., 2017; Zhang et al., 2017).

In the patient who has an arterial line present, arterial pulse waveform analysis or pulse contour may be used to determine the patient's stroke volume and responsiveness to IV fluid replacement to meet tissue perfusion needs (Simmons & Ventetuolo, 2017). More commonly, passive leg raising (PLR) is used to determine which patients will or will not respond to IV fluid bolus challenges. PLR involves raising the patient's legs to a 30- to 45-degree angle to increase venous return and thus cardiac output (Fig. 11-3). If the blood pressure improves with PLR, the patient will respond to additional fluids. If the blood pressure does not improve, giving more IV fluids will not improve

the patient's condition and can precipitate fluid overload (Laher, Watermeyer, Buchanan, et al., 2017; Pickett, Bridges, Kritek, et al., 2018). If the patient is mechanically ventilated, functional hemodynamic monitoring will be used to assess fluid volume needs and the patient's response to IV fluid administration (i.e., preload, cardiac output, and blood pressure). An improvement in preload, cardiac output, and blood pressure indicates a favorable response. Functional hemodynamic monitoring has replaced static measures obtained from central venous pressure (CVP) or pulmonary artery (PA) monitoring. Functional hemodynamic monitoring assesses real-time dynamic changes between the patient's breathing patterns and circulating blood volume. Assessing functional hemodynamic parameters requires the patient to be mechanically ventilated and have an invasive arterial catheter placed and connected to monitoring devices that measure fluid volume (Bridges, 2013; Hallisey & Greenwood, 2019; Simmons & Ventetuolo, 2017).

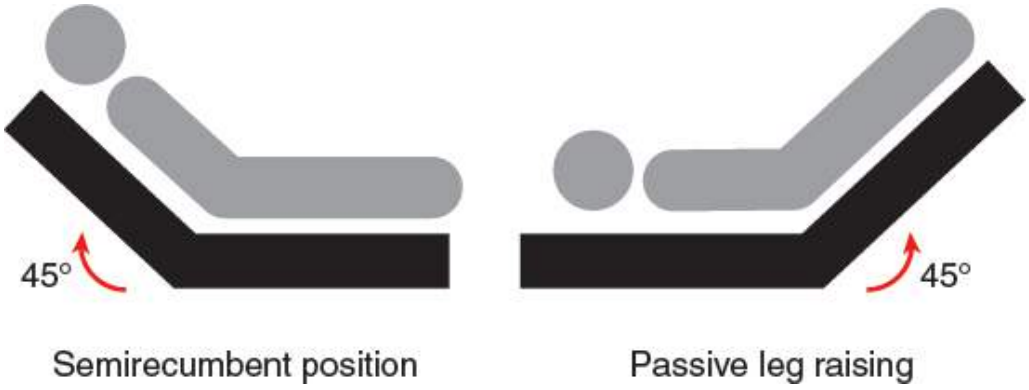

Figure 11-3 • Passive leg raise.

Although treatments are prescribed and initiated by the primary provider, the nurse usually implements them, operates and troubleshoots equipment used in treatment, monitors the patient's status during treatment, and evaluates the immediate effects of treatment. In addition, the nurse assesses the response of the family to the crisis and its treatment.

Reducing Anxiety

Patients and their families often become anxious and apprehensive when they face a major threat to health and well-being and are the focus of attention of many health care providers. Providing brief explanations about the diagnostic and treatment procedures, supporting the patient during these procedures, and providing information about their outcomes are usually effective in reducing stress and anxiety and thus promoting the patient's physical and mental well-being. Speaking in a calm, reassuring voice and using gentle touch also help ease the patient's concerns. These actions may provide comfort for patients who are critically ill and frightened (Reaza-Alarcón & Rodríguez-Martín,

2019). Evidence suggests that family members have certain needs during a health-related crisis, which include that health care professionals provide honest, consistent, and thorough communication; are present with the patient to facilitate physical and emotional support; demonstrate caring behaviors, see the patient frequently, and know the daily, short-term, and long-term plan of care for the patient (Reaza-Alarcón & Rodríguez-Martín, 2019; Wong, Redley, Digby, et al., 2019).

The nurse should advocate for family members to be present during procedures and routine patient care activities. The presence of family provides an important connection and support for the patient during a time of crisis. Clinical practice guidelines suggest that sharing decision making with the patient and the family enhances communication with the health care team, reduces patient anxiety, and improves overall satisfaction with care (Davidson, Aslakson, Long, et al., 2017).

Clarifying Advance Directives

Because shock can progress rapidly and its course may be unpredictable, it is important for the nurse to ask patients on admission if they have advance directives, including durable power of attorney for health care or living wills, or if they have had conversations with anyone about their health care wishes. When appropriate, the patient and family (with patient permission) should be approached regarding preferences for resuscitation and Physician Orders for Life-Sustaining Treatment (POLST) (see Chapter 13). The POLST helps ensure that the patient's wishes are honored if their condition deteriorates rapidly and they lose the ability to speak for themselves (Turner & Hylton, 2019).

Promoting Safety

The nurse must be vigilant for potential threats to the patient's safety, because a high anxiety level and changes in mental status may impair judgment. Patients who were previously cooperative and followed instructions may now disrupt IV lines and catheters, increasing the risk for potential complications. Close monitoring, frequent reorientation, hourly rounding, and implementing interventions to prevent falls (e.g., bed alarms) are essential.

Progressive Stage

In the second stage of shock, the mechanisms that regulate BP can no longer compensate, and the MAP falls below normal limits. Patients are clinically hypotensive; this is defined as a systolic BP of 100 mm Hg or lower, or a decrease in systolic BP of 40 mm Hg from baseline. The patient shows signs of declining mental status (Rhodes et al., 2017; Singer et al., 2016).

Pathophysiology

Although all organ systems suffer from hypoperfusion at this stage, several events perpetuate the shock syndrome. First, the overworked heart becomes dysfunctional, the body's inability to meet increased oxygen requirements produces ischemia, and biochemical mediators cause myocardial depression (Massaro, 2018). This leads to failure of the heart, even if the underlying cause of the shock is not of cardiac origin. Second, the autoregulatory function of the microcirculation fails in response to the numerous biochemical mediators released by the cells, resulting in increased capillary permeability, with areas of arteriolar and venous constriction further compromising cellular perfusion (Massaro, 2018). At this stage, the prognosis worsens. The relaxation of precapillary sphincters causes fluid to leak from the capillaries, creating interstitial edema and decreased return to the heart. In addition, the inflammatory response is activated, and proinflammatory and anti-inflammatory mediators are released, which activate the coagulation system in an effort to reestablish homeostasis (Seymour & Angus, 2018). The body mobilizes energy stores and increases oxygen consumption to meet the increased metabolic needs of the underperfused tissues and cells. Anaerobic metabolism ensues, resulting in a buildup of lactic acid and disruption of normal cell function.

Even if the underlying cause of the shock is reversed, the sequence of compensatory responses to the decrease in tissue perfusion perpetuates the shock state, and a vicious cycle ensues. The cellular reactions that occur during the progressive stage of shock are an active area of clinical research. It is believed that the body's response to shock or lack of response in this stage of shock may be the primary factor determining the patient's survival. Early recognition of shock signs and symptoms is essential to improving morbidity and mortality.

Clinical Manifestations

Chances of survival depend on the patient's general health before the shock state as well as the amount of time it takes to restore tissue perfusion. As shock progresses, organ systems decompensate (see Table 11-1).

Respiratory Effects

The lungs, which become compromised early in shock, are affected at this stage. Subsequent decompensation of the lungs increases the likelihood that mechanical ventilation will be needed. Respirations are rapid and shallow. Crackles are heard over the lung fields. Decreased pulmonary blood flow causes arterial oxygen levels to decrease and CO_2 levels to increase. Hypoxemia and biochemical mediators cause an intense inflammatory

response and pulmonary vasoconstriction, perpetuating pulmonary capillary hypoperfusion and hypoxemia. The hypoperfused alveoli stop producing surfactant and subsequently collapse. Pulmonary capillaries begin to leak, causing pulmonary edema, diffusion abnormalities (shunting), and additional alveolar collapse. This condition is called *acute lung injury* (ALI); as ALI continues, interstitial inflammation and fibrosis are common consequences, leading to acute respiratory distress syndrome (ARDS) (Mitchell & Seckel, 2018). Further explanation of ALI and ARDS, as well as their nursing management, can be found in Chapter 19.

Cardiovascular Effects

A lack of adequate blood supply leads to arrhythmias and ischemia. The heart rate is rapid, sometimes exceeding 150 bpm. The patient may complain of chest pain and even suffer a myocardial infarction (MI). Levels of cardiac biomarkers (e.g., cardiac troponin I [cTn-I]) increase. In addition, myocardial depression and ventricular dilation may further impair the heart's ability to pump enough blood to the tissues to meet increasing oxygen requirements.

Neurologic Effects

As blood flow to the brain becomes impaired, mental status deteriorates. Changes in mental status occur with decreased cerebral perfusion and hypoxia. Initially, the patient may exhibit subtle changes in behavior, become agitated, confused, or demonstrate signs of delirium. (See Chapter 61 for more information about delirium.) Subsequently, lethargy increases, and the patient begins to lose consciousness.

Renal Effects

When the MAP falls below 65 mm Hg (Hallisey & Greenwood, 2019), the glomerular filtration rate of the kidneys cannot be maintained, and significant changes in renal function occur. Acute kidney injury (AKI) is characterized by an increase in blood urea nitrogen (BUN) and serum creatinine levels, fluid and electrolyte shifts, acid–base imbalances, and a loss of the renal–hormonal regulation of BP. Urinary output usually decreases to less than 0.5 mL/kg/h (or less than 30 mL/h) but may vary depending on the phase of AKI. (See Chapter 48 for further information about AKI.)

Hepatic Effects

Decreased blood flow to the liver impairs the ability of liver cells to perform metabolic and phagocytic functions. Consequently, the patient is less able to metabolize medications and metabolic waste products, such as ammonia and lactic acid. Metabolic activities of the liver, including gluconeogenesis and glycogenolysis, are impaired. The patient becomes more susceptible to

infection as the liver fails to filter bacteria from the blood. Liver enzymes (aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase) and bilirubin levels are elevated, and the patient develops jaundice.

Gastrointestinal Effects

GI ischemia can cause stress ulcers in the stomach, putting the patient at risk for GI bleeding. In the small intestine, the mucosa can become necrotic and slough off, causing bloody diarrhea. Beyond the local effects of impaired perfusion, GI ischemia leads to bacterial translocation and organ dysfunction, in which bacterial toxins enter the bloodstream through the lymphatic system. In addition to causing infection, bacterial toxins can cause cardiac depression, vasodilation, increased capillary permeability, and an intense inflammatory response with activation of additional biochemical mediators. The net result is interference with healthy cellular functioning and the ability to metabolize nutrients (Rhodes et al., 2017).

Hematologic Effects

The combination of hypotension, sluggish blood flow, metabolic acidosis, coagulation system imbalance, and generalized hypoxemia can interfere with normal hemostatic mechanisms. In shock states, the inflammatory cytokines activate the clotting cascade, causing deposition of microthrombi in multiple areas of the body and consumption of clotting factors. The alterations of the hematologic system, including imbalance of the clotting cascade, are linked to the overactivation of the inflammatory response (Massaro, 2018; Seymour & Angus, 2018). Disseminated intravascular coagulation (DIC) may occur either as a cause or as a complication of shock. In this condition, widespread clotting and bleeding occur simultaneously. Ecchymoses (bruises) and petechiae (bleeding) may appear in the skin. Coagulation times (e.g., prothrombin time, activated partial thromboplastin time) are prolonged. Clotting factors and platelets are consumed and require replacement therapy to achieve hemostasis. (Further discussion of DIC appears in Chapter 29.)

Medical Management

Specific medical management in the progressive stage of shock depends on the type of shock, its underlying cause, and the degree of decompensation in the organ systems. Medical management specific to each type of shock is discussed later in this chapter. Although medical management in the progressive stage differs by type of shock, some medical interventions are common to all types. These include the use of appropriate IV fluids and medications to restore tissue perfusion by the following methods:

- Supporting the respiratory system
- Optimizing intravascular volume
- Supporting the pumping action of the heart
- Improving the competence of the vascular system

Other aspects of management may include early enteral nutritional support, targeted hyperglycemic control with IV insulin and use of antacids, histamine-2 (H_2) blockers, or antipeptic medications to reduce the risk of GI ulceration and bleeding.

Tight glycemic control (i.e., maintaining serum glucose close to the normal parameters of 80 to 100 mg/dL) is not recommended in patients who are critically ill because this therapy has been found to result in adverse patient outcomes (Griesdale, DeSouza, VanDam, et al., 2009). Current evidence suggests that maintaining serum glucose less than 180 mg/dL with insulin therapy and close monitoring is indicated in the management of the patient who is critically ill (American Diabetes Association, 2019; Rhodes et al., 2017).

Quality and Safety Nursing Alert

Glycemic control is linked to outcomes in the patient in shock. Although tight glycemic control is not indicated, evidence shows that maintaining serum glucose less than 180 mg/dL is linked to best outcomes.

Nursing Management

Nursing care of patients in the progressive stage of shock requires expertise in assessing and understanding shock and the significance of changes in assessment data. Early interventions are essential to the survival of patients; therefore, suspecting that a patient may be in shock and reporting subtle changes in assessment are imperative. Patients in the progressive stage of shock are cared for in the intensive care setting to facilitate close monitoring (hemodynamic monitoring, electrocardiographic [ECG] monitoring, arterial blood gases, serum electrolyte levels, physical and mental status changes); rapid and frequent administration of various prescribed medications and fluids; and possibly interventions with supportive technologies, such as mechanical ventilation, dialysis (e.g., continuous renal replacement therapy), and intra-aortic balloon pump (IABP).

Working closely with other members of the health care team, the nurse carefully documents treatments, medications, and fluids that are given; the

time, dosage or volume, and patient responses are recorded. In addition, the nurse coordinates care, including the scheduling of diagnostic procedures that may occur at the bedside, and communication among health care personnel, family members, and the patient.

Preventing Complications

The nurse monitors the patient for early signs of complications to help reduce potential risks to the patient. Monitoring includes evaluating blood levels of medications, observing invasive vascular lines and catheters for signs of infection, and checking neurovascular status if arterial lines are inserted, especially in the lower extremities. Simultaneously, the nurse promotes the patient's safety and comfort by ensuring that all procedures, including invasive procedures and arterial and venous punctures, are carried out using correct aseptic techniques and that venous and arterial puncture and infusion sites are maintained with the goal of preventing infection. Nursing interventions that reduce the incidence of ventilator-associated pneumonia (VAP) must also be implemented. These include frequent oral care with a toothbrush, aseptic suction technique, turning, elevating the head of the bed at least 30 degrees to prevent aspiration, and implementing daily interruption of sedation as prescribed to evaluate patient readiness for extubation (Mitchell, Russo, Cheng, et al., 2019). See Chart 19-6 for an overview of the evidence-based ("bundled") interventions aimed at preventing VAP. Positioning and repositioning of the patient to promote comfort and maintain skin integrity are essential.

The nurse must also be vigilant in assessing for acute delirium, characterized by an acute change in mental status, inattention, disorganized thinking, and altered level of consciousness. Delirium is potentially preventable (Devlin, Skrobik, Gelians, et al., 2018; Makic, 2018). Patients who are critically ill and have delirium have longer mechanical ventilation support needs, experience higher functional decline, and have higher rates of morbidity and mortality than those without delirium. Furthermore, they are at a higher risk of developing postintensive care syndrome (PICS), which manifests as new or worsening impairments in the patient's physical, cognitive, or mental status after a critical illness has resolved and that persists beyond the acute hospitalization (Devlin et al., 2018). Delirium should be assessed at a minimum each shift using a standardized delirium assessment tool, such as the Confusion Assessment Method (CAM)-ICU (Critical Illness, Brain Dysfunction, and Survivorship (CIBS) Center, 2020). The CAM-ICU is a modified version of the CAM, specifically designed for use in patients who are critically ill (see Chapter 8, Chart 8-7 for discussion of the CAM). Nursing interventions that can prevent delirium include engaging the patient in frequent reorientation activities (e.g., to date, time, place), assessing and treating pain, promoting sleep, providing early mobilization activities, and limiting sedation,

especially sedation with benzodiazepines (e.g., lorazepam) (Devlin et al., 2018; Makic, 2018).

Promoting Rest and Comfort

Efforts are made to minimize the cardiac workload by reducing the patient's physical activity and treating pain and anxiety. Because promoting patient rest and comfort is a priority, the nurse performs essential nursing activities in blocks of time, allowing the patient to have periods of uninterrupted sleep, which may prevent acute delirium, as noted previously (Devlin et al., 2018). To conserve the patient's energy, the nurse should protect the patient from temperature extremes (e.g., excessive warmth or cold, shivering), which can increase the metabolic rate and oxygen consumption and thus the cardiac workload.

Supporting Family Members

Because patients in shock receive intense attention by the health care team, families may be overwhelmed and frightened. Family members may be reluctant to ask questions or seek information for fear that they will be in the way or will interfere with the attention given to the patient. The nurse should make sure that the family is comfortably situated and kept informed about the patient's status. Often, families need encouragement from the health care team to get some rest; family members are more likely to take this advice if they feel that the patient is being well cared for and that they will be notified of any significant changes in the patient's status. A visit from the hospital chaplain may be comforting and provides some attention to the family while the nurse concentrates on the patient. Ensuring patient- and family-centered care is central to the delivery of high-quality care. This helps meet the emotional well-being as well as the physiologic needs of the patient and the family (Wong et al., 2019).

Irreversible Stage

The irreversible (or refractory) stage of shock represents the point along the shock continuum at which organ damage is so severe that the patient does not respond to treatment and cannot survive. Despite treatment, BP remains low. Renal and liver dysfunction, compounded by the release of biochemical mediators, creates an acute metabolic acidosis. Anaerobic metabolism contributes to a worsening lactic acidosis. Reserves of ATP are almost totally depleted, and mechanisms for storing new supplies of energy have been destroyed. Respiratory system dysfunction prevents adequate oxygenation and ventilation despite mechanical ventilatory support, and the cardiovascular system is ineffective in maintaining an adequate MAP for tissue perfusion.

Multiple organ dysfunction progressing to complete organ failure has occurred, and death is imminent. Multiple organ dysfunction can occur as a progression along the shock continuum or as a syndrome unto itself and is described in more detail later in this chapter.

Medical Management

Medical management during the irreversible stage of shock is similar to interventions and treatments used in the progressive stage. Although the patient may have progressed to the irreversible stage, the judgment that the shock is irreversible can only be made after the patient has failed to respond to treatment. Strategies that may be experimental (e.g., investigational medications, such as immunomodulation therapy) may be tried to reduce or reverse the severity of shock.

Nursing Management

As in the progressive stage of shock, the nurse focuses on carrying out prescribed treatments, monitoring the patient, preventing complications, protecting the patient from injury, and providing comfort. Offering brief explanations to the patient about what is happening is essential even if there is no certainty that the patient hears or understands what is being said. Simple comfort measures, including reassuring touches, should continue to be provided despite the patient's nonresponsiveness to verbal stimuli (Wong et al., 2019).

As it becomes obvious that the patient is unlikely to survive, the family needs to be informed about the prognosis and likely outcome. Opportunities should be provided throughout the patient's care for the family to see, touch, and talk to the patient. Close friends or spiritual or religious advisors may be of comfort to the family members in dealing with the inevitable death of their loved one.

During this stage of shock, the family may misinterpret the actions of the health care team. They have been told that nothing has been effective in reversing the shock and that the patient's survival is very unlikely, yet they find primary providers and nurses continuing to work feverishly on the patient. Distraught, grieving families may interpret this as a chance for recovery when none exists, and family members may become angry when the patient dies. Conferences with all members of the health care team and the family promote better understanding by the family of the patient's prognosis and the purpose for management interventions. Engaging palliative care specialists can be beneficial in developing a plan of care that maximizes comfort and effective

symptom management as well as assisting the family with difficult decisions (Ivany & Aitken, 2019). During these conferences, it is essential to explain that the equipment and treatments being provided are intended for patient comfort and do not suggest that the patient will recover. Family members should be encouraged to express their views of life-support measures. In some cases, ethics committees may be consulted to assist families and health care teams make complex end-of-life decisions (Ivany & Aitken, 2019; Turner & Hylton, 2019).

General Management Strategies in Shock

As described previously and in the discussion of types of shock to follow, management in all types and all phases of shock includes the following:

- Support of the respiratory system with supplemental oxygen and/or mechanical ventilation to provide optimal oxygenation (see Chapter 19)
- Fluid replacement to restore intravascular volume
- Vasoactive medications to restore vasomotor tone and improve cardiac function
- Nutritional support to address the metabolic requirements that are often dramatically increased in shock

Therapies described in this section require collaboration among all members of the health care team.

Fluid Replacement

Fluid replacement, also referred to as fluid resuscitation, is given in all types of shock. The type of fluids administered, and the speed of delivery vary; however, fluids are given to improve cardiac and tissue oxygenation, which in part depends on flow. The fluids given may include **crystalloids** (electrolyte solutions that move freely between intravascular compartment and interstitial spaces), **colloids** (large-molecule IV solutions), and blood components (packed red blood cells, fresh-frozen plasma, and platelets).

Crystalloid and Colloid Solutions

In emergencies, the "best" fluid is often the fluid that is readily available. Fluid resuscitation should be initiated early in shock to maximize intravascular volume. Isotonic crystalloid solutions are often selected because they contain the same concentration of electrolytes as the extracellular fluid and, therefore, can be given without altering the concentrations of electrolytes in the plasma. IV crystalloids commonly used for resuscitation in hypovolemic shock include

0.9% sodium chloride solution (normal saline) and lactated Ringer's solution. Lactated Ringer's is an electrolyte solution containing the lactate ion, which should not be confused with lactic acid. The lactate ion is converted to bicarbonate, which helps buffer the overall acidosis that occurs in shock. Lactated Ringer's solution more closely resembles plasma and is considered a more appropriate first choice solution over 0.9% normal saline (de-Madaria, Herrera-Marante, Gonzalez-Camacho, et al., 2018). While normal saline is an isotonic solution, large infusions may cause hypernatremia, hypokalemia, and hyperchloremic metabolic acidosis (de-Madaria et al., 2018; Sethi, Owyang, Meyers, et al., 2018). Hypertonic crystalloid solution, often 3% sodium chloride, does not improve patient outcomes and may result in unintended complications and is not recommended as a fluid for resuscitation (Bauer, MacLaren, & Erstad, 2019). A disadvantage of using isotonic crystalloid solutions is that some of the volume given is lost to the interstitial compartment and some remains in the intravascular compartment. This occurs as a consequence of cellular permeability that occurs during shock. Diffusion of crystalloids into the interstitial space means that more fluid may need to be given than the amount lost to support tissue perfusion (Lewis, Pritchard, Evans, et al., 2018).

Care must be taken when rapidly administering isotonic crystalloids to avoid both underresuscitating and overresuscitating the patient in shock. Insufficient fluid replacement is associated with a higher incidence of morbidity and mortality from lack of tissue perfusion, whereas excessive fluid administration can cause systemic and pulmonary edema that progresses to ALI (see Chapter 19), intra-abdominal hypertension (IAH) and abdominal compartment syndrome (ACS), and MODS (see later discussion).

ACS is a serious complication that may occur when large volumes of fluid are given. It may also occur after trauma, abdominal surgery, pancreatitis, or sepsis (Harrell & Miller, 2017). In ACS, fluid leaks into the intra-abdominal cavity, increasing pressure that is displaced onto surrounding vessels and organs. Venous return, preload, and cardiac output are compromised. The pressure also elevates the diaphragm, making it difficult to breathe effectively. The renal and GI systems also begin to show signs of dysfunction (e.g., decreased urine output, absent bowel sounds, intolerance of tube feeding). Abdominal compartment pressure can be measured. Normally, it is 0 to 5 mm Hg, and a pressure of 12 mm Hg is considered to be indicative of IAH (Harrell & Miller, 2017). If ACS is present, interventions that usually include surgical decompression are necessary to relieve the pressure.

Generally, IV colloidal solutions are similar to plasma proteins, in that they contain molecules that are too large to pass through capillary membranes. Colloids expand intravascular volume by exerting oncotic pressure, thereby pulling fluid into the intravascular space, increasing intravascular volume. In addition, colloids have a longer duration of action than crystalloids, because

the molecules remain within the intravascular compartment longer. Typically, if colloids are used to treat tissue hypoperfusion, albumin is the agent prescribed. Albumin is a plasma protein; an albumin solution is prepared from human plasma and is heated during production to reduce its potential to transmit disease. The disadvantage of albumin is its high cost compared to crystalloid solutions. Resuscitation with colloid solutions has not reduced the risk of morbidity or death compared to resuscitation with crystalloid solutions; moreover, colloids can be considerably more expensive than crystalloid solutions (Annane, Siami, Jaber, et al., 2013; Lewis et al., 2018).

Quality and Safety Nursing Alert

With all colloidal solutions, side effects include the rare occurrence of anaphylactic reactions. Nurses must monitor patients closely.

Complications of Fluid Administration

Close monitoring of the patient during fluid replacement is necessary to identify side effects and complications. The most common and serious side effects of fluid replacement are cardiovascular overload, pulmonary edema, and ACS. The patient receiving fluid replacement must be monitored frequently for adequate urinary output, changes in mental status, skin perfusion, and changes in vital signs. Lung sounds are auscultated frequently to detect signs of fluid accumulation. Adventitious lung sounds, such as crackles, may indicate pulmonary edema and ALI and ARDS.

Quality and Safety Nursing Alert

When administering large volumes of crystalloid solutions, the nurse must monitor the lungs for adventitious sounds, signs and symptoms of interstitial edema, work of breathing (i.e., increasing effort required for the patient to breathe, depth of breathing, respiratory rate), and changes in oxygen saturation.

