Chemotherapy is given only by those who have the knowledge and established competencies for vesicant and extravasation management (Neuss et al., 2017; Olsen et al., 2019). Prevention and management of extravasation are essential. Vesicant chemotherapy should never be given in peripheral veins involving the hand or wrist. Peripheral administration is permitted for short-duration infusions only, and placement of the venipuncture site should be on the forearm area using a soft, plastic catheter. For any frequent or prolonged administration of antineoplastic vesicants, right atrial silastic catheters, implanted venous access devices, or peripherally inserted central catheters (PICCs) should be inserted to promote safety during medication administration and reduce problems with access to the circulatory system (Figs. 12-3 and 12-4).

Hypersensitivity Reactions

Although hypersensitivity reactions (HSRs) can occur with any medication, many chemotherapy agents pose a high risk and have been associated with life-threatening outcomes (Olsen et al., 2019). HSRs are a subgroup of adverse drug reactions that are unexpected and associated with mild or progressively worsening signs and symptoms, such as rash, urticaria, fever, hypotension, cardiac instability, dyspnea, wheezing, throat tightness, and syncope. Immediate HSRs may appear within 5 minutes and up to 6 hours of an infusion. Delayed HSRs may occur after the completion of the infusion. Although patients may or may not react to the first infusion of a chemotherapy agent, repeated exposure increases the likelihood of a reaction.

TABLE 12-7 Select Antineoplastic Agents

Drug Class and Examples	Mechanism of Action	Cell Cycle Specificity	Common Side Effects
Alkylating Agents			
Busulfan, carboplatin, chlorambucil, cisplatin, cyclophosphamide, dacarbazine, altretamine ifosfamide, melphalan, nitrogen mustard, oxaliplatin, thiotepa	Bond with DNA, RNA, and protein molecules leading to impaired DNA replication, RNA transcription, and cell functioning; all resulting in cell death	Cell cycle—nonspecific	Bone marrow suppression, nausea, vomiting, cystitis (cyclophosphamide, ifosfamide), stomatitis, alopecia, gonadal suppression, renal toxicity (cisplatin), and development of secondary malignancies
Nitrosoureas			
Carmustine, lomustine or CCNU, semustine, streptozocin	Similar to alkylating agents; cross the blood–brain barrier	Cell cycle—nonspecific	Delayed and cumulative myelosuppression, especially thrombocytopenia; nausea, vomiting, pulmonary, hepatic, and renal damage
Topoisomerase I Inhibitors			
Irinotecan Topotecan ***Topoisomerase II Inhibitors*** Etoposide Teniposide	Induce breaks in the DNA strand by binding to enzyme topoisomerase, preventing cells from dividing	Cell cycle—specific (S phase)	Bone marrow suppression, diarrhea, nausea, vomiting, flulike symptoms (topotecan), rash (etoposide), hepatotoxicity (teniposide)
Antimetabolites			
5-Azacytidine, capecitabine, cytarabine, edatrexate fludarabine, 5-fluorouracil (5-FU), gemcitabine, hydroxyurea, cladribine, 6-mercaptopurine, methotrexatepentostatin, 6-thioguanine	Interferes with the biosynthesis of metabolites or nucleic acids necessary for RNA and DNA synthesis; inhibits DNA replication and repair	Cell cycle—specific (S phase)	Nausea, vomiting, diarrhea, bone marrow suppression, stomatitis, renal toxicity (methotrexatepentostatin), hepatotoxicity (6-thioguanine), hand-foot syndrome (capecitibine)
Antitumor Antibiotics			
Bleomycin, dactinomycin, daunorubicin, doxorubicin, epirubicin, idarubicin, mitomycin,	Interfere with DNA synthesis by binding DNA;	Cell cycle—nonspecific	Bone marrow suppression, nausea, vomiting, alopecia, anorexia, cardiac toxicity

mitoxantrone, plicamycin	prevent RNA synthesis		(daunorubicin, doxorubicin), red urine (doxorubicin, idarubicin, epirubicin), pulmonary fibrosis (bleomycin)
Mitotic Spindle Inhibitors			
Plant alkaloids: vinblastine, vincristine, vinorelbine	Arrest metaphase by inhibiting mitotic tubular formation (spindle); inhibit DNA and protein synthesis	Cell cycle—specific (M phase)	Bone marrow suppression (mild with vincristine), peripheral neuropathies, nausea and vomiting
Taxanes: paclitaxel, docetaxel	Arrest metaphase by inhibiting tubulin depolymerization	Cell cycle—specific (M phase)	Hypersensitivity reactions, bone marrow suppression, alopecia, peripheral neuropathies, mucositis
Epothilones: ixabepilone	Alters microtubules and inhibits mitosis	Cell cycle—specific (M phase)	Peripheral neuropathies, bone marrow suppression, hypersensitivity reactions, hepatic impairment
Hormonal Agents			
Androgens and antiandrogens, estrogens and antiestrogens, progestins and antiprogestins, aromatase inhibitors, luteinizing hormone-releasing hormone analogues, steroids	Bind to hormone receptor sites that alter cellular growth; block binding of estrogens to receptor sites (antiestrogens); inhibit RNA synthesis; suppress cytochrome P450 system	Cell cycle—nonspecific	Hypercalcemia, jaundice, increased appetite, masculinization, feminization, sodium and fluid retention, nausea, vomiting, hot flashes, vaginal estrogen dryness
Miscellaneous Agents			
Asparaginase, procarbazine	Inhibits protein, DNA, and RNA synthesis	Varies	Anorexia, nausea, vomiting, bone marrow suppression, hepatotoxicity, hypersensitivity reaction, pancreatitis
Arsenic trioxide	Causes fragmentation of DNA resulting in cell death; in acute promyelocytic leukemia, it		Nausea, vomiting, electrolyte imbalances, fever, headache, cough, dyspnea, electrocardiogram abnormalities

	corrects protein changes and changes malignant T–cells into normal white blood cells.

DNA, deoxyribonucleic acid; RNA, ribonucleic acid.

(2017). 2016 updated American Society of Clinical Oncology/Oncology Nursing Society chemotherapy administration safety standards, including standards for pediatric oncology. *Oncology Nursing Forum*, *44*(1), 31–43.

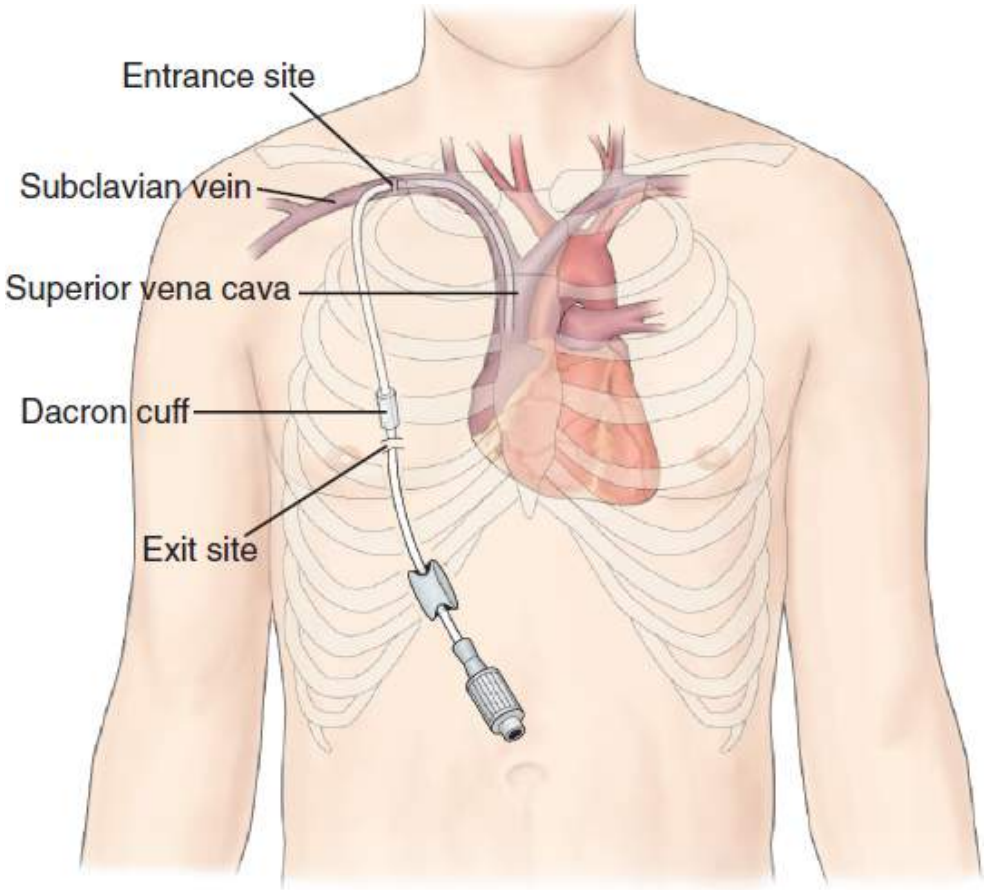

Figure 12-3 • Right atrial catheter. The right atrial catheter is inserted into the subclavian vein and advanced until its tip lies in the superior vena cava just above the right atrium. The proximal end is then tunneled from the entry site through the subcutaneous tissue of the chest wall and brought out through an exit site on the chest. The Dacron cuff anchors the catheter in place and serves as a barrier to infection.

Most immediate HSRs are immunoglobulin E (IgE)-mediated reactions—an allergic reaction (Olsen et al., 2019). Examples of agents that may cause an

allergic, IgE-mediated response include carboplatin, oxaliplatin, and L-asparaginase. However, some HSRs, such as anaphylactoid reactions, are non–IgE-mediated (nonallergic) and a result of cytokine release syndrome (CRS). Rituximab and cetuximab are examples of agents associated with non–IgE-mediated (nonallergic) HSRs. When signs and symptoms of HSR occur, the medication should be discontinued immediately, and emergency procedures initiated. Many institutions have developed specific protocols for responding to HSRs, including standing orders for administration of emergency medications (Roselló, Blasco, García Fabregat, et al., 2017). (See Chapter 33 for further discussion of allergic reactions.)

For some chemotherapeutic agents, especially if they are essential in the treatment plan, desensitization procedures may be possible, and the patient is retreated with the agent at reduced dosages or slower infusion rates. Premedication regimens are used for certain chemotherapy agents to prevent or minimize reactions.

Toxicity

Toxicity associated with chemotherapy can be acute or chronic. Cells with rapid growth rates (e.g., epithelium, bone marrow, hair follicles, sperm) are very susceptible to damage, and the effects may manifest in virtually any body system.

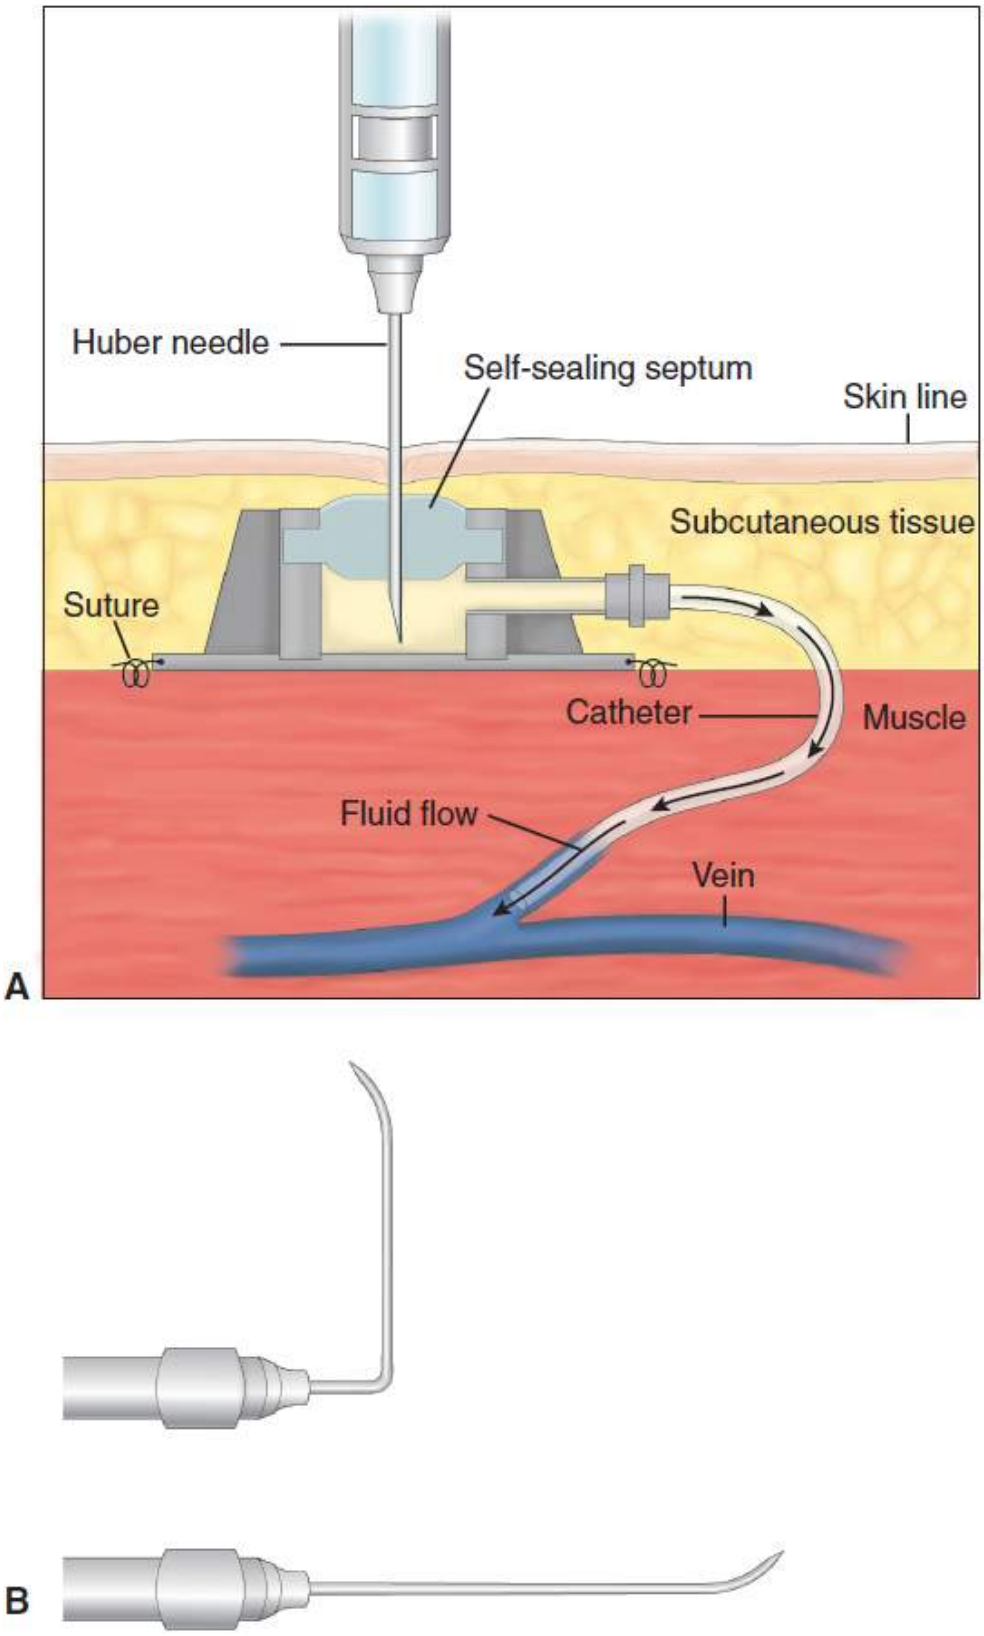

Figure 12-4 • Implanted vascular access device. **A.** A schematic diagram of an implanted vascular access device used for administration of medications, fluids, blood products, and nutrition. The self-sealing septum permits repeated puncture by Huber needles without damage or leakage. **B.** Huber needles used to enter the

implanted vascular port. The 90-degree needle is used for top-entry ports for continuous infusions.