Often, a CVP line is inserted (typically into the subclavian or jugular vein) and is advanced until the tip of the catheter rests near the junction of the SVC and the right atrium. CVP measurements have traditionally been used to assess preload in the right side of the heart and fluid responsiveness during shock states. However, research confirms there is no direct relationship between CVP, circulating blood volume, and fluid responsiveness; thus, CVP is no longer used as a reliable measure to guide fluid replacement therapy (Laher et al., 2017; Marik, Baram, & Vahid, 2008; Marik & Cavallazzi, 2013;

Simmons & Ventetuolo, 2017). CVP devices provide access for large volumes of fluid replacement, and administration of blood products and vasoactive agents. If CVP measurements are still used to evaluate fluid needs of the patient, assessment variables such as BP, urine output, heart rate, and PLR should be considered when interpreting the CVP for clinical decisions (Laher et al., 2017; Simmons & Ventetuolo, 2017). Some CVP catheters allow the monitoring of intravascular measures and venous oxygen levels. Assessment of venous oxygenation (venous oxygen saturation $S\bar{v}O_2$, or $Sc\bar{v}O_2$ with a CVP line) may be helpful in evaluating the adequacy of intravascular volume (Rhodes et al., 2017; Rivers, McIntyre, Morro, et al., 2005). Hemodynamic monitoring with arterial lines may be implemented to allow close monitoring of the patient's BP and tissue perfusion. A pulmonary artery catheter may be inserted to assist with closer monitoring of a patient's cardiac status as well as response to therapy. Advances in noninvasive or minimally invasive technology (e.g., esophageal Doppler, arterial pulse contour analysis, cardiac output devices, intrathoracic impedance monitoring) provide additional hemodynamic monitoring options (Hallisey & Greenwood, 2019; Laher et al., 2017; Zhang et al., 2017). (For additional information about hemodynamic monitoring, see Chapter 21.)

Placement of central lines for fluid administration and monitoring requires collaborative practice between the provider and the nurse to ensure that all measures to prevent central line–associated bloodstream infection (CLABSI) are implemented. Several interventions aimed at preventing CLABSI should be implemented collaboratively while the central line is being placed as well as during ongoing nursing management of the central line itself. Chart 11-2 describes the evidence-based ("bundled") interventions that have been found to reduce CLABSI.

Vasoactive Medication Therapy

Vasoactive medications are given in all forms of shock to improve the patient's hemodynamic stability when fluid therapy alone cannot maintain adequate MAP. Specific medications are selected to correct the particular hemodynamic alteration that is impeding cardiac output. These medications help increase the strength of myocardial contractility, regulate the heart rate, reduce myocardial resistance, and initiate vasoconstriction.

Vasoactive medications are selected for their action on receptors of the sympathetic nervous system. These receptors are known as alpha-adrenergic and beta-adrenergic receptors. Beta-adrenergic receptors are further classified as beta-1 and beta-2 adrenergic receptors. When alpha-adrenergic receptors are stimulated, blood vessels constrict in the cardiorespiratory and GI systems, skin, and kidneys. When beta-1 adrenergic receptors are stimulated, heart rate and myocardial contraction increase. When beta-2 adrenergic receptors are

stimulated, vasodilation occurs in the heart and skeletal muscles, and the bronchioles relax. The medications used in treating shock consist of various combinations of vasoactive medications to maximize tissue perfusion by stimulating or blocking the alpha- and beta-adrenergic receptors.

When vasoactive medications are given, vital signs must be monitored frequently (at least every 15 minutes until stable, or more often if indicated). Vasoactive medications should be given through a central venous line, because infiltration and extravasation of some vasoactive medications can cause tissue necrosis and sloughing (Maclaren, Mueller, & Dasta, 2019). Individual medication dosages are usually titrated by the nurse, who adjusts drip rates on the basis of the prescribed dose and target outcome parameter (e.g., BP, heart rate) and the patient's response. Dosages are changed to maintain the MAP at a physiologic level that ensures adequate tissue perfusion (usually greater than 65 mm Hg).

Quality and Safety Nursing Alert

Vasoactive medications should never be stopped abruptly, because this could cause severe hemodynamic instability, perpetuating the shock state.

Dosages of vasoactive medications must be tapered. When vasoactive medications are no longer needed or are necessary to a lesser extent, the infusion should be weaned with frequent monitoring of BP (e.g., every 15 minutes). Table 11-2 presents some of the commonly prescribed vasoactive medications used in the treatment of shock.

Nutritional Support

Nutritional support is an important aspect of care for critically ill patients. Increased metabolic rates during shock increase energy requirements and therefore caloric requirements. Patients in shock may require more than 3000 calories daily. The release of catecholamines early in the shock continuum causes rapid depletion of glycogen stores. Nutritional energy requirements are then met by breaking down lean body mass. In this catabolic process, skeletal muscle mass is broken down even when the patient has large stores of fat or adipose tissue. Loss of skeletal muscle greatly prolongs the patient's recovery time.

Parenteral or enteral nutritional support should be initiated as soon as possible. Enteral nutrition is preferred, promoting GI function through direct exposure to nutrients and limiting infectious complications associated with parenteral feeding (Reintam, Blaser, Starkopf, et al., 2017). Implementation of

an evidence-based enteral feeding protocol that is tolerant of increased gastric residual volumes ensures the delivery of adequate nutrition to patients who are critically ill (Wang, Ding, Fang, et al., 2019). Gastric residual volume does not predict a patient's risk of aspiration (Wang et al., 2019). Implementing early enteral nutrition has been found to promote gut-mediated immunity, reduce metabolic response to stress, and improve overall patient morbidity and mortality (Reintam et al., 2017). (See Chapter 39 for further discussion of monitoring gastric residual volumes.)

Chart 11-2

Collaborative Practice Interventions to Prevent Central Line–Associated Bloodstream Infections (CLABSIs)

Current best practices can include the implementation of specific evidence-based bundle interventions that when used together (i.e., as a "bundle") improve patient outcomes. This chart outlines specific parameters for the central line bundled collaborative interventions that have been found to reduce central line–associated bloodstream infections (CLABSI).

What are the five key elements of the central line bundle?

- Hand hygiene
- Maximal sterile barrier precautions during line insertion (see later discussion)
- Chlorhexidine skin antisepsis
- Optimal catheter site selection with avoidance of using the femoral vein for central venous access in adult patients
- Daily review of line necessity, with prompt removal of unnecessary lines

When should hand hygiene be performed in the care of a patient with a central line?

- All clinicians who provide care to the patient should adhere to good hand hygiene practices, particularly:
  - Before and after palpating the catheter insertion site
  - With all dressing changes to the intravascular catheter access site
  - When hands are visibly soiled or contamination of hands is suspected
  - Before donning and after removing gloves

What changes can be made to improve hand hygiene?

- Implement a central line procedure checklist that requires that clinicians perform hand hygiene as an essential step in care.
- Post signage stating the importance of hand hygiene.
- Have soap and alcohol-based hand sanitizers prominently placed to facilitate hand hygiene practices.
- Model hand hygiene practices.
- Provide patient and family education and engage family in hand hygiene practices during visitation.

What are maximal sterile barrier precautions?

- These are implemented during central line insertion:
  - For the primary provider, this means strict adherence with wearing a cap, mask, sterile gown, and sterile gloves. The cap should cover all hair, and the mask should cover the nose and the mouth tightly. The nurse should also wear a cap and a mask.
  - For the patient, this means covering the patient from head to toe with a sterile drape, with a small opening for the site of insertion. If

a full-size drape is not available, two drapes may be applied to cover the patient, or the operating room may be consulted to determine how to procure full-size sterile drapes, because these are routinely used in surgical settings.

- Nurses should be empowered to enforce use of a central line checklist to be sure that all processes related to central line placement are properly executed for every line placed.

Which antiseptic should be used to prepare the patient's skin for central line insertion?

- Chlorhexidine skin antisepsis has been proven to provide better skin antisepsis than other antiseptic agents, such as povidone–iodine solution.
- An alcohol chlorhexidine antiseptic should be applied using a back-and-forth friction scrub for at least 30 s; this should not be wiped or blotted dry.
- The antiseptic solution should be allowed time to dry completely before the insertion site is punctured/accessed (approximately 2 min).

What nursing interventions are essential to reduce the risk of infection?

- Maintaining sterile technique when changing the central line dressing
- Always performing hand hygiene before manipulating or accessing the line ports
- Wearing clean gloves before accessing the line port
- Performing a 15- to 30-s "hub scrub" using chlorhexidine or alcohol and friction in a twisting motion on the access hub (reduces biofilm on the hub that may contain pathogens)
- Using chlorhexidine-containing dressings in patients older than 2 mo
- Consider using antiseptic-containing port protectors to cover connectors

When should central lines be discontinued?

- Assessment for removal of central lines should be included as part of the nurse's daily goal sheets.
- The time and date of central line placement should be recorded and evaluated by staff to aid in decision making.
- The need for the central line access should be reviewed as part of multidisciplinary rounds.
- During these rounds, the "line day" should be stated to remind everyone how long the central line has been in place (e.g., "Today is line day 6").
- An appropriate time frame for regular review of the necessity for a central line should be identified, such as weekly, when central lines are placed for long-term use (e.g., chemotherapy, extended antibiotic administration).

Quality improvement processes that trend CLABSI rates and the adherence with CLABSI bundle prevention strategies have been found to effectively engage the multidisciplinary team in achieving goals to reduce infections related to central lines.

Adapted from Institute for Healthcare Improvement (IHI). (2012). How-to guide: Prevent central line-associated bloodstream infection. Retrieved on 9/10/2019 at: www.ihi.org/resources/Pages/Tools/HowtoGuidePreventCentralLineAssociatedBloodstreamInfection.aspx; Marschall, J., Mermel, L. A., Fakih, M., et al. (2014). Strategies to prevent central-line associated bloodstream infections in acute care hospitals: 2014 update. *Infection Control and Hospital Epidemiology, 35*(7), 753–771.

Stress ulcers occur frequently in acutely ill patients because of the compromised blood supply to the GI tract. Therefore, antacids, H_2 blockers (e.g., famotidine), and proton pump inhibitors (e.g., lansoprazole, esomeprazole magnesium) are prescribed to prevent ulcer formation by inhibiting gastric acid secretion or increasing gastric pH.

TABLE 11-2 Select Vasoactive Agents Used in Treating Shock

Medication	Desired Action in Shock	Disadvantages
Inotropic Agents		
Dobutamine Dopamine Epinephrine Milrinone	Improve contractility, increase stroke volume, increase cardiac output	Increase oxygen demand of the heart
Vasodilators		
Nitroglycerin Nitroprusside	Reduce preload and afterload, reduce oxygen demand of heart	Cause hypotension
Vasopressor Agents		
Norepinephrine Dopamine Phenylephrine Vasopressin Epinephrine Angiotensin II	Increase blood pressure by vasoconstriction	Increase afterload, thereby increasing cardiac workload; compromise perfusion to skin, kidneys, lungs, gastrointestinal tract

Adapted from Annane, D., Ouanes-Besbes, L., DeBacker, D., et al. (2018). A global perspective on vasoactive agents in shock. *Intensive Care Medicine*, *44*(6), 833–346; Maclaren, R., Mueller, S. W., & Dasta, J. F. (2019). Use of vasopressors and inotropes in the pharmacotherapy of shock. In J. T. DiPiro, R. L. Talbert, G. C. Yee, et al. (Eds.). *Pharmacotherapy: A pathophysiologic approach* (11th ed.). New York: McGraw-Hill Medical.

Hypovolemic Shock

Hypovolemic shock, the most common type of shock, is characterized by decreased intravascular volume. Body fluid is contained in the intracellular and extracellular compartments. Intracellular fluid accounts for about two thirds of the total body water. The extracellular body fluid is found in one of two compartments: intravascular (inside blood vessels) or interstitial (surrounding tissues). The volume of interstitial fluid is about three to four times that of intravascular fluid. Hypovolemic shock occurs when there is a reduction in intravascular volume by 15% to 30%, which represents an approximate loss of 750 to 1500 mL of blood in a 70-kg (154-lb) person (American College of Surgeons, 2018).

Pathophysiology

Hypovolemic shock can be caused by external fluid losses, as in traumatic blood loss, or by internal fluid shifts, as in severe dehydration, severe edema, or ascites (Chart 11-3). Intravascular volume can be reduced by both fluid loss and fluid shifting between the intravascular and interstitial compartments.

Chart 11-3 RISK FACTORS

Hypovolemic Shock

External: Fluid Losses	Internal: Fluid Shifts
Trauma	Hemorrhage
Surgery	Burns
Vomiting	Ascites
Diarrhea	Peritonitis
Diuresis	Dehydration
Diabetic ketoacidosis	Necrotizing pancreatitis
Diabetes insipidus	

The sequence of events in hypovolemic shock begins with a decrease in the intravascular volume. This results in decreased venous return of blood to the heart and subsequent decreased ventricular filling. Decreased ventricular filling results in decreased stroke volume (amount of blood ejected from the heart) and decreased cardiac output. When cardiac output drops, BP drops and tissues cannot be adequately perfused (Fig. 11-4).

Medical Management

Major goals in the treatment of hypovolemic shock are to restore intravascular volume to reverse the sequence of events leading to inadequate tissue perfusion, to redistribute fluid volume, and to correct the underlying cause of the fluid loss as quickly as possible. Depending on the severity of shock and the patient's condition, often all three goals are addressed simultaneously.

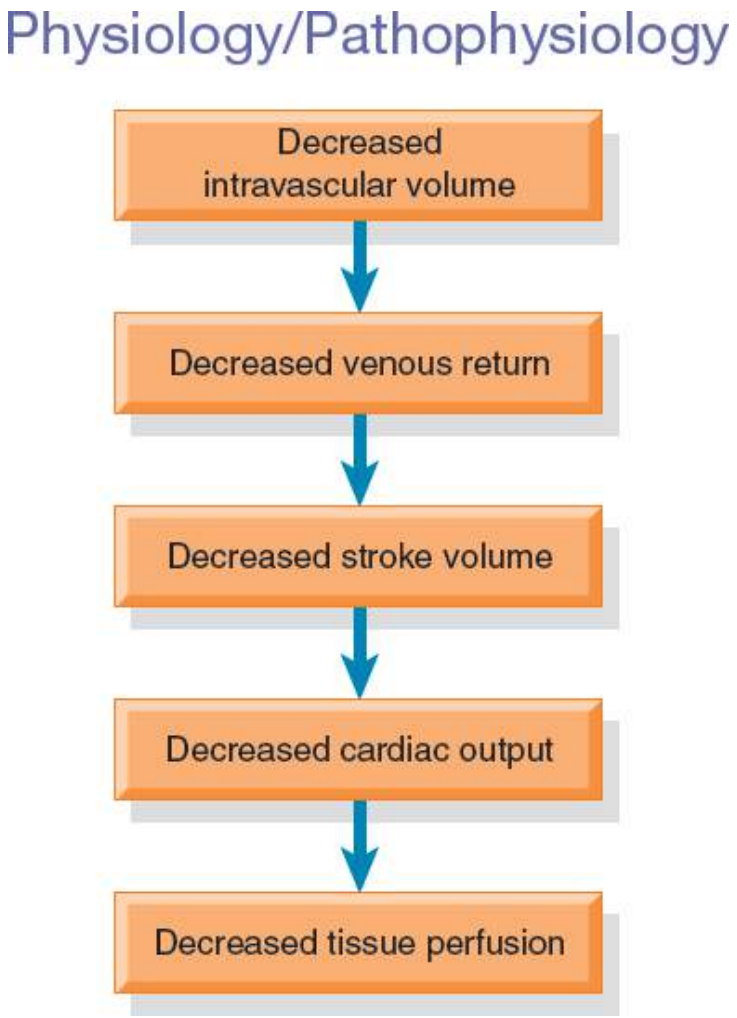

Figure 11-4 • Pathophysiologic sequence of events in hypovolemic shock.

Treatment of the Underlying Cause

If the patient is hemorrhaging, efforts are made to stop the bleeding. This may involve applying pressure to the bleeding site or surgical interventions to stop internal bleeding. If the cause of the hypovolemia is diarrhea or vomiting, medications to treat diarrhea and vomiting are given while efforts are made to identify and treat the cause. In older adult patients, dehydration may be the cause of hypovolemic shock.

Fluid and Blood Replacement

Beyond reversing the primary cause of the decreased intravascular volume, fluid replacement is of primary concern. At least two large-gauge IV lines are inserted to establish access for fluid administration. If an IV catheter cannot be quickly inserted, an intraosseous catheter may be used for access in the sternum, legs (tibia), or arms (humerus) to facilitate rapid fluid replacement (Clemency, Tanaka, May, et al., 2017). Multiple IV lines allow simultaneous

administration of fluid, medications, and blood component therapy if required. Because the goal of the fluid replacement is to restore intravascular volume, it is necessary to administer fluids that will remain in the intravascular compartment to avoid fluid shifts from the intravascular compartment into the intracellular compartment. Table 11-3 summarizes the fluids commonly used in the treatment of shock.

As discussed earlier, crystalloid solutions such as lactated Ringer's solution or 0.9% sodium chloride solution are commonly used to treat hypovolemic shock, as large amounts of fluid must be given to restore intravascular volume. If hypovolemia is primarily due to blood loss, the American College of Surgeons (2018) recommends administration of 3 mL of crystalloid solution for each milliliter of estimated blood loss. This is referred to as the 3:1 rule. Colloid solutions (e.g., albumin) may also be used. Hetastarch and dextran solutions are not indicated for fluid administration because these agents interfere with platelet aggregation.

TABLE 11-3 Fluid Replacement in Shock[a]

Fluids	Advantages	Disadvantages
Crystalloids		
Lactated Ringer's	Widely available; Lactate ion that helps buffer metabolic acidosis	Requires large volume of infusion; overresuscitation can result in pulmonary edema, abdominal compartment syndrome
0.9% Sodium chloride (normal saline solution)	Widely available	Requires large volume of infusion; can cause hypernatremia, hypokalemia, hyperchloremic metabolic acidosis; overresuscitation can result in pulmonary edema, abdominal compartment syndrome
Colloids		
Albumin (5%, 25%)	Rapidly expands plasma volume	Expensive; requires human donors; limited supply; can cause heart failure
Blood Products		
Plasma, packed red blood cells, and platelets	Rapidly replaces volume lost due to hemorrhage	Crossmatch type-specific blood is desired for optimal massive transfusion protocols to reduce transfusion-related complications (e.g., transfusion-related acute lung injury, hemolytic reactions, transfusion-associated circulatory overload)

[a]Deliver a minimum of 30 mL/kg of crystalloid.

Adapted from Holcomb, J. B., Tiley, B. C., Baraniuk, S., et al. (2015). Transfusion of plasma, platelets, and red blood cells in a 1:1:1 vs a 1:1:2 ratio and mortality in patients with severe trauma. *JAMA*, *313*(5), 471–482; Lewis, S. R., Pritchard, M. W., Evans, D. J. W., et al. (2018). Colloids versus crystalloids for fluid resuscitation in critically ill people. The *Cochrane Database of Systematic Reviews*, *8*(8), CD000567;

Rhodes, A., Evans, L., Alhazzani, W., et al. (2017). Surviving Sepsis Campaign: International guidelines for management of sepsis and septic shock: 2016. *Critical Care Medicine*, *45*(3), 486–552.

Blood products, which are also colloids, may need to be given, particularly if the cause of the hypovolemic shock is hemorrhage. The decision to give blood is based on the patient's lack of response to crystalloid resuscitation, the volume of blood lost, the need for hemoglobin to assist with oxygen transport, and the necessity to correct the patient's coagulopathy. Patients requiring massive transfusion respond better when blood products are given in a 1:1:1

ratio, meaning units of plasma, platelets, and packed red blood cells (Holcomb, Tiley, Baraniuk, et al., 2015).

Packed red blood cells are given to replenish the patient's oxygen-carrying capacity in conjunction with other fluids that will expand volume. Plasma and platelets are transfused to assist with coagulation and hemostasis. The need for transfusions is based on the patient's oxygenation needs and coagulation status, which are determined by vital signs, blood gas, chemistry, coagulation laboratory values, and clinical appearance.

Redistribution of Fluid

In addition to administering fluids to restore intravascular volume, positioning the patient properly assists fluid redistribution. PLR may be used to evaluate the patient's responsiveness to fluids and continued resuscitation efforts (Simmons & Ventetuolo, 2017). The nurse assesses for an improvement in the patient's vital signs, specifically a rise in the BP. Trendelenburg is not indicated as this position makes breathing difficult and does not increase BP or cardiac output (Bridges & Jarquin-Valdivia, 2005).

Pharmacologic Therapy

If fluid administration fails to reverse hypovolemic shock, then vasoactive medications that prevent cardiac failure are given. Medications are also given to reverse the cause of the dehydration. For example, insulin is given if dehydration is secondary to hyperglycemia, desmopressin is given for diabetes insipidus, antidiarrheal agents for diarrhea, and antiemetic medications for vomiting.

Nursing Management

Primary prevention of shock is an essential focus of nursing care. Hypovolemic shock can be prevented in some instances by closely monitoring patients who are at risk for fluid deficits and assisting with fluid replacement before intravascular volume is depleted. In other circumstances, nursing care focuses on assisting with treatment targeted at the cause of the shock and restoring intravascular volume.

General nursing measures include ensuring safe administration of prescribed fluids and medications and documenting their administration and effects. Volumetric IV pumps should be used to administer prescribed vasopressor medications. Another important nursing role is monitoring for complications and side effects of treatment and reporting them promptly.

Administering Blood and Fluids Safely

Administering blood transfusions safely is a vital nursing role. In emergency situations, it is important to acquire blood specimens quickly, to obtain a baseline complete blood count, and to type and crossmatch the blood in anticipation of blood transfusions. A patient who receives a transfusion of blood products must be monitored closely for adverse effects (see Chapter 28).

Fluid replacement complications can occur, especially when large volumes are given rapidly. Therefore, the nurse monitors the patient closely for cardiovascular overload and signs of difficulty breathing, a condition known as transfusion-associated circulatory overload. Transfusion-related ALI may occur and is characterized by pulmonary edema, hypoxemia, respiratory distress, and pulmonary infiltrates, usually within hours after massive transfusion (Vlaar & Kleinman, 2019). The risk of these complications is increased in older adults, in patients with preexisting cardiac disease, and with increasing number of blood products given. ACS is also a possible complication of excessive fluid resuscitation and may initially present with respiratory symptoms (difficulty breathing) and decreased urine output. Hemodynamic pressure, vital signs, arterial blood gases, serum lactate levels, hemoglobin and hematocrit levels, bladder pressure monitoring, and fluid intake and output (I&O) are among the parameters monitored. Temperature should also be monitored closely to ensure that rapid fluid resuscitation does not cause hypothermia. IV fluids may need to be warmed when large volumes are given. Physical assessment focuses on observing the jugular veins for distention and monitoring jugular venous pressure. Jugular venous pressure is low in hypovolemic shock; it increases with effective treatment and is significantly increased with fluid overload and heart failure. The nurse must monitor cardiac and respiratory status closely and report changes in BP, pulse pressure, CVP, heart rate and rhythm, and lung sounds to the primary provider.

Implementing Other Measures

Oxygen is given to increase the amount of oxygen carried by available hemoglobin in the blood. A patient who is confused may feel apprehensive with an oxygen mask or cannula in place, and frequent explanations about the need for the mask may reduce some of the patient's fear and anxiety. Simultaneously, the nurse must direct efforts to the safety and comfort of the patient.

Cardiogenic Shock

Cardiogenic shock occurs when the heart's ability to contract and to pump blood is impaired and the supply of oxygen is inadequate for the heart and the tissues. The causes of cardiogenic shock are known as either coronary or noncoronary. Coronary cardiogenic shock is more common than noncoronary

cardiogenic shock and is seen most often in patients with acute MI resulting in damage to a significant portion of the left ventricular myocardium (Wilcox, 2019). Patients who experience an anterior wall MI are at greatest risk for cardiogenic shock because of the potentially extensive damage to the left ventricle caused by occlusion of the left anterior descending coronary artery. Noncoronary causes of cardiogenic shock are related to conditions that stress the myocardium (e.g., severe hypoxemia, acidosis, hypoglycemia, hypocalcemia, tension pneumothorax) as well as conditions that result in ineffective myocardial function (e.g., cardiomyopathies, valvular damage, cardiac tamponade, arrhythmias).

Pathophysiology

In cardiogenic shock, cardiac output, which is a function of both stroke volume and heart rate, is compromised. When stroke volume and heart rate decrease or become erratic, BP falls and tissue perfusion is reduced. Blood supply for tissues and organs and for the heart muscle itself is inadequate, resulting in impaired tissue perfusion. Because impaired tissue perfusion weakens the heart and impairs its ability to pump, the ventricle does not fully eject its volume of blood during systole. As a result, fluid accumulates in the lungs. This sequence of events can occur rapidly or over a period of days (Fig. 11-5).

Clinical Manifestations

Patients in cardiogenic shock may experience the pain of angina, develop arrhythmias, complain of fatigue, express feelings of doom, and show signs of hemodynamic instability.