Gastrointestinal System

The most common side effects of chemotherapy are nausea and vomiting, which may persist for 24 to 48 hours; delayed nausea and vomiting may occur up to 1 week after administration. The experience of chemotherapy-induced nausea and vomiting (CINV) may affect quality of life, psychological status, nutrition, fluid and electrolyte status, functional ability, compliance with treatment, and utilization of health care resources (Natale, 2018). Comorbidities, the underlying malignancy, other treatment modalities, and medications, as well as symptoms (e.g., pain), may contribute to CINV. Acute CINV is experienced in the first 24 hours after chemotherapy with a maximal intensity after 5 to 6 hours; delayed CINV occurs 24 hours posttreatment and may last as many as 7 days with a maximal intensity 48 to 72 hours after drug administration (anticipatory nausea and vomiting, occurring prior to administration of chemotherapy, may be a conditioned response triggered by a stimulus such as the smell of the infusion setting, the sight of the nurse, or the outpatient center waiting room) (Olsen et al., 2019).

Several mechanisms are responsible for the occurrence of nausea and vomiting, including activation of multiple receptors found in the vomiting center of the medulla, the chemoreceptor trigger zone, the gastrointestinal tract, the pharynx, and the cerebral cortex. Activation of neurotransmitter receptors in these areas is thought to induce CINV. Stimulation may originate through peripheral, autonomic, vestibular, or cognitive pathways. The primary neuroreceptors known to be implicated in CINV are 5-hydroxytryptamine (5-HT or serotonin) and dopamine receptors (Olsen et al., 2019).

The approach for managing CINV is based on the knowledge of the probability of emesis of the chemotherapy agents used. Algorithms are used to prevent and treat CINV based on national guidelines that consider this classification of chemotherapy agents (NCCN, 2019g).

Corticosteroids, phenothiazines, sedatives, and histamines are helpful, especially when used in combination with serotonin blockers to provide antiemetic protection (NCCN, 2019g). In order to manage delayed nausea and vomiting, antiemetic medications may be combined and are given for the first week at home after chemotherapy. Nonpharmacologic approaches such as relaxation techniques, imagery, acupressure, or acupuncture can help decrease stimuli contributing to symptoms and may be most helpful for patients with anticipatory nausea and vomiting. Small, frequent meals, bland foods, and comfort foods may reduce the frequency or severity of symptoms.

Stomatitis is commonly associated with some chemotherapy agents because of the rapid turnover of epithelium that lines the oral cavity. The entire gastrointestinal tract is susceptible to mucositis. Antimetabolites and antitumor

antibiotics are the major culprits in mucositis and other gastrointestinal symptoms, which can be severe in some patients.

Hematopoietic System

Many chemotherapy agents cause some degree of **myelosuppression** (depression of bone marrow function), resulting in leukopenia (decreased WBCs), **neutropenia** (decreased granulocytes), anemia (decreased red blood cells [RBCs]), thrombocytopenia (decreased platelets), and increased risk of infection and bleeding (Olsen et al., 2019). Depression of these cells is the usual reason for limiting the dose of the chemotherapy. Myelosuppression is predictable; for most agents, patients usually reach the point at which blood counts are lowest 7 to 14 days after chemotherapy has been given. During these 2 weeks, nurses anticipate associated toxicities, especially a fever associated with neutrophil count less than 1,500 cells/mm^3. Frequent monitoring of blood cell counts is essential, and patients are educated about strategies to protect against infection, injury, and blood loss, particularly while counts are low.

Other agents—colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF] and granulocyte-macrophage colony-stimulating factor [GM-CSF])—can be given after chemotherapy to stimulate the bone marrow to produce WBCs, especially neutrophils, at an accelerated rate, thus decreasing the duration of neutropenia. G-CSF and GM-CSF decrease the episodes of infection and the need for antibiotics and allow for more timely treatment cycles of chemotherapy with less need to reduce the dosage. Erythropoietin (EPO) stimulates RBC production, thus decreasing the symptoms of treatment-induced chronic anemia and reducing the need for blood transfusions. Interleukin 11 (IL-11) (oprelvekin) stimulates the production of megakaryocytes (precursors to platelets) and can be used to prevent and treat severe thrombocytopenia but has had limited use because of toxicities, such as HSR; capillary leak syndrome; pulmonary edema; atrial arrhythmias; and nausea, vomiting, and diarrhea (Olsen et al., 2019).

Renal System

Some chemotherapy agents can cause renal dysfunction by damaging the blood vessels or filtering structures of the kidneys (Olsen et al., 2019). Clinical manifestations of renal dysfunction from conventional chemotherapy can range from the asymptomatic elevation of serum electrolytes and creatinine levels to acute kidney injury (Merchan, Jhaveri, Berns, et al., 2017). Cisplatin, methotrexate, and mitomycin are particularly toxic to the kidneys (Olsen et al., 2019). Damage to the kidneys may also result in impaired water secretion, leading to syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Rapid tumor cell lysis after chemotherapy results in increased urinary excretion of uric acid, which can cause renal damage. In addition, intracellular contents are released into circulation, resulting in hyperkalemia,

hyperphosphatemia, and hypocalcemia and obstructive nephropathy. (See later discussion of tumor lysis syndrome.)

The monitoring of laboratory values, including blood urea nitrogen (BUN), serum creatinine, creatinine clearance, and serum electrolytes is essential (Olsen et al., 2019). Adequate hydration and diuresis to prevent formation of uric acid crystals and administration of allopurinol may be used to prevent renal toxicity. Amifostine has demonstrated an ability to minimize renal toxicities associated with cisplatin, cyclophosphamide, and ifosfamide therapy.

Hemorrhagic cystitis is a bladder toxicity that can result from cyclophosphamide and ifosfamide, and alkylating agent (e.g., busulfan and thiotepa) therapy (Olsen et al., 2019). Hematuria can range from microscopic to frank bleeding with symptoms ranging from transient irritation during urination, dysuria, and suprapubic pain to life-threatening hemorrhage. Protection of the bladder focuses on aggressive IV hydration, frequent voiding, and diuresis.

Cardiopulmonary System

Several chemotherapy agents are associated with cardiac toxicity. Anthracyclines (e.g., daunorubicin, doxorubicin) are known to cause irreversible cumulative cardiac toxicities when total dosage reaches 400 mg/m^2 (Henriksen, 2018). If these agents are given in the presence of thoracic radiation therapy or other agents with cardiotoxicity potential, the cumulative dose limit is lower. Patients at increased risk for the development of cardiac toxicities include: extreme ages >65 years or <18 years, female gender, African American race, chest radiation, kidney failure, and preexisting cardiac disease (including hypertension) (Henriksen, 2018). Dexrazoxane has been used on a limited basis as a cardio-protectant when doxorubicin is needed in individuals who have already received a cumulative dose limit and continuation of therapy is deemed beneficial. Patients with known cardiac disease (e.g., heart failure) are treated with lower doses or agents not known to be associated with cardiac toxicity. Cardiac ejection fraction (volume of blood ejected from the heart with each beat) and other signs of heart failure must be monitored closely.

Bleomycin, carmustine, busulfan, mitomycin C, and paclitaxel/docetaxel, among other agents, have toxic effects on lung function, such as alveolar damage, bronchospasm, pneumonitis, and pulmonary fibrosis (Olsen et al., 2019). Therefore, patients are monitored closely for changes in pulmonary function, including pulmonary function test results. Patients with known lung disease are treated with alternative agents not known to cause pulmonary toxicity. When pulmonary toxicity occurs, the agent is discontinued and patients are treated with steroids and other supportive therapies.

Capillary leak syndrome with resultant pulmonary edema is an effect of cytarabine, mitomycin C, cyclophosphamide, and carmustine (Olsen et al., 2019). Subtle onset of dyspnea and cough may progress rapidly to acute respiratory distress and subsequent respiratory failure. Patients who are at significant risk for capillary leak syndrome are monitored closely.

Reproductive System

Testicular and ovarian function can be affected by chemotherapeutic agents, resulting in possible infertility (Olsen et al., 2019). Women may develop problems with ovulation or early menopause, whereas men may develop temporary or permanent azoospermia (absence of spermatozoa). Because treatment may damage reproductive cells, banking of sperm is often recommended for men before treatment is initiated (Oktay, Harvey, Partridge, et al., 2018). Options available for women prior to initiation of chemotherapy include cryopreservation (freezing) of oocytes, embryos, or ovarian tissue. Patients and their partners are informed about potential changes in reproductive function resulting from chemotherapy. In addition, many chemotherapy agents are known or thought to be teratogenic. Therefore, patients are advised to use reliable methods of birth control while receiving chemotherapy and not to assume that infertility has resulted (Olsen et al., 2019).

Neurologic System

Chemotherapy-induced neurotoxicity, a potentially dose-limiting toxicity, can affect the central, peripheral, and autonomic nervous systems (Olsen et al., 2019). Neurotoxicity characterized by metabolic encephalopathy can occur with ifosfamide, high-dose methotrexate, and cytarabine. With repeated doses, the taxanes and plant alkaloids, especially vincristine, can cause cumulative peripheral nervous system damage with sensory alterations in the feet and hands. These sensations can be described as tingling, pricking, or numbness of the extremities; burning or freezing pain; sharp, stabbing, or electric shock–like pain; and extreme sensitivity to touch. If unreported by patients or undetected, progressive motor axon damage can lead to loss of deep tendon reflexes, with muscle weakness, loss of balance and coordination, and paralytic ileus.

Some chemotherapy agents (e.g., paclitaxel and gemcitabine) can cause severe peripheral neuropathies that may lead to diminished quality of life and functional abilities and result in dose reductions, a change in chemotherapy regimen, or early cessation of treatment (Haryani, Fetzer, Wu, et al., 2017). Although often reversible, these side effects may take many months to resolve or persist indefinitely. Along with the usual paresthesias of the hands and feet, oxaliplatin has a unique and frightening neurotoxicity presentation that is often precipitated by exposure to cold and is characterized by pharyngolaryngeal dysesthesia consisting of lip paresthesia, discomfort or tightness in the back of the throat, inability to breathe, and jaw pain (Olsen et al., 2019).

Quality and Safety Nursing Alert

Patients receiving oxaliplatin must be instructed to avoid drinking cold fluids or going outside with hands and feet exposed to cold temperatures to avoid exacerbation of these symptoms for 3 to 4 days after therapy (Olsen et al., 2019). Cisplatin may cause peripheral neuropathies and hearing loss due to damage to the acoustic nerve.

Cognitive Impairment

Many patients with cancer have trouble with remembering dates, multitasking, managing numbers and finances, organization, face or object recognition, inability to follow directions, feeling easily distracted, and motor and behavioral changes. Although not completely understood, these are viewed as symptoms of cognitive impairment. Cognitive impairment is a multidimensional concept involving a decline in information-handling processes in several domains, including attention and concentration, executive function, information processing speed, language, motor function, visuospatial skill, learning, and memory (Jansen, 2017). Commonly referred to by patients as "chemo brain" or "chemo fog," cognitive impairment has been associated with both cancer and cancer treatments, including surgery, radiation, chemotherapy, and targeted agents. The symptoms may be subtle or profound with potential negative effects on functional abilities, employment, independence, quality of life, and psychosocial status. Comorbidities, age, medications, pain, impaired nutrition, anemia, fatigue, fluid and electrolyte disturbances, organ dysfunction, infection, and hormonal imbalances are factors that may contribute to the experience of cognitive impairment and make it difficult to fully understand. Underlying mechanisms of cognitive impairment in patients with cancer being explored include neurotoxic effects, oxidative stress, hormonal changes, immune dysregulation, cytokine release, clotting, genetic predisposition, and accelerated aging processes (Jansen, 2017).

Fatigue

Cancer-related fatigue has been defined as an unusual, persistent, and subjective sense of tiredness that is not proportional to recent activity and interferes with usual functioning (NCCN, 2019f). Fatigue is a distressing side effect for most patients that greatly affects quality of life, during treatment and for months after treatment. The health care team works together to identify effective pharmacologic and nonpharmacologic approaches for fatigue management.

Nursing Management

Nurses play an important role in assessing and managing many of the problems experienced by patients receiving chemotherapy. Chemotherapy agents affect

both normal and malignant cells; therefore, their effects are often widespread, affecting many body systems.

Laboratory and physical assessments of metabolic indices and the dermatologic, hematologic, hepatic, renal, cardiovascular, neurologic, and pulmonary systems are critical in evaluating the body's response to chemotherapy. These assessments are performed prior to, during, and after a course of chemotherapy to determine optimal treatment options, evaluate the patient's response, and monitor toxicity. Patients are monitored for long-term effects of chemotherapy after active treatment has been completed during the period of survivorship (see Chart 12-4).

Assessing Fluid and Electrolyte Status

Anorexia, nausea, vomiting, altered taste, mucositis, and diarrhea put patients at risk for nutritional and fluid and electrolyte disturbances. Therefore, it is important for the nurse to assess the patient's nutritional and fluid and electrolyte status on an ongoing basis and to identify creative ways to encourage an adequate fluid and dietary intake.

Assessing Cognitive Status

Nurses should assess patients routinely for indications of cognitive impairment. Prior to the initiation of treatment, patients and families should be informed about the possibility of cognitive impairment. Nursing assessment plays an important role in determining the need for referral for neurocognitive evaluation and intervention (Jansen, 2017).

Chart 12-4

Potential Long-Term Complications of Cancer Chemotherapy

- Abnormalities in senses of taste, smell, and touch
- Abnormal balance, tremors, or weakness
- Avascular necrosis
- Cardiovascular toxicity (coronary artery disease, myocardial infarction, congestive heart failure, valvular heart disease, peripheral arterial disease)
- Decreased libido
- Dental caries
- Dry mouth
- Dysphagia
- Dyspnea on exertion
- Growth retardation in children
- Herpes infections (zoster and varicella)
- Hypothyroidism
- Immune dysfunction
- Infertility
- Osteoporosis
- Pericarditis (acute or chronic)
- Pneumococcal sepsis
- Pneumonitis (acute or chronic)
- Secondary cancers:
  - Acute myeloid leukemia
  - Myelodysplastic syndromes
  - Non-Hodgkin lymphomas
  - Solid tumors (especially bone and soft tissue, lung, breast)
  - Thyroid cancer
  - Thymic hyperplasia

Adapted from Yarbro, C. H., Wujcik, D., & Gobel, B. H. (2018). *Cancer nursing: Principles and practice*. Burlington, MA: Jones & Bartlett Publishers.

Modifying Risks for Infection and Bleeding

Suppression of the bone marrow and immune system is expected and frequently serves as a guide in determining appropriate chemotherapy dosage but increases the risk of anemia, infection, and bleeding disorders. Nursing assessment and care address factors that would further increase the patient's risk. The nurse's role in decreasing the risk of infection and bleeding is discussed further in the Nursing Care of the Patient with Cancer section.

Administering Chemotherapy

Nurses must be aware of chemotherapy and other agents most associated with HSRs, strategies for prevention, signs and symptoms characteristic of HSRs, and the appropriate early and time-sensitive interventions for preventing progression to anaphylaxis. Nurses provide patient and family education that emphasizes two

key points: the importance of adhering to prescribed self-administered premedication before presenting to the infusion center and recognizing and reporting the signs and symptoms to the nurse once the infusion has started. Patients and families are also educated about signs and symptoms that may occur at home following discharge from the infusion area that may warrant medication administration or immediate transport to the emergency department for further assessment and treatment.

The local effects of the chemotherapeutic agent are also of concern. The patient is observed closely during administration of the agent because of the risk and consequences of extravasation. Prevention of extravasation is essential and relies on vigilant nursing care (Neuss et al., 2017). Selection of peripheral veins, skilled venipuncture, and careful administration of medications are essential. Peripheral administration is limited to short duration (less than 1 hour; IV push or bolus) infusions using only a soft, plastic catheter placed in the forearm area (Olsen et al., 2019). Continuous infusion of vesicants that takes longer than 1 hour or are given frequently are given only via a central line, such as a right atrial silastic catheter, implanted venous access device, or PICC. These long-term venous access devices promote safety during medication administration and reduce problems with repeated access to the circulatory system (see Figs. 12-3 and 12-4). Indwelling or subcutaneous venous access devices require consistent nursing care. Complications include infection and thrombosis (Voog, Campion, Du Rusquec, et al., 2018).

Indications of extravasation during administration of vesicant agents include the following:

- Absence of blood return from the IV catheter
- Resistance to flow of IV fluid
- Burning or pain, swelling, or redness at the site

Quality and Safety Nursing Alert

If extravasation is suspected, the medication administration is stopped immediately.

An extravasation kit should be readily available with emergency equipment and antidote medications, as well as a quick reference for how to properly manage an extravasation of the specific vesicant agent used (although evidence-based data regarding effective antidotes are limited) (Neuss et al., 2017; Olsen et al., 2019). Nurses should refer to their organization's policy and procedures for reporting, managing, and documenting extravasation. Safety standards require the availability of defined extravasation management procedures, including antidote order sets and accessibility of antidotes in all settings where vesicant chemotherapy is given (Neuss et al., 2017). Recommendations and guidelines for managing vesicant extravasation, which vary with each agent, have been issued

by individual medication manufacturers, pharmacies, and the ONS (Neuss et al., 2017; Olsen et al., 2019).

Difficulties or problems with administration of chemotherapeutic agents are brought to the attention of the primary provider promptly so that corrective measures can be taken to minimize local tissue damage.

The nurse evaluates the patient receiving neurotoxic chemotherapy, communicates findings with the medical oncologist, provides education to patients and families, and makes appropriate referrals for complete neurologic evaluation and occupational or rehabilitative therapies.

Preventing Nausea and Vomiting

Nurses are integral to the prevention and management of CINV. They collaborate with other members of the oncology care team to identify factors contributing to the experience of CINV and select effective antiemetic regimens that maximize currently available therapies. Nurses provide education for patients and families regarding antiemetic regimens and care for delayed CINV that may continue at home after the chemotherapy infusion has completed (NCCN, 2019g).

Managing Cognitive Changes

Although several approaches have been explored, no evidence-based guidelines for the prevention, treatment, or management of cognitive impairment have been established. Examples of nonpharmacologic approaches that nurses recommend to patients include exercise, natural restorative environmental intervention (walking in nature or gardening), and cognitive training programs (Jansen, 2017). Nurses should assist patients to address factors, such as fluid and electrolyte imbalances, nutrition deficits, fatigue, pain, and infection to minimize their contribution to cognitive impairment.

Managing Fatigue

Fatigue is a common side effect of chemotherapy. Nurses assist patients to explore the role that the underlying disease processes, combined treatments, other symptoms, and psychosocial distress play in the patient's experience of fatigue. In addition, nurses work with the patient and other team members to identify effective approaches for fatigue management (NCCN, 2019h).

Protecting Caregivers

Nurses involved in handling chemotherapeutic agents may be exposed to low doses of the agents by direct contact, inhalation, or ingestion (Menonna-Quinn, Polovich, & Marshall, 2019). Skin and eye irritation, nausea, vomiting, nasal mucosal ulcerations, infertility, low-birth-weight babies, congenital anomalies, spontaneous abortions, and mutagenic substances in urine have been reported in nurses preparing and handling chemotherapy agents. The Occupational and

Safety Health Administration (OSHA), the ONS, hospitals, and other health care agencies have developed specific precautions for health care providers involved in the preparation and administration of chemotherapy and for handling materials exposed to body fluids of those who have received these hazardous agents (see Chart 12-5) (Neuss et al., 2017; Olsen et al., 2019). Nurses must be familiar with their institutional policies and procedures regarding personal protective equipment, handling and disposal of chemotherapy agents and supplies, and management of accidental spills or exposures. Emergency spill kits should be readily available in any treatment area where chemotherapy is prepared or given. Precautions must also be taken when handling any bodily fluids or excreta from the patient, as many agents are excreted unaltered in urine and feces. Nurses in all treatment settings have a responsibility to educate patients, families, caregivers, assistive personnel, and housekeepers concerning precautions.

Hematopoietic Stem Cell Transplantation

HSCT has been used to treat several malignant and nonmalignant diseases for many years (Yarbro et al., 2018). In adults, HSCT is most commonly used to treat certain hematologic malignancies (e.g., malignant myeloma, acute leukemia, non-Hodgkin lymphoma), and less commonly some solid tumors (e.g., germ cell tumors, breast cancer, neuroblastomas).

The process of obtaining hematopoietic stem cells (HSCs) has evolved over the years (Yarbro et al., 2018). Historically, HSCs were obtained in the operating room by harvesting large amounts of bone marrow tissue from a donor under general anesthesia. However, peripheral blood stem cell collection using the process of apheresis now accounts for the vast majority of HSCT procedures (Yarbro et al., 2018). The cells collected are specially processed and reinfused into the patient. This method of collecting HSCs is a safe and a more cost-effective means of collection than the process of harvesting of marrow. Stem cells can also be collected from umbilical cord blood harvested from the placenta of newborns at birth that is cryopreserved and stored for later use (Yarbro et al., 2018).

Types of Hematopoietic Stem Cell Transplantation

Types of HSCT are based on the source of donor cells and the treatment (conditioning) regimen used to prepare the patient for stem cell infusion and eradicate malignant cells (Yarbro et al., 2018). These include:

- *Allogeneic HSCT* (AlloHSCT): From a donor other than the patient (may be a related donor such as a family member or a matched unrelated donor from the National Bone Marrow Registry or Cord Blood Registry)
- *Autologous:* From the patient

- *Syngeneic:* From an identical twin
- *Myeloablative:* Consists of giving patients high-dose chemotherapy and, occasionally, total-body irradiation
- *Nonmyeloablative:* Also called *mini-transplants;* does not completely destroy bone marrow cells

Chart 12-5

Safety in Handling Chemotherapy for Health Care Providers

- When preparing (compounding, reconstituting) chemotherapy for administration, use the following safety equipment to prevent exposure through inhalation, direct contact, and ingestion:
  - Class II or III biologic safety cabinet (BSC)
  - Closed-system transfer devices
  - Puncture and leak-proof containers, IV bags
  - Needleless systems (e.g., IV tubing and syringes)
- If BSC is not available when preparing chemotherapy for administration, use the following safety equipment to minimize exposure:
  - Surgical N-95 respirator to provide respiratory and splash protection
  - Eye and face protection (both face shield and goggles) working at or above eye level or cleaning a spill
- When preparing or administering chemotherapy or handling linens and other materials contaminated with chemotherapy or blood and body fluids of patients receiving chemotherapy, wear the following for personal protection:
  - Double layer of powder-free gloves specifically designated for chemotherapy handling (the inner glove is worn under the gown cuff and the outer glove is worn over the cuff)
  - Long sleeve, disposable gowns (without seams or closures that can allow drugs to pass through) made of polyethylene-coated polypropylene or other laminate materials
- Linens contaminated with chemotherapy or blood and body fluids of patients receiving chemotherapy should be placed in the following:
  - Closed-system, puncture- and leak-proof containers labeled “hazardous: chemotherapy contaminated linens”
  - Above referenced container maintained in the infusion center soiled utility room for outpatient settings
  - Above referenced container maintained in the patient room or soiled utility room for inpatient settings
- Chemotherapy preparation equipment (e.g., syringes, tubing, empty vials, etc.), gowns, and gloves should be disposed of in:
  - Closed-system, puncture- and leak-proof containers labeled “hazardous: chemotherapy contaminated waste”
- Wash hands with soap and water after removing gloves used to prepare or administer chemotherapy or clean contaminated linens and other materials
- “Spill kits” with the appropriate gowns, gloves, disposable absorbent materials for cleansing large areas, and hazard sign should be kept in all areas where chemotherapy is prepared and given
- Implement a quality improvement program addressing safe chemotherapy handling that includes the following:
  - Standard operating policies and procedures for:
    - Chemotherapy handling, preparation, and disposal

    - Handling and disposal of chemotherapy spills
    - Handling and disposal of blood and body fluids and contaminated materials of patients receiving chemotherapy
- Conduct competency-based education, training, and performance evaluations regarding chemotherapy safety procedures at orientation and at subsequent regular intervals
- Medical monitoring program to identify indicators of exposure
- Root cause analysis for all chemotherapy spills and exposure incidents

Adapted from National Institute for Occupational Safety and Health. (2008). Personal protective equipment for health care workers who work with hazardous drugs. (2019). *Chemotherapy and immunotherapy guidelines and recommendations for practice*. Pittsburgh, PA: Oncology Nursing Society.

AlloHSCTs are used primarily for diseases of the bone marrow and are dependent on the availability of a human leukocyte antigen–matched donor, which greatly limits the number of possible transplants. An advantage of AlloHSCT is that the transplanted cells should not be immunologically tolerant of a patient's malignancy and should cause a lethal **graft-versus-tumor effect** in which the donor cells recognize the malignant cells and act to eliminate them.

AlloHSCT may involve either myeloablative (high-dose) or nonmyeloablative (mini-transplant) chemotherapy (Yarbro et al., 2018). In ablative AlloHSCT, the recipient receives high doses of chemotherapy and possibly total-body irradiation to completely eradicate (ablate) the bone marrow and any malignant cells and help prevent rejection of the donor stem cells. The collected HSCs that are infused IV into the recipients travel to sites in the body where they produce bone marrow and establish themselves through the process of engraftment. Once engraftment is complete (8 to 10 days, sometimes longer), the new bone marrow becomes functional and begins producing RBCs, WBCs, and platelets. In nonablative AlloHSCT, the chemotherapy doses are lower and aimed at destroying malignant cells (without completely eradicating the bone marrow), thus suppressing the recipient's immune system to allow engraftment of donor stem cells. The lower doses of chemotherapy, associated with less organ toxicity and infection, can be used for older patients or those with underlying organ dysfunction for whom high-dose chemotherapy would be prohibitive (Yarbro et al., 2018). After engraftment, it is hoped that the donor cells will create a graft-versus-tumor effect. Before engraftment, patients are at high risk for infection, sepsis, and bleeding. Side effects of the high-dose chemotherapy and total-body irradiation can be acute and chronic (Negrin, 2018; Yarbro et al., 2018). Acute side effects include headache, alopecia, nausea, vomiting, mucositis, diarrhea, fluid and electrolyte imbalances, and acute kidney injury. Chronic side effects include infertility; pulmonary, cardiac, liver, and kidney

dysfunction; osteoporosis and avascular bone necrosis; diabetes; and secondary malignancies.

During the first 30 days after the conditioning regimen, AlloHSCT patients are at risk for developing hepatic sinusoidal obstructive syndrome (HSOS) (previously referred to as veno-oclusive disease) related to chemotherapy-induced inflammation of the sinusoidal epithelium (Negrin & Bonis, 2019). Inflammation causes embolization of RBCs, resulting in destruction, fibrosis, and occlusion of the sinusoids. Clinical manifestations of HSOS may include weight gain, hepatomegaly, increased bilirubin, and ascites. Although various approaches have been used to treat HSOS, evidence-based strategies have not emerged. The use of peripheral stem cells, specific chemotherapy dosing, and nonmyeloablative regimens have been associated with a decreased incidence (Negrin, 2018; Yarbro et al., 2018).

Graft-versus-host disease (GVHD), a major cause of morbidity and mortality in 30% to 50% of the allogeneic transplant population, occurs when the donor lymphocytes initiate an immune response against the recipient's tissues (e.g., skin, gastrointestinal tract, liver) during the beginning of engraftment (Yarbro et al., 2018). The donor cells view the recipient's tissues as foreign or immunologically different from what they recognize as "self" in the donor. To prevent GVHD, patients receive immunosuppressant drugs, such as cyclosporine, methotrexate, tacrolimus, or mycophenolate mofetil.

GVHD may be acute, occurring within the first 100 days, or chronic, occurring after 100 days (Yarbro et al., 2018). Clinical manifestations of acute GVHD include diffuse rash progressing to blistering and desquamation similar to second-degree burns; mucosal inflammation of the eyes and the entire gastrointestinal tract with subsequent diarrhea that may exceed 2 L per day; and biliary stasis with abdominal pain, hepatomegaly, and elevated liver enzymes progressing to obstructive jaundice. The first 100 days or so after AlloHSCT is crucial for patients; the immune system and blood-making capacity (hematopoiesis) must recover sufficiently to prevent infection and hemorrhage.

Autologous HSCT (AuHSCT) is considered for patients with disease of the bone marrow who do not have a suitable donor for AlloHSCT or for patients who have healthy bone marrow but require bone marrow–ablative doses of chemotherapy to cure an aggressive malignancy (Yarbro et al., 2018). The most common malignancies treated with AuHSCT include lymphoma and multiple myeloma. However, the use of AuHSCT has gained increasing acceptance in treating neuroblastoma, Ewing sarcoma, and germ cell tumors. Stem cells are collected from the patient and preserved for reinfusion; if necessary, they are treated to kill any malignant cells within the marrow, called *purging.* The patient is then treated with ablative chemotherapy and, possibly, total-body irradiation to eradicate any remaining tumor. Stem cells are then reinfused. Until engraftment occurs in the bone marrow sites of the body, there is a high risk of infection, sepsis, and bleeding. Acute and chronic toxicities from chemotherapy and radiation therapy may be severe. The risk of HSOS is also present after

autologous transplantation. No immunosuppressant medications are necessary after AuHSCT, because the patient does not receive foreign tissue. A disadvantage of AuHSCT is the risk that tumor cells may remain in the bone marrow despite high-dose chemotherapy (conditioning regimens).