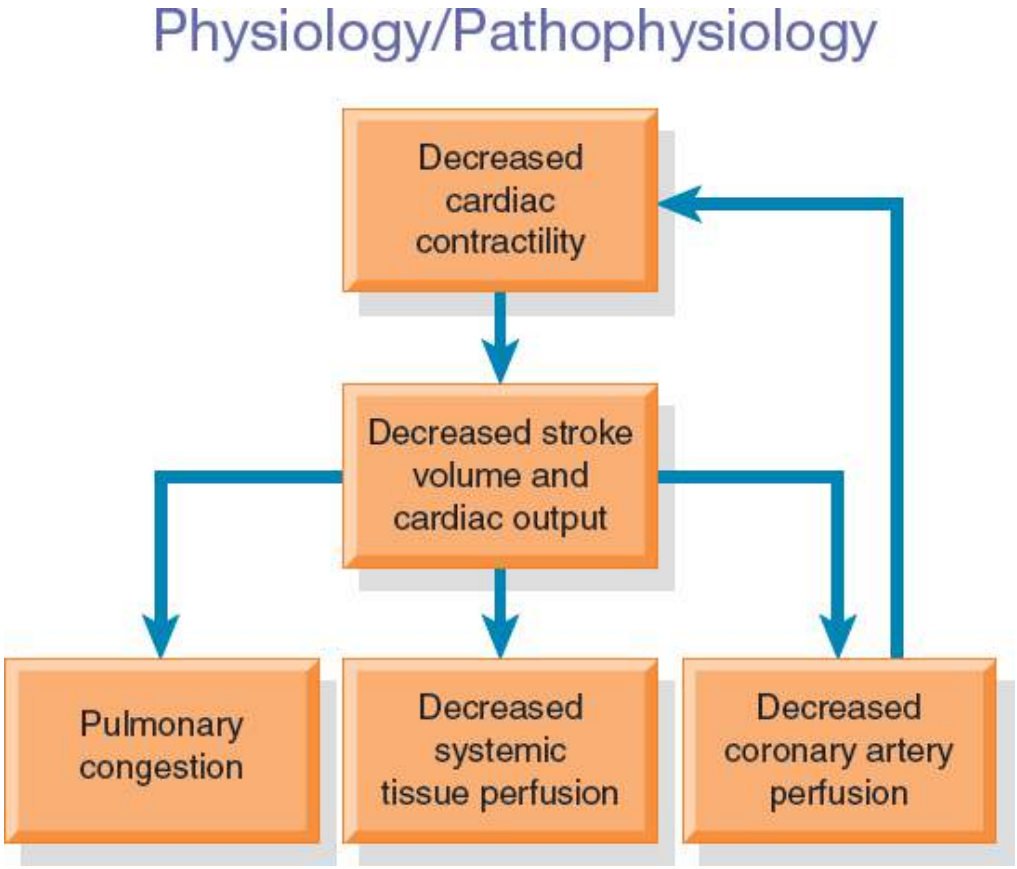

Figure 11-5 • Pathophysiologic sequence of events in cardiogenic shock.

Assessment and Diagnostic Findings

To assess the degree of myocardial damage, laboratory biomarkers for ventricular dysfunction (e.g., B-type natriuretic peptide), cardiac enzyme levels and biomarkers (cTn-I), and serum lactate are measured. In addition, a transthoracic echocardiography may be performed at the bedside, and serial 12-lead electrocardiograms are obtained (Bellumkonda, Gul, & Masri, 2018; Wilcox, 2019). Continuous ECG and ST segment monitoring is also done to closely monitor the patient for ischemic changes.

Medical Management

The goals of medical management in cardiogenic shock are to limit further myocardial damage and preserve the healthy myocardium and to improve cardiac function by increasing cardiac contractility, decreasing ventricular afterload, or both (Wilcox, 2019). In general, these goals are achieved by increasing oxygen supply to the heart muscle while reducing oxygen demands.

Correction of Underlying Causes

As with all forms of shock, the underlying cause of cardiogenic shock must be corrected. It is necessary first to treat the oxygenation needs of the heart muscle to ensure its continued ability to pump blood to other organs. In the case of coronary cardiogenic shock (e.g., acute coronary syndromes, ischemic cardiomyopathy, nonischemic cardiomyopathies, and myocarditis), the patient may require thrombolytic (fibrinolytic) therapy, a percutaneous coronary intervention, coronary artery bypass graft surgery, IABP therapy, ventricular assist device, or some combination of these treatments (Bellumkonda et al., 2018; Wilcox, 2019). In the case of noncoronary cardiogenic shock, interventions focus on correcting the underlying cause, such as replacement of an impaired cardiac valve, correction of an arrhythmia, correction of acidosis and electrolyte disturbances, or treatment of a tension pneumothorax. If the cause of the cardiogenic shock was related to a cardiac arrest, once the patient is successfully resuscitated, targeted temperature management, also called *therapeutic hypothermia,* may be initiated to actively lower the body temperature to a targeted core temperature (e.g., 32°C [89.6°F] to 36°C [96.8°F]) to preserve neurologic function (American Heart Association, 2018). (See Chapter 23 for more information regarding MI.)

Initiation of First-Line Treatment

Treatment priorities for patients in cardiogenic shock are focused upon ensuring adequate oxygenation, pain control, and maintaining hemodynamic stability.

Oxygenation

In the early stages of shock, if the patient's oxygen saturation is less than 90%, supplemental oxygen is given by nasal cannula at a rate of 2 to 6 L/min (Neto, 2018). Monitoring of arterial blood gas values, pulse oximetry values, and ventilatory effort (i.e., work of breathing) helps determine whether the patient requires a more aggressive method of oxygen delivery (including noninvasive and invasive mechanical ventilation).

Pain Control

If a patient experiences chest pain, IV morphine may be given for pain relief. In addition to relieving pain, morphine may dilate the blood vessels, reducing the workload of the heart by both decreasing the cardiac filling pressure (preload) and reducing the pressure against which the heart muscle has to eject blood (afterload). However, recent evidence suggests morphine may adversely affect antiplatelet agents used to treat the ischemic event; thus, the benefits of morphine may not outweigh its risks (McCarthy, Bhambhani, Pomerantsev, et al., 2018; Neto, 2018).

Hemodynamic Monitoring

Hemodynamic monitoring is initiated to assess the patient's response to treatment. In many institutions, this is performed in the intensive care unit (ICU), where an arterial line can be inserted. The arterial line enables accurate and continuous monitoring of BP and provides a port from which to obtain frequent arterial blood samples without having to perform repeated arterial punctures. A multilumen CVP and PA catheter may be inserted to allow measurement of myocardial filling pressures, pulmonary artery pressures, cardiac output, and pulmonary and systemic resistance. (For more information, see Chapter 21.)

Fluid Therapy

Appropriate fluid administration is also necessary in the treatment of cardiogenic shock. Administration of fluids must be monitored closely to detect signs of fluid overload. Incremental IV fluid boluses are cautiously given to determine optimal filling pressures for improving cardiac output.

Quality and Safety Nursing Alert

A fluid bolus should never be given rapidly, because rapid fluid administration in patients with cardiac failure may result in acute pulmonary edema.

Pharmacologic Therapy

Vasoactive medication therapy consists of multiple pharmacologic strategies to restore and maintain adequate cardiac output. In coronary cardiogenic shock, the aims of vasoactive medication therapy are improved cardiac contractility, decreased preload and afterload, and stabilized heart rate and rhythm.

Because improving contractility and decreasing cardiac workload are opposing pharmacologic actions, two types of medications may be given in combination: inotropic agents and vasodilators. Inotropic medications increase cardiac output by mimicking the action of the sympathetic nervous system, activating myocardial receptors to increase myocardial contractility (inotropic action), or increasing the heart rate (chronotropic action). These agents may also enhance vascular tone, increasing preload. Vasodilators are used primarily to decrease afterload, reducing the workload of the heart and oxygen demand. Vasodilators also decrease preload. Medications commonly combined to treat cardiogenic shock include dobutamine, nitroglycerin, and dopamine (see Table 11-2).

Dobutamine

Dobutamine produces inotropic effects by stimulating myocardial beta-receptors, increasing the strength of myocardial activity and improving cardiac output. Myocardial alpha-adrenergic receptors are also stimulated, resulting in decreased pulmonary and systemic vascular resistance (decreased afterload) (Maclaren et al., 2019).

Nitroglycerin

IV nitroglycerin in low doses acts as a venous vasodilator and therefore reduces preload. At higher doses, nitroglycerin causes arterial vasodilation and therefore reduces afterload as well. These actions, in combination with dobutamine, increase cardiac output while minimizing cardiac workload. In addition, vasodilation enhances blood flow to the myocardium, improving oxygen delivery to the weakened heart muscle (Maclaren et al., 2019; Wilcox, 2019).

Dopamine

Dopamine is a sympathomimetic agent that has varying vasoactive effects depending on the dosage. It may be used with dobutamine and nitroglycerin to improve tissue perfusion. Doses of 2 to 8 µg/kg/min improve contractility (inotropic action), slightly increase the heart rate (chronotropic action), and may increase cardiac output. Doses that are higher than 8 µg/kg/min predominantly cause vasoconstriction, which increases afterload and thus increases cardiac workload. Because this effect is undesirable in patients with cardiogenic shock, dopamine doses must be carefully titrated.

In severe metabolic acidosis, which occurs in the later stages of shock, metabolic acidosis must first be corrected to ensure maximum effectiveness of vasoactive medications (Maclaren et al., 2019).

Other Vasoactive Medications

Additional vasoactive agents that may be used in managing cardiogenic shock include norepinephrine, epinephrine, milrinone, vasopressin, phenylephrine, and angiotensin II. Each of these medications stimulates different receptors of the sympathetic nervous system. A combination of these medications may be prescribed, depending on the patient's response to treatment. All vasoactive medications have adverse effects, making specific medications more useful than others at different stages of shock (see Table 11-2). Diuretics such as furosemide may be given to reduce the workload of the heart by reducing fluid accumulation.

Antiarrhythmic Medications

Multiple factors, such as hypoxemia, electrolyte imbalances, and acid–base imbalances, contribute to serious cardiac arrhythmias in all patients with shock. In addition, as a compensatory response to decreased cardiac output and BP, the heart rate increases beyond normal limits. This impedes cardiac output further by shortening diastole and thereby decreasing the time for ventricular

filling. Consequently, antiarrhythmic medications are required to stabilize the heart rate. General principles regarding the administration of vasoactive medications are discussed later in this chapter. (For a full discussion of cardiac arrhythmias as well as commonly prescribed medications, see Chapter 22.)

Mechanical Assistive Devices

If cardiac output does not improve despite supplemental oxygen, vasoactive medications, and fluid boluses, mechanical assistive devices are used temporarily to improve the heart's ability to pump. Intra-aortic balloon counterpulsation with an IABP is one means of providing temporary circulatory assistance (Hochman & Reyentovich, 2019). The IABP is a catheter with an inflatable balloon at the end. The catheter is usually inserted through the femoral artery and threaded toward the heart, and the balloon is positioned in the descending thoracic aorta (Fig. 11-6). The IABP uses internal counterpulsation through the regular inflation and deflation of the balloon to augment the pumping action of the heart. It inflates during diastole, increasing the pressure in the aorta during diastole and therefore increasing blood flow through the coronary and peripheral arteries. It deflates just before systole, lessening the pressure within the aorta before left ventricular contraction, decreasing the amount of resistance the heart has to overcome to eject blood and therefore decreasing left ventricular workload. The device is connected to a console that synchronizes the inflation and deflation of the balloon with the ECG or the arterial pressure (as indicators for systole and diastole). Hemodynamic monitoring is often used to determine the patient's response to the IABP. The IABP provides short-term (days) support for the failing myocardium.

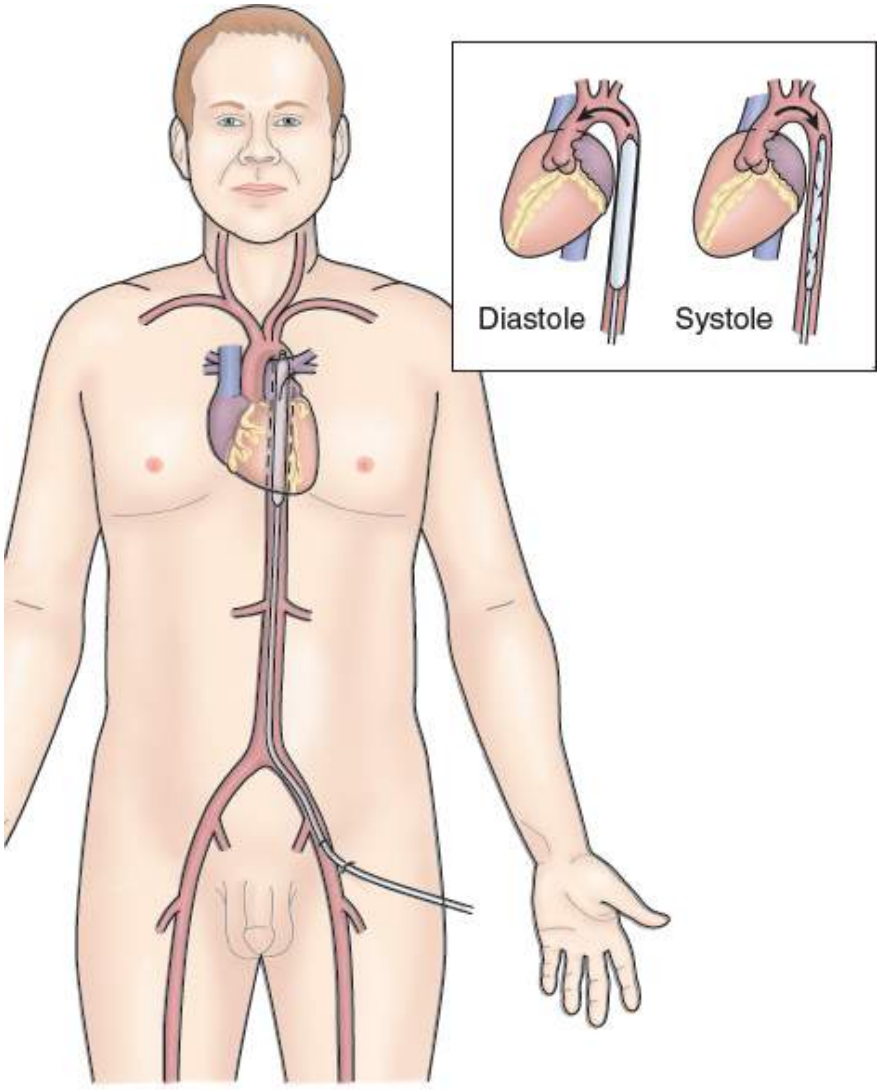

Figure 11-6 • The intra-aortic balloon pump inflates at the beginning of diastole, which results in increased perfusion of the coronary and peripheral arteries. It deflates just before systole, which results in a decrease in afterload (resistance to ejection) and in the left ventricular workload.

Other means of mechanical assistance include left and right ventricular assist devices and total temporary artificial hearts (see Chapters 24 and 25). Another short-term means of providing cardiac or pulmonary support to the patient in cardiogenic shock is through an extracorporeal device similar to the cardiopulmonary bypass (CPB) system used in open-heart surgery (see Chapter 23). CPB is used only in emergency situations until definitive treatment, such as heart transplantation, can be initiated.

Nursing Management

The role of the nurse managing the care of a patient with cardiogenic shock revolves around preventing its serious complications, monitoring hemodynamics, administering medications and fluids, maintaining intra-aortic counterpulsation as indicated, and promoting safety and comfort.

Preventing Cardiogenic Shock

Identifying at-risk patients early, promoting adequate oxygenation of the heart muscle, and decreasing cardiac workload can prevent cardiogenic shock. This can be accomplished by conserving the patient's energy, promptly relieving angina, and administering supplemental oxygen. Often, however, cardiogenic shock cannot be prevented. In such instances, nursing management includes working with other members of the health care team to prevent shock from progressing and to restore adequate cardiac function and tissue perfusion.

Monitoring Hemodynamic Status

A major role of the nurse is monitoring the patient's hemodynamic and cardiac status. Arterial lines and ECG monitoring equipment must be well maintained and functioning properly. The nurse anticipates the medications, IV fluids, and equipment that might be used and is ready to assist in implementing these measures. Changes in hemodynamic, cardiac, and pulmonary status and laboratory values are documented and reported promptly. In addition, adventitious breath sounds, changes in cardiac rhythm, and other abnormal physical assessment findings are reported immediately.

Administering Medications and Intravenous Fluids

The nurse plays a critical role in the safe and accurate administration of IV fluids and medications. Fluid overload and pulmonary edema are risks because of ineffective cardiac function and accumulation of blood and fluid in the pulmonary tissues. The nurse documents medications and treatments that are given as well as the patient's response to treatment.

The nurse must be knowledgeable about the desired effects as well as the side effects of medications. For example, the nurse monitors the patient for decreased BP after administering morphine or nitroglycerin. Arterial and venous puncture sites must be observed for bleeding, and pressure must be applied at the sites if bleeding occurs. IV infusions must be observed closely because tissue necrosis and sloughing may occur if vasopressor medications infiltrate the tissues. When possible, vasoactive medications should be given using central IV lines (Bauer et al., 2019). Furthermore, the need for the central IV access devices should be reviewed daily to reduce the risk of CLABSIs (Marschall, Mermel, Fakih, et al., 2014). The nurse must also monitor urine output, serum electrolytes, BUN, and serum creatinine levels to

detect decreased renal function secondary to the effects of cardiogenic shock or its treatment.

Maintaining Intra-Aortic Balloon Counterpulsation

The nurse plays a critical role in caring for the patient receiving intra-aortic balloon counterpulsation. The nurse makes ongoing timing adjustments of the balloon pump to maximize its effectiveness by synchronizing it with the cardiac cycle. The patient is at risk for circulatory compromise to the leg on the side where the catheter for the balloon has been inserted; therefore, the nurse must check the neurovascular status of the lower extremities frequently.

Enhancing Safety and Comfort

The nurse must take an active role in safeguarding the patient, enhancing comfort, and reducing anxiety. This includes administering medication to relieve chest pain, preventing infection at the multiple arterial and venous line insertion sites, protecting the skin, and monitoring respiratory and renal function. Proper positioning of the patient promotes effective breathing without decreasing BP and may also increase patient comfort while reducing anxiety.

Brief explanations about procedures that are being performed and the use of comforting touch often provide reassurance to the patient and the family. The family is usually anxious and benefits from opportunities to see and talk to the patient. Explanations of treatments and the patient's responses are often comforting to family members.

Family presence during a patient's critical illness has been a concern for family members, patients, nurses and other health care providers. Evidence-based clinical practice guidelines have outlined several elements that may enhance and support the patient and family experience during critical illness. Davidson and colleagues (2017) identified the importance of frequent, clear communication, an environment which encourages comfortable visitation, flexible visitation policies, including the option for family to stay overnight, and patient and family engagement in clinical decisions as mechanisms to enhance family support. A qualitative research study conducted by Wong and colleagues (2020) explored family perspectives of participation in patient care in the adult ICU. The nurse researchers interviewed and observed 30 family members. Findings demonstrated that families' perceptions of their contribution to the patient's psychosocial and emotional well-being were influenced by their engagement in care. See the Nursing Research Profile in Chart 11-4.

Distributive Shock

Distributive shock occurs when intravascular volume pools in peripheral blood vessels. This abnormal displacement of intravascular volume causes a relative hypovolemia because not enough blood returns to the heart, which leads to inadequate tissue perfusion. The ability of the blood vessels to constrict helps return the blood to the heart. Vascular tone is determined both by central regulatory mechanisms, as in BP regulation, and by local regulatory mechanisms, such as tissue demands for oxygen and nutrients. Therefore, distributive shock can be caused by either a loss of sympathetic tone or a release of biochemical mediators from cells that causes vasodilation.

The varied mechanisms leading to the initial vasodilation in distributive shock provide the basis for the further subclassification of shock into three types: septic shock, neurogenic shock, and anaphylactic shock. These subtypes of distributive shock cause variations in the pathophysiologic chain of events and are explained below separately. In all types of distributive shock, massive arterial and venous dilation promotes peripheral pooling of blood. Arterial dilation reduces systemic vascular resistance. Initially, cardiac output can be high, both from the reduction in afterload (systemic vascular resistance) and from the heart muscle's increased effort to maintain perfusion despite the incompetent vasculature. Pooling of blood in the periphery results in decreased venous return. Decreased venous return results in decreased stroke volume and decreased cardiac output. Decreased cardiac output, in turn, causes decreased BP and ultimately decreased tissue perfusion. Figure 11-7 presents the pathophysiologic sequence of events in distributive shock.

Chart 11-4 **NURSING RESEARCH PROFILE**

Family Participation in the Intensive Care Unit

Wong, P., Redley, B., Digby, R., et al. (2020). Families' perspectives of participation in patient care in an adult intensive care unit: A qualitative study. *Australian Critical Care, 33*(4), 317–325.

Purpose

The aim of this study was to describe family participation in patient care in the adult intensive care unit (ICU).

Design

This was a qualitative, descriptive observational study that enrolled a convenience sample of 30 family members who had an adult family member admitted to the ICU for more than 72 h. Researchers observed the family members' engagement in patient care activities and conducted semi-structured interviews focused on their experiences and perceptions of providing care.

Findings

Most of the family participants (77%) were female. Ages of the patient and family member were similar ranging from 28 to 73, with a median age for family members of 53. Researchers observed 193 activities in which 25% involved physical care for the patient, while the remaining 75% of activities were intangible care interventions such as communication and psychosocial/emotional care. Themes that emerged from the interviews revealed that the families felt part of the health care team and thus wanted to support the care and recovery of the loved one. Family members reported being motivated to provide care because they wanted the best care for the patient, desired to know the prognosis, treatment, and condition of the patient, and desired to help the patient recover. Lastly, family members wanted to advocate for their relatives, provide psychosocial and emotional care, and be supportive during medical treatments. The researchers observed that the physical environment was either a contributor or barrier to the family member's ability to engage in care. Equipment sometimes created physical barriers that made it hard for family to get close to the patient. Staff support and communication either encouraged or discouraged family participation in care. When nurses communicated openly, keeping families informed, family members felt more welcomed and better able to support the patient's treatment plans.

Nursing Implications

Most families wish to be engaged and to advocate for their loved ones in the treatment decision making process. The ability for family to feel part of the health care team and develop trust in the plan of care is influenced by positive relationships with the nursing and medical staff as well as the welcoming nature of the environment. Patient- and family-centered care is

facilitated when families are considered collaborative partners in the care of adult patients who are critically ill.

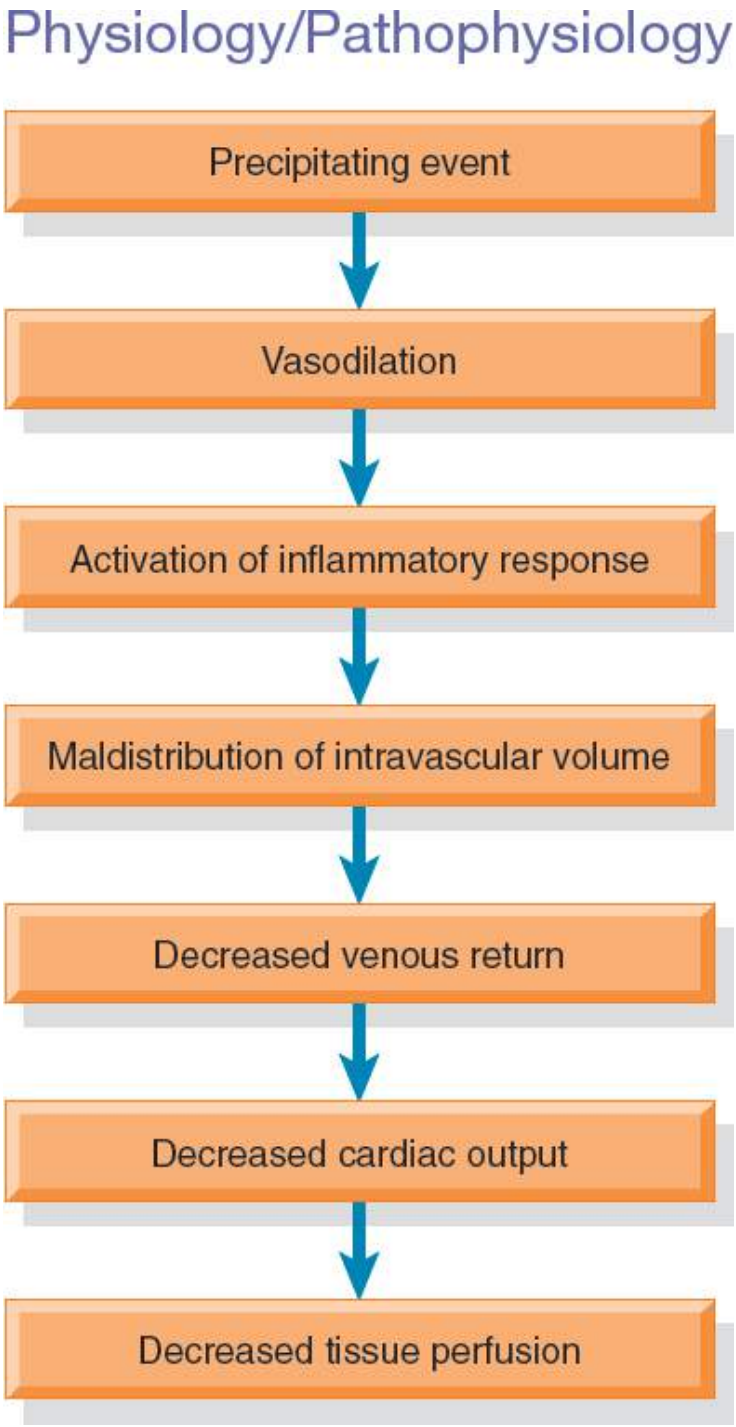

Figure 11-7 • Pathophysiologic sequence of events in distributive shock.

Sepsis and Septic Shock

Septic shock, the most common type of distributive shock, is caused by widespread infection or sepsis. According to the Third International Consensus Definitions for Sepsis and Septic Shock (*Sepsis-3*) Task Force, **sepsis** is "life-threatening organ dysfunction caused by a dysregulated host response to infection (Singer et al., 2016, p. 804)," and **septic shock** is "a subset of sepsis in which underlying circulatory and cellular metabolism abnormalities are profound enough to substantially increase mortality (Singer et al., 2016, p. 806)."

Despite the increased sophistication of antibiotic therapy, the incidence of both sepsis and septic shock has continued to rise; today sepsis and septic shock are the leading causes of death in noncoronary ICU patients. Worldwide, sepsis impacts more than 31 million people, and more than 6 million people die from it annually (Global Sepsis Alliance, 2017). The number of hospital admissions related to sepsis has increased threefold over the last decade (Surviving Sepsis Campaign, 2019). Identifying and aggressively treating the source of infection and quickly restoring tissue perfusion are important interventions that may positively influence clinical outcomes.

Hospital-acquired conditions, which may include hospital-associated infections (i.e., infections not present at the time of admission to the health care setting) in critically ill patients that may progress to septic shock, most frequently originate in the bloodstream (bacteremia), lungs (pneumonia), and urinary tract (urosepsis). Other infections include intra-abdominal infections and wound infections. Of increasing concern are bacteremias associated with intravascular catheters and indwelling urinary catheters (Centers for Disease Control and Prevention [CDC], 2019).

Additional risk factors that contribute to the growing incidence of sepsis are the increased use of invasive procedures and indwelling medical devices, the increased number of antibiotic-resistant microorganisms, and the aging population (CDC, 2019). Older adult patients are at particular risk for sepsis because of decreased physiologic reserves, an aging immune system, comorbid conditions and often nonspecific presentation of infection (Rowe & McKoy, 2017) (see Chapter 8). Other patients at risk are those undergoing surgical and other invasive procedures, especially patients who have undergone emergency surgery or multiple surgeries (Rhodes et al., 2017); those with malnutrition or immunosuppression; and those with chronic illness such as diabetes, hepatitis, chronic kidney disease, and immunodeficiency disorders (Keeley, Hine, & Nsutebu, 2017) (Chart 11-5).

The incidence of sepsis can be reduced by using strict infection control practices, beginning with thorough hand hygiene techniques (Dunne, Kingston, Slevin, et al., 2018). Other interventions include implementing programs to prevent central line infections and ventilator-associated events (e.g., aspiration) and pneumonia; ensuring early removal of invasive devices that are no longer necessary (e.g., indwelling urinary catheters); promoting

early ambulation and timely débridement of wounds; and adhering to standard precautions and infection prevention/control practices, including the use of meticulous aseptic technique and proper cleaning of equipment and the patient environment.

Chart 11-5 RISK FACTORS

Distributive Shock

Septic Shock

- Immunosuppression
- Extremes of age (<1 y and >65 y)
- Malnourishment
- Chronic illness
- Invasive procedures
- Emergent and/or multiple surgeries

Neurogenic Shock

- Spinal cord injury
- Spinal anesthesia
- Depressant action of medications

Anaphylactic Shock

- History of medication sensitivity
- Transfusion reaction
- History of reaction to insect bites/stings
- Food allergies
- Latex sensitivity

(2016). The Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3). *JAMA, 315*(8), 801–810.

Pathophysiology

Gram-negative bacteria traditionally were the most commonly implicated microorganisms in sepsis. However, there is an increased incidence of gram-positive bacterial infections, viral infections, and fungal infections that can also cause sepsis (Keeley et al., 2017). Although a site of infection is identified in most cases, in up to 30% of patients with sepsis an identifiable source of infection is not determined (Surviving Sepsis Campaign, 2019).

When microorganisms invade body tissues, patients exhibit an immune response. This immune response provokes the activation of biochemical cytokines and mediators associated with an inflammatory response and produces a complex cascade of physiologic events that leads to poor tissue perfusion. Increased capillary permeability results in fluid seeping from the capillaries. Capillary instability and vasodilation interrupt the body's ability to provide adequate perfusion, oxygen, and nutrients to the tissues and cells. The widespread inflammatory response that occurs is called the **systemic inflammatory response syndrome** (SIRS). SIRS, which is a type of cytokine release syndrome and is often referred to as cytokine storm, results from a clinical insult that initiates an inflammatory response that is systemic, rather than localized to the site of the insult (see Chapter 12 for further discussion of cytokine release syndrome). The insult may be a significant injury (e.g., multitrauma) or an infection (e.g., sepsis). A patient presenting with manifestations of SIRS may be exhibiting a protective inflammatory response to the initiating insult or may be exhibiting a response to infection, which may lead to sepsis. The clinical criteria used to identify SIRS, which include a temperature greater than 38.3°C (101°F) or less than 36°C (96.8°F), tachycardia, tachypnea, and a white blood cell (WBC) count greater than 12,000 cells/mm^3, less than 4000 cells/mm^3, or greater than 10% immature WBC (bands), have been found to be not helpful in diagnosing sepsis, however (Singer et al., 2016).

In addition to SIRS, proinflammatory and anti-inflammatory cytokines released during the inflammatory response activate the coagulation system, which begins to form clots regardless of whether or not bleeding is present (Seymour & Angus, 2018). This results not only in microvascular occlusions that further disrupt cellular perfusion but also in an inappropriate consumption of clotting factors. Imbalances among the inflammatory response and the clotting and fibrinolysis cascades are considered critical elements of the devastating physiologic progression that occurs in patients with sepsis.

Sepsis is an evolving process that may result in septic shock and life-threatening organ dysfunction if not recognized and treated early. In the early stage of septic shock, BP may remain within normal limits, or the patient may be hypotensive but responsive to fluids. The heart rate increases, progressing to tachycardia. Hyperthermia and fever, with warm, flushed skin and bounding pulses, are present. The respiratory rate is elevated. Urinary output may remain at normal levels or decrease. GI status may be compromised, as evidenced by

nausea, vomiting, diarrhea, or decreased gastric motility. Hepatic dysfunction is evidenced by rising bilirubin levels and worsening coagulopathies (e.g., decreasing platelet counts). Signs of hypermetabolism include increased serum glucose and insulin resistance. Subtle changes in mental status, such as confusion or agitation, may be present. The lactate level is elevated because of the maldistribution of blood. Inflammatory markers such as WBC counts, plasma C-reactive protein (CRP), and procalcitonin levels are also elevated (Rhodes et al., 2017; Seymour & Angus, 2018; Singer et al., 2016).

As sepsis progresses, tissues become less perfused and acidotic, compensation begins to fail, and the patient begins to show signs of organ dysfunction. The cardiovascular system also begins to fail, the BP does not respond to fluid resuscitation and vasoactive agents, and signs of end-organ damage are evident (e.g., AKI, pulmonary dysfunction, hepatic dysfunction, confusion progressing to nonresponsiveness). As sepsis progresses to septic shock, the BP drops and the skin becomes cool, pale, and mottled. Temperature may be normal or below normal. Heart and respiratory rates remain rapid. Urine production ceases, and multiple organ dysfunction progressing to death occurs.

Medical Management

A significant body of research has been conducted in the past few decades that is aimed at reducing the morbidity and mortality caused by sepsis and septic shock. In 1991, 2003, 2008, 2012, and again in 2016 (i.e., *Sepsis-3*), critical-care experts systematically reevaluated the body of research and provided evidence-based recommendations for the acute management of patients with sepsis and septic shock (Rhodes et al., 2017; Singer et al., 2016; Surviving Sepsis Campaign, 2019). Developing and implementing protocols, sepsis bundles, that focus on prevention and early detection and management of patients with sepsis have reduced the mortality of hospitalized patients (Kahn, Davis, Yabes, et al., 2019). *Sepsis-3* provides an overview of key concepts and principles germane to sepsis that must be understood in order for primary providers and nurses to be able to identify and manage patients with sepsis, including the following (Levy & Townsend, 2019; Singer et al., 2016):

- As the leading cause of death from infection, sepsis must be recognized and treated promptly.
- Sepsis is different from infection in that in sepsis there is a dysregulated host response with organ dysfunction. An infection may cause specific organ dysfunction without a dysregulated host response.
- Sepsis is caused by an interplay between infectious pathogens and a myriad of patient-specific risks, including genetics, age, and the

presence of other diseases/disorders.

- The organ dysfunction that occurs with sepsis may not be readily apparent; on the contrary, a new onset of organ dysfunction may be caused by an unrecognized infectious process.

Research efforts are focusing on better identification and early aggressive treatment of patients with sepsis, rapid and effective restoration of tissue perfusion, evaluation and treatment of the patient's immune response, and treatment of dysregulation of the coagulation system that occurs with sepsis (Keeley et al., 2017; Makic & Bridges, 2018).

Correction of Underlying Causes

Current treatment of sepsis and septic shock involves rapid identification and elimination of the cause of infection. Current goals are to identify and initiate treatment for patients in early sepsis within 1 hour to optimize patient outcomes (Levy et al., 2018; Levy & Townsend, 2019). Several evidence-based screening tools can be used to help identify patients for sepsis (see later discussion of assessment tools under the section Nursing Management).

In an effort to continue to reduce deaths from sepsis, Centers for Medicare and Medicaid Services (CMS) has identified sepsis and sepsis bundle adherence as a *Core Measure.* The focus on adherence with these evidence-based bundled interventions is to foster early recognition and interventions in patients with sepsis so that patient outcomes improve. These assessments and interventions are collectively referred to as the *Sepsis Bundles* (Chart 11-6).

Rapid identification of the infectious source is a critical element in managing sepsis. Specimens of blood, sputum, urine, wound drainage, and tips of invasive catheters are collected for culture using aseptic technique. IV lines are removed and reinserted at alternate sites. If possible, urinary catheters are removed or changed. Any abscesses are drained, and necrotic areas are débrided. All cultures should be obtained prior to antibiotic administration. Current guidelines suggest that antibiotics should be initiated within the first hour of treatment of a patient with sepsis (Surviving Sepsis Campaign, 2019).

Fluid Replacement Therapy

Fluid replacement must be instituted to correct tissue hypoperfusion that results from the incompetent vasculature and the inflammatory response. Reestablishing tissue perfusion through aggressive fluid resuscitation is key to the management of sepsis and septic shock (Rhodes et al., 2017; Singer et al., 2016). An initial fluid challenge, which includes an IV infusion of at least 30 mL/kg of crystalloids over 30 minutes, may be required to aggressively treat sepsis-induced tissue hypoperfusion. In addition to monitoring BP, patient mentation, respiratory rate, fluid responsiveness after PLR, urine output, and serum lactate levels are monitored to assess effectiveness of fluid resuscitation.

Pharmacologic Therapy

If the infecting organism is unknown, broad-spectrum antibiotic agents are started until culture and sensitivity reports are received (Levy & Townsend, 2019; Rhodes et al., 2017), at which time the antibiotic agents may be changed to agents that are more specific to the infecting organism and less toxic to the patient.

If fluid therapy alone does not effectively improve tissue perfusion, vasopressor agents, specifically norepinephrine or dopamine, may be initiated to achieve a MAP of 65 mm Hg or higher. Inotropic agents may also be given to provide pharmacologic support to the myocardium. Packed red blood cells may be prescribed to support oxygen delivery and transport to the tissues. Neuromuscular blockade agents and sedation agents may be required to reduce metabolic demands and provide comfort to the patient. Deep vein thrombosis (DVT) prophylaxis with low-dose unfractionated heparin or low-molecular-weight heparin, in combination with mechanical prophylaxis (e.g., sequential compression devices) should be initiated, as well as medications for stress ulcer prophylaxis (e.g., H_2-blocking agents, proton pump inhibitors).

Chart 11-6

Surviving Sepsis Campaign Bundle and CMS Core Measure Monitoring Metrics

Complete within 1 h of patient presentation/symptoms

- Measure lactate level. Remeasure if initial lactate is >2 mmol/L
- Obtain blood cultures prior to administration of antibiotics
- Administer broad-spectrum antibiotics
- Begin rapid administration of 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L (within 30 min)
- Administer vasopressors if patients is hypotensive during or after fluid resuscitation to maintain MAP ≥65 mm Hg

Reprinted with permission from Levy, M., Evans, L., & Rhodes, A. (2018). The Surviving Sepsis Campaign bundle: 2018 update. *Critical Care Medicine, 46*(6), 997–1000.

CMS Core Measure Metrics and Surviving Sepsis Bundles 2016:

Complete within 3 h of patient presentation/symptoms

- Obtain serum lactate level
- Obtain blood culture prior to administration of antibiotics
- Administer prescribed broad-spectrum antibiotics
- Initiate aggressive fluid resuscitation in patients with hypotension or elevated serum lactate (>4 mmol/L):
  - Minimum initial fluid bolus of 30 mL/kg using crystalloid solutions

Complete as soon as possible or within the first 6 h of patient presentation/symptoms

- Begin vasopressor agents if hypotension is not improved (MAP <65 mm Hg) after initial fluid resuscitation
- If hypotension persists after initial fluid administration (MAP <65 mm Hg) or initial lactate was ≥4 mmol/L, reassess intravascular volume status and tissue perfusion using two of the following assessment parameters, including vital signs, capillary refill, pulse, and skin findings, or two of the following:
  - Measurement of CVP and/or $Scv\bar{O}_2$ (goal >70%)
  - Bedside cardiovascular ultrasound
  - Dynamic assessment of fluid responsiveness with passive leg raise or fluid challenge

Additional interventions and targets for therapy in the early management of sepsis

- Support blood pressure to achieve a urine output of >0.5 mL/kg/h over a 6-h period
- Administer vasopressor agents if fluid resuscitation does not restore an effective BP and cardiac output:
  - Norepinephrine centrally given is the initial vasopressor of choice.

    - Epinephrine, phenylephrine, or vasopressin should not be given as the initial vasopressor in septic shock.
- Obtain blood, sputum, urine, and wound cultures and administer broad-spectrum antibiotics:
    - Cultures should be obtained prior to antibiotic administration.
    - Antibiotic administration should occur within 3 h of admission to the emergency department or within 1 h of inpatient admission.
- Support the respiratory system with supplemental oxygen and mechanical ventilation.
- Transfuse with packed red blood cells when hemoglobin is <7 g/dL to achieve a target hemoglobin of 7–9 g/dL in adults.
- Provide adequate IV sedation and analgesia; avoid the use of neuromuscular blockade agents when possible.
- Control serum glucose <180 mg/dL with IV insulin therapy.
- Implement interventions and medications to prevent deep vein thrombosis and stress ulcer prophylaxis.
- Discuss advance care planning with patients and families.

BP, blood pressure; CVP, central venous pressure; IV, intravenous; MAP, mean arterial pressure.

Nutritional Therapy

Aggressive nutritional supplementation should be initiated within 24 to 48 hours of ICU admission to address the hypermetabolic state present with septic shock (Reintam et al., 2017; Wang et al., 2019). Malnutrition further impairs the patient's resistance to infection. Enteral feedings are preferred to the parenteral route because of the increased risk of iatrogenic infection associated with IV catheters; however, enteral feedings may not be possible if decreased perfusion to the GI tract reduces peristalsis and impairs absorption.

Nursing Management

Nurses caring for patients in any setting must keep in mind the risks of sepsis and the high mortality rate associated with sepsis and septic shock. All invasive procedures must be carried out with aseptic technique after careful hand hygiene. In addition, IV lines, arterial and venous puncture sites, surgical incisions, traumatic wounds, and urinary catheters must be monitored for signs

of infection. Nursing interventions to prevent infection need to be implemented in the care of all patients. Nurses should identify patients who are at particular risk for sepsis and septic shock (i.e., older adults and immunosuppressed patients and those with extensive trauma, burns, or diabetes), keeping in mind that these high-risk patients may not develop typical or classic signs of infection and sepsis. However, confusion with or without agitation along with an increased respiratory rate may be the first sign of infection and sepsis in any adult patient (Ferguson, Coates, Osborn, et al., 2019).

Sepsis-3 recommends that patients in the ICU setting with infection be monitored for the development of sepsis by using the *Sepsis-Related Organ Failure Assessment Score* (also known as the *Sequential Organ Failure Assessment* [SOFA] score) (Singer et al., 2016; Vincent, Moreno, Takala, et al., 1996) (Table 11-4). The parameters that are monitored on the SOFA which include assessment of respiratory rate, platelets, bilirubin, MAP (and use of any vasopressors), serum creatinine, urine output, and Glasgow Coma Scale (GCS) score (see Chapter 63), may all be gathered and assessed by the nurse in the ICU setting. A drop of 2 points or more in a patient's SOFA score from baseline is suggestive of organ dysfunction. In a patient with infection, the presence of organ dysfunction suggests the development of sepsis (Singer et al., 2016).

For a patient not in the ICU setting who has an infection, *Sepsis-3* recommends that the Quick SOFA (qSOFA) scale be used to screen for the development of sepsis. The qSOFA is an easy measurement tool that nurses may readily use; the presence of any two of the three parameters on this scale suggests the development of sepsis. These parameters include a respiratory rate of 22 breaths/min or higher, a GCS score of less than 15 (any change in the patient's mentation), and a systolic BP of 100 mm Hg or less. In order to facilitate ease of use, therefore, *Sepsis-3* recommends that any change in the patient's mentation status be used when computing the qSOFA scale score (Singer et al., 2016). Another assessment tool that is frequently used in hospital-based settings that can identify patients with sepsis is the *Modified Early Warning System* (MEWS) (Institute for Healthcare Improvement [IHI], 2017). The nurse assesses the patient for changes in respiratory rate, heart rate, BP, consciousness, temperature, and urine output. Scores ranging from 0 to 3 are assigned to each variable, and a MEWS score greater than 4 is suggestive of the development of sepsis (IHI, 2017) (Table 11-5).

TABLE 11-4 The Sepsis-Related Organ Failure Assessment Score (Sequential Organ Failure Assessment [SOFA] Score)

SOFA Score	1	2	3	4
Respiration PaO_2/FiO_2, mm Hg	<400	<300	<200	<100 —with respiratory support—
Coagulation Platelets × 10^3/mm^3	<150	<100	<50	<20
Liver Bilirubin, mg/dL (μmol/L)	1.2–1.9 (20–32)	2.0–5.9 (33–101)	6.0–11.9 (102–204)	>12.0 (>204)
Cardiovascular Hypotension	MAP <70 mm Hg	Dopamine ≤5 or dobutamine (any dose)*	Dopamine >5 or epinephrine ≤0.1 or norepinephrine ≤0.1	Dopamine >15 or epinephrine >0.1 or norepinephrine >0.1
Central Nervous System Glasgow Coma Scale	13–14	10–12	6–9	<6
Renal Creatinine, mg/dL (μmol/L) or urine output	1.2–1.9 (110–170)	2.0–3.4 (171–299)	3.5–4.9 (300–440) or <500 mL/day	>5.0 (>440) or <200 mL/day

MAP, mean arterial pressure.
*Adrenergic agents given for at least 1 h (doses given are in μg/kg/min).

When caring for a patient with sepsis or septic shock, the nurse collaborates with other members of the health care team to identify the site and source of sepsis and the specific organisms involved. The nurse often obtains appropriate specimens for culture and sensitivity. Prescribed antibiotics are not given until these specimens are obtained. Hyperthermia (elevated body temperature) is common with sepsis and raises the patient's metabolic rate and oxygen consumption. Efforts may be made to reduce the temperature by administering acetaminophen or applying a hypothermia blanket. During these therapies, the nurse monitors the patient closely for shivering, which increases oxygen consumption. Efforts to increase comfort are important if the patient experiences fever, chills, or shivering.

The nurse administers prescribed IV fluids and medications, including antibiotic agents and vasoactive medications, to restore vascular volume. Because of decreased perfusion, serum concentrations of antibiotic agents that are normally cleared by the kidneys and liver may increase and produce toxic effects. Therefore, the nurse monitors blood levels (serum levels of antibiotic agents, procalcitonin, CRP, BUN, creatinine, WBC count, hemoglobin, hematocrit, platelet levels, coagulation studies) and reports changes to the primary provider. As with other types of shock, the nurse monitors the patient's hemodynamic status, fluid I&O, daily weight, and nutritional status. Close monitoring of serum albumin and prealbumin levels helps determine the patient's protein requirements.

TABLE 11-5 The MEWS (Modified Early Warning System)

	NEWS (Modified Early Warning System)						
	3	2	1	0	1	2	3
Respiration rate per minute		<8		9–14	15–20	21–29	>30
Heart rate per minute		<40	40–50	51–100	101–110	111–129	>129
Systolic blood pressure	<70	71–80	81–100	101–199		>200	
Conscious level (AVPU)	Unresponsive	Responds to Pain	Responds to Voice	Alert	New agitation, Confusion		
Temperature (°C)		<35.0	35.1–36	36.10–38	38.1–38.5	>38.6	
Hourly urine for 2 h	<10 mL/h	<30 mL/h	<45 mL/h

Neurogenic Shock

In **neurogenic shock,** vasodilation occurs as a result of a loss of balance between parasympathetic and sympathetic stimulation. Sympathetic stimulation causes vascular smooth muscle to constrict, and parasympathetic stimulation causes vascular smooth muscle to relax or dilate. The patient experiences a predominant parasympathetic stimulation that causes vasodilation lasting for an extended period, leading to a relative hypovolemic state. However, blood volume is adequate, because the vasculature is dilated; the blood volume is displaced, producing a hypotensive (low BP) state. The overriding parasympathetic stimulation that occurs with neurogenic shock causes a drastic decrease in the patient's systemic vascular resistance and bradycardia. Inadequate BP results in the insufficient perfusion of tissues and cells that is common to all shock states.

Neurogenic shock can be caused by spinal cord injury, spinal anesthesia, or other nervous system damage. It may also result from the depressant action of medications or from lack of glucose (e.g., insulin reaction) (see Chart 11-5). Neurogenic shock may have a prolonged course (spinal cord injury) or a short one (syncope or fainting). Normally, during states of stress, the sympathetic stimulation causes the BP and heart rate to increase. In neurogenic shock, the sympathetic system is not able to respond to body stressors. Therefore, the clinical characteristics of neurogenic shock are signs of parasympathetic stimulation. It is characterized by dry, warm skin rather than the cool, moist skin seen in hypovolemic shock. Another characteristic is hypotension with bradycardia, rather than the tachycardia that characterizes other forms of shock.

Medical Management

Treatment of neurogenic shock involves restoring sympathetic tone, either through the stabilization of a spinal cord injury or, in the instance of spinal

anesthesia, by positioning the patient properly. Specific treatment depends on the cause of the shock. (Further discussion of management of patients with a spinal cord injury is presented in Chapter 63.)

Nursing Management

It is important to elevate and maintain the head of the bed at least 30 degrees to prevent neurogenic shock when a patient receives spinal or epidural anesthesia. Elevation of the head helps prevent the spread of the anesthetic agent up the spinal cord. In suspected spinal cord injury, neurogenic shock may be prevented by carefully immobilizing the patient to prevent further damage to the spinal cord (Kessler, Traini, Welk, et al., 2018). Nursing interventions are directed toward supporting cardiovascular and neurologic function until the usually transient episode of neurogenic shock resolves.

Patients with neurogenic shock have a higher risk for venous thromboembolism (VTE) formation because of increased pooling of blood from vascular dilation; this risk is greater in patients with neurogenic shock related to spinal cord injury. The nurse must assess the patient daily for any lower extremity pain, redness, tenderness, and warmth. If the patient complains of pain and objective assessment of the calf is suspicious, the patient should be evaluated for DVT. Passive range of motion of the immobile extremities helps promote circulation. Early interventions to prevent VTE include the application of pneumatic compression devices often combined with antithrombotic agents (e.g., low-molecular-weight heparin).

A patient who has experienced a spinal cord injury may not report pain caused by internal injuries. Therefore, in the immediate post-injury period, the nurse must monitor the patient closely for signs of internal bleeding that could lead to hypovolemic shock.

Anaphylactic Shock

Anaphylactic shock is caused by a severe allergic reaction when patients who have already produced antibodies to an antigen (foreign substance) develop a systemic antigen–antibody reaction; specifically, an immunoglobulin E (IgE)-mediated response. This antigen–antibody reaction provokes mast cells to release potent vasoactive substances, such as histamine or bradykinin, and activates inflammatory cytokines, causing widespread vasodilation and capillary permeability. The most common triggers are foods (especially peanuts), medications, and insect stings and bites (Pajno, Fernandez-Rivas, Arasi, et al., 2018) (see Chart 11-5). Anaphylaxis has three defining characteristics:

- Acute onset of symptoms

- Presence of two or more symptoms that include respiratory compromise, reduced BP, GI distress, and skin or mucosal tissue irritation
- Cardiovascular compromise from minutes to hours after exposure to the antigen

Signs and symptoms of anaphylaxis may present within 2 to 30 minutes of exposure to the antigen; however, occasionally some reactions may not develop for several hours (Chan & John, 2020). The patient may report headache, lightheadedness, nausea, vomiting, acute abdominal pain or discomfort, pruritus, and feeling of impending doom. Assessment may reveal diffuse erythema and generalized flushing, dyspnea (laryngeal edema), bronchospasm, cardiac arrhythmias, and hypotension. Characteristics of severe anaphylaxis usually include rapid onset of hypotension, neurologic compromise, respiratory distress, and cardiac arrest (Chan & John, 2020). Anaphylactoid reactions present similarly to anaphylaxis but are not mediated by IgE responses. Anaphylaxis and anaphylactoid reactions are often clinically indistinguishable (Pajno et al., 2018).

Medical Management

Treatment of anaphylactic shock requires removing the causative antigen (e.g., discontinuing an antibiotic agent), administering medications that restore vascular tone, and providing emergency support of basic life functions. Fluid management is critical, as massive fluid shifts can occur within minutes due to increased vascular permeability (Pajno et al., 2018). Intramuscular epinephrine is given for its vasoconstrictive action. Diphenhydramine is given intravenously to reverse the effects of histamine, thereby reducing capillary permeability. Nebulized medications, such as albuterol, may be given to reverse histamine-induced bronchospasm.

If cardiac arrest and respiratory arrest are imminent or have occurred, cardiopulmonary resuscitation (CPR) is performed. Endotracheal intubation may be necessary to establish an airway. IV lines are inserted to provide access for administering fluids and medications. See Chapter 33 for further discussion of anaphylaxis and specific chemical mediators.

Nursing Management

The nurse has an important role in prevention and early recognition of anaphylactic shock. The nurse must assess all patients for allergies or previous reactions to antigens (e.g., medications, blood products, foods, contrast agents, latex) and communicate the existence of these allergies or reactions to others. In addition, the nurse assesses the patient's understanding of previous reactions

and steps taken by the patient and the family to prevent further exposure to antigens. When new allergies are identified, the nurse advises the patient to wear or carry identification that names the specific allergen or antigen.

When administering any new medication, the nurse observes all patients for allergic reactions. This is especially important with antibiotics, beta-blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, aspirin, and nonsteroidal anti-inflammatory drugs (Chan & John, 2020). Previous adverse drug reactions increase the risk that the patient will develop a reaction to a new medication. If the patient reports an allergy to a medication, the nurse must be aware of the risks involved in the administration of similar medications.