Syngeneic transplants result in less incidence of GVHD and graft rejection; however, there is also less graft-versus-tumor effect to fight the malignancy. For this reason, even when an identical twin is available for marrow donation, another matched sibling or even an unrelated donor may be the most suitable donor to combat an aggressive malignancy (Yarbro et al., 2018).

Nursing Management

Nursing care of the patient undergoing HSCT is complex and demands a high level of skill. The success of HSCT is greatly influenced by nursing care throughout the transplantation process.

Implementing Care Before Treatment

All patients must undergo extensive evaluations before HSCT to assess the current clinical status of the disease. Nutritional assessments, extensive physical examinations, organ function tests, and psychological evaluations are conducted. Blood work includes assessing past infectious antigen exposure (e.g., hepatitis virus, cytomegalovirus, herpes simplex virus, human immunodeficiency virus, syphilis). The patient's social support systems and financial and insurance resources are also evaluated. Informed consent and patient education about the procedure and care before and after HSCT are vital.

Providing Care During Treatment

Skilled nursing care is required during the treatment phase of HSCT when high-dose chemotherapy (conditioning regimen) and total-body irradiation are given. The acute toxicities of nausea, diarrhea, mucositis, and hemorrhagic cystitis require close monitoring and symptom management by the nurse.

Nursing management during stem cell infusion consists of monitoring the patient's vital signs and blood oxygen saturation; assessing for adverse effects, such as fever, chills, shortness of breath, chest pain, cutaneous reactions, nausea, vomiting, hypotension or hypertension, tachycardia, anxiety, and taste changes; and providing strategies for symptom control, ongoing support, and patient education. During stem cell infusion, patients may experience adverse reactions to the cryoprotectant dimethylsulfoxide (DMSO) used to preserve the harvested stem cells. Less common toxicities include neurologic and renal impairment (Yarbro et al., 2018).

Quality and Safety Nursing Alert

Until engraftment of the new marrow occurs, the patient undergoing HSCT is at high risk for death from sepsis and bleeding.

A cluster of symptoms referred to as engraftment syndrome may occur during the neutrophil recovery phase in both allogeneic and autologous transplants. Clinical features of this syndrome vary widely but may include noninfectious fever associated with skin rash, weight gain, diarrhea, and pulmonary infiltrates, with improvement noted after the initiation of corticosteroid therapy rather than antibiotic therapy (Mutahar & Al-Anazi, 2017). Until engraftment is well established, the patient requires support with blood products and hematopoietic growth factors.

Potential infections may be bacterial, viral, fungal, or protozoan in origin. During the first 30 days following transplant, the patient is most at risk for developing reactivations of viral infections, including herpes simplex, EBV, cytomegalovirus, and varicella zoster. Mucosal denudement poses a risk for *Candida* (yeast) infection locally and systemically. Pulmonary toxicities offer the opportunity for fungal infections such as *Aspergillus*. Renal complications arise from the nephrotoxic chemotherapy agents used in the conditioning regimen or those used to treat infection (amphotericin B, aminoglycosides). A neutropenic diet is usually prescribed for patients to decrease the risk of exposure to foodborne infections from bacteria, yeast, molds, viruses, and parasites (Yarbro et al., 2018).

Tumor lysis syndrome and acute tubular necrosis are also potential complications after HSCT. Nursing assessment for signs of these complications is essential for early identification and treatment. GVHD requires skillful nursing assessment to detect early effects on the skin, liver, and gastrointestinal tract. HSOS resulting from the conditioning regimens used can result in fluid retention, jaundice, abdominal pain, ascites, tender and enlarged liver, and encephalopathy. Pulmonary complications, such as pulmonary edema, interstitial pneumonia, and other pneumonias, often complicate recovery.

Providing Care After Treatment

Nursing care following HSCT includes care of recipients and donors. These are discussed in the following sections.

Caring for Recipients

Ongoing nursing assessment during follow-up visits is essential to detect late effects of therapy after HSCT, which may occur 100 days or more after the procedure (Yarbro et al., 2018). Late effects include infections (e.g., varicella-zoster infection), restrictive pulmonary abnormalities, and recurrent pneumonias. Infertility often results due to total-body irradiation, chemotherapy, or both as components of the ablative regimen. Chronic GVHD can involve the skin, liver,

intestine, esophagus, eyes, lungs, joints, and vaginal mucosa. Cataracts may also develop after total-body irradiation.

There is a high potential of psychological distress following an HSCT, which has been associated with delayed recovery, mortality, and increased rates of complications, such as GVHD (Hermioni, Christina, Melanie, et al., 2019). Thus, psychosocial assessments by nursing staff must be ongoing and a priority. In addition to the multiple physical and psychological stressors affecting patients at each phase of the transplantation experience, the nature of the treatment and patient experience can place extreme emotional, social, financial, and physical demands on family, friends, and donors. Nurses assess the family and other caregivers' needs and provide education, support, and information about resources.

Caring for Donors

Like HSCT recipients, donors also require nursing care. They may experience mood alterations, decreased self-esteem, and guilt from feelings of failure if the transplantation fails. Family members must be educated and supported to reduce anxiety and promote coping during this difficult time. In addition, they must also be assisted to maintain realistic expectations of themselves as well as of the patient.

Immunotherapy and Targeted Therapy

Immunotherapy

Immunotherapy involves the use of medications or biochemical mediators to stimulate or suppress components of the immune system to kill cancer cells (ACS, 2019g). Over the past decade, advances in the understanding of the immune system and about its interaction with cancer have led to significant advances in immunotherapy. This has dramatically changed how patients with cancer are treated and has resulted in improvements in overall survival for many forms of cancer. There are several types of immunotherapy currently being used to treat cancer, including nonspecific immunotherapies, monoclonal antibodies, checkpoint inhibitors, cancer vaccines, and chimeric antigen receptor (CAR) T–cell therapy. Many immunotherapies are targeted therapies. Targeted therapies are discussed later in this chapter.

Nonspecific Immunotherapy

Nonspecific immunotherapy does not target the cancer cell directly, but rather boosts the immune system to enhance cancer cell destruction alone or along with other cancer treatments, such as chemotherapy or radiation therapy (ACS, 2019f). Common nonspecific immunotherapy agents include bacille Calmette-

Guérin (BCG) and cytokines (interferon, interleukins, and colony-stimulating factors).

BCG is one of the earliest immunotherapy agents used to treat cancer. BCG is a live attenuated strain of *Mycobacterium bovis*, which is closely related to the bacterium that causes tuberculosis in people. BCG is most commonly used to treat localized bladder cancer (ACS, 2019h). When instilled into the bladder, BCG serves as an antigen to stimulate an immune response. The intention is that the stimulated immune system will then eradicate malignant cells. Common toxicities associated with BCG therapy include mild flulike symptoms (e.g., fever, chills, malaise), bladder burning/discomfort, urinary frequency, and blood tinged urine, which typically last 2 to 3 days after treatment (ACS, 2019h).

The most commonly used nonspecific immunotherapy agents are cytokines. **Cytokines** are messenger substances that may be released by a cell to create an action at that site or may be carried by the bloodstream to a distant site before being activated; they are also called *biochemical* or *inflammatory mediators.* These substances are produced primarily by cells of the immune system to enhance or suppress the production and functioning of other components of the immune system and thus can be used to treat cancer or the adverse effects of some cancer treatments. Cytokines are grouped into families, such as interferons (IFNs), interleukins (ILs), and colony-stimulating factors. Colony-stimulating factors were described earlier in this chapter for their supportive role in myelosuppressive treatment modalities. (Refer to Chapter 31 for more detailed discussion of the immune system.)

IFNs are cytokines with antiviral, antitumor, and immunomodulatory (inhibition or stimulation of the immune system) properties. Multiple antitumor effects of IFNs include antiangiogenesis, direct destruction of tumor cells, inhibition of growth factors, and disruption of the cell cycle (Yarbro et al., 2018). IFNs are used on a limited basis for the treatment of some solid and hematologic cancers. Similar to IFNs, ILs have immunomodulatory effects on other components of the immune response. IL-2, an interleukin made in a laboratory, has been approved as a treatment option for advanced kidney cancer and metastatic melanoma in adults.

Adverse effects such as fever, myalgia, nausea, and vomiting, as seen with IFN and IL-2 therapy, may not be life-threatening. However, other adverse effects with these therapies (e.g., capillary leak syndrome, pulmonary edema, hypotension) may become life-threatening. These severe toxicities have restricted the use of IFN and IL-2 clinically and have prompted clinicians to seek alternative anticancer therapies (Waldmann, 2018).

Monoclonal Antibodies (MoAbs)

MoAbs, another type of immunotherapy, have become available through technologic advances, enabling investigators to grow and produce targeted antibodies for specific malignant cells. Theoretically, this type of specificity allows MoAbs to destroy the cancer cells and spare normal cells. The specificity

of MoAbs is dependent on identifying key antigen proteins on the surface (outside) of tumors that are not present on normal tissues. When the MoAb attaches to the cell surface antigen, an important signal transduction pathway for communication between the malignant cells and the extracellular environment is blocked. The results may include an inability to initiate apoptosis, reproduce, or invade surrounding tissues.

The production of MoAbs involves injecting tumor cells that act as antigens into mice. B-cell lymphocytes in the spleen of the mouse produce immunoglobulin (antibodies) made in response to the injected antigens. Antibody-producing B-cells are combined with a cancer cell that can grow indefinitely in culture medium and continue producing more antibodies.

The combination of spleen cells and the cancer cells is referred to as a hybridoma. From hybridomas that continue to grow in the culture medium, the desired antibodies are harvested, purified, and prepared for diagnostic or therapeutic use (see Fig. 12-5). Advances in genetic engineering have led to the production of MoAbs with combinations of mouse and human components (*chimeric MoAbs*) or all-human components (*human MoAbs*). MoAbs made with human genes have greater immunologic properties and are less likely to cause allergic and infusion reactions (Norris, 2019).

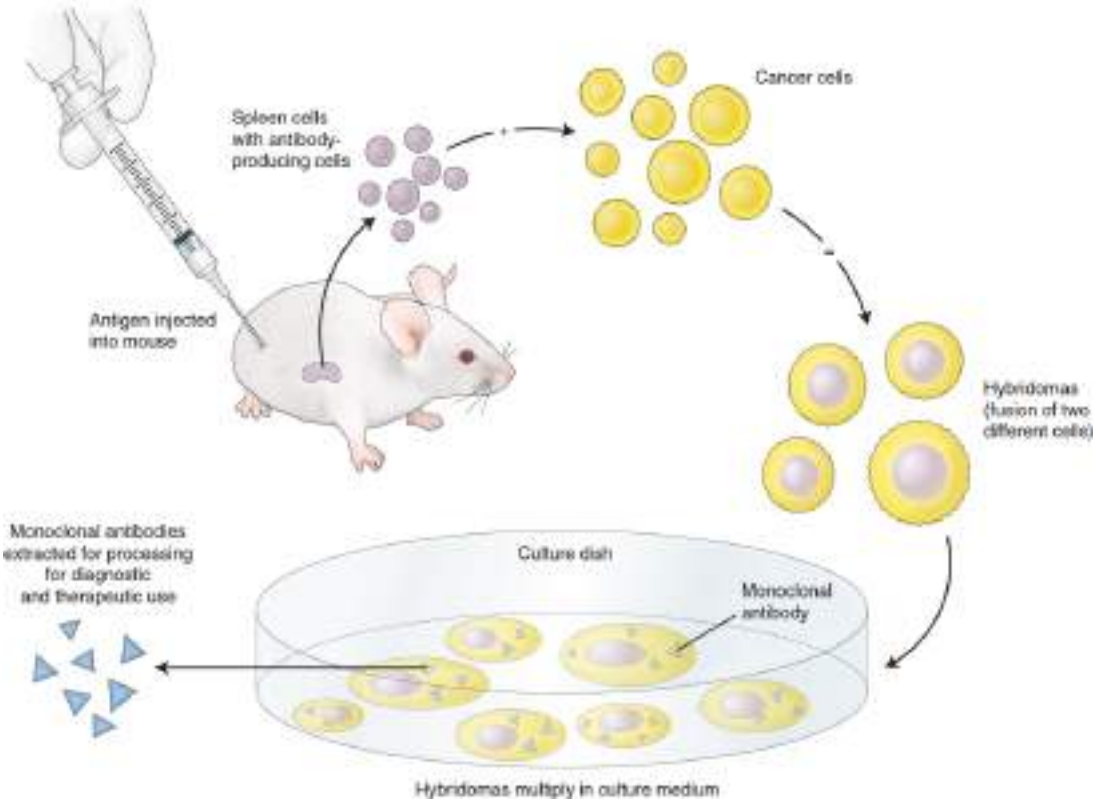

Figure 12-5 • Antibody-producing spleen cells are fused with cancer cells. This process produces cells called *hybridomas.* These cells, which can grow indefinitely in a culture medium, produce antibodies that are harvested, purified, and prepared for diagnostic or treatment purposes.

MoAbs (with names usually ending in -mab) are large particles that work on extracellular molecules, which are usually administered intravenously. Several MoAbs are used for the treatment in cancer using various extracellular (on the cell membrane) and intracellular targets. Trastuzumab targets the HER2 protein, an error of gene overexpression found in breast and other cancers (ACS, 2019g). Rituxumab is a MoAb that binds specifically with the CD20 antigen expressed by non-Hodgkin lymphoma and B-cell chronic lymphocytic leukemia.

Some MoAbs are used alone (termed naked MoAbs), whereas others are used in combination with agents that facilitate their antitumor actions (termed conjugated MoAbs). Ibritumomab tiuxetan, a MoAb conjugated with a radioactive isotope, is used in the treatment of certain types of lymphoma (ACS, 2019g). MoAbs are also used as aids in diagnostic evaluation of both primary and metastatic tumors through radiologic imaging and laboratory techniques (Olsen et al., 2019). For example, the process of immunohistochemistry uses a MoAb tagged with a stain that binds with the protein of interest, providing a visual stain for the presence or absence of the protein (Bishop, Cole, Zhang, et al., 2018). This type of test is used to identify the presence of estrogen and progesterone receptors on breast cancer cells to see if the cells will be responsive

to hormonal agents. Immunohistochemistry testing is also used to detect several proteins associated with hereditary nonpolyposis colon cancers. MoAbs are used to assist in the diagnosis of ovarian, colorectal, breast, and prostate cancers and some types of leukemia and lymphoma. MoAbs are also used in purging residual tumor cells from peripheral stem cell collections for patients who are undergoing HSCT after high-dose cytotoxic therapy. Researchers continue to explore the development and use of MoAbs, either alone or in combination with other substances such as radioactive materials, chemotherapy agents, toxins, and hormones.

MoAbs are associated with both common and unique toxicities (ACS, 2019g). Common toxicities associated with MoAbs include flulike symptoms (e.g., chills, weakness, malaise) headache, nausea and vomiting, diarrhea, rash, proteinuria, hypothyroidism, hypertension, and hepatoxicity. Although mild to moderate allergic and infusion reactions are more commonly associated with chimeric MoAbs, severe HSRs have been seen with MoAb infusions. Other toxicities are specific to the substance attached to the MoAbs.

Checkpoint Inhibitors

The immune system uses inhibitory and acceleratory pathways and immune checkpoints to regulate the antitumor response (ACS, 2019g; Bayer, Amaya, Baniewicz, et al., 2017). Checkpoints are specific proteins on T–cells that need to be blocked (or inactivated) to initiate an immune response against cancer cells. Cancer cells use different mechanisms to avoid recognition by the immune system, thus allowing them to grow unchecked. Immune checkpoint inhibitors block proteins that diminish immune system function and prevent T lymphocytes from identifying and destroying cancer cells. When these mechanisms are blocked, the “brakes are off” and T–cells are released, allowing the immune system to identify and mount an immune response against cancer cells (this is termed an antitumor response).

Recently, special type of MoAbs were developed that block specific checkpoints on T–cells to enhance cancer cell surveillance and destruction by the immune system. These MoAbs are called check point inhibitors. Three classes of checkpoint inhibitors have been approved by the FDA for the treatment of cancer, including cytotoxic T-lymphocyte antigen-4 (CTLA-4), anti-programmed cell death protein 1 (PD-1) receptor, and anti-programmed cell death ligand 1(PD-L1) (Olsen et al., 2019). The CTLA-4 is an intracellular protein within resting T lymphocytes. CTLA receptors on certain T–cells prevent the overactivation of the immune response; thus, blocking this receptor allows for a persistent T–cell antitumor response (Bayer et al., 2017). An example of an immune check point inhibitor that blocks CTLA-4 is ipilimumab. Ipilimumab is currently approved for some forms of melanoma, colorectal cancer, and kidney cancer.

PD-1 is a checkpoint protein on activated T–cells that when bound to another protein called PD-L1 prevents the immune system from mounting a response

against normal cells (Olsen et al., 2019). PD-L1 is also located on some cancer cells, which disrupts immune surveillance and the antitumor response, thus allowing cancer cells to grow unchecked. Immune checkpoint inhibitors that block PD-1 (e.g., nivolumab and pembrolizumab) and PD-L1 (e.g., atezolizumab, avelumab, durvvalumab) are used to treat a wide range of cancers, including: melanoma of the skin, non–small cell lung cancer, kidney cancer, bladder cancer, head and neck cancers, and Hodgkin lymphoma.

Immune checkpoint inhibitors exhibit a different toxicity profile from other anticancer therapies. Thus, the unique toxicities associated with immune checkpoint inhibitors are termed "immune-related adverse events" (irAes). These irAes are thought to be related to an inflammatory response to immune-related activity that can affect any organ or organ system; however, the exact etiology is not fully known (Olsen et al., 2019). IrAes often present with a delayed onset and the severity of toxicities can range from mild to potentially life-threatening. The most common irAes include dermatologic (e.g., rash and pruritus); gastrointestinal (e.g., diarrhea and colitis); pulmonary (e.g., pneumonitis); renal (e.g., nephritis); endocrine (e.g., hypophysitis [inflammation of the pituitary gland], thyroiditis, hyper- and hypothyroidism) toxicities. Prompt recognition of immune-related toxicities is essential to prevent treatment delays and to ensure prompt initiation of effective management strategies, which often include the use of anti-inflammatory medications, such as corticosteroids (Olsen et al., 2019).

Cancer Vaccines

Cancer vaccines mobilize the body's immune response to prevent or treat cancer. These vaccines contain either portions of cancer cells alone or portions of cells in combination with other substances (adjuvants) that can augment or boost immune responses. *Autologous* vaccines are made from the patient's own cancer cells, which are taken from tumor tissue obtained during biopsy or surgical intervention. The cancer cells are killed and prepared for injection back into the patient. *Allogeneic* vaccines are made from cancer cell lines that are immortalized cells that were originally obtained from other people who had a specific type of cancer. These cancer cells are grown in a laboratory and eventually killed and prepared for injection.

Prophylactic vaccines prevent disease. Three vaccines have been approved by the FDA for the prevention of HPV. HPV2 (Cervarix), recommended for use in females only, protects against HPV types 16 and 18 that are responsible for about 70% of all cervical cancers (ACS, 2019g). HPV4 (Gardasil) provides protection against four HPV types (6, 11, 16, and 18) and is recommended for use in both genders. HPV9 (Gardasil-9), recommended for both males and females, protects against nine HPV types associated with cervical, anal, vaginal, and vulvar cancers. HPV9 also protects against genital warts. All of the HPV vaccines are given as a series of three doses over 6 months. Although the role of HPV vaccines in prevention of oropharyngeal cancers related to HPV16 has not

been fully established, there are preliminary data to suggest effectiveness (Wang, Dickie, Sutavani, et al., 2018).

Vaccines are also used to treat existing disease. Therapeutic vaccines kill existing cancer cells and inhibit further cancer development. Sipuleucel-T (ACS, 2019g) is indicated for men with metastatic prostate cancer that is no longer responding to hormone therapy. It is the only therapeutic vaccine currently FDA approved. Therapeutic vaccines do not cure cancer but are associated with improved patient survival.

Chimeric Antigen Receptor (CAR) T–Cell Immunotherapy

A new addition to the treatment of cancer with immunotherapy is chimeric antigen receptor (CAR) T–cell therapy. CAR T–cell is a type of targeted immunotherapy that uses tumor-specific antigen recognition to target specific malignancies. CAR T–cell therapy involves the use of genetically modified T–cells to kill cancer cells (Lamprecht & Dansereau, 2019; Olsen et al., 2019). For example, in CART-19 therapy, cluster of differentiation (CD)–19 is the target antigen. This antigen is commonly overexpressed in acute lymphoblastic leukemia and certain types of non-Hodgkin lymphoma (Bayer et al., 2017). The only two CAR T–cell immunotherapy agents currently FDA-approved both target CD19 (tisagenlecleucel and axicabtagene ciloleucel). Tisagenlecleucel is approved to treat adults with relapsed or refractory non-Hodgkin lymphoma and young adults (up to 25 years old) with relapsed or refractory acute lymphoblastic leukemia. Axicabtagene and ciloleucel are approved to treat certain types of relapsed or refractory B-cell lymphoma (Olsen et al., 2019).

The process of making CAR genetically modified T–cells begins with collecting T–cells. T–cells may be collected from the patient (autologous) or collected from a healthy donor (allogeneic) using leukapheresis. The T–cells are sent to the laboratory where they are genetically altered by adding a specific chimeric antigen receptor. This process takes several weeks to make enough CAR T–cells needed for therapy. When there are enough CAR T–cells (based on the patient's body weight), the cells are infused to the patient in a procedure similar to a blood transfusion (Lamprecht & Dansereau, 2019). A few days before a CAR T–cell infusion, the patient may be given chemotherapy to reduce the number of other immune cells to make room for the new CAR T–cells to expand and proliferate. Once infused, the CAR T–cells will continue to grow (up to a year or more postinfusion) while binding with tumor-specific antigen to kill cancer cells.

The two most common toxicities related to CAR T–cell therapy are CRS and neurologic toxicities (Anderson & Latchford, 2019). CRS, also referred to as cytokine storm, is the most common toxicity of CAR T–cell therapy and is experienced to some degree by most patients. During therapy, the infused CAR T–cells and other immune cells stimulate the release of inflammatory cytokines resulting in a systemic inflammatory response, which usually occurs within a few days of treatment. Clinical manifestations of CRS most commonly include

fever (hallmark sign), tachycardia, chills, myalgias, arthralgias, and fatigue. Although, if the CRS is severe, hypotension, dyspnea, hypoxia, respiratory distress, coagulopathies, and end-organ toxicities may occur (Anderson & Latchford, 2019). Neurologic toxicities can range from a headache and mild confusion to cerebral edema or intracranial hemorrhage. Although the exact etiology of neurologic toxicities related to CAR T–cell therapy is not yet known, it has been postulated that increased vascular permeability, increased cytokine levels, and the ability of the cells to cross the blood–brain barriers may be factors (Anderson & Latchford, 2019). Other toxicities seen with CAR T–cell therapy include tumor lysis syndrome, myelosuppression (neutropenia, anemia, and thrombocytopenia), and hypogammaglobulinemia.

Targeted Therapies

Normal cell growth is regulated by well-defined communication pathways between the environment surrounding the cell and the internal cell environment, the nucleus, and the intracellular cytoplasm. The cell membrane contains important protein receptors that respond to signals transmitted from the external cell environment and transmit that signal to the internal cell environment using enzymatic pathways called *signal transduction pathways.* Although normal cells have transduction pathways, scientific advances have led to the recognition that cancer, at the cellular level, is characterized by deregulated cell signaling transduction pathways (both intra- and extracellular pathways), as well as altered cell membrane receptors and proteins that play an important role in tumor initiation, growth, and spread (Norris, 2019). This improved understanding of cancer cell behavior has allowed scientists to develop molecular-based therapies, called targeted therapies.

Targeted therapies involve the use of agents to kill or prevent the spread of cancer cells by targeting a specific part of the cell, with less negative effects on healthy cells than conventional chemotherapy. These agents specifically target (like a lock and key mechanism) receptors, proteins, signal transduction pathways, and other processes to prevent the continued growth of cancer cells (NCI, 2019d). Targeted therapies allow for cancer treatment to be "personalized" to the unique molecular basis of the patient's cancer. To determine if a patient would benefit from a targeted therapy, the patient's cancer cells must be evaluated in the laboratory to determine if they have enough of the target molecule for the therapy to be effective. Thus, not all patients with the same type of cancer may benefit from the same targeted treatment. New unique molecular targets are regularly being identified, resulting in the discovery of many new targeted agents over the past decade (Olsen et al., 2019).

There are two main types of targeted therapies: monoclonal antibodies (previously discussed in the immunotherapy section) and small molecule drugs. Small molecule drugs (with names usually ending in -nib) target specific molecules on the inside of the cancer cells and are usually administered orally.

Targeted therapies are further classified in accordance with their mechanism of action (or the unique molecule targeted) (Olsen et al., 2019). There is a good amount of overlap in the mechanism of action of these agents because many targeted therapies work via complex pathways and have more than one target molecule. An overview of common categories of targeted therapies including tyrosine kinase inhibitors, EGFR inhibitors, vascular endothelial growth factor/receptor inhibitors, multikinase inhibitors, and proteasome inhibitors are discussed below using small molecule drugs as exemplars.

Tyrosine kinase inhibitors block a group of enzymes called tyrosine kinases, which regulate many cellular functions including signaling cellular growth and division (Olsen et al., 2019). Overexpression (too much) of tyrosine kinase is found in some cancer cells. Blocking these enzymes may prevent cancer cell growth. An example of a tyrosine kinase inhibitor is imatinib mesylate, which is used to treat cancers with an overexpression of BCR-ABL, such as chronic myeloid leukemias, acute lymphoblastic leukemias, and gastrointestinal stromal tumors (Comerford & Durkin, 2020).

Epidermal growth factor receptor (EGFR) inhibitors block a specific surface protein called epidermal growth factor (EGF), which is present on both normal and cancer cells. The overexpression of EGF in cancer cells promotes division and growth; thus, blocking EGFR can result in decreased cancer cell proliferation (Olsen et al., 2019). For example, erlotinib blocks the tyrosine kinase domain of the EGF protein to reduce cancer cell growth. Elotinib is approved to treat advanced non–small cell lung cancer and advanced pancreatic cancer in combination with chemotherapy (Comerford & Durkin, 2020).

Vascular endothelial growth factor/receptor inhibitors (VEGFRIs) are agents that block vascular endothelial growth factor, which is produced by cells to stimulate **angiogenesis** (the growth of new blood vessels). As such, VEGFRIs inhibit angiogenesis, which prevents cancer cells from receiving adequate amounts of oxygen and nutrients needed for growth. VEGFRIs are used to treat various types of cancer, including soft tissue sarcomas, and thyroid, lung, kidney, and colorectal cancers. For example, axitinib is a VEGFRI approved to treat advanced renal cell carcinoma (kidney cancer) after failure of one prior systemic therapy (Comerford & Durkin, 2020; Olsen et al., 2019).

Multikinase inhibitors (MKIs) inhibit several intracellular and extracellular (surface) kinases that play a role in cellular growth and metastatic processes to reduce cancer cell growth and replication (Comerford & Durkin, 2020; Olsen et al., 2019). Sorafenib is an example of an MKI that inhibits several kinase receptor pathways (e.g., c-KIT, PDGFR, RAF, RET, VEGFR-1, VEGFR-2, VEGFR-3). Sorafenib is used to treat several different cancer types including liver, kidney, and thyroid cancers.

Proteasome inhibitors inhibit proteasome cellular complexes, that prevent certain enzymes from making proteins (Comerford & Durkin, 2020; Olsen et al., 2019). Proteasome helps maintain intracellular homeostasis by regulating proteins that facilitate cell division and prevent cell death. Thus, blocking

proteasome interferes with cell division and enhances cancer cell death. An example of a proteasome inhibitor is bortezomib, which is approved to treat multiple myeloma and certain types of lymphoma (e.g., mantle cell lymphoma).

Common toxicities that occur with targeted therapies include mucositis, nausea, vomiting, diarrhea, abdominal pain, electrolyte and fluid imbalances, skin rash, impaired wound healing, hypertension, and myelosuppression (decreased red blood cells, WBCs, and platelets) (Comerford & Durkin, 2020; Olsen et al., 2019). Peripheral neuropathy can also occur with some proteasome inhibitors. More serious complications of targeted therapy include cardiotoxicity (e.g., brotezomib) and hepatoxicity (e.g., sorafenib).

Nursing Management

Patients receiving immunotherapy and targeted therapy have many of the same needs as patients undergoing other conventional cancer treatments. However, manipulation and stimulation of the immune system also creates unique challenges (Bayer et al., 2017; Olsen et al., 2019). Nurses must be aware of the adverse effects of these therapies and recognize the signs and symptoms of serious reactions to emergently institute appropriate interventions and supportive care. Nurses monitor patients for the impact of adverse effects on performance status and quality of life so that appropriate measures can be implemented to improve patient outcomes. The nurse must also assist in planning and evaluating patient care, and assess the need for education, support, and additional resources for both the patient and the family.

Patient education is important, as many of the toxicities are not only a source of physical discomfort, but they may also affect quality of life and patient adherence to treatment (Olsen et al., 2019; Yarbro et al., 2018). Key points of education related to immunotherapy and targeted therapy include providing information about (Bayer et al., 2017; Olsen et al., 2019; Yarbro et al., 2018):

- prescribed treatment(s) and associated toxicities to allow for prompt recognition of potentially treatment-limiting (e.g., peripheral neuropathy) and life-threatening (i.e., heart and liver failure) toxicities;
- the importance of reporting new symptoms or the exacerbation of existing symptoms promptly to the health care provider;
- how and when to contact the primary provider and seek the assistance of emergency medical services; and
- how to provide self-care during and after treatment.