At any diagnostic testing site, the nurse must identify patients who are at risk for anaphylactic reactions to contrast agents (radiopaque, dyelike substances that may contain iodine) used for diagnostic tests. The nurse must be knowledgeable about the clinical signs of anaphylaxis, must take immediate action if signs and symptoms occur, and must be prepared to begin CPR if cardiorespiratory arrest occurs.

Quality and Safety Nursing Alert

Patients with a known allergy to iodine or fish and those who have had previous allergic reactions to contrast agents are at high risk for anaphylactic reactions. The nurse should ask the patient about the allergy, signs and symptoms and severity, and if the patient has been tested for the allergy or carries an autoinjectable epinephrine device. This information must be communicated to the staff at the diagnostic testing site, including x-ray personnel.

Community health and home health nurses who administer medications, including antibiotic agents, in the patient's home or other settings, must be prepared to administer epinephrine intramuscularly in the event of an anaphylactic reaction.

After recovery from anaphylaxis, the patient and the family require an explanation of the event. Furthermore, the nurse provides education about avoiding future exposure to antigens and administering emergency medications to treat anaphylaxis (see Chapter 33).

Multiple Organ Dysfunction Syndrome

MODS is altered organ function in acutely ill patients that requires medical intervention to support continued organ function. It is another phase in the

progression of shock states. The actual incidence of MODS is difficult to determine, because it develops with acute illnesses that compromise tissue perfusion. Dysfunction of one organ system is associated with 20% mortality, and if more than four organs fail, the mortality is at least 60% (Sauaia, Moore, & Moore, 2017).

Pathophysiology

The precise mechanism by which MODS occurs remains unknown, but it is most commonly seen in patients with sepsis as a result of inadequate tissue perfusion. MODS frequently occurs toward the end of the continuum of septic shock when tissue perfusion cannot be effectively restored. It is not possible to predict which patients who experience shock will develop MODS, partly because much of the organ damage occurs at the cellular level and, therefore, cannot be directly observed or measured.

The clinical presentation of MODS is insidious; tissues become hypoperfused at both a microcellular and macrocellular level, eventually causing organ dysfunction that requires mechanical and pharmacologic intervention to support organ function. Organ failure usually begins in the lungs, and cardiovascular instability, as well as failure of the hepatic, GI, renal, immunologic, and central nervous systems, follows (Sauaia et al., 2017).

Clinical Manifestations

While it is not possible to predict MODS, clinical severity assessment tools may be used to anticipate patient risk of organ dysfunction and mortality. These clinical assessment tools include APACHE (Acute Physiology and Chronic Health Evaluation); SAPS (Simplified Acute Physiology Score); PIRO (Predisposing factors, the Infection, the host Response, and Organ dysfunction); and SOFA score (see Table 11-4) (Gustot, 2011; Kress & Hall, 2018).

In MODS, the sequence of organ dysfunction varies depending on the patient's primary illness and comorbidities before experiencing shock. Advanced age, malnutrition, and coexisting disease appear to increase the risk of MODS in acutely ill patients. For simplicity of presentation, the classic pattern is described. Typically, the lungs are the first organs to show signs of dysfunction. The patient experiences progressive dyspnea and respiratory failure that are manifested as ALI or ARDS, requiring intubation and mechanical ventilation (see Chapters 19). The patient usually remains hemodynamically stable but may require increasing amounts of IV fluids and vasoactive agents to support BP and cardiac output. Signs of a hypermetabolic state, characterized by hyperglycemia (elevated blood glucose level), hyperlactic acidemia (excess lactic acid in the blood), and increased BUN, are

present. The metabolic rate may be 1.5 to 2 times the basal metabolic rate. At this time, there is a severe loss of skeletal muscle mass (autocatabolism) to meet the high energy demands of the body.

After approximately 7 to 10 days, signs of hepatic dysfunction (e.g., elevated bilirubin and liver function tests) and renal dysfunction (e.g., elevated creatinine and anuria) are evident. As the lack of tissue perfusion continues, the hematologic system becomes dysfunctional, with worsening immunocompromise, increasing the risk of bleeding. The cardiovascular system becomes unstable and unresponsive to vasoactive agents, and the patient's neurologic response progresses to a state of unresponsiveness or coma.

The goal of all shock states is to reverse the tissue hypoperfusion and hypoxia. If effective tissue perfusion is restored before organs become dysfunctional, the patient's condition stabilizes. Along the septic shock continuum, the onset of organ dysfunction is an ominous prognostic sign; the more organs that fail, the worse the outcome.

Medical Management

Prevention remains the top priority in managing MODS. Older adult patients are at increased risk for MODS because of the lack of physiologic reserve and the natural degenerative process, especially immune compromise (Kress & Hall, 2018). Early detection and documentation of initial signs of infection are essential in managing MODS in older adult patients. Subtle changes in mentation and a gradual rise in temperature are early warning signs. Other patients at greater risk for MODS are those with chronic illness, malnutrition, immunosuppression, or surgical or traumatic wounds.

If preventive measures fail, treatment measures to reverse MODS are aimed at (1) controlling the initiating event, (2) promoting adequate organ perfusion, (3) providing nutritional support, and (4) maximizing patient comfort.

Nursing Management

The general plan of nursing care for patients with MODS is the same as that for patients with shock. Primary nursing interventions are aimed at supporting the patient and monitoring organ perfusion until primary organ insults are halted. Providing information and support to family members is a critical role of the nurse. The health care team must address end-of-life decisions to ensure that supportive therapies are congruent with the patient's wishes (see Chapter 13).

Promoting Communication

Nurses should encourage frequent and open communication about treatment modalities and options to ensure that the patient's wishes regarding medical management are met. Patients who survive MODS must be informed about the goals of rehabilitation and expectations for progress toward these goals, because massive loss of skeletal muscle mass makes rehabilitation a long, slow process. A strong nurse–patient relationship built on effective communication provides needed encouragement during this phase of recovery.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Patients who experience and survive any type of shock or sepsis may have been unable to get out of bed for an extended period of time and are likely to have a slow, prolonged recovery. The patient and the family are educated about strategies to prevent further episodes of shock or sepsis by identifying the factors implicated in the initial episode (Ferguson et al., 2019). In addition, the patient and the family require education about assessments needed to identify the complications that may occur after the patient is discharged from the hospital. Depending on the type of shock and its management, the patient or the family may require education about treatment modalities such as emergency administration of medications, IV therapy, parenteral or enteral nutrition, skin care, exercise, and ambulation. The patient and the family are also educated about the need for gradual increases in ambulation and other activity. The need for adequate nutrition is another crucial aspect of education.

Continuing and Transitional Care

Because of the physical toll associated with recovery from shock and sepsis, patients may be cared for in a long-term care facility or rehabilitation setting after hospital discharge. Alternatively, a referral may be made for home, community-based, or transitional care. Patients may also experience PICS, a condition that is gaining increased recognition. PICS occurs after critically ill patients are discharged from the hospital. PICS involves physical, cognitive, and mental impairments that may adversely impact the patient's long-term recovery (Inoue, Hatakeyama, Kondo, et al., 2019). Nursing interventions to prevent PICS occur during the patient's critical illness and include early mobilization, assessment and management of delirium, promoting adequate

sleep, and assisting with mechanical ventilation liberation (e.g., weaning) as soon as possible. The nurse assesses the patient's physical status and monitors recovery. The adequacy of treatments continued at home and the ability of the patient and the family to cope with these treatments are also assessed. The patient is likely to require close medical supervision until complete recovery occurs. The nurse reinforces the importance of continuing medical care and helps the patient and the family identify and mobilize community resources.

CRITICAL THINKING EXERCISES

1 pq A 32-year-old patient is admitted after falling from a second-story balcony. The patient has a fractured femur, several fractured ribs, and possible head injury. The primary provider has prescribed lactated Ringer's solution to be infused at 250 mL/h to maintain a blood pressure >120 mm Hg and urine output >50 mL/h. Two large-bore IVs are started in each arm and IV fluids are initiated. The patient is alert to name only. The patient is typed and crossed for blood products, and a series of metabolic labs and a lactate level are drawn for analysis. The patient becomes unresponsive to name and begins moaning and grimacing. Vital signs are as follows: BP 92/72, HR 132 bpm, RR 32 bpm, SpO_2 92% on 40% FiO_2 via a facemask with a urine output of 15 mL over the last hour. Identify 3–5 priority interventions that you should implement, the order in which they should be implemented, and explain how you made these decisions.

2 ebp A 76-year-old patient is scheduled for surgery for benign prostatic enlargement that is causing significant obstruction to his urinary function. The patient's past medical history includes chronic obstructive pulmonary disease, hypertension, and type 2 diabetes. Due to his medical history and surgical risks, he is not a candidate for general anesthesia and instead receives spinal anesthesia. Midway through the surgery his vital signs decrease abruptly to BP 88/32 mm Hg and HR 62 bpm, while his RR remains stable controlled by anesthesia with ventilatory support. Surgery is aborted for suspected neurogenic shock. The patient is transferred to the postanesthesia care unit (PACU) for monitoring. The surgeon explains the complication that has occurred to the patient's wife and tells her that a nurse will continue to provide updates to her by phone. The wife asks to see her husband, but the waiting room clerk says that family is not allowed in the PACU. An hour passes and the nurse does not call to update the wife. The clerk observes the wife quietly crying in a corner and calls the nurse caring for the patient to inform her of the wife's distress. As the nurse, what actions would you implement to facilitate patient- and family-centered care? What evidence supports these actions?

3 ipc An 88-year-old woman is admitted from an assisted living facility with acute decline in mental status. On admission vital signs are as follows: BP 100/76 mm Hg, HR 126 bpm, and RR 26 bpm. The patient is also incontinent of urine. As the nurse, you suspect a possible urinary tract infection and immediately assess the patient for sepsis. What other members of the interprofessional team will you need to collaborate with to facilitate early interventions to minimize the risk of complications? To implement a sepsis protocol, what additional information should you obtain prior to calling the provider? What should you anticipate from the

provider? How will you effectively communicate your assessment and recommendations to the provider and other members of the interprofessional team?

12 Management of Patients with Oncologic Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Differentiate between characteristics of benign and malignant tumors.
2. Discuss the role of the nurse in the prevention and management of cancer.
3. Compare and contrast the goals of cancer care in prevention, diagnosis, cure, control, and palliation.
4. Describe the role of surgery, radiation therapy, chemotherapy, hematopoietic stem cell transplantation, immunotherapy, and targeted therapy in the treatment of cancer.
5. Use the nursing process as a framework for the care of the patient with cancer throughout the disease trajectory, from the time of diagnosis, to survivorship, and at the end of life.

NURSING CONCEPTS

Cellular Regulation
Managing Care
Tissue Integrity

GLOSSARY

alopecia: hair loss

anaplasia: pattern of growth in which cells lack normal characteristics and differ in shape and organization with respect to their cells of origin; usually, anaplastic cells are malignant

angiogenesis: growth of new blood vessels that allow cancer cells to grow

apoptosis: a normal cell mechanism of programmed cell death

benign: not cancerous; benign tumors may grow but are unable to spread to other organs or body parts

brachytherapy: delivery of radiation therapy through internal implants placed inside or adjacent to the tumor

cancer: a group of disorders characterized by abnormal cell proliferation, in which cells ignore growth-regulating signals in the surrounding environment

carcinogenesis: process of transforming normal cells into malignant cells

carcinogens: chemicals, physical factors, and other agents that cause cancer

chemotherapy: the use of medications to kill tumor cells by interfering with cellular functions and reproduction

cytokines: messenger substances that may be released by a cell to create an action at that site or may be carried by the bloodstream to a distant site before being activated; (*synonyms*: biochemical mediators, inflammatory mediations)

extravasation: leakage of intravenous medication from the veins into the subcutaneous tissues

grading: identification of the type of tissue from which the tumor originated and the degree to which the tumor cells retain the functional and structural characteristics of the tissue of origin

graft-versus-host disease (GVHD): an immune response initiated by T lymphocytes of donor tissue against the recipient's tissues (skin, gastrointestinal tract, liver); an undesirable response

graft-versus-tumor effect: the donor immune cell response against the malignancy; a desirable response

immunotherapy: the use of medications or other agents to stimulate or suppress components of the immune system to kill cancer cells

malignant: having cells or processes that are characteristic of cancer

metastasis: spread of cancer cells from the primary tumor to distant sites

mucositis: inflammation of the lining of the mouth, throat, and gastrointestinal tract often associated with cancer therapies

myelosuppression: suppression of the blood cell–producing function of the bone marrow

nadir: the lowest serum level of blood cells (i.e., white blood cells, red blood cells, and platelets) after therapy that has toxic effects on the bone marrow. Clinically, the nadir is most often used to describe the lowest absolute neutrophil count following chemotherapy

neoplasia: uncontrolled cell growth that follows no physiologic demand; cancer

neutropenia: abnormally low absolute neutrophil count

oncology: field or study of cancer

palliation: relief of symptoms and promotion of comfort and quality of life regardless of the disease stage

precision medicine: using advances in research, technology, and policies to develop individualized plans of care to prevent and treat disease

radiation therapy: the use of ionizing radiation to kill malignant cells

staging: process of determining the extent of disease, including tumor size and spread or metastasis to distant sites

stomatitis: inflammation of the oral tissues, often associated with some chemotherapeutic agents and radiation therapy to the head and neck region

targeted therapies: the use of medications or other agents to kill or prevent the spread of cancer cells by targeting specific part of the cell, with less negative effects on healthy cells

thrombocytopenia: decrease in the number of circulating platelets; associated with the potential for bleeding

toxicity: an unfavorable and unintended sign, symptom, or condition associated with cancer treatment

vesicant: substance that can cause inflammation, damage, and necrosis with extravasation from blood vessels and contact with tissues

Cancer is a large group of disorders with different causes, manifestations, treatments, and prognoses. Because cancer can involve any organ system and treatment approaches have the potential for multisystem effects, cancer nursing practice overlaps with numerous nursing specialties. Cancer nursing practice covers all age groups and is carried out in various settings, including acute care institutions, outpatient centers, physician offices, rehabilitation facilities, the home, and long-term care facilities. The scope, responsibilities, and goals of cancer nursing, also called **oncology** nursing, are as diverse and complex as those of any nursing specialty. Nursing management of the patient with oncologic disorders includes care of patients throughout the cancer trajectory from prevention through end-of-life care (see Fig. 12-1).

Precision medicine is possible because of the recent development of biologic databases (e.g., human genome sequencing), technologic advances that can identify unique characteristics of individual persons (e.g., genomics, cellular

assay tests), and computer-driven systems that can mine and analyze datasets (see Chapter 1). This is an exciting time for oncology as the overall goal of the precision medicine initiative is to focus on preventing and curing cancers (Ginsburg & Phillips, 2018).

Epidemiology

Cancer is a common health problem worldwide. In the United States, it was estimated in 2019 that more than 1,700,000 new cancer cases would be diagnosed, and that more than 600,000 Americans would die as a result of cancer (Siegel, Miller, & Jemal, 2019). Despite significant advances in science and technology, cancer is the second leading cause of death in the United States. The leading causes of cancer-related death in the United States in order of frequency and location are lung, prostate, and colorectal cancer in men and lung, breast, and colorectal cancer in women. Most cancer occurs in older adults; according to the American Cancer Society (ACS), 80% of all cancer diagnoses are in people 55 years of age or older (2019a). Overall, the incidence of cancer is slightly higher in women than in men (ACS, 2019a).

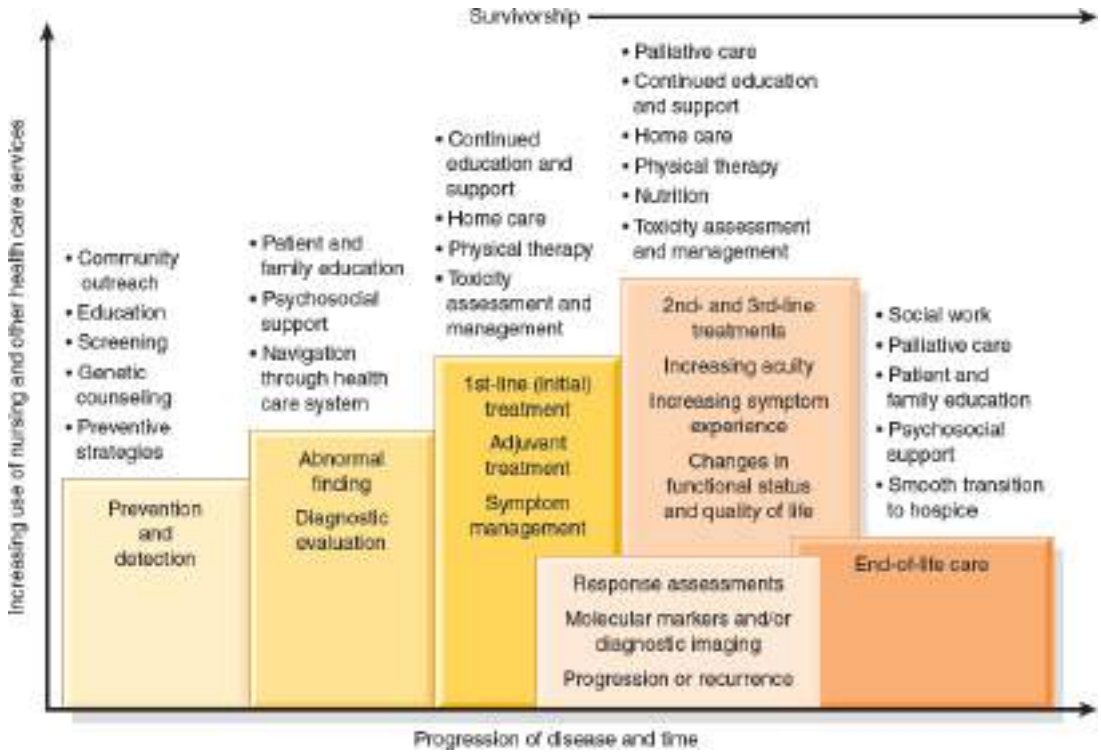

Figure 12-1 • Cancer care trajectory. The cancer care trajectory reflects the phases and care required during the continuum of the cancer experience from prevention and early detection through end-of-life care. Specialized nursing care is provided throughout the entire trajectory.

Cancer affects all groups of people; however, some groups are more adversely affected by cancer than others (National Cancer Institute [NCI], 2019a). Differences in cancer measures (e.g., incidence, screening rates, stage of diagnosis, morbidity, mortality) or cancer-related health conditions are termed *cancer health disparities*. These disparities often result from multiple, complex interrelated factors, including indicators of socioeconomic status (e.g., income, educational level, health care access), culture, diet, stress, the environment, and biology.

Cancer health disparities are most often observed among people of low-socioeconomic status, certain races/ethnicities, and those who reside in particular geographical locations (NCI, 2019a). For example, even though the overall rate of cancer deaths has declined, cancer death rates in non-Hispanic Black men and women remain substantially higher compared to all other racial and ethnic groups for most cancer types (DeSantis, Miller, Goding Sauer, et al., 2019). Hispanic/Latino Americans have a lower overall cancer incidence when compared to non-Hispanic White Americans; however, the incidence of infection-related cancers (e.g., liver cancer) is two times higher in those of Hispanic/Latino origin compared to non-Hispanic White Americans (Miller, Goding Sauer, Ortiz, et al., 2018).

Cancer incidence and death rates also vary by geography. In states where the prevalence of tobacco use is high (e.g., Kentucky), the incidence of lung cancer tends to be greater than in states where smoking is not as common (e.g., Utah) (Siegel et al., 2019). In locations where there is greater socioeconomic disparity, the incidence of cancer and overall cancer death rates are higher than in regions where there is not such a disparity (Siegel et al., 2019). For example, the incidence of cancers of the lung, colon and rectum, and cervix are substantially higher in Appalachian Ohio (southwestern region of the state) than in more affluent and more populated regions of the state (NCI, 2019a).

Pathophysiology of the Malignant Process

Cancer is a disease process that begins when a cell is transformed by genetic mutations of the cellular deoxyribonucleic acid (DNA). Genetic mutations may be inherited or acquired, leading to abnormal cell behavior (Norris, 2019). The initial genetically altered cell forms a clone and begins to proliferate abnormally, evading normal intracellular and extracellular growth-regulating processes or signals as well as the immune system defense mechanisms of the body. Genetic mutations may lead to abnormalities in cell signaling transduction processes (signals from outside and within cells that turn cell activities either on or off) that can in turn lead to cancer development. Ultimately cells acquire a variety of capabilities that allow them to invade surrounding tissues or gain access to lymph and blood vessels, which carry the cells to other areas of the body

resulting in **metastasis** or spread of the cancer (Pachmayr, Treese, & Stein, 2017).

Benign (noncancerous) and **malignant** (cancerous) cells differ in many cellular growth characteristics, including the method and rate of growth, ability to metastasize or spread, destruction of tissue, and ability to cause death. These differences are summarized in Table 12-1. The degree of **anaplasia** (a pattern of growth in which cells lack normal characteristics and differ in shape and organization with respect to their cells of origin) is associated with increased malignant potential.

TABLE 12-1 Characteristics of Benign and Malignant Cells

Characteristics	Benign	Malignant
Cell	Well-differentiated cells resemble normal cells of the tissue from which the tumor originated.	Cells are undifferentiated and may bear little resemblance to the normal cells of the tissue from which they arose.
Mode of growth	Tumor grows by expansion and does not infiltrate the surrounding tissues; usually encapsulated.	Grows at the periphery and overcomes contact inhibition to invade and infiltrate surrounding tissues
Rate of growth	Rate of growth is usually slow.	Rate of growth is variable and depends on level of differentiation; the more anaplastic the tumor, the faster its growth.
Metastasis	Does not spread by metastasis.	Gains access to the blood and lymphatic channels and metastasizes to other areas of the body or grows across body cavities such as the peritoneum.
General effects	Usually a localized phenomenon that does not cause generalized effects unless its location interferes with vital functions.	Often causes generalized effects, such as anemia, weakness, systemic inflammation, weight loss, and CACS.
Tissue destruction	Does not usually cause tissue damage unless its location interferes with blood flow.	Often causes extensive tissue damage as the tumor outgrows its blood supply or encroaches on blood flow to the area; may also produce substances that cause cell damage.
Ability to cause death	Does not usually cause death unless its location interferes with vital functions.	Eventually causes death unless growth can be controlled.

CACS, cancer-related anorexia-cachexia syndrome.

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Carcinogenesis

Understanding the pathophysiology of cancer involves knowledge of the molecular process and proliferation patterns of cancers as well as the numerous etiologic factors that induce the malignant transformation of cells.

Molecular Process

Malignant transformation, or **carcinogenesis**, is thought to be at least a three-step cellular process, involving initiation, promotion, and progression (Norris, 2019). Agents that initiate or promote malignant transformation are referred to as **carcinogens**. A complete carcinogen is an agent that both initiates and promotes the development of cancer (e.g., cigarette smoking, asbestos).

During *initiation,* carcinogens (substances that can cause cancer), such as chemicals, physical factors, or biologic agents, cause mutations in the cellular DNA. Normally, these alterations are reversed by DNA repair mechanisms or the changes initiate **apoptosis** (programmed cellular death) or cell senescence. Cells can escape these protective mechanisms with permanent cellular mutations occurring, but these mutations usually are not significant to cells until the second step of carcinogenesis.

During *promotion,* repeated exposure to promoting agents (co-carcinogens) causes proliferation and expansion of initiated cells with increased expression or manifestations of abnormal genetic information, even after long latency periods. Promoting agents are not mutagenic and do not need to interact with the DNA. Promotion is reversible if the promoting substance is removed (a key focus in the prevention of cancer). Latency periods for the promotion of cellular mutations vary with the type of agent, the dosage of the promoter, and the innate characteristics and genetic stability of the target cell.

During *progression,* the altered cells exhibit increasingly malignant behavior. These cells acquire the ability to stimulate **angiogenesis** (growth of new blood vessels that allow cancer cells to grow), to invade adjacent tissues, and to metastasize. Cellular oncogenes are responsible for vital cell functions, including proliferation and differentiation. Cellular proto-oncogenes, such as those for the epidermal growth factor receptor (EGFR), transcription factors such as *c-Myc,* or cell signaling proteins such as *Kirsten ras* (*KRAS*), act as "on switches" for cellular growth. Amplification of proto-oncogenes or overexpression of growth factors, such as epidermal growth factor (EGF), can lead to uncontrolled cell proliferation. Mutations that increase the activity of oncogenes also deregulate cell proliferation. Genetic alterations in the gene for *KRAS* have been associated with pancreatic, lung, and colorectal cancers (Mainardi, Mulero-Sánchez, Prahallad, et al., 2018). Just as proto-oncogenes "turn on" cellular growth, cancer suppressor genes "turn off," or regulate, unneeded cellular proliferation. When suppressor genes are mutated, resulting in loss of function or expression, the cells begin to produce mutant cell populations that are different from their

original cellular ancestors. See Chart 12-1 for further discussion of genetics concepts and cancer.

Proliferative Patterns

During the lifespan, various body tissues normally undergo periods of rapid or proliferative growth that must be distinguished from malignant growth activity. Several patterns of cellular adaptation include atrophy, hypertrophy, hyperplasia, metaplasia, and dysplasia (see Chapter 5, Fig. 5-4). Cancerous cells, described as malignant, demonstrate **neoplasia**, or uncontrolled cell growth that follows no physiologic demand. Although both benign and malignant growths are classified and named by tissue of origin, the *International Classification of Diseases for Oncology* (Fritz, Percy, Jack et al., 2013) is used by scientists and clinicians around the world as the nomenclature for malignant disease (see Table 12-2).

Etiology

Factors implicated or known to induce carcinogenesis include viruses and bacteria, physical agents, chemicals, genetic or familial factors, lifestyle factors, and hormones. Additional research is needed for a better understanding of the relationships among etiologic factors and cancer.

Viruses and Bacteria

It is estimated that 10% to 12% of all cancers worldwide are linked to viral infections (Lunn, Jahnke, & Rabkin, 2017). After infecting individuals, DNA viruses insert a part of their own DNA near the infected cell genes causing cell division. The newly formed cells that now carry viral DNA lack normal controls on growth. Examples of these viruses that are known to cause cancer include human papillomavirus (HPV) (cervical and head and neck cancers), hepatitis B virus (HBV) (liver cancer), and Epstein–Barr virus (EBV) (Burkitt lymphoma and nasopharyngeal cancer).

While there is little evidence to support a direct link between most bacteria and cancer, secondary responses to certain bacterial infections, such as the production of carcinogenic metabolites and inflammatory reactions, are suspected mechanisms of cancer development (van Elsland & Neefjes, 2018). Examples of bacteria that are associated with an increased risk of cancer include: *Helicobacter pylori* (stomach cancer), *Salmonella enteritidis* (colon cancer), and *Chlamydia trachomatis* (ovarian and cervical cancers).

Physical Agents

Physical factors associated with carcinogenesis include exposure to sunlight, radiation, chronic irritation or inflammation, tobacco carcinogens, industrial chemicals, and asbestos (ACS, 2019b).

Excessive exposure to the ultraviolet rays of the sun is associated with skin cancers in all individuals, although those with fair-skin are at highest risk.

Factors such as clothing styles (sleeveless shirts or shorts), the use of sunscreens, occupation, recreational habits, and environmental variables, including humidity, altitude, and latitude, all play a role in the amount of exposure to ultraviolet light (ACS, 2019c).

Chart 12-1 GENETICS IN NURSING PRACTICE

Genetics Concepts and Oncologic Disorders

Cancer is a genetic disease. Every phase of carcinogenesis is affected by multiple gene mutations. Some of these mutations are inherited (present in germ-line cells) and present a greater risk for a person to develop oncologic disorders; however, most (90%) are somatic mutations that are acquired mutations in specific cells. Examples of cancers influenced by genetics include:

Autosomal dominant:

- Breast and ovarian cancer
- Colorectal cancer
- Familial adenomatous polyposis
- Cowden syndrome
- Li–Fraumeni syndrome
- Lynch syndrome (hereditary nonpolyposis colon cancer)
- Multiple endocrine neoplasia types 1 and 2
- Neurofibromatosis types 1 and 2
- Prostate cancer
- Retinoblastoma
- Von Hippel–Lindau syndrome
- Wilms tumor

Autosomal recessive:

- Ataxia telangiectasis
- Endometrial cancer
- Gastrointestinal stromal tumor
- Familial melanoma syndrome
- Xeroderma pigmentosum

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Oncologic Disorders

- Obtain information about both maternal and paternal sides of family for three generations.
- Obtain cancer history for at least three generations.
- Look for clustering of cancers that occur at young ages, multiple primary cancers in one individual, cancer in paired organs, and two or more close relatives with the same type of cancer suggestive of hereditary cancer syndromes.

Patient Assessment

- Assess for the following:
  - Physical findings that may predispose the patient to cancer, such as multiple colon polyps or the presence of more than one tumor. If a

tumor was previously diagnosed, inquire about the age of the patient when the first tumor was noted.
    - Skin findings, such as atypical moles, that may be related to familial melanoma syndrome.
    - Multiple *café-au-lait* spots, axillary freckling, and two or more neurofibromas associated with neurofibromatosis type 1.
    - Facial trichilemmomas, mucosal papillomatosis, multinodular thyroid goiter or thyroid adenomas, macrocephaly, fibrocystic breasts, and other fibromas or lipomas related to Cowden syndrome.
- Assess for lifestyle risks (e.g., smoking, obesity, alcohol use).
- Determine potential occupational or environmental hazards that may generate exposure to inhaled chemicals, gases, or other irritants (e.g., toxic metals, asbestos, radon).

Management Issues Specific to Oncologic Disorders

- Assess patient's understanding of genetics factors related to their cancer.
- Offer appropriate genetics information and resources.
- Refer for cancer risk assessment when a hereditary cancer syndrome is suspected so that patient and family can discuss inheritance risk with other family members and availability of genetic testing.
- Provide support to patients and families with known genetic test results for hereditary cancer syndromes. Refer to support groups as appropriate.
- Participate in the management and coordination of risk reduction measures for those with known gene mutations.

Genetics Resources Specific to Oncologic Disorders

American Cancer Society: www.cancer.org
National Cancer Institute: www.cancer.gov
See also Chapter 6, Chart 6-7 for additional components of genetic counseling.

Exposure to ionizing radiation from repeated diagnostic x-ray procedures or with radiation therapy used to treat disease can cause cancer (ACS, 2019c). Improved x-ray equipment minimizes the risk of extensive radiation exposure. Radiation therapy used in cancer treatment and exposure to radioactive materials at nuclear weapon manufacturing sites or nuclear power plants in the past have been associated with a higher incidence of leukemia, multiple myeloma, and cancers of the breast, thyroid, and other tissues. Background radiation from the natural decay processes that produce radon has also been associated with lung cancer. Ventilation is advised in homes with high levels of trapped radon to allow the gas to disperse into the atmosphere.

Chemical Agents

Most cancers are thought to be related to environmental factors (ACS, 2019b). Most hazardous chemicals produce their toxic effects by altering DNA structure. This can occur in body sites distant from that of initial chemical exposure.

Tobacco use is thought to be the single most lethal chemical carcinogen; it accounts for about 30% of all cancer-related deaths (ACS, 2019a). Cigarette smoking is strongly associated with 12 different cancer types including: cancers of the oral cavity and pharynx, larynx, lung, esophagus, pancreas, uterine cervix, kidney, bladder, stomach, colorectal, liver, and myeloid leukemia.

Environmental tobacco smoke (ETS), otherwise known as secondhand smoke, has been linked to lung cancer—even in people who never smoked (ACS, 2019d). Nonsmokers who were exposed to ETS in the home or workplace have about a 20% to 30% greater risk of developing lung cancer (Centers for Disease Control and Prevention [CDC], 2019). There is also some evidence that ETS may be linked with cancers of the larynx, pharynx, nasal sinuses, brain, bladder, rectum, stomach, and breast (ACS, 2019d).

Other combustible forms of tobacco, such as cigars, pipes, roll-your-own products, and water pipes (or hookah), are also associated with increased cancer risk (ACS, 2019d).

TABLE 12-2 Classification of Cancer by Tissue of Origin

Classification	Tissue of Origin	Characteristics	Term	Examples
Carcinoma	Epithelial • Glandular epithelium	Account for 80–90% of all cancers Organs or glands capable of secretion	Adenocarcinoma	Adenocarcinoma of the breast, lung, prostate
	• Squamous epithelium	Covers or lines all external and internal body surfaces	Squamous cell carcinoma	Squamous cell cancer of the skin, lung, esophagus
Sarcoma	Connective or Supportive • Bone	Most common form of cancer of the bone	Osteosarcoma	Osteosarcoma of the femur, humerus
	• Cartilage	Rare, arises from within bones	Chondrosarcoma	Chondrosarcoma of the femur, pelvis
	• Adipose	Arises from deep soft tissue	Liposarcoma	Liposarcoma of the retroperitoneum, thigh
	• Smooth muscle	Very rare	Leiomyosarcoma	Leiomyosarcoma of the uterus, intestines, stomach
	• Skeletal muscle	Most common in young children	Rhabdosarcoma	Rhabdosarcoma of the head and neck, limbs
	• Fibrous tissue	Often involves long or flat bones	Fibrosarcoma	Fibrosarcoma of the femur, ribs, mandible
	• Membranes lining body cavities	Most often related to asbestos exposure	Mesothelial sarcoma or mesothelioma	Mesothelioma of the pleura or peritoneum
	• Blood vessels	With liver involvement may be related to occupational exposure to vinyl chloride monomer	Angiosarcoma	Angiosarcoma of the liver, heart
Myeloma	Plasma cells	Produced by B-cell lymphocytes; plasma cells produce antibodies	Not applicable (N/A)	N/A
Lymphoma	Lymphocytes	Two main classifications; may involve lymph nodes or body organs	Non-Hodgkin lymphoma	B-cell lymphoma, T-cell lymphoma
			Hodgkin lymphoma	N/A
Leukemia	Hematopoietic cells in the bone marrow	May involve various cell lines produced in the bone marrow		
	• White blood cells (WBCs)	N/A	Myelogenous	Acute myelogenous leukemia
	• Lymphocytes	N/A	Lymphocytic	Acute lymphocytic leukemia
	• Red blood cells (RBCs)	Involves overproduction of RBCs and is associated with increased levels of WBCs and platelets; also risk of additional bone marrow disease	Erythremia	Polycythemia vera

Adapted from Fritz, A., Percy, C., Jack, A., et al.; World Health Organization. (2013). International classification of diseases for oncology (ICD-O)–3rd edition, 1st revision. Retrieved on 1/22/2019 at: codes.iarc.fr/home

Electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah and e-cigars have gained increased popularity as an alternative to tobacco. While ENDS do not contain tobacco, most contain nicotine, which is highly addictive, and other potentially harmful substances, such as volatile organic compounds, formaldehyde, and flavoring chemicals (ACS, 2019d). Given that ENDS are relatively new to the market, the long-term health effects of these products remain unknown.

Smokeless tobacco products, such as chewing tobacco, snuff and snus, used most often by young adults aged 18 to 25 years, are associated with an increased risk of oral, pancreatic, and esophageal cancer (ACS, 2019d; Lipari & Van Horn, 2017).

Many chemical substances found in the workplace are carcinogens or co-carcinogens (ACS, 2019e). In the United States, carcinogens are classified by two federal agencies: the National Toxicology Program of the Department of Health and Human Services (HHS) and the Environmental Protection Agency's (EPA) Integrated Risk Information System (IRIS) (CDC, 2017). The CDC established the National Institute for Occupational Safety and Health (NIOSH) to provide occupational exposure limits and guidelines for protection of the workforce as regulated by the Occupational Safety and Health Act of 1970 (U.S. EPA, 2017). The extensive list of suspected chemical substances continues to grow and includes aromatic amines and aniline dyes; pesticides and formaldehydes; arsenic, soot, and tars; asbestos; benzene; cadmium; chromium compounds; nickel and zinc ores; wood dust; beryllium compounds; and polyvinyl chloride (ACS, 2019e). Betel quid, which are chewed as stimulants in some cultures, are also included (ACS, 2019e; Chen, Mahmood, Mariottini, et al., 2017).

Genetics and Familial Factors

Almost every cancer type has been shown to run in families. This may be due to a combination of genetic, environmental, and lifestyle factors. Genetic factors play a fundamental role in cancer cell development. Cancer has been associated with extra chromosomes, too few chromosomes, or translocated chromosomes (NCI, 2019b).

Approximately 5% to 10% of cancers in adults display a pattern of cancers suggestive of a familial predisposition (NCI, 2019b). Hereditary cancer syndromes represent a cluster of cancers identified by a specific genetic alteration that is inherited across generations. In these families, the associated genetic mutation is found in all cells in the body (germline mutation) and represents an inherited susceptibility to cancer for all family members who carry the mutation.

There are more than 50 hereditary syndromes identified by scientists that may predispose individuals to develop certain cancers (NCI, 2019b). The hallmarks of families with a hereditary cancer syndrome include cancer in two or more first-degree relatives (the parent, sibling, or child of an individual), onset of

cancer in family members younger than 50 years, the same type of cancer in several family members, individual family members with more than one type of cancer, and a rare cancer in one or more family members. There is also evidence of an autosomal dominant inheritance pattern of cancers affecting several generations of a family (NCI, 2019b).

There have been considerable advances in the recognition of inherited cancer susceptibility syndromes and in the ability to isolate and identify the inherited genetic mutations responsible. These advances have enabled the appropriate identification of families at risk for certain syndromes. Examples include hereditary breast and ovarian cancer syndrome (*BRCA1* and *BRCA2*) and multiple endocrine neoplasia syndrome (*MEN1* and *MEN2*) (see Chart 12-1). Other cancers associated with familial inheritance syndromes include nephroblastomas, pheochromocytomas, and colorectal, stomach, thyroid, renal, prostate, and lung cancers (NCI, 2019b).

Lifestyle Factors

Lifestyle factors (e.g., obesity, alcohol intake, poor diet, physical inactivity) were estimated to account for 16% of all cancer cases and 18% of all cancer deaths in 2017 (Islami, Goding Sauer, Miller, et al., 2018). These lifestyle factors were second only to cigarette smoking as a major modifiable risk factor associated with both cancer development and cancer mortality.

The risk of cancer increases with long-term ingestion of carcinogens or co-carcinogens or the absence of protective substances in the diet. Dietary substances that appear to increase the risk of cancer include fats, alcohol, salt-cured or smoked meats, nitrate- and nitrite-containing foods, and red and processed meats (World Cancer Research Fund [WCRF], 2018). Heavy alcohol use increases the risk of cancers of the mouth, pharynx, larynx, esophagus, liver, colon, rectum, and breast (WCRF, 2018).

Obesity has been linked to the development of cancers of the breast (in postmenopausal women), colon and rectum, endometrium, esophagus, kidney, and pancreas (WCRF, 2018). Obesity may be also associated with an increased risk for cancers of the gallbladder, liver, ovary, and cervix, and for multiple myeloma, Hodgkin lymphoma, and aggressive forms of prostate cancer. While there is a clear relationship between obesity and cancer, the etiology of cancer in the context of obesity remains poorly understood (NCI, 2017). Several possible mechanisms have been suggested, however, including that excess fat may cause chronic inflammation resulting in DNA damage, increased levels of certain hormones (e.g., estrogen, insulin, adipokines), and disruptions in levels of cell growth regulators (e.g., mammalian target of rapamycin and AMP-activated protein kinase)—all of which may increase the development of certain types of cancer. Multiple studies have long linked a sedentary lifestyle and lack of regular exercise to cancer development (Cannioto, Etter, Guterman, et al., 2017; Cannioto, Etter, LaMonte, et al., 2018).

Hormonal Agents

Tumor growth may be promoted by disturbances in hormonal balance, either by the body's own (endogenous) hormone production or by administration of exogenous hormones (Norris, 2019). Cancers of the breast, prostate, ovaries, and endometrium are thought to depend on endogenous hormonal levels for growth. Prenatal exposure to diethylstilbestrol (a synthetic form of the female hormone estrogen) has long been recognized as a risk factor for clear cell adenocarcinoma of the lower genital tract (Huo, Anderson, Palmer, et al., 2017).

Hormonal changes related to the female reproductive cycle are also associated with cancer incidence. Early onset of menses before age 12 and delayed onset of menopause after age 55, null parity (never giving birth), and delayed childbirth after age 30 are all associated with an increased risk of breast cancer (Chen, 2019). Increased numbers of pregnancies are associated with a decreased incidence of breast, endometrial, and ovarian cancers.

Women who take estrogen after menopause appear to have a decreased risk of breast cancer, but an increased risk of developing endometrial cancers (NCI, 2018). Thus, estrogen replacement alone is not used in women who have not had a hysterectomy. Combination estrogen and progesterone therapy is linked to a higher risk of breast cancer. The longer the combined therapy is used, the higher the risk of developing breast cancer. However, the risk substantially decreases when therapy is discontinued (NCI, 2018).

Role of the Immune System

In humans, transformed cells arise on a regular basis, but are recognized by surveillance cells of the immune system that destroy them before cell growth becomes uncontrolled (immune surveillance) (Norris, 2019). When the immune system fails to identify and stop the growth of transformed cells, a tumor can develop and progress.

Patients who are immunocompromised have an increased incidence of cancer. Transplant recipients who receive immunosuppressive therapy to prevent rejection of the transplanted organ have an increased incidence of cancer (Norris, 2019). Patients with acquired immune deficiency syndrome (AIDS) have an increased incidence of Kaposi sarcoma and other cancers. Patients who were previously treated for one cancer are at increased risk for secondary cancers (Norris, 2019).

Normal Immune Responses

Through the process of immune surveillance, an intact immune system usually has the ability to recognize and combat cancer cells through multiple, interacting cells and actions of the innate, humoral, and cellular components of the immune system (Jameson, Fauci, Kasper, et al., 2018; Norris, 2019). Tumor-associated antigens (TAAs; also called *tumor cell antigens*) are found on the membranes of many cancer cells. TAAs are processed by antigen-presenting cells (APCs) (e.g.,

macrophages and dendritic cells [very specialized cells of the immune system] that present antigens to both T and B lymphocytes) and are presented to T lymphocytes that recognize the antigen-bearing cells as foreign. Multiple TAAs have been identified—some are found in many types of cancer, some exist in the normal tissues of origin as well as the cancer cells, some exist in both normal and cancer cells but are overexpressed (exist in higher concentrations) in cancer cells, and others are very specific to certain cancer types (Norris, 2019).

In response to recognizing TAAs as foreign, T lymphocytes release several cytokines that elicit various immune system actions, including (1) proliferation of cytotoxic (cell-killing) T lymphocytes capable of direct destruction of cancer cells, (2) induction of cancer cell apoptosis, and (3) recruitment of additional immune system cells (B-cell lymphocytes that produce antibodies, natural killer cells, and macrophages) that contribute to the destruction and degradation of cancer cells (Jameson et al., 2018; Norris, 2019).

Immune System Evasion

Several theories postulate how malignant cells survive and proliferate, evading the elaborate immune system defense mechanisms (Jameson et al., 2018; Norris, 2019). If the body fails to recognize the TAAs on cancer cells or the function of the APCs is impaired, the immune response is not stimulated. Some cancer cells have been found to have altered cell membranes that interfere with APC binding and presentation to T lymphocytes. Tumors can also express molecules that induce T-lymphocyte anergy or tolerance such as PD-1 ligand. These molecules bind to PD-1 proteins on T lymphocytes and either block the killing of the tumor or induce cell death in the lymphocyte. In addition, cancer cells have been found to release cytokines that inhibit APCs as well as other cells of the immune system. When tumors do not possess TAAs that label them as foreign, the immune response is not alerted. This allows the tumor to grow too large to be managed by normal immune mechanisms.

The immunogenicity (immunologic appearance) of cancer cells can be altered through genetic mutations, allowing the cells to evade immune cell recognition (Norris, 2019). Conversely, mutations are the source for some TAAs. Tumor antigens may combine with the antibodies produced by the immune system and hide or disguise themselves from normal immune defense mechanisms. The tumor antigen–antibody complexes that evade recognition lead to a false message to decrease further production of antibodies as well as other immune system components.

Overexpression (abnormally high concentrations) of host suppressor T lymphocytes induced through the release of cytokines by malignant cells is thought to downregulate the immune response, thus permitting uncontrolled cell growth (Jameson et al., 2018). Suppressor T lymphocytes normally assist in regulating lymphocyte production and diminishing immune responses (e.g., antibody production) when they are no longer required. Low levels of antibodies and high levels of suppressor cells have been found in patients with multiple

myeloma, which is a cancer associated with hypogammaglobulinemia (low amounts of serum antibodies). Conversely, there is evidence that proliferation of helper T lymphocytes, which promote the immune response, is impaired by cytokines produced by cancer cells (Jameson et al., 2018). Without helper T lymphocytes, the immune system response is limited, and the cancer cells continue to proliferate. Understanding the role of the immune system and identification of the ways in which cancer evades the body's natural defenses provide the foundation for therapeutic approaches that seek to support and enhance the immune system's role in combating cancer (see Chapter 31).

Detection and Prevention of Cancer

Nurses in all settings play a key role in cancer detection and prevention. Primary, secondary, and tertiary prevention of cancer are all important.

Primary Prevention

Primary prevention is about reducing the risks of disease through health promotion and risk reduction strategies. Guidelines on nutrition and physical activity for cancer prevention can be found in Chart 12-2.

An example of primary prevention is the use of immunization to reduce the risk of cancer through prevention of infections associated with cancer. The HPV vaccine is recommended to prevent cervical and head and neck cancers (Hashim, Genden, Posner, et al., 2019). The vaccine to prevent HBV infection is recommended by the CDC (2018) to reduce the risk of hepatitis and subsequent development of liver cancer.

Secondary Prevention

Secondary prevention involves screening and early detection activities that seek to identify precancerous lesions and early-stage cancer in individuals who lack signs and symptoms of cancer. ACS screening is advocated for many types of cancer (see Table 12-3) (ACS, 2018). Detection of cancer at an early stage may reduce costs, use of resources, and the morbidity associated with advanced stages of cancer and their associated complex treatment approaches. Many screening and detection programs target people who do not regularly practice health-promoting behaviors or lack access to health care. Nurses continue to develop community-based screening and detection programs that address barriers to health care or reflect the socioeconomic and cultural beliefs of the target population (Rees, Jones, Jones, et al., 2018; So, Kwong, Chen, et al., 2019).

The evolving understanding of the role of genetics in cancer cell development has contributed to prevention and screening efforts. Many centers offer cancer

risk evaluation programs that provide interdisciplinary in-depth assessment, screening, education, and counseling as well as follow-up monitoring for people at high risk for cancer (National Comprehensive Cancer Network [NCCN] 2019a,b). The NCI provides guidance for cancer risk assessment, counseling, education, and genetic testing (NCI, 2019b).

Chart 12-2 **HEALTH PROMOTION**

American Cancer Society Guidelines on Nutrition and Physical Activity for Cancer Prevention

Individual Choices

Achieve and Maintain a Healthy Weight Throughout Life

- Be as lean as possible throughout life without being underweight.
- Avoid excessive weight gain at all ages. For those who are currently overweight or have obesity, losing even a small amount of weight has health benefits and is a good place to start.
- Engage in regular physical activity and limit consumption of high-calorie foods and beverages as key strategies for maintaining a healthy weight.

Adopt a Physically Active Lifestyle

- Adults should engage in at least 150 minutes of moderate-intensity or 75 minutes of vigorous-intensity physical activity each week, or an equivalent combination, preferably spread throughout the week.
- Children and adolescents should engage in at least 1 hour of moderate- or vigorous-intensity physical activity each day, with vigorous-intensity activity at least 3 days each week.
- Limit sedentary behavior such as sitting, lying down and watching television, and other forms of screen-based entertainment.
- Doing any intentional physical activity above usual activities, no matter what one's level of activity, can have many health benefits.

Consume a Healthy Diet, with an Emphasis on Plant Sources

- Choose foods and beverages in amounts that help achieve and maintain a healthy weight.
- Limit consumption of processed meat and red meats.
- Eat at least 2½ cups of vegetables and fruits each day.
- Choose whole grains in preference to processed (refined) grains.

If You Drink Alcoholic Beverages, Limit Consumption

- Drink no more than one drink per day for women or two per day for men.

Community Action

Public, private, and community organizations should work collaboratively at national, state, and local levels to implement policy environmental changes that:

- Increase access to affordable, healthy foods in communities, worksites, and schools, and decrease access to and marketing of foods and beverages of low nutritional value, particularly to youth.
- Provide safe, enjoyable, and accessible environments for physical activity in schools and worksites, and for transportation and recreation in communities.

Unfolding Patient Stories: Doris Bowman • Part 1

Doris Bowman, a 39-year-old diagnosed with uterine fibroids, dysmenorrhea, and menorrhagia, is scheduled for a total abdominal hysterectomy with bilateral salpingoopherectomy. She has a family history of uterine and ovarian cancer. She asks the nurse what she can do to further reduce her risk for cancer and is also concerned for her family members. What patient and family education should the nurse present on risk reduction strategies, health promotion, and cancer screening? (Doris Bowman's story continues in Chapter 51.)

Care for Doris and other patients in a realistic virtual environment: vSim (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Tertiary Prevention

Improved screening, diagnosis, and treatment approaches have led to an estimated 16.9 million cancer survivors in the United States (ACS, 2019f). Tertiary prevention efforts focus on monitoring for and preventing recurrence of the primary cancer as well as screening for the development of second malignancies in cancer survivors. Survivors are assessed for the development of second malignancies such as lymphoma and leukemia, which have been associated with certain chemotherapy agents and the use of radiation therapy (ACS, 2019f). Survivors may also develop second malignancies not related to treatment, but rather genetic mutations related to inherited cancer syndromes, environmental exposures, and lifestyle factors.

Diagnosis of Cancer

A cancer diagnosis is based on assessment of physiologic and functional changes and results of the diagnostic evaluation. Patients with suspected cancer undergo extensive testing to (1) determine the presence and extent of cancer, (2) identify possible disease metastasis, (3) evaluate the function of involved and uninvolved body systems and organs, and (4) obtain tissue and cells for analysis, including evaluation of tumor stage and grade. The diagnostic evaluation includes a review

of systems; physical examination; imaging studies; laboratory tests of blood, urine, and other body fluids; procedures; and pathologic analysis. A selection of diagnostic tests is found in Table 12-4.

Patients undergoing extensive testing may be fearful of the procedures and anxious about possible test results. Nurses help address the patient's fear and anxiety by explaining the tests to be performed, the sensations likely to be experienced, and the patient's role in the test procedures. The nurse encourages the patient and family to voice their fears about the test results, supports the patient and family throughout the diagnostic evaluation, and reinforces and clarifies information conveyed by the primary provider. The nurse also encourages the patient and family to communicate, share their concerns, and discuss their questions and concerns with one another.

Tumor Staging and Grading

A complete diagnostic evaluation includes identifying the stage and grade of the tumor. This is accomplished prior to treatment to provide baseline data for evaluating outcomes of therapy and to maintain a systematic and consistent approach to ongoing diagnosis and treatment. Cancer treatment options and prognosis are based on the cancer type; stage and grade of cancer; as well as the individual's health status and response to treatment (NCI, 2019c).