Patient and family education should also include attention to general standards of care relevant to all anticancer treatment (such as principles of infection control, hand hygiene, nutrition and hydration, safe sexual practices, good skin care) and instructions to notify the health care provider about any newly prescribed or over-the-counter medications, including herbs, vitamins, and dietary supplements (Bayer et al., 2017).

Promoting Home, Community-Based, and Transitional Care

The nurse educates patients about self-care and assists in providing for continuing care. Some cancer immunotherapy and targeted therapies can be given subcutaneously (e.g., trastuzumab and denosumab) by the patient or family members at home. As needed, the home health nurse educates the patient and family how to administer these agents and monitors the use of appropriate technique as well as safe disposal of sharps and contaminated materials. The nurse also provides education about toxicities and helps the patient and family identify strategies to manage common side effects of immunotherapy and targeted therapy.

The use of oral medications to treat cancer has risen greatly in the past several years, especially with advances in targeted therapies, many of which are given by mouth. Since 2015, more than 50 oral anticancer medications were approved by FDA and it is estimated between 25% and 35% of all anticancer therapies being developed are orally administered (Dusetzina, Huskamp, Winn, et al., 2018; Kays, 2018). The rising use of oral therapies shifts the responsibility for delivery of treatment to patients and families in the home setting. Treatment approaches with newer mechanisms of action and associated toxicities, as well as the transition of responsibility to patients and families, increase the need for nurses to identify factors affecting adherence and to develop strategies to address adherence barriers (see Table 12-8).

TABLE 12-8 Strategies for Promoting Adherence to Oral Antineoplastic Agents

Assess for factors that may interfere with adherence to oral antineoplastic agents; develop plan of care that identifies and addresses specific assessment findings.

Barriers to Adherence	Strategies for Promoting Adherence
Sociodemographic Factors • Limited financial resources • Competing priorities for financial resources • Joblessness • Limited or no insurance • Racial or ethnic disparities • Lower level of education • Poor health literacy • Illiteracy • Non–English speaking • Lack of transportation • Lack of or limited social support • Rural residence	• Refer to financial counseling through health care facility, local nonprofit health/oncology support/advocacy, or other nonprofit community advocacy organizations. • Refer to social worker for referrals as described above and/or for disability applications through employer or Social Security Administration, Medicaid, or Medicare applications. • Explore patient assistance programs for costs of health care, copays, medications, household costs, transportation services (costs or availability), and home care available through nonprofit organizations, oncology support/advocacy or other nonprofit community advocacy organizations, religious institutions, philanthropic organizations, pharmaceutical industry–sponsored programs, health care institution–specific programs; assist with financial documentation and application procedures as needed. • Explore assistance programs for other priorities competing for financial resources (e.g., for utility costs, gas, child care, food). • Assist patient to identify family, friends, or other available supports to assist with activities of daily living, household responsibilities, errands, shopping, meals, transportation or other responsibilities; assist with delegation of needs and schedules of availability if needed. • Assess preferred method of learning (e.g., verbal, visual, written materials); tailor instructional materials to patient needs, including language. • Include family, significant other, and friends in education whenever feasible. • Use return demonstration of behaviors and devices used to support adherence. • Provide contact information that spans 24 h for questions or problems. • Contact patient by phone or other means (e-mail, texting, video conference, telehealth) to assess for concerns in between follow-up visits to provider. • Encourage patient to use adherence reminders, such as pill boxes, medication calendars, checklists, medication diaries, alarms on cell phone or other devices/timers; explore availability of programmed telephone reminder services, text messages from family member, friend, or other caregiver; review diary at each visit. • Instruct patient to bring pill bottles to each follow-up visit; perform pill counts to monitor adherence. • Send postcard reminder to patient weekly (or less often) or 1 wk prior to due date for medication refill.

	• Refer to home care for continued education and follow-up on adherence. • Identify local pharmacies that supply oral medications for cancer therapies. Instruct patients to contact nurse if the pharmacy cannot fill the prescription within 24 h. • Remind patients to anticipate need for adequate supply of medications prior to travel or vacation.
Age • Older adults; especially those >75 yrs	• Ensure that printed education materials and instructions are printed in black using at least 14-point sans serif font such as Arial or Calibri. • Use illustrated education materials. • Review and revise adherence strategies if patient status declines or changes. • Explore availability of alarmed medication box.
Beliefs • Oral medications less effective or important than IV treatments • Fatalism about disease outcomes	• Provide education regarding oral versus IV medications. • Discuss goals of care and ongoing assessment of response to treatment.
Comorbidities • Preexisting chronic disease • Vision or hearing impairments	• Communicate with primary care and other providers involved in care of patient regarding current cancer disease status and treatment; collaborate with other providers for ongoing management of nononcology issues or exacerbation of issues that may impact cancer treatment adherence. • Collaborate with appropriate resources to assist with special needs and assistive devices for vision or hearing impairments.
Polypharmacy • Multiple medications for comorbidities or cancer treatment and symptom management	• Review all medications prescribed by oncology physicians and other providers involved in care of patient for preexisting chronic disease. • Assess patient use of over-the-counter medications and other agents. • Consult with pharmacist to identify medications and other agents that may be contraindicated or that may interfere with antineoplastic regimen. • Collaborate with all providers prescribing medications in order to simplify or reduce number of required medications if possible.

	• Provide patient, family, or other caregiver education regarding specific instructions when multiple medications are required. • Provide written checklist for patient to utilize daily to check off each medication when taken. • Check if patient prescriptions allow for refills; prescriptions should be for a finite period of time that concludes with next scheduled visit.
Psychiatric, Psychological, or Cognitive Concerns • Psychiatric disease • Depression • Cognitive impairments • Anxiety	• Avoid initial education regarding oral medications at the same time of first provider visit; have patient and other learners return for another appointment to see nurse for education and follow-up with subsequent visit if deemed to be at high risk for adherence challenges. • Discuss with provider the necessity for referral to psychiatrist to evaluate need for psychotropic medications. • Refer patient for professional mental health counseling as needed. • Identify additional supports for care and education as discussed earlier.
Disease Factors • Symptoms such as pain, nausea, fatigue, skin rashes, etc. • Impaired mobility	• Proactively assess and manage symptoms related to underlying disease or treatments. • Provide patient, family, or other caregivers education about expected side effects and management strategies. • Instruct patient to premedicate with antiemetic as prescribed 30 min prior to taking oral antineoplastic agent if needed for nausea or vomiting. • Identify additional supports for care as discussed earlier. • Assess need for referral to home physical or occupational therapy to address impaired mobility and need for assistive devices.
Communication Issues • Patient–Clinician • Clinician–Clinician	• Establish rapport and allow patients, families, and other caregivers time and opportunity to ask questions. • Do not assume adherence to oral antineoplastic agents; emphasize the value and importance of adherence and assess potential barriers consistently throughout course of treatment at each follow-up visit. • Communicate with primary provider regarding current cancer disease status, treatment and information regarding antineoplastic agents, such as drug–drug interactions, expected toxicities, and toxicities requiring prompt intervention.

IV, intravenous.

Adapted from Olsen, M. M., LeFebvre, K. B., & Brassil, K. (Eds.). (2019). *Chemotherapy and immunotherapy guidelines and recommendations for practice*. Pittsburgh, PA:

The nurse collaborates with physicians, social workers, third-party payers, and pharmaceutical companies to help the patient obtain reimbursement or support for the cost of oral cancer therapies and other required medications (Dusetzina et al., 2018). The nurse also reminds the patient about the importance of keeping follow-up appointments with the primary provider and assesses the patient's need for symptom management related to the underlying diseases or adverse effects of treatment. Home health nurses maintain communication with the primary provider regarding patient adherence and tolerance of treatment so that changes in care can be implemented in a timely fashion.

Complementary, Alternative, and Integrative Health Therapies

Integrative health care is viewed as a comprehensive, interdisciplinary approach to preventing and treating illness and promoting health that brings together complementary, alternative, and conventional therapies. The use of an integrative approach to health and wellness has grown within mainstream health care settings in the United States, particularly within oncology care (National Center for Complementary and Integrative Health [NCCIH], 2018).

Individuals use complementary approaches to prevent and treat cancer, although there are no data to support efficacy. Patients also use complementary approaches to manage symptoms related to cancer and associated treatments; some approaches are supported by clinical research while others are not. It is estimated that as many as 67% of people diagnosed with cancer use some form of complementary medicine (Wanchai, Armer, Smith, et al., 2017). However, many patients do not routinely communicate complementary practices to their health care providers because they usually are not asked about its use; they withhold the information, fearing that their provider would not approve, or they feel that the use of these approaches will not affect the conventional treatment they are receiving.

Although many complementary modalities can be a source of comfort and emotional support for patients, assessment of complementary therapy use is important for patient safety. Patients often perceive vitamins and dietary supplements as harmless, natural products that have no side effects or potential toxicities. In patients receiving any conventional therapies, the use of herbs or botanicals may interfere with drug metabolism, decrease or increase desired effects, or contain elements of uncertain pharmacologic capacities (NCCIH, 2018). Deep tissue massage and other manipulative therapies are contraindicated in patients with open wounds, radiodermatitis, thrombocytopenia, VTE, and coagulation disorders, and in those taking anticoagulants. See Chapter 4 for more information on complementary, alternative, and integrative health therapies.

COVID-19 Considerations

The novel coronavirus disease 2019 (COVID-19) pandemic began in Wuhan, China, in late 2019. Since that time, several risks for both severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection and pathogenesis to COVID-19 have been posed (see Chapter 66). Epidemiologic findings from early data in China suggest that having cancer could be an important risk factor for becoming infected with SARS-CoV-2 as well as increasing the risk of mortality from COVID-19 (Deng, Yin, Chen, et al., 2020). Many cancer clinicians and researchers worldwide recognized during the early days of the pandemic that there was an urgent need to identify idiosyncratic risks and treatment issues that revolve around managing adults with both COVID-19 and cancer. As a result, the COVID-19 and Cancer Consortium (CCC19) was established (see Resources section for link to CCC19). An early cohort study sponsored by CCC19 of 928 patients from the United States, Canada, and Spain with either a history of cancer or active malignancy identified prognostic factors for mortality and severe COVID-19 (Kuderer, Choueiri, Shah, et al., 2020). Overall 13% of the patients died (Kuderer et al., 2020), a higher mortality rate than the 5.6% case fatality rate for all adult patients in the United States with COVID-19 (Johns Hopkins University & Medicine Coronavirus Resource Center, 2020). The researchers identified the following factors as associated with an increase in 30-day mortality: older age, male sex, a history of smoking, having two or more comorbidities, having an active cancer, and having received azithromycin plus hydroxychloroquine during treatment for COVID-19 (Kuderer et al., 2020). The four most common presenting symptoms of COVID-19 in these patients included fever, cough, fatigue or malaise, and dyspnea; the same as for all patients with COVID-19 (Kuderer et al., 2020). There was no association between having recently had surgery and either having severe COVID-19 or dying, suggesting that surgery indicated for patients with cancer should not be postponed due to pandemic concerns (Kuderer et al., 2020). CCC19 will continue to analyze registry data of patients with COVID-19 and cancer and publicize noteworthy findings as they become available, to facilitate optimal management of patients with COVID-19 and cancer (Kuderer et al., 2020).

Nursing Care of the Patient with Cancer

The outlook for patients with cancer has greatly improved because of scientific and technologic advances. However, as a result of the underlying disease or various treatment modalities, patients with cancer may experience a variety of secondary problems such as reduced WBC counts, infection, bleeding, skin and nutritional problems, pain, fatigue, and psychological stress. Chart 12-6 provides a nursing care plan for the patient with cancer.

Maintaining Tissue Integrity

Some of the most frequently encountered disturbances of tissue integrity include stomatitis, skin and tissue reactions to radiation therapy, cutaneous toxicities associated with targeted therapy, alopecia, and metastatic skin lesions.

Stomatitis

Mucositis, a common side effect of radiation and some types of chemotherapy, refers to an inflammatory process involving the mucous membranes of the oral cavity and the gastrointestinal tract. **Stomatitis**, a form of mucositis, is an inflammatory process of the mouth, including the mucosa and tissues surrounding the teeth. Stomatitis is characterized by changes in sensation, erythema (mild redness), and edema or, if severe, by painful ulcerations, bleeding, and secondary infection. Stomatitis commonly develops within 3 to 14 days after patients receive certain chemotherapeutic agents (e.g., 5-fluorouracil and doxorubicin), immunotherapies (e.g., IL-2 and nivolumab); and targeted therapies (e.g., temsirolimus and everolimus). Stomatitis affects up to 100% of patients undergoing high-dose chemotherapy with HSCT, 90% of patients with malignancies of the head and neck receiving radiotherapy, and up to 40% of patients receiving standard-dose chemotherapy (Eilers, Asakura, Blecher, et al., 2017; Olsen et al., 2019). Stomatitis may be worse in patients with head and neck cancers who receive combined modality therapy of both radiation and chemotherapy. When severe, stomatitis can lead to interruptions, delays, and modifications in the course of treatment, all of which may contribute to less desirable patient outcomes. Severe oral pain can significantly affect swallowing, nutritional intake, speech, quality of life, coping abilities, and willingness to adhere to treatment regimens. In addition, stomatitis may lead to more frequent health care visits, hospitalizations, and increased health care costs (Berger, Schopohl, Bollig, et al., 2018). Stomatitis and mucositis are attributed to a cascade of molecular processes and submucosal endothelial cell destruction that begin almost immediately after the initiation of radiation and certain types of chemotherapy, prior to the development of signs and symptoms. Mucositis develops because of a sequence of related and interacting biologic events, culminating in injury and apoptosis of basal epithelial cells, leading to the loss of epithelial renewal, atrophy, and ulceration. Gram-positive and gram-negative organisms can invade the ulcerated tissue and result in infection.

Nursing assessment begins with an understanding of the patient's usual practices for oral hygiene and identification of individuals at risk for stomatitis. Oral cavity assessment is performed daily or at each patient visit (Olsen et al., 2019). Risk factors and comorbidities associated with stomatitis include poor oral hygiene, general debilitation, existing dental disease, prior irradiation to the head and neck region, impaired salivary gland function, the use of other medications that dry mucous membranes, myelosuppression, tobacco use, previous cancer treatment with a stomatotoxic agent or radiation therapy, diminished renal function, impaired nutritional status, and both older (>65 years) and younger (<20 years) ages (Olsen et al., 2019). The patient is also assessed for dehydration, infection, pain, and nutritional impairment resulting from mucositis.

Optimal evidence-based prevention and treatment approaches for stomatitis remain limited but continue to be studied across disciplines (Bowen, Gibson, Coller,

et al., 2019; Eilers et al., 2017). Most clinicians agree that maintenance of good oral hygiene, including brushing, flossing, rinsing, and dental care, is necessary to minimize the risk of oral complications associated with cancer therapies.