TABLE 12-3 American Cancer Society Screening Guidelines for the Early Detection of Cancer[a]

Cancer Site	Population	Test or Procedure	Recommendation
Breast	Women, ages 40–54	Mammography	Women should undergo regular screening mammography starting at age 45 yrs. Women ages 45–54 should be screened annually. Women should have the opportunity to begin annual screening between the ages of 40 and 44.
	Women age 55 and over	Mammography	Transition to biennial screening or can continue annual screening. Continue screening if overall health is good and life expectancy is 10+ yrs.
Cervix	Women, ages 21–29	Papanicolaou (Pap) test	Screening should be done every 3 yrs with conventional or liquid-based Pap tests. HPV DNA testing only for abnormal Pap test.
	Women ages 30–65 Women ages 66+	Pap test and HPV DNA test	Screening should be done every 5 yrs with both the HPV test and the Pap test (preferred), or every 3 yrs with the Pap test alone (acceptable). Women ages 66+ who have regular cervical cancer screening with negative results should stop cervical cancer screening. Women who have had a total hysterectomy should stop cervical cancer screening.
Colorectal[b]	Men and women, ages 45–75. People aged 76–84, should discuss continued screening with their provider. People 85+ should no longer participate in colorectal cancer screenings.	Highly sensitive guaiac-based fecal occult blood test (gFOBT) or highly sensitive fecal immunochemical test (FIT)	Annual highly sensitive gFOBT or FIT testing.
		Multi-targeted	MT-sDNA testing every 3 yrs.

		stool DNA test (MT-sDNA) test	
		Flexible sigmoidoscopy (FSIG), or	Every 5 yrs.
		Colonoscopy, or	Every 10 yrs.
		CT colonography (virtual colonoscopy)	Every 5 yrs.
Endometrial	Women, at menopause	At the time of menopause, women at average risk should be informed about risks and symptoms of endometrial cancer and encouraged to report any unexpected bleeding or spotting to their providers.	Not applicable (N/A)
Lung	Current or former smokers (quit within past 15 yrs) ages 55–74 in fairly good health with at least a 30 pack-year history.	Low-dose CT (LDCT)	LDCT annually. Providers with access to high-volume, high-quality lung cancer screening and treatment centers should initiate a discussion about lung cancer screening with apparently healthy patients aged 55–74 who have at least a 30 pack-year smoking history, and who currently smoke or have quit within the past 15 yrs. Patient has been involved in the process of informed and shared decision making with a provider related to the potential benefits, limitations, and harms associated with screening for lung cancer with LDCT should occur before any decision is made to initiate lung cancer screening. Smoking cessation counseling remains a high priority for clinical attention in discussions with current smokers, who should be informed of their continuing risk of lung cancer. Screening should not be

			viewed as an alternative to smoking cessation.
Prostate	Men, age 50+, African American Men, age 45+	Digital rectal examination (DRE) and prostate-specific antigen (PSA) test	Men who have at least a 10-yr life expectancy should have an opportunity to make an informed decision with their providers about whether to be screened for prostate cancer, after receiving information about the potential benefits, risks, and uncertainties associated with prostate cancer screening. Prostate cancer screening should not occur without an informed decision making process.
Cancer-related checkup	Men and women, age 20+	On the occasion of a periodic health examination, the cancer-related checkup should include examination for cancers of the thyroid, testicles, ovaries, lymph nodes, oral cavity, and skin, as well as health counseling about tobacco, sun exposure, diet and nutrition, risk factors, sexual practices, and environmental and occupational exposures.	N/A

CT, computed tomography; DNA, deoxyribonucleic acid; HPV, human papillomavirus.

[a]All individuals should become familiar with the potential benefits, limitations, and harms associated with cancer screening.

[b]All positive tests (other than colonoscopy) should be followed up with colonoscopy.

Adapted from American Cancer Society (ACS). (2018). American Cancer Society guidelines for the early detection of cancer. Retrieved on 7/5/2019 at: www.cancer.org/healthy/find-cancer-early/cancer-screening-guidelines/american-cancer-society-guidelines-for-the-early-detection-of-cancer.html

TABLE 12-4 Select Diagnostic Tests Used to Detect Cancer

Test	Description	Examples of Diagnostic Uses
Tumor marker identification	Analysis of biochemical mediators found in tumor tissue, blood, or other body fluids that are indicative of cancer cells or specific characteristics of cancer cells. These biochemical mediators may also be found in some normal body tissues.	Breast, colon, lung, ovarian, testicular, prostate cancers
Genetic tumor markers (also called prognostic indicators)	Analysis for the presence of mutations (alterations) in genes found in tumors or body tissues. Assists in diagnosis, selection of treatment, prediction of response to therapy, and risk of progression or recurrence.	Breast, lung, kidney, ovarian, brain cancers; leukemia; and lymphoma. Many uses of genetic profiling are considered investigational.
Mammography	Use of x-ray images of the breast.	Breast cancer
Magnetic resonance imaging (MRI)	Use of magnetic fields and radiofrequency signals to create sectioned images of various body structures.	Neurologic, pelvic, abdominal, thoracic, breast cancers
Computed tomography (CT) scan	Use of narrow-beam x-ray to scan successive layers of tissue for a cross-sectional view.	Neurologic, pelvic, skeletal, abdominal, thoracic cancers
Fluoroscopy	Use of x-rays that identify contrasts in body tissue densities; may involve the use of contrast agents.	Skeletal, lung, gastrointestinal cancers
Ultrasonography (ultrasound)	High-frequency sound waves echoing off body tissues are converted electronically into images; used to assess tissues deep within the body.	Abdominal and pelvic cancers
Endoscopy	Direct visualization of a body cavity or passageway by insertion of an endoscope into a body cavity or opening; allows tissue biopsy, fluid aspiration, and excision of small tumors. Used for diagnostic and therapeutic purposes.	Bronchial, gastrointestinal cancers
Nuclear medicine imaging	Uses IV injection or ingestion of radioisotopes followed by imaging of tissues that have concentrated the radioisotopes.	Bone, liver, kidney, spleen, brain, and thyroid cancers
Positron emission tomography (PET)	Through the use of a tracer, provides black-and-white or color-coded images of the biologic activity of a particular area, rather than its structure. Used in	Lung, colon, liver, pancreatic, head and neck cancers; Hodgkin and non-

	detection of cancer or its response to treatment.	Hodgkin lymphoma and melanoma
PET fusion	Use of a PET scanner and a CT scanner in one machine to provide an image combining anatomic detail, spatial resolution, and functional metabolic abnormalities.	See PET
Radioimmunoconjugates	Monoclonal antibodies are labeled with a radioisotope and injected IV into the patient; the antibodies that aggregate at the tumor site are visualized with scanners.	Colorectal, breast, ovarian, head and neck cancers; lymphoma and melanoma
Vascular imaging	Use of contrast agents that are injected into veins or arteries and monitored by fluoroscopy, CT, or MRI imaging in order to assess tumor vasculature. Used to assess tumor vascularity prior to surgical procedures.	Liver and brain cancers

Chart 12-3

TNM Classification System

T The extent of the primary tumor
N The absence or presence and extent of regional lymph node metastasis
M The absence or presence of distant metastasis
The use of numerical subsets of the TNM components indicates the progressive extent of the malignant disease.

Primary Tumor (T)

Tx Primary tumor cannot be assessed
T0 No evidence of primary tumor
Tis Carcinoma in situ
T1, T2, T3, T4 Increasing size or local extent of the primary tumor

Regional Lymph Nodes (N)

Nx Regional lymph nodes cannot be assessed
N0 No regional lymph node metastasis
N1, N2, N3 Increasing involvement of regional lymph nodes

Distant Metastasis (M)

Mx Distant metastasis cannot be assessed
M0 No distant metastasis
M1 Distant metastasis

Adapted from National Comprehensive Cancer Network (NCCN). (2019c). Cancer staging guide. Retrieved on 7/20/2019 at: www.nccn.org/patients/resources/diagnosis/staging.aspx

Staging describes the size of the tumor, the existence of local invasion, lymph node involvement, and distant metastasis. Several systems exist for classifying the anatomic extent of disease. The tumor, nodes, and metastasis (TNM) system (see Chart 12-3) is the most common system used to describe the stage of many solid tumors (Amin, Greene, Edge, et al., 2017; NCCN, 2019c).

Staging provides a common language used by health care providers and scientists to accurately communicate about cancer across clinical settings and in research. These systems also provide a convenient shorthand notation that condenses lengthy descriptions into manageable terms for comparisons of treatments and prognoses.

Grading is the pathologic classification of tumor cells (NCI, 2019c). Grading systems seek to define the type of tissue from which the tumor originated and the degree to which the tumor cells retain the functional and histologic characteristics of the tissue of origin (differentiation). Samples of cells used to establish the tumor grade may be obtained from tissue scrapings, body fluids, secretions, washings, biopsy, or surgical excision. This information helps providers predict the behavior and prognosis of various tumors. The grade corresponds with a numeric value ranging from I to IV. Grade I tumors, also

known as well-differentiated tumors, closely resemble the tissue of origin in structure and function. Tumors that do not clearly resemble the tissue of origin in structure or function are described as poorly differentiated or undifferentiated and are assigned grade IV. These tumors tend to be more aggressive, less responsive to treatment, and associated with a poorer prognosis as compared to well-differentiated, grade I tumors. Various staging and grading systems are used to characterize cancers.

Anatomic Stage Group

Once the diagnosis, clinical stage, and histologic grade have been determined, the anatomic stage group, designated by I through IV (representing increasing severity of disease), is assigned to facilitate communication, treatment decisions, and estimation of prognosis. The anatomic stage group is also useful for comparing clinical outcomes.

Management of Cancer

Treatment options offered to patients with cancer are based on treatment goals for each specific type, stage, and grade of cancer. The range of possible treatment goals includes cure, a complete eradication of malignant disease; control, which includes prolonged survival and containment of cancer cell growth; or **palliation,** which involves relief of symptoms associated with the disease and improvement of quality of life. Treatment approaches are not initiated until the diagnosis of cancer has been confirmed and staging and grading have been completed.

The health care team and the patient and family must have a clear understanding of the treatment options and goals. Open communication and support are vital as those involved periodically reassess treatment plans and goals when complications of therapy develop or disease progresses.

Multiple modalities are commonly used in cancer treatment. Various approaches, including surgery, radiation therapy, chemotherapy, hematopoietic stem cell transplantation (HSCT), immunotherapy, and targeted therapy may be used together or at different times throughout treatment. Understanding the principles of each and how they interrelate is important in understanding the rationale and goals of treatment.

Surgery

Surgical removal of the entire cancer remains the ideal and most frequently used treatment method. However, the specific surgical approach may vary for several reasons. Diagnostic surgery is the definitive method for obtaining tissue to identify the cellular characteristics that influence all treatment decisions. Surgery

may be the primary method of treatment, or it may be prophylactic, palliative, or reconstructive.

Diagnostic Surgery

Diagnostic surgery, or biopsy, is performed to obtain a tissue sample for histologic analysis of cells suspected to be malignant. In most instances, the biopsy is taken from the actual tumor; however, in some situations, it is necessary to take a sample of lymph nodes near a suspicious tumor. Many cancers can metastasize from the primary site to other areas of the body through the lymphatic circulation. Knowing whether adjacent lymph nodes contain tumor cells helps the health care team plan the best therapeutic approach to combat cancer that has spread beyond the primary tumor site. The use of injectable dyes and nuclear medicine imaging can help identify the sentinel lymph node or the initial lymph node to which the primary tumor and surrounding tissue drain. Sentinel lymph node biopsy (SLNB), also known as sentinel lymph node mapping, is a minimally invasive surgical approach that in many instances has replaced lymphadenectomy (more invasive lymph node dissections) and the associated complications such as lymphedema and delayed healing. SLNB has been widely adopted for regional lymph node staging in selected cases of melanoma and breast cancer (NCCN, 2019d, 2019e).

Biopsy Types

Biopsy methods include excisional, incisional, and needle biopsy. The biopsy type is determined by the size and location of the tumor, the type of treatment anticipated if the cancer diagnosis is confirmed, and the need for surgery and general anesthesia. The biopsy method that allows for the least invasive approach while permitting the most representative tissue sample is chosen. Diagnostic imaging techniques can be used to assist in locating the suspicious lesion and to facilitate accurate tissue sampling. The patient and family are provided the opportunity and time to discuss the options before definitive plans are made.

Excisional biopsy is used for small, easily accessible tumors. In many cases, the surgeon can remove the entire tumor as well as the surrounding marginal tissues. The removal of normal tissue beyond the tumor area decreases the possibility that residual microscopic malignant cells may lead to a recurrence of the tumor. This approach not only provides the pathologist with the entire tissue specimen for the determination of stage and grade but also decreases the chance of seeding tumor cells (disseminating cancer cells throughout surrounding tissues).

Incisional biopsy is performed if the tumor mass is too large to be removed. In this case, a wedge of tissue from the tumor is removed for analysis. The cells of the tissue wedge must be representative of the tumor mass so that the pathologist can provide an accurate diagnosis. If the specimen does not contain

representative tissue and cells, negative biopsy results do not guarantee the absence of cancer.

Excisional and incisional approaches are often performed through endoscopy. However, a surgical procedure may be required to determine the anatomic extent or stage of the tumor. For example, a diagnostic or staging laparotomy (the surgical opening of the abdomen to assess malignant abdominal disease) may be necessary to assess malignancies such as gastric or colon cancer.

Needle biopsy is performed to sample suspicious masses that are easily and safely accessible, such as some masses in the breasts, thyroid, lung, liver, and kidney. Needle biopsies are most often performed on an outpatient basis. They are fast, relatively inexpensive, easy to perform, and may require only local anesthesia. In general, the patient experiences slight and temporary physical discomfort. In addition, the surrounding tissues are minimally disturbed, thus decreasing the likelihood of seeding cancer cells. Fine-needle aspiration (FNA) biopsy involves aspirating cells rather than intact tissue through a needle that is guided into a suspected diseased area. This type of specimen can only be analyzed by cytologic examination (viewing only cells, not tissue). Often, x-ray, computed tomography (CT) scanning, ultrasonography, or magnetic resonance imaging (MRI) is used to help locate the suspicious area and guide placement of the needle. FNA does not always yield enough material to permit accurate diagnosis, necessitating additional biopsy procedures. A core needle biopsy uses a specially designed needle to obtain a small core of tissue that permits histologic analysis. Most often, this specimen is sufficient to permit accurate diagnosis.

Surgery as Primary Treatment

When surgery is the primary approach in treating cancer, the goal is to remove the entire tumor or as much as is feasible (a procedure sometimes called *debulking*) as well as any involved surrounding tissue, including regional lymph nodes.

Two common surgical approaches used for treating primary tumors are local and wide excisions. Local excision, often performed on an outpatient basis, is warranted when the mass is small. It includes removal of the mass and a small margin of normal tissue that is easily accessible. Wide or radical excisions (en bloc dissections) include removal of the primary tumor, lymph nodes, adjacent involved structures, and surrounding tissues that may be at high risk for tumor spread. This surgical method may result in disfigurement and altered functioning, necessitating rehabilitation, reconstructive procedures, or both. However, wide excisions are considered if the tumor can be removed completely and the chances of cure or control are good.

Minimally invasive surgical techniques are increasingly replacing traditional surgery associated with large incisions for a variety of cancers (Yarbro, Wujcik, & Gobel, 2018). Advantages of minimally invasive approaches include less

surgical trauma, decreased blood loss, decreased incidence of wound infection and other complications associated with surgery, decreased surgical time and requirement for anesthesia, decreased postoperative pain and limited mobility, and shorter periods of recovery (Pache, Hübner, Jurt, et al., 2017).

Endoscopic surgery, an example of minimally invasive surgery, uses an endoscope with intense lighting and an attached multichip mini camera that is inserted into the body through a small incision. The surgical instruments are inserted into the surgical field through one or two additional small incisions, each about 1 to 2 cm in length. The camera transmits the image of the involved area to a monitor so that the surgeon can manipulate the instruments to perform the necessary procedure. Endoscopic surgery is used to treat many cancer-related conditions of the thorax (thoracoscopy) and abdomen (laparoscopy).

The use of robotics is another advancement in the surgical treatment of cancer (Yarbro, et al., 2018). The use of robotics during laparoscopic procedures permits the removal of tumors with more precision and dexterity than could be accomplished by laparoscopic surgery alone. Laparoscopic robotic-assisted surgery has been used to treat cancers of the colon, prostate and uterus; however, it remains unclear if long-term cancer-related outcomes are improved with robotic surgery when compared to more conventional surgical approaches (U.S. Food and Drug Administration [FDA], 2019).

Salvage surgery is an additional treatment option that uses an extensive surgical approach to treat the local recurrence of cancer after the use of a less extensive primary approach. Mastectomy to treat recurrent breast cancer after primary lumpectomy and radiation is an example of salvage surgery.

Surgery may completely excise limited areas of metastatic disease (referred to as oligometastatic disease) as well. An example would be colon cancer with one to three small areas of liver metastasis and no evidence of cancer elsewhere. In the past, patients with recurrent or metastatic disease were treated with palliation only as their disease was considered incurable. However, evidence now suggests that there is a possibility of a cure or prolonged survival for select subgroups of patients with certain cancer types (Jang, Kim, Jeong, et al., 2018; Ruiz, Sebagh, Wicherts, et al., 2018).

In addition to surgery that uses surgical blades or scalpels to excise the mass and surrounding tissues, several other types of techniques are available. Table 12-5 provides examples of select techniques.

A multidisciplinary approach to patient care is essential for the patient undergoing cancer-related surgery. The effects of surgery on the patient's body image, self-esteem, and functional abilities are addressed. If necessary, a plan for postoperative rehabilitation is made before the surgery is performed. The growth and dissemination of cancer cells may have produced distant micrometastases by the time the patient seeks treatment. Therefore, attempting to remove wide margins of tissue in the hope of "getting all the cancer" may not be feasible. This reality substantiates the need for a coordinated multidisciplinary approach to cancer therapy.

Once the surgery has been completed, one or more additional (or adjuvant) modalities may be chosen to increase the likelihood of eradicating the remaining microscopic cancer cells that are undetectable by available diagnostic procedures. However, some cancers that are treated surgically in the very early stages (e.g., skin and testicular cancers) are curable without additional therapy.

TABLE 12-5 Select Techniques Used for Localized Destruction of Tumor Tissue

Type of Procedure	Description	Examples of Use
Chemosurgery	Use of chemicals or chemotherapy applied directly to tissue to cause destruction.	Intraperitoneal chemotherapy for ovarian cancer involving the abdomen and peritoneum.
Cryoablation	Use of liquid nitrogen or a very cold probe to freeze tissue and cause cell destruction.	Cervical, prostate, and rectal cancers.
Electrosurgery	Use of an electric current to destroy tumor cells.	Basal and squamous cell skin cancers.
Laser surgery	Use of light and energy aimed at an exact tissue location and depth to vaporize cancer cells (also referred to as photocoagulation or photoablation).	Dyspnea associated with endobronchial obstructions.
Photodynamic therapy	Intravenous (IV) administration of a light-sensitizing agent (hematoporphyrin derivative) that is taken up by cancer cells, followed by exposure to laser light within 24–48 h; causes cancer cell death.	Palliative treatment of dysphagia associated with esophageal and dyspnea associated with endobronchial obstructions.
Radiofrequency ablation (RFA)	Uses localized application of thermal energy that destroys cancer cells through heat: temperatures exceed 50°C (122°F).	Nonresectable liver tumors, pain control with bone metastasis.

Adapted from DeVita, V. T., Rosenberg S. A., & Lawrence, T. S., (Eds.). (2018). *Cancer: Principles & practice of oncology* (11th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

TABLE 12-6 Types of Palliative Surgery and Interventions

Procedure	Indications
Abdominal shunt placement	Ascites
Biliary stent placement	Biliary obstruction
Bone stabilization	Displaced bone fracture related to metastatic disease
Colostomy or ileostomy	Bowel obstruction
Cordotomy	Pain
Epidural catheter placement (for administering epidural analgesics)	Pain
Excision of solitary metastatic lesion	Metastatic lung, liver, or brain lesion
Gastrostomy, jejunostomy tube placement	Upper gastrointestinal tract obstruction
Hormone manipulation (removal of ovaries, testes, adrenals, pituitary)	Tumors that depend on hormones for growth
Nerve block	Pain
Percutaneous enteral gastrostomy (PEG) tube placement	Enteral nutrition
Pericardial drainage tube placement	Pericardial effusion
Peritoneal drainage tube placement	Ascites
Pleural drainage tube placement	Pleural effusion
Ureteral stent placement	Ureteral obstruction
Venous access device placement (for administering parenteral analgesics)	Pain

Prophylactic Surgery

Prophylactic or risk reduction surgery involves removing nonvital tissues or organs that are at increased risk of developing cancer. The following factors are considered when discussing possible prophylactic surgery:

- Family history and genetic predisposition
- Presence or absence of signs and symptoms
- Potential risks and benefits
- Ability to detect cancer at an early stage
- Alternative options for managing increased risk
- The patient's acceptance of the postoperative outcome

Colectomy, mastectomy, and oophorectomy are examples of prophylactic surgeries. Identification of genetic markers indicative of inherited cancer syndromes or a predisposition to develop some types of cancer plays a role in decisions concerning prophylactic surgeries. However, what is adequate justification for prophylactic surgery remains controversial. For example, several

factors are considered when deciding to proceed with a prophylactic mastectomy, including a family history of breast cancer; positive *BRCA1* or *BRCA2* findings; severity of overall breast cancer risk; a personal history of breast cancer; and individual factors (e.g., younger age, psychological well-being that may influence the patient's decision making process) (Chagpar, 2018; Schott, Vetter, Keller, et al., 2017). Prophylactic surgery is discussed with patients and families along with other approaches for managing increased risk of cancer development. Preoperative education and counseling, as well as long-term follow-up, are provided.

Palliative Surgery

The overall goal of palliative surgery in cancer care is to relieve symptoms and to improve the patient's quality of life (Fahy, 2019; Hanna, Blazer, & Mosca, 2012). Palliative surgery is often performed in an attempt to relieve symptoms such as ulceration, obstruction, hemorrhage, pain, and malignant effusions (see Table 12-6). When surgical cure is not possible, honest and informative communication with the patient and family about the goal of palliative surgery is essential to avoid false hope and disappointment. In certain cases, however, surgical intervention with palliative intent may also be performed as a supportive treatment to relieve symptoms along with other potentially curative cancer treatments (Fahy, 2019; Hanna et al., 2012). Thus, the role of palliative surgery today is no longer limited to end-of-life care.

Reconstructive Surgery

Reconstructive surgery may follow curative or extensive surgery in an attempt to improve function or obtain a more desirable cosmetic effect. It may be performed in one operation or in stages. The surgeon who will perform the surgery discusses possible reconstructive surgical options with the patient before the primary surgery is performed. Reconstructive surgery may be indicated for breast, head and neck, and skin cancers.

The nurse assesses the patient's needs and the impact that altered functioning and body image may have on quality of life. Nurses provide patients and families with opportunities to discuss these issues. The individual needs of the patient undergoing reconstructive surgery and their families must be accurately recognized and addressed.

Nursing Management

Patients undergoing surgery for cancer require general perioperative nursing care (see Chapters 14, 15, and 16). Surgical care is individualized according to age, organ impairment, specific deficits, comorbidities, cultural implications, and altered immunity. Combining other treatment methods, such as radiation and

chemotherapy, with surgery also contributes to postoperative complications, such as infection, impaired wound healing, altered pulmonary or renal function, and the development of venous thromboembolism (VTE). The nurse completes a thorough preoperative assessment for factors that may affect the patient undergoing the surgical procedure.

Preoperatively, the nurse provides the patient and family with verbal and written information about the surgical procedure as well as other interventions that may take place intraoperatively (e.g., radiation implants). Instructions concerning prophylactic antibiotic requirements, diet, and bowel preparation are also provided.

Patients who are undergoing surgery for the diagnosis or treatment of cancer may be anxious about the surgical procedure, possible findings, postoperative limitations, changes in normal body functions, and prognosis. The patient and family require time and assistance to process this information, possible changes, and expected outcomes resulting from the surgery.

The nurse serves as the patient advocate and liaison and encourages the patient and family to take an active role in decision making when possible. If the patient or family asks about the results of diagnostic testing and surgical procedures, the nurse's response is guided by the information that was conveyed previously. The nurse may be asked to explain and clarify information for patients and families that was provided initially but was not grasped because of intense anxiety. It is important that the nurse, as well as other members of the health care team, provide information that is consistent.

Postoperatively, the nurse assesses patient responses to surgery and monitors the patient for possible complications, such as infection, bleeding, thrombophlebitis, wound dehiscence, fluid and electrolyte imbalance, and organ dysfunction. The nurse also provides for the patient's comfort. Postoperative education addresses wound care, pain management, activity, nutrition, and medication information.

Plans for discharge, follow-up, home care, and subsequent treatment and rehabilitation are initiated as early as possible to ensure continuity of care from hospital to home or from a cancer referral center to the patient's local hospital and health care provider. Patients and families are encouraged to use community resources such as the ACS for support and information (see the Resources section at the end of this chapter).

Radiation Therapy

Approximately 60% of patients with cancer receive **radiation therapy** at some point during treatment (Halperin, Wazer, Perez, et al., 2019). Radiation may be used to cure cancer, as in thyroid carcinomas, localized cancers of the head and neck, and cancers of the cervix. Radiation therapy may also be used to control cancer when a tumor cannot be removed surgically or when local nodal metastasis is present. Neoadjuvant (prior to local definitive treatment) radiation

therapy, with or without chemotherapy, is used to reduce tumor size in order to facilitate surgical resection. Radiation therapy may be given prophylactically to prevent local recurrence or spread of microscopic cells from the primary tumor to a distant area (e.g., irradiating the breast and axilla following lumpectomy or mastectomy for breast cancer). Palliative radiation therapy is used to relieve the symptoms of locally advanced or metastatic disease, especially when the cancer has spread to the brain, bone, or soft tissue, or to treat oncologic emergencies, such as superior vena cava syndrome, bronchial airway obstruction, or spinal cord compression.

Two types of ionizing radiation—electromagnetic radiation (x-rays and gamma rays) and particulate radiation (electrons, beta particles, protons, neutrons, and alpha particles)—can be used to kill cells. The most lethal damage is the direct alteration of the DNA molecule within the cells of both malignant and normal tissues. Ionizing radiation can directly break the strands of the DNA helix, leading to cell death. It can also indirectly damage DNA through the formation of free radicals. If the DNA cannot be repaired, the cell may die immediately or may initiate apoptosis (Yarbro et al., 2018).