Palifermin, an IV-administered synthetic form of human keratinocyte growth factor, is beneficial in the prevention and management of stomatitis in patients with hematologic malignancies who are preparing for HSCT and in those undergoing chemotherapy for head and neck cancer (Bowen et al., 2019; Eilers et al., 2017). Palifermin promotes epithelial cell repair and accelerated replacement of cells in the mouth and gastrointestinal tract. Careful timing of administration and monitoring are essential for effectiveness and to detect adverse effects. Other approaches recommended for practice include cryotherapy (topical application of oral ice during infusions), consistent oral hygiene, low-level laser therapy, and sodium bicarbonate mouth rinses (Bowen et al., 2019; Eilers et al., 2017; Olsen et al., 2019). Additional aspects of care are discussed in Chart 12-6: nursing care plan for patients with cancer.

Chart 12-6 **PLAN OF NURSING CARE**

The Patient with Cancer

NURSING DIAGNOSIS: Risk for infection associated with inadequate defenses related to myelosuppression secondary to radiation or antineoplastic agents
GOAL: Prevention of infection

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient for evidence of infection. a. Check vital signs every 4 hours. b. Monitor white blood cell (WBC) count and differential each day. c. Inspect all sites that may serve as entry ports for pathogens (IV sites, wounds, skin folds, bony prominences, perineum, and oral cavity). 2. Report fever (≥38.3°C [101°F] or ≥38°C [100.4°F] for >1 hour) (see Table 12-10), chills, diaphoresis, swelling, heat, pain, erythema, exudate on any body surfaces. Also report change in respiratory or mental status, urinary frequency or burning, malaise, myalgias, arthralgias, rash, or diarrhea. 3. Obtain cultures and sensitivities as indicated before initiation of antimicrobial treatment (wound exudate, sputum, urine, stool, blood). 4. Initiate measures to minimize infection.	1. Signs and symptoms of infection may be diminished in the immunocompromised host. Prompt recognition of infection and subsequent initiation of therapy will reduce morbidity and mortality associated with infection. 2. Early detection of infection facilitates early intervention. 3. Tests identify the organism and indicate the most appropriate antimicrobial therapy. The use of inappropriate antibiotics enhances proliferation of additional flora and encourages growth of antibiotic-resistant organisms. 4. Exposure to infection is reduced. a. Preventing contact with pathogens helps prevent infection. b. Hands are significant source of contamination. c. Incidence of rectal and perianal abscesses and subsequent	• Demonstrates normal temperature and vital signs • Exhibits absence of signs of inflammation: local edema, erythema, pain, and warmth • Exhibits normal breath sounds on auscultation • Takes deep breaths and coughs every 2 hours to prevent respiratory dysfunction and infection. • Exhibits absence of pathogens on cultures • Avoids contact with others with infections • Avoids crowds • All personnel carry out hand hygiene after each voiding and bowel movement. • Excoriation and trauma of

a. Discuss with patient and family:
   1. Placing patient in private room if absolute WBC count <1000/mm^3.
   2. Importance of patient avoiding contact with people who have known or recent infection or recent vaccination.

b. Instruct all personnel in careful hand hygiene before and after entering room.

c. Avoid rectal or vaginal procedures (rectal temperatures, examinations, suppositories; vaginal tampons).

d. Use stool softeners to prevent constipation and straining.

e. Assist patient in practice of meticulous personal hygiene.

f. Instruct patient to use electric razor.

g. Encourage patient to ambulate in room unless contraindicated.

h. Provide patient and family education on food hygiene and safe food handling.

i. Each day change water pitcher, systemic infection is high. Manipulation may cause disruption of membrane integrity and enhance progression of infection.

d. Minimizes trauma to tissues

e. Prevents skin irritation

f. Minimizes skin trauma

g. Minimizes chance of skin breakdown and stasis of pulmonary secretions

h. No evidence supports dietary restrictions of avoiding raw or fresh fruit and vegetables for patients who are neutropenic. General precautions regarding food handling and storage are recommended.

i. Stagnant water is a source of infection.

5. Hospital-acquired sepsis is closely associated with IV catheters.
   a. Incidence of infection is increased when catheter is in place >72 hours.
   b. Chlorhexidine is effective against many gram-positive

skin are avoided.

- Trauma to mucous membranes is avoided (avoidance of rectal thermometers, suppositories, vaginal tampons, perianal trauma).
- Uses evidence-based procedures and techniques if participating in management of invasive lines or catheters
- Uses electric razor
- Is free of skin breakdown and stasis of secretions
- Adheres to dietary and environmental precautions
- Exhibits no signs of sepsis or septic shock
- Exhibits normal vital signs, cardiac output, and arterial pressures when monitored

denture cleaning fluids, and respiratory equipment containing water. 5. Assess IV sites every day for evidence of infection. a. Change peripheral short-term IV sites every other day. b. Cleanse skin with chlorhexidine before arterial puncture or venipuncture. c. Change central venous catheter dressings every 48 hours. d. Change all solutions and infusion sets every 72–96 hours. e. Follow Infusion Nursing Society guidelines for care of peripheral and central venous access devices. 6. Avoid intramuscular injections. 7. Avoid insertion of urinary catheters; if catheters are necessary, use aseptic technique. 8. Educate patient or family member to administer granulocyte (or granulocyte-macrophage) colony-stimulating factor when prescribed. 9. Advise patient to avoid exposure to animal excreta, discuss dental procedures with primary provider, avoid	and gram-negative pathogens. c. Allows observation of site and removes source of contamination. d. Once introduced into the system, microorganisms can grow in infusion sets despite replacement of container and high flow rates. e. Infusion Nursing Society collaborates with other nursing subspecialties in determining guidelines for IV access care. 6. Reduces risk for skin abscesses. 7. Rates of infection greatly increase after urinary catheterization. 8. Granulocyte colony-stimulating factor decreases the duration of neutropenia and the potential for infection. 9. Minimizes exposure to potential sources of infection and disruption of skin integrity	• Demonstrates ability to administer colony-stimulating factor • Has bowel movements at regular intervals without constipation or straining • Patient hygiene is maintained. • Absence of IV catheter–related infection • Absence of skin abscesses • Absence of urinary catheter–related infection

vaginal douche, and avoid vaginal or rectal manipulation during sexual contact during the period of neutropenia.		
NURSING DIAGNOSIS: Risk for impaired skin integrity: erythematous and wet desquamation reactions to radiation therapy **GOAL:** Maintenance of skin integrity		
Nursing Intervention	**Rationale**	**Expected Outcomes**
1. In erythematous areas: a. Avoid the use of soaps, cosmetics, perfumes, powders, lotions, and ointments; non–aluminum-based deodorant may be used on intact skin. b. Use only lukewarm water to bathe the area. c. Avoid rubbing or scratching the area. d. Avoid shaving the area with a straight-edged razor. e. Avoid applying hot-water bottles, heating pads, ice, and adhesive tape to the area. f. Avoid exposing the area to sunlight or cold weather. g. Avoid tight clothing in the area. Use cotton clothing. h. Topical agents such as Aquaphor,	1. Care to the affected areas must focus on preventing further skin irritation, drying, and damage. a. These substances may cause pain and additional skin irritation and damage. b. Avoiding water of extreme temperatures and soap minimizes additional skin damage, irritation, and pain. c. Rubbing, scratching, or both will lead to additional skin irritation, damage, and increased risk of infection. d. The use of razors may lead to additional irritation and disruption of skin integrity and increased risk of infection. e. Avoiding extreme temperatures minimizes	• Avoids use of soaps, powders, and other cosmetics on site of radiation therapy • States rationale for special care of skin • Exhibits minimal change in skin • Avoids trauma to affected skin region (avoids shaving, constricting and irritating clothing, extremes of temperature, and the use of adhesive tape) • Reports change in skin promptly • Demonstrates proper care of blistered or open areas

radiacare gel, aloe vera, or biafine may be used, and low- or medium-potency corticosteroid cream may be given if pruritus is present.

2. If wet desquamation occurs:

   a. Do not disrupt any blisters that have formed.

   b. Avoid frequent washing of the area.

   c. Report any blistering.

   d. Use prescribed creams or ointments; topical antibacterial creams may help to dry a wet wound (e.g., Silvadene cream).

   e. If area weeps, apply a nonadhesive absorbent dressing.

   f. If the area is without drainage, moisture and vapor-permeable dressings, such as hydrocolloids and hydrogels on noninfected areas, have been used in many settings.

   g. Consult with wound-ostomy-continence nurse (WOCN) and primary provider if eschar forms.

additional skin damage, irritation, burns, and pain.

   f. Sun exposure or extreme cold weather may lead to additional skin damage and pain.

   g. Allows air circulation to affected area

   h. May aid healing; however, evidence supporting the benefits of topical agents is lacking.

2. Open weeping areas are susceptible to bacterial infection. Care must be taken to prevent introduction of pathogens.

   a. Disruption of skin blisters disrupts skin integrity and may lead to increased risk of infection.

   b. Frequent washing may lead to increased irritation and skin damage, with increased risk of infection.

   c. Blistering of skin represents progression of skin damage.

   d. Anecdotally believed to decrease irritation and inflammation of the area and promote healing; although a variety of products are used in many settings, there are

- Exhibits absence of infection of blistered and opened areas.
- Wound is free of development of eschar

few randomized controlled trials with evidence to support one product or intervention over another.

e. Easier to remove and associated with less pain and trauma when drainage dries and adheres to dressing.

f. May promote healing; however, randomized controlled clinical trial support is lacking in the setting of moist desquamation. Hydrocolloid dressings may enhance comfort.

g. Eschar must be removed to promote healing and prevent infection. WOCNs have expertise in the care of wounds.

NURSING DIAGNOSIS: Impaired oral mucous membrane integrity: stomatitis
GOAL: Maintenance of intact oral mucous membranes

Nursing Intervention	Rationale	Expected Outcomes
1. Assess oral cavity daily using the same assessment criteria or rating scale. 2. Identify individuals at increased risk for stomatitis and related complications. 3. Instruct patient to report oral burning, pain, areas of redness, open lesions on oropharyngeal mucosa and lips, pain associated with swallowing, or decreased tolerance to temperature extremes of food. 4. Encourage and assist as needed in oral hygiene.	1. Provides baseline for later evaluation; maintains consistency in assessment findings 2. Patient and treatment variables are associated with the incidence and severity of stomatitis as well as related complications such as delayed healing and infection. 3. Identification of initial stages of stomatitis will facilitate prompt interventions, including modification of treatment as prescribed by primary provider. 4. Patients who are having discomfort or pain, or other symptoms related to the disease and treatment, may require encouragement and assistance in performing oral hygiene. Oral hygiene is maintained to prevent complications of	• States rationale for frequent oral assessment and hygiene • Factors associated with the incidence, severity, and complications are identified prior to initiation of cancer treatment • Oral mucosal assessment is conducted at baseline and on an ongoing basis • Oral hygiene practices are initiated prior to development of stomatitis. • Identifies signs and symptoms of stomatitis to report to nurse or primary provider • Participates in recommended oral hygiene regimen • Avoids mouthwashes with alcohol • Brushes teeth and mouth with soft toothbrush • Uses lubricant to keep lips soft and nonirritated • Avoids hard-to-chew, spicy, hot foods or other irritating foods

	stomatitis, such as infection.	• Maintains adequate hydration
Nursing Intervention	**Rationale**	**Expected Outcomes**
Preventive		
1. Advise patient to avoid irritants such as commercial mouthwashes, alcoholic beverages, and tobacco. 2. Brush with soft toothbrush using nonabrasive toothpaste for 90 seconds after meals and at bedtime; allow toothbrush to air dry before storing; floss at least once daily or as advised by the clinician; patients who have not previously flossed regularly should not initiate flossing during stomatoxic treatment; rinse mouth four times a day with a bland rinse (normal saline, sodium bicarbonate, or saline and sodium bicarbonate); avoid irritating foods (acidic, hot, rough, and spicy); use water-based moisturizers to protect lips. 3. Consider use of oral ice chips during stomatoxic chemotherapy infusions. 4. Consider use of low-level laser therapy.	1. Alcohol content of mouthwashes and tobacco smoke will dry oral tissues and potentiate breakdown. 2. Limits trauma and removes debris. Patients who have not previously flossed regularly should not initiate flossing during stomatoxic treatment due to potential for injury to the oral mucosa and increased susceptibility to infection. 3. Oral cryotherapy has demonstrated reduced oral mucositis incidence, severity, and pain; improved quality of life; and minimizes chances of complications of oral mucositis 4. Low-energy level laser therapy has demonstrated decreased severity, duration, and pain associated with stomatitis.	• Exhibits clean, intact oral mucosa • Exhibits no ulcerations or infections of oral cavity • Exhibits no evidence of bleeding • Reports absent or decreased oral pain • Reports no difficulty swallowing • Exhibits healing (reepithelialization) of oral mucosa within 5–7 days (mild stomatitis)

5. Consider administration of palifermin as prescribed for patients receiving high-dose chemotherapy. 6. Maintain adequate hydration. 7. Provide written instruction and education to patients on the above items.	5. Palifermin, a recombinant keratinocyte growth factor (KGF) that stimulates the growth of cells lining the mouth and intestinal tract, has been shown to decrease the severity and duration of stomatitis. 6. Maintenance of hydration prevents mucosal drying and breakdown. 7. Written information reinforces patient education and provides the patient and family with a source.	
Mild stomatitis (generalized erythema, limited ulcerations, small white patches: *Candida*) 1. Use normal saline mouth rinses every 1–4 hours. 2. Use soft toothbrush or toothette. 3. Remove dentures except for meals; be certain that dentures fit well. 4. Apply water-soluble lip lubricant. 5. Avoid foods that are spicy or hard to chew and those with extremes of temperature.	1. Assists in removing debris, thick secretions, and bacteria 2. Minimizes trauma 3. Minimizes friction and discomfort 4. Promotes comfort 5. Prevents local trauma	• Exhibits healing of oral tissues within 10–14 days (severe stomatitis) • Exhibits no bleeding or oral ulceration • Consumes adequate fluid and food • Exhibits absence of dehydration and weight loss • Exhibits no evidence of infection
Severe stomatitis		

(confluent ulcerations with bleeding and white patches covering >25% of oral mucosa)		
1. Obtain tissue samples for culture and sensitivity tests of areas of infection. 2. Assess ability to chew and swallow; assess gag reflex. 3. Use oral rinses (may combine in solution saline, anti-*Candida* agent, such as mycostatin, and topical anesthetic agent [described later]) as prescribed, or place patient on side and irrigate mouth; have suction available. 4. Remove dentures. 5. Use toothette or gauze soaked with solution for cleansing. 6. Use water-soluble lip lubricant. 7. Provide liquid or pureed diet. 8. Monitor for dehydration. 9. Minimize discomfort. a. Consult primary provider for use of topical anesthetic, such as dyclonine and diphenhydramine, or viscous lidocaine. b. Administer systemic analgesics as prescribed.	1. Assists in identifying need for antimicrobial therapy 2. Patient may be in danger of aspiration 3. Facilitates cleansing and provides for safety and comfort 4. Prevents trauma from ill-fitting dentures 5. Limits trauma and promotes comfort 6. Promotes comfort and minimizes loss of skin integrity 7. Ensures intake of easily digestible foods without chewing 8. Decreased oral intake and ulcerations potentiate fluid deficits 9. Promotes healing a. Alleviates pain and increases sense of well-being; promotes participation in oral hygiene and nutritional intake b. Adequate management of pain related to	a. Adheres to oral care regimen b. Exhibits healing of oral tissues within 10–14 days (severe stomatitis) • Consumes adequate fluid and food • Exhibits absence of dehydration and weight loss • Exhibits no evidence of infection • Reports absent or decreased discomfort or pain

c. Perform mouth care as described.	severe stomatitis can facilitate improved quality of life, participation in other aspects of activities of daily living, oral intake, and verbal communication. c. Promotes removal of debris, healing, and comfort	