Replicating cells are most vulnerable to the disruptive effects of radiation (during DNA synthesis and mitosis, e.g., early S, G_2, and M phases of the cell cycle; see Fig. 12-2). Therefore, those body tissues that undergo frequent cell division are most sensitive to radiation therapy. These tissues include bone marrow, lymphatic tissue, epithelium of the gastrointestinal tract, hair follicles, and gonads. Slower-growing tissues and tissues at rest (e.g., muscle, cartilage, nervous system, connective tissues) are relatively radioresistant (less sensitive to the effects of radiation). However, it is important to remember that radiation therapy is localized treatment, and only the tissues that are within the treatment field are affected.

A radiosensitive tumor is one that can be destroyed by a dose of radiation that still allows for cell repair and regeneration in the surrounding normal tissue. If the radiation is delivered when most tumor cells are cycling through the cell cycle, the number of cancer cells destroyed (cell kill) is maximal. Radiation sensitivity is enhanced in tumors that are smaller in size and that contain cells that are rapidly dividing (highly proliferative) and poorly differentiated (no longer resembling the tissue of origin).

Radiation Dosage

The radiation dosage depends on the sensitivity of the target tissues to radiation, the size of the tumor, radiation tolerance of the surrounding normal tissues, and critical structures adjacent to the tumor target. The lethal tumor dose is defined as the dose that will eradicate 95% of the tumor yet preserve normal tissue. In external-beam radiation therapy (EBRT), the total radiation dose is delivered over several weeks in daily doses called *fractions*. This allows healthy tissue to repair and achieves greater cell kill by exposing more cells to the radiation as

they begin active cell division. Repeated radiation treatments over time (fractionated doses) also allow for the periphery of the tumor to be reoxygenated repeatedly, because tumors shrink from the outside inward. This increases the radiosensitivity of the tumor, thereby increasing tumor cell death (Morgan, Ten Haken, & Lawrence, 2018). Newer approaches take advantage of increased radiation beam conformality (better tumor targeting) to administer radiation in fewer doses with larger fractions sizes (hypo-fractionation and stereotactic body radiotherapy [SBRT]).

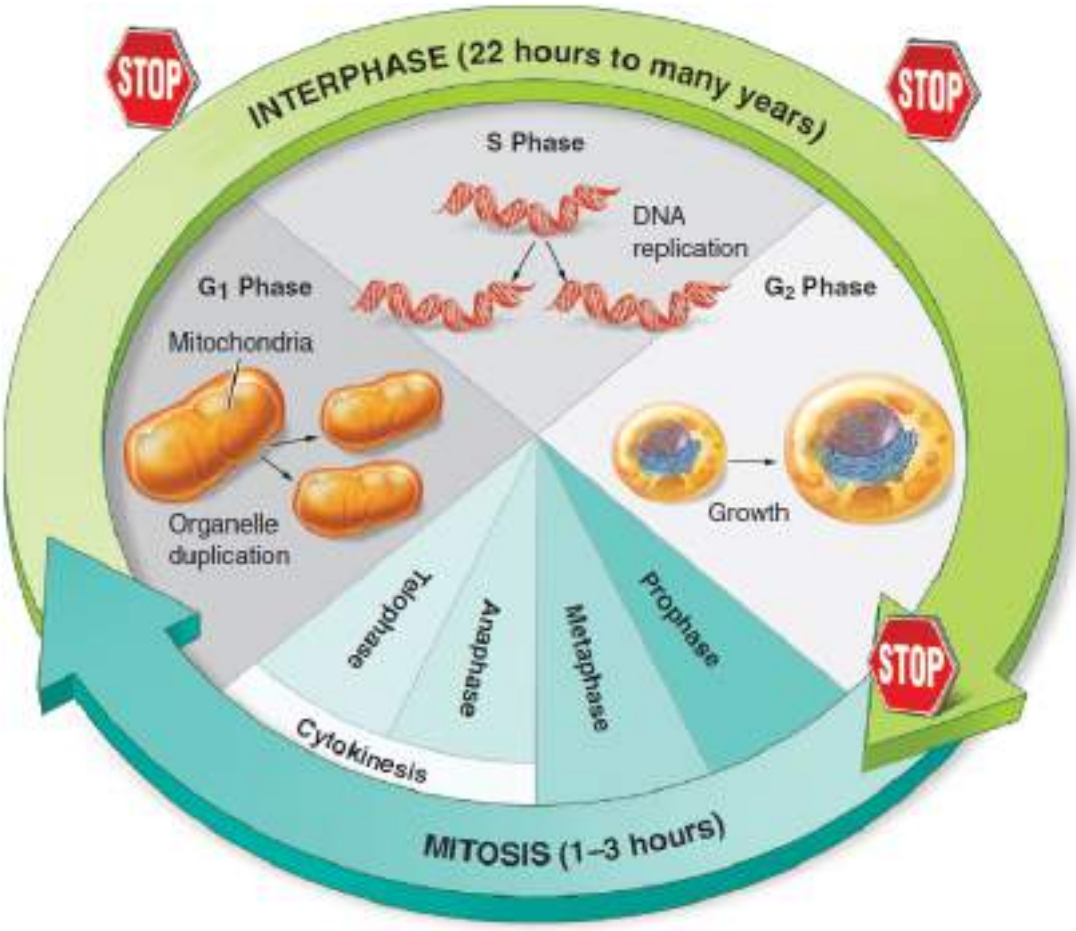

Figure 12-2 • Cell cycle. The cell cycle's four steps are illustrated beginning with G_1 and proceeding to M. The first growth phase (G_1), DNA synthesis phase (S), second growth phase ($G_{2)}$, and mitosis (M) are illustrated. Reprinted with permission from Grossman, S. G., & Porth, C. M. (2014). *Porth's pathophysiology: Concepts of altered health states* (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Administration of Radiation

Radiation therapy can be given in various ways depending on the source of radiation used, the location of the tumor, and the type of cancer. The primary

radiotherapy modalities include EBRT, **brachytherapy** (a form of internal radiation), systemic (radioisotopes), and contact or surface molds.

External Radiation

EBRT is the most commonly used form of radiation therapy. The energy utilized in EBRT is generated either from a linear accelerator or from a unit that generates energy directly from a core source of radioactive material such as a GammaKnife™ unit. Through computerized software programs, both approaches can shape an invisible beam of highly charged photons or gamma rays to penetrate the body and target the tumor with pinpoint accuracy.

Advances in computer technology allow multiple imaging modalities (CT, MRI, and PET scans) to be used to provide three-dimensional images of the tumor, neighboring tissues at risk for microscopic spread, and surrounding normal tissues or organs at risk for radiation-induced injury. These images, referred to as volumetric images, allow the radiation oncologist to plan for multiple radiation beams directed from different angles and different planes so that the beams conform precisely around the tumor (referred to as conformal radiation). The dose of radiation that reaches the surrounding normal tissues is reduced, leading to much less tissue injury than in older forms of radiation therapy (Halperin et al., 2019). Treatment enhancements in EBRT include the ability to control different intensity or energy levels of radiation beams at different angles directed at the tumor, a process known as intensity-modulated radiation therapy (IMRT), which enables higher doses to be delivered to the tumor while sparing the important healthy structures surrounding the tumor (Halperin et al., 2019). IMRT can be given as standard daily fractions or as "hyperfractionated" twice-daily fractions, which shortens the duration of the patient's treatment schedule. Image-guided radiation therapy (IGRT) uses continuous monitoring of the tumor with ultrasound, x-ray, or CT scans during the treatment to allow for automatic adjustment of the beams as the tumor changes shape or position in an effort to spare the healthy surrounding tissue and reduce side effects. Additional treatment enhancements include respiratory gating, where the treatment delivery is synchronized with the patient's respiratory cycle, enabling the beam to be adjusted as the tumor or organ moves. These treatment advancements improve tumor destruction while reducing acute and long-term toxicities (Halperin et al., 2019).

Gamma rays generated from the spontaneous decay of naturally occurring solid source of radioactivity, such as cobalt-60, are one of the oldest forms of EBRT. With the advent of modern linear accelerators, the use of solid radioactive elements is confined primarily to the GammaKnife™ stereotactic radiosurgery unit, which is used as a one-time, high-dose delivery of EBRT for treatment of both benign and malignant intracranial lesions.

SBRT is another form of EBRT that uses higher doses of radiation to penetrate very deeply into the body to control deep-seated tumors that cannot be treated by other approaches such as surgery. SBRT is delivered with

considerably higher treatment fraction doses over a short span of time, usually 1 to 5 treatment days, in contrast to daily treatments for 5 days per week for 6 to 8 weeks for conventional EBRT. Specialized linear accelerators with the capability of robotically moving around the patient are used to deliver SBRT, such as the CyberKnife™, Trilogy™, and TomoTherapy™ delivery systems, which are now more commonly available.

Proton therapy is another approach to EBRT. Proton therapy utilizes high linear energy transfer (LET) in the form of charged protons generated by a large magnetic unit called a *cyclotron.* The advantage of proton therapy is that it is capable of delivering its high-energy dose to a deep-seated tumor, with decreased doses of radiation to the tissues in front of the tumor while virtually no energy exits through the patient's healthy tissue behind the tumor (Halperin et al., 2019). Proton therapy permits treatment of deep tumors near critical structures, such as the heart or major blood vessels.

Internal Radiation

Internal radiation includes localized implantation or systemic radionuclide administration. Brachytherapy delivers the dose of radiation to a localized area while systemic radiotherapy relies on strategies for getting the radionuclides closer to the tumor. The specific radioisotope used is selected based on its half-life, which is the time it takes for half of its radioactivity to decay, and the depth of penetration of the radiation.

Brachytherapy

Brachytherapy is the placement of radioactive sources within or immediately next to the cancer site in order to provide a highly targeted, intense dose of radiation beyond a dose that is usually provided by EBRT. In addition, this form of radiation delivery helps to spare exposure to normal surrounding tissue. The radiation source can be implanted by means of needles or rods, seeds, beads, ribbons, or catheters placed into body cavities (vagina, abdomen, pleura), lumens within organs, or interstitial tissue compartments (breast, prostate). Multiple imaging techniques such as ultrasound, CT, or MRI are used to guide placement of radiation sources. Patients may have many fears or concerns about internal radiation, and the nurse explains the various approaches and safety precautions that will be used to protect the patient, family, and health care staff.

Brachytherapy may be delivered as a temporary or a permanent implant. Temporary applications are delivered as high-dose radiation (HDR) for short periods of time, while low-dose radiation (LDR) is delivered over a more extended period. The primary advantage of HDR brachytherapy is that treatment time is shorter, there is reduced exposure to personnel, and the procedure can be performed on an outpatient basis over several days. HDR brachytherapy can be used for intraluminal, surface, interstitial, and intracavitary lesions. Intraluminal HDR brachytherapy involves the insertion of catheters or hollow tubes into the lumens of organs so that the radioisotope can be delivered as close to the tumor

bed as possible. Lesions in the bronchus, esophagus, rectum, or bile duct can be treated with this approach. Contact or surface application is used for treatment of tumors of the eye, such as retinoblastoma in children or ocular melanoma in adults.

Interstitial HDR implants, used in treating such malignancies as prostate, pancreatic, or breast cancer, may be temporary or permanent, depending on the site and radioisotope used. Based on the dose to be delivered (LDR or HDR), the implants may consist of seeds, needles, wires, strands, or small catheters positioned to provide a local radiation source. Prostate HDR therapy is one form of interstitial brachytherapy, in which radioactive strands or wires are placed, while the patient is under anesthesia, into hollow catheters that have been inserted in the perineum close to the prostate gland (Halperin et al., 2019).

Intracavitary radioisotopes are used to treat gynecologic cancers. In these malignancies, the radioisotopes are inserted into specially positioned applicators within the vagina. The applicator placement is verified by x-ray. Treatment can be achieved with either HDR or LDR brachytherapy sources, depending on the extent of disease. LDR therapy requires hospitalization because the patient is treated over several days. HDR intraoperative radiotherapy (IORT) has been used as a treatment approach for advanced gynecologic cancer that has spread to the paraaortic area or pelvic wall (Krengli, Pisani, Deantonio, et al., 2017).

Systemic radiotherapy (radiopharmaceutical therapy) involves oral or intravenous (IV) administration of a therapeutic radioactive isotope targeted to a specific tumor. Radioactive iodine (I-131) is a widely used form of systemic brachytherapy that is the primary treatment for thyroid cancer (Divgi, 2018). Radium-223 dichloride selectively targets prostate cancer bone metastases with high-energy, short-range alpha particles and is approved for the treatment of patients with symptomatic bone metastases and no known visceral metastatic disease (NCCN, 2019f). Radioisotopes are also used as a form of radioimmunotherapy for the treatment of refractory non-Hodgkin lymphoma (see Chapter 30 for more information on lymphoma).

Toxicity

A **toxicity** is an unfavorable and unintended sign, symptom, or condition associated with cancer treatment. Toxicities associated with radiation therapy are most often localized in the region being irradiated and may be increased if concomitant chemotherapy is given (Yarbro et al., 2018). Acute or early toxicities most often begin within 2 weeks of the initiation of treatment and occur when normal cells within the treatment area are damaged and cellular death exceeds regeneration. Body tissues most affected are those that normally proliferate rapidly, such as the skin, the epithelial lining of the gastrointestinal tract, and the bone marrow.

Altered skin integrity is common and can include **alopecia** (hair loss) associated with whole brain radiation. Other skin reactions, referred to as

radiodermatitis, occur along a continuum ranging from erythema and dry desquamation (flaking of skin) to moist or wet desquamation (dermis exposed, skin oozing serous fluid) to, potentially, ulceration. Factors that contribute to the severity of radiodermatitis include the dose and form of radiation; use of concurrent chemotherapy, immunotherapy, or targeted therapy; inclusion of skin folds in the irradiated area; increased age, poor nutritional status, chronic sun exposure, current smoking status, and the presence of medical comorbidities, such as diabetes or kidney failure (Yarbro et al., 2018). Symptoms of radiodermatitis may necessitate treatment interruption, delays, or cessation of therapy. Re-epithelialization occurs after treatments have been completed. Hyperpigmentation, a less severe radiation-associated skin reaction, may develop about 2 to 4 weeks after the initiation of treatment.

Alterations in oral mucosa secondary to radiation therapy in the head and neck region include stomatitis (inflammation of the oral tissues), decreased salivation and xerostomia (dryness of the mouth), and change in or loss of taste. Depending on the targeted region, any portion of the gastrointestinal mucosa may be involved, causing **mucositis** (inflammation of the lining of the mouth, throat, and gastrointestinal tract). For example, patients receiving thoracic irradiation for lung cancer may experience acute esophageal irritation—associated chest pain and dysphagia. Anorexia, nausea, vomiting, and diarrhea may occur if the stomach or colon is in the radiation field. Symptoms subside and gastrointestinal re-epithelialization occurs after treatments have been completed. Bone marrow cells proliferate rapidly, and if sites containing bone marrow (e.g., the iliac crest or sternum) are included in the radiation field, anemia, leukopenia (decreased white blood cells [WBCs]), and thrombocytopenia (a decrease in platelets) may result. The patient is then at increased risk for infection and bleeding until blood cell counts return to normal.

Systemic side effects are commonly experienced by patients receiving radiation therapy. These include fatigue, malaise, and anorexia that may be secondary to biochemical mediators released when tumor cells are destroyed. Fatigue is commonly reported as one of the most distressing cancer-related symptoms. According to Kessels, Husson, and Van Der Feltz-Cornelis (2018), up to 99% of patients with cancer undergoing radiation therapy will experience fatigue. Additionally, patients often report increased severity of fatigue when radiation therapy is used along with other cancer treatments. These early effects tend to be temporary and most often subside within 6 months of the cessation of treatment.

Late effects (approximately 6 months to years after treatment) of radiation therapy may occur in body tissues that were in the field of radiation. These effects are chronic, usually a result of permanent damage to tissues, loss of elasticity, and changes secondary to a decreased vascular supply. Severe late effects include fibrosis, atrophy, ulceration, and necrosis and may affect the lungs, heart, central nervous system, and bladder. With advances in treatment planning and the accuracy of treatment delivery, the occurrence of late toxicities

has diminished. However, late or chronic symptoms, such as dysphagia, incontinence, cognitive impairment, and sexual dysfunction, may persist for several years with implications for survivors' overall health and quality of life (Kessels et al., 2018).

Nursing Management

Nurses anticipate, prevent, and work collaboratively with other providers to manage symptoms associated with radiation therapy in order to promote healing, patient comfort, and quality of life. Symptoms that are not appropriately managed may lead to poor outcomes as a result of interruptions, decreased doses, or early cessation of treatment (Lazarev, Gupta, Ghiassi-Nejad, et al., 2018; Wagner, Zhao, Goss, et al., 2018).

Ideally, nurses consider factors that may be predictive of radiation toxicities or radiosensitivity of tissues. In particular, advanced age, elevated radiation dose, and BMI have been associated with greater toxicity and symptoms (O'Gorman, Sasiadek, Denieffe, et al., 2015). The nature of the relationship between body mass index (BMI) and radiation toxicities is less clear. For example, a decreased BMI was found to be associated with an increased incidence of toxicities in women with cervical cancer (Rubinsak, Kang, Fields, et al., 2018); whereas, an increased BMI (obesity) was associated with increased incidence of late toxicities in men being treated for prostate cancer (Akthar, Liao, Eggener, et al., 2019). Consequently, the area of the body being irradiated must be used as the focus of nursing assessments of radiation toxicities.

In patients receiving EBRT, the nurse assesses the patient's skin, nutritional status, and general feelings of well-being throughout the course of treatment. Evidence-based protocols for nursing management of the toxicities associated with radiation therapy are used. If systemic symptoms such as fatigue occur the nurse explains that these symptoms are a result of the treatment and do not represent deterioration or progression of the disease. The nurse should recommend evidence-based interventions for the management of fatigue, which should include aerobic exercise, which is most effective when adherence is high (Kessels et al., 2018).

Protecting Caregivers

When the patient has a radioactive implant in place, the nurse and other health care providers need to protect themselves, as well as the patient, from the effects of radiation. Patients receiving internal radiation emit radiation while the implant is in place; therefore, contact with the health care team is guided by principles of time, distance, and shielding to minimize exposure of personnel to radiation. Specific instructions are provided by the radiation safety officer from the radiology department and specify the maximum time that can be spent safely in the patient's room, the shielding equipment to be used, and special precautions

and actions to be taken if the implant is dislodged (Halperin et al., 2019). Safety precautions used in caring for a patient receiving brachytherapy include assigning the patient to a private room, posting appropriate notices about radiation safety precautions, having staff members wear dosimeter badges, making sure that pregnant staff members are not assigned to the patient's care, prohibiting visits by children or pregnant visitors, limiting visits from others to 30 minutes daily, and seeing that visitors maintain a 6-foot distance from the radiation source.

Patients with seed implants typically return home; radiation exposure to others is minimal. Information about any precautions, if needed, is provided to the patient and family members to ensure safety. Depending on the dose and energy emitted by a systemic radionuclide, patients may or may not require special precautions or hospitalization (Halperin et al., 2019). The nurse should explain the rationale for these precautions to keep the patient from feeling unduly isolated.

Chemotherapy

Chemotherapy involves the use of antineoplastic drugs in an attempt to destroy cancer cells by interfering with cellular functions, including replication and DNA repair (Norris, 2019). Chemotherapy is used primarily to treat systemic disease rather than localized lesions that are amenable to surgery or radiation. Chemotherapy may be combined with surgery, radiation therapy, or both to reduce tumor size preoperatively (neoadjuvant), to destroy any remaining tumor cells postoperatively (adjuvant), or to treat some forms of leukemia or lymphoma (primary). The goals of chemotherapy (cure, control, or palliation) must be realistic because they will determine the medications that are used and the aggressiveness of the treatment plan.

Cell Kill and the Cell Cycle

Each time a tumor is exposed to chemotherapy, a percentage of the tumor cells (20% to 99%, depending on dosage and agent) are destroyed. Repeated doses of chemotherapy are necessary over a prolonged period to achieve regression of the tumor. Eradication of 100% of the tumor is almost impossible; the goal of treatment is eradication of enough of the tumor so that the remaining malignant cells can be destroyed by the body's immune system (Norris, 2019).

Actively proliferating cells within a tumor are the most sensitive to chemotherapy (the ratio of dividing cells to resting cells is referred to as the growth fraction). Nondividing cells capable of future proliferation are the least sensitive to antineoplastic medications and consequently are potentially dangerous. However, the nondividing cells must be destroyed to eradicate the disease. Repeated cycles of chemotherapy or sequencing of multiple

chemotherapeutic agents is used to achieve more tumor cell destruction by destroying the nondividing tumor cells as they begin active cell division.

Reproduction of both healthy and malignant cells follows the cell cycle pattern (see Fig. 12-2). All cells in the body (healthy and malignant) are affected by chemotherapy. The effect of chemotherapy on the body's cells is best described in relation to the cell cycle. The cell cycle time is the time required for one cell to divide and reproduce two identical daughter cells. The cell cycle of any cell has four distinct phases, each with a vital underlying function (Norris, 2019):

- G_1 phase—RNA and protein synthesis occurs
- S phase—DNA synthesis occurs
- G_2 phase—premitotic phase; DNA synthesis is complete, mitotic spindle forms
- Mitosis—duplicated chromosomes separate, and cell division occurs

Classification of Chemotherapeutic Agents

Chemotherapeutic agents may be classified by their mechanism of action in relation to the cell cycle. Agents that exert their maximal effect during specific phases of the cell cycle are termed *cell cycle–specific agents* (e.g., docetaxal, vinblastine, etoposide). These agents destroy cells that are actively reproducing by means of the cell cycle; most affect cells in the S phase by interfering with DNA and RNA synthesis. Other agents, such as plant alkaloids, are specific to the M phase, where they halt mitotic spindle formation. Chemotherapeutic agents that act independently of the cell cycle phases are termed *cell cycle–nonspecific agents* (e.g., busulfan, cisplatin, bleomycin). These agents usually have a prolonged effect on cells, leading to cellular damage or death. Many treatment plans combine agents that target different phases of the cell cycle to increase the number of vulnerable tumor cells killed during a treatment period (Dickens & Ahmed, 2018).

Chemotherapeutic agents are also classified by chemical group, each with a different mechanism of action. These include the alkylating agents, nitrosoureas, antimetabolites, antitumor antibiotics, topoisomerase inhibitors, plant alkaloids (also referred to as mitotic inhibitors), hormonal agents, and miscellaneous agents. The classification, mechanism of action, cell cycle specificity, and common side effects of select antineoplastic agents are listed in Table 12-7.

Chemotherapeutic agents from multiple categories may be used together to maximize cell destruction. Combination chemotherapy relies on agents with varying mechanisms, potential synergistic actions, and differing toxicities. The use of combination therapy also helps prevent the development of drug-resistant cells (Dickens & Ahmed, 2018).

Adjunct Chemotherapeutic Agents

In certain regimens, additional medications are given with chemotherapy agents to enhance activity or protect normal cells from injury. For example, leucovorin is often given with fluorouracil to treat colorectal cancer. Leucovorin, a compound similar to folic acid, helps fluorouracil bind with an enzyme inside of cancer cells and enhances the ability of fluorouracil to remain in the intracellular environment. Leucovorin also rescues normal cells from the toxic effects of high doses of methotrexate. When given at certain doses for the treatment of some forms of leukemia or lymphoma, methotrexate causes a folic acid deficiency in cells, resulting in cell death. Significant toxicity, including severe bone marrow suppression, mucositis, diarrhea and liver, and lung and kidney damage, can occur. Leucovorin helps to prevent or lessen these toxicities.

Administration of Chemotherapeutic Agents

Chemotherapy may be given in the hospital, outpatient center, or home setting by multiple routes. The route of administration depends on the type of agent; the required dose; and the type, location, and extent of malignant disease being treated. Standards for the safe administration of chemotherapy have been developed by the Oncology Nursing Society (ONS) and the American Society of Clinical Oncology (ASCO) (Neuss, Gilmore, Belderson, et al., 2017). Patient education is essential to maximize safety when chemotherapy is given in the home.

Dosage

The dosage of chemotherapeutic agents is based primarily on the patient's total body surface area, weight, previous exposure and response to chemotherapy or radiation therapy, and function of major organ systems. Dosages are determined to maximize cell kill while minimizing impact on healthy tissues and subsequent toxicities. The therapeutic effect may be compromised if modified and inadequate dosing is required due to toxicities. Modification of dosage is often required if critical laboratory values or the patient's symptoms indicate unacceptable or dangerous toxicities. Chemotherapy treatment regimens include standard-dose therapy, dose-dense regimens (giving chemotherapy more frequently than standard treatment regimens), and myeloablative therapy for HSCT. For certain chemotherapeutic agents, there is a maximum lifetime dose limit that must be adhered to because of the danger of long-term irreversible organ complications (e.g., because of the risk of cardiomyopathy, doxorubicin has a cumulative lifetime dose limit of 550 mg/m^2).

Extravasation

Intravenously administered chemotherapy agents are additionally classified by their potential to damage tissue if they inadvertently leak from a vein into surrounding tissue; this leakage is called **extravasation**. The consequences of extravasation range from mild discomfort to severe tissue destruction, depending

on whether the agent is classified as an irritant or vesicant. Irritant agents induce a localized inflammatory reaction at the infusion or injection site, but usually do not cause permanent tissue damage (Olsen, LeFebvre, & Brassil, 2019).

Unlike irritants, **vesicants** are agents that cause inflammation, tissue damage, and possibly necrosis of tendons, muscles, nerves, and blood vessels if extravasation occurs (Olsen et al., 2019). Although the mechanism of vesicant actions varies with each drug, some agents bind to cell DNA and cause cell death that progresses to involve neighboring cells, whereas other agents are metabolized into cells and cause a localized, painful reaction that usually improves over time. Sloughing and ulceration of the tissue may progress to tissue necrosis that is so severe that skin grafting becomes necessary. The full extent of tissue damage may take several weeks to become apparent. Examples of commonly used agents classified as vesicants include dactinomycin, daunorubicin, doxorubicin, nitrogen mustard, mitomycin, vinblastine, and vincristine. Chemotherapy administration safety standards require the availability of defined extravasation management procedures, including antidote order sets and accessibility of antidotes in all settings where vesicant chemotherapy is given (Neuss et al., 2017; Olsen et al., 2019).