NURSING DIAGNOSIS: Impaired skin integrity associated with rash
GOALS: Maintenance of skin integrity

Nursing Intervention	Rationale	Expected Outcomes
Prevention		
1. Instruct patients to avoid sunlight through use of protective clothing, use of sun screen with SPF of 30 with physical blockers (zinc oxide, titanium dioxide), or avoidance of direct sun exposure. 2. Maintain adequate oral hydration. 3. Avoid long hot showers or baths, harsh soaps and laundry detergents, perfumes, and nonhypoallergenic cosmetics. 4. Apply emollients; apply hydrocortisone 1% cream with moisturizer at least twice daily; administer doxycycline 100 mg	1. Many agents are associated with photosensitivity; sunburn would intensify inflammation associated with rash and potentiate loss of skin integrity 2. Prevents skin dryness related to dehydration 3. Prevents skin irritation, dryness, flaking, and inflammation 4. Minimizes dryness, flaking, and disruption of skin integrity	• Sun exposure will be limited; no development of sun burn • Absence of dehydration • Participates in skin care regimen as instructed • Absence of dryness, flaking

twice per day or minocycline, as prescribed		
Treatment		
1. Apply topical treatment as prescribed: clindamycin 1%, fluocinonide 0.05% cream twice a day, or alclometasone 0.05% cream twice a day 2. For severe papulopustular rash: Administer systemic treatment as prescribed: doxycycline 100 mg twice per day; minocycline 100 mg daily; or isotretinion at low doses of 20–30 mg per day 3. Assess for development of infection: obtain cultures of pustules and administer appropriate antibiotics as prescribed by the physician	1. Recommended as treatment to minimize skin disruption and prevent infection by Multinational Association of Supportive Care in Cancer (MASCC) 2. Recommended as treatment to minimize skin disruption and prevent infection by Multinational Association of Supportive Care in Cancer (MASCC) 3. Prompt recognition and treatment of infection are necessary to prevent bacteremia, sepsis, and further patient compromise	• Rash severity does not interfere with level of comfort and adherence to targeted therapy as prescribed; absence of local or systemic infection • Rash severity does not interfere with level of comfort and adherence to targeted therapy as prescribed; absence of local or systemic infection • Local infection is controlled; absence of sepsis

NURSING DIAGNOSIS: Impaired tissue integrity: alopecia
GOAL: Maintenance of tissue integrity; coping with hair loss

Nursing Intervention	Rationale	Expected Outcomes
1. Discuss potential hair loss and regrowth with patient and family; advise that hair loss may occur on body parts other than the head. 2. Explore potential impact of hair loss on self-image, interpersonal relationships, and sexuality. 3. Prevent or minimize hair loss through the following: a. Use scalp cooling (hypothermia), if appropriate. b. Cut long hair before treatment. c. Use mild shampoo and conditioner, gently pat dry, and avoid excessive shampooing. d. Avoid electric curlers, curling irons, dryers, clips, barrettes, hair sprays, hair dyes, hair extensions, weaves, braids, dreadlocks, hair straightening products, and permanent waves. e. Avoid excessive combing or brushing; use wide-toothed comb. 4. Prevent trauma to scalp. a. Use sunscreen or wear hat when in the	1. Provides information so that patient and family can begin to prepare cognitively and emotionally for loss 2. Facilitates coping and maintenance of interpersonal relationships 3. Retains hair as long as possible. a. Decreases hair follicle uptake of chemotherapy (not used for patients with leukemia or lymphoma because tumor cells may be present in blood vessels or scalp tissue) b. Minimizes hair loss due to the weight and manipulation of hair 4. Preserves tissue integrity a. Assists in maintaining skin integrity b. Prevents ultraviolet light exposure 5. Minimizes change in appearance a. Wig that closely resembles hair color and style is	• Identifies alopecia as potential side effect of treatment • Identifies positive and negative feelings and threats to self-image • Verbalizes meaning that hair and possible hair loss have for them • States rationale for modifications in hair care and treatment • Uses mild shampoo and conditioner, and shampoos hair only when necessary • Avoids hair dryer, curlers, sprays, and other stresses on hair and scalp • Wears hat or scarf over

sun. 5. Suggest ways to assist in coping with hair loss. a. Purchase wig or hairpiece before hair loss. b. If hair loss has occurred, take photograph to wig shop to assist in selection. c. Begin to wear wig before hair loss. d. Contact the American Cancer Society for donated wigs or a store that specializes in this product. e. Wear hat, scarf, or turban. 6. Encourage patient to wear own clothes and retain social contacts. 7. Explain that hair growth usually begins again once therapy is completed.	more easily selected if hair loss has not begun. b. Facilitates adjustment c. Enables patient to be prepared for loss and facilitates adjustment d. Provides options to patient and assists with financial burden if necessary e. Conceals loss and protects scalp 6. Assists in maintaining personal identity 7. Reassures patient that hair loss is usually temporary	hair when exposed to sun • Takes steps to deal with possible hair loss before it occurs; purchases wig or hairpiece if desired • Maintains hygiene and grooming • Interacts and socializes with others

NURSING DIAGNOSIS: Impaired nutritional status associated with nausea and vomiting

GOAL: Patient experiences less nausea and vomiting associated with therapies; weight loss is minimized

Nursing Intervention	Rationale	Expected Outcomes
1. Assess the patient's previous experiences and expectations of nausea and vomiting, including causes and interventions used.	1. Identifies patient concerns, misinformation, and potential strategies for intervention; also gives patient sense of empowerment and control.	• Identifies previous triggers of nausea and vomiting
2. Adjust diet before and after drug administration according to patient preference and tolerance.	2. Each patient responds differently to food after chemotherapy. A diet containing foods that relieve or prevent nausea or vomiting is most helpful.	• Exhibits decreased apprehension and anxiety
3. Prevent unpleasant sights, odors, and sounds in the environment.	3. Unpleasant sensations can stimulate the nausea and vomiting center.	• Identifies previously used successful interventions for nausea and vomiting
4. Use distraction, music therapy, biofeedback, self-hypnosis, relaxation techniques, and guided imagery before, during, and after chemotherapy.	4. Decreases anxiety, which can contribute to nausea and vomiting. Psychological conditioning may also be decreased.	• Reports decrease in nausea
5. Administer prescribed antiemetics, sedatives, and corticosteroids before chemotherapy and afterward as needed.	5. Administration of antiemetic regimen before onset of nausea and vomiting limits the adverse experience and facilitates control. Combination drug therapy reduces nausea and vomiting through various triggering mechanisms.	• Reports decrease in incidence of vomiting
6. Ensure adequate fluid hydration before, during, and after drug administration; assess intake and output.	6. Adequate fluid volume dilutes drug levels, decreasing stimulation of vomiting receptors.	• Consumes adequate fluid and food when nausea subsides
7. Encourage frequent oral hygiene.		• Demonstrates use of distraction, relaxation, and imagery when indicated
		• Exhibits normal skin turgor and

8. Provide pain-relief measures, if necessary. 9. Consult with dietician as needed. 10. Assess and address other contributing factors to nausea and vomiting, such as other symptoms, constipation, gastrointestinal irritation, electrolyte imbalance, radiation therapy, medications, and central nervous system metastasis.	7. Reduces unpleasant taste sensations 8. Increased comfort increases physical tolerance of symptoms. 9. Interdisciplinary collaboration is essential in addressing complex patient needs. 10. Multiple factors may contribute to nausea and vomiting.	moist mucous membranes • No additional weight loss

NURSING DIAGNOSIS: Impaired nutritional status associated with anorexia, cachexia, or malabsorption

GOAL: Maintenance of nutritional status and of weight within 10% of pretreatment weight

Nursing Intervention	Rationale	Expected Outcomes
1. Assess and address factors that interfere with oral intake or are associated with increased risk of decreased nutritional status. 2. Initiate appropriate referrals for interdisciplinary collaboration to manage factors that interfere with oral intake. 3. Educate patient to avoid unpleasant sights, odors, and sounds in the environment during mealtime. 4. Suggest foods that are preferred and well tolerated by the patient, preferably high-calorie and high-protein foods. Respect ethnic and cultural food preferences. 5. Encourage adequate fluid intake, but limit fluids at mealtime.	1. Multiple patient or treatment-related factors are associated with increased risk of impaired nutritional intake, such as radiation to the head, neck, and thorax; stomatoxic or emetogenic chemotherapy; prior oral, head, and neck surgery; mucositis; impaired swallowing or dysphagia; poor dentition; cough or dyspnea. 2. Other disciplines may be more appropriate for assessment and management of issues such as swallowing impairments (speech therapy), fatigue and decreased physical ability (physical and occupational therapy), nutritional assessment and determination of patient needs (nutritionist), cough and dyspnea (respiratory therapy), poor dentition (dental medicine), depression/anxiety (social worker, psychologist, or psychiatrist). 3. Anorexia can be stimulated or increased with noxious stimuli.	• Factors associated with increased risk for impaired nutritional intake are identified • Factors associated with increased risk of impaired nutritional intake are identified and addressed, whenever possible, through interdisciplinary collaboration • Patient and family identify minimal nutritional requirements • Maintains or increases weight and body cell mass as per goals identified by nutritionist • Reports decreasing anorexia and increased interest in eating • Demonstrates normal skin turgor

6. Suggest smaller, more frequent meals. 7. Promote relaxed, quiet environment during mealtime with increased social interaction as desired. 8. If patient desires, serve alcoholic beverages at mealtime with foods. 9. Consider cold foods, if desired. 10. Encourage nutritional supplements and high-protein foods between meals. 11. Encourage frequent oral hygiene, particularly prior to meals. 12. Address pain and other symptom management needs. 13. Increase activity level as tolerated. 14. Decrease anxiety by encouraging verbalization of fears and concerns; use relaxation techniques and guided imagery at mealtime. 15. Instruct patient and family about body alignment and proper positioning at mealtime. 16. Collaborate with dietician to provide nutritional	4. Foods preferred, well tolerated, and high in calories and protein maintain nutritional status during periods of increased metabolic demand. 5. Fluids are necessary to eliminate wastes and prevent dehydration. Increased fluids with meals can lead to early satiety. 6. Smaller, more frequent meals are better tolerated because early satiety is less likely to occur. 7. A quiet environment promotes relaxation. Social interaction at mealtime may foster appetite, divert focus on food, and promote enjoyment of eating. 8. Alcoholic beverages may stimulate appetite and add calories. 9. Cold, high-protein foods are often more tolerable and less odorous than hot foods. 10. Supplements and snacks add protein and calories to meet nutritional requirements. 11. Oral hygiene may stimulate appetite and increase saliva production. 12. Pain and other symptoms impair appetite and nutritional intake. 13. Increased activity promotes appetite. 14. Relief of anxiety may increase appetite.	• Identifies rationale for dietary modifications; patient and family verbalize strategies to minimize nutritional deficits • Participates in calorie counts and diet histories • Uses relaxation techniques and guided imagery before meals • Exhibits laboratory and clinical findings indicative of adequate nutritional intake: normal serum levels of protein, albumin, transferrin, iron, blood urea nitrogen (BUN), creatinine, vitamin D, electrolytes, hemoglobin, hematocrit, and lymphocytes; normal urinary creatinine levels • Consumes diet containing required nutrients • Carries out oral hygiene before meals

counseling; instruct patient and family regarding enteral tube feedings of commercial liquid diets, elemental diets, or other foods as prescribed. 17. Collaborate with dietician or nutrition support team to instruct patient and family regarding home parenteral nutrition with lipid supplements as prescribed. 18. Administer appetite stimulants as prescribed by primary provider. 19. Encourage family and friends not to nag or cajole patient about eating. 20. Assess and address other contributing factors to nausea, vomiting, and anorexia such as electrolyte imbalance, radiation therapy, medications, and central nervous system metastasis.	15. Proper body position and alignment are necessary to aid chewing and swallowing. 16. Nutritional counseling may improve outcomes. Tube feedings may be necessary in the severely debilitated patient who has a functioning gastrointestinal system but is unable to maintain adequate oral intake. 17. Parenteral nutrition with supplemental fats supplies needed calories and proteins to meet nutritional demands, especially in the nonfunctional gastrointestinal system. 18. Although the mechanism is unclear, medications such as megestrol acetate have been noted to improve appetite in patients with cancer and human immunodeficiency virus infection. 19. Pressuring patient to eat may cause conflict and unnecessary stress. 20. Multiple factors contribute to anorexia and nausea.	• Reports decreased pain or other symptoms; symptoms do not interfere with oral intake • Reports decreasing episodes of nausea and vomiting • Participates in increasing levels of activity as measured by assessment of performance status • Family and friends do not focus efforts on encouraging food intake • States rationale for use of tube feedings or parenteral nutrition • Demonstrates ability to manage enteral feedings or parenteral nutrition, if prescribed • Maintains body position and alignment needed to facilitate chewing and swallowing

NURSING DIAGNOSIS: Fatigue
GOAL: Decreased fatigue level

Nursing Intervention	Rationale	Expected Outcomes
1. Assess patient and treatment factors that are associated with or increase fatigue (e.g., anemia, fluid and electrolyte imbalances, pain, anxiety, etc.)	1. Multiple factors are associated with or contribute to cancer-related fatigue. Although fatigue is common in patients receiving chemotherapy or radiation therapy, there are several factors that can be modified or addressed, such as dehydration, electrolyte abnormalities, organ impairment, anemia, impaired nutrition, pain and other symptoms, depression, anxiety, impaired mobility, and dyspnea	• Factors contributing to fatigue are assessed and managed whenever possible • Exhibits acceptable serum value levels for nutritional indices (see Imbalanced Nutrition) • Reports decreased pain or other symptoms • Consumes diet with recommended nutritional intake • Achieves or maintains appropriate weight and body mass • Maintains adequate hydration • Reports decreasing levels of fatigue • Adopts healthy lifestyle practices • Rests when fatigued
2. Institute interventions to address factors contributing to fatigue (e.g., correct electrolyte imbalance, manage pain, collaborative management of anemia, administer prescribed antidepressants, anxiolytics, hypnotics, or psychostimulants, as indicated)	2. Addressing factors contributing to fatigue assists in managing fatigue (e.g., lowered hemoglobin and hematocrit predispose patient to fatigue due to decreased oxygen availability especially in a setting of impaired mobility that requires increased energy expenditure).	
3. Encourage balance of rest and exercise; avoiding extended periods of inactivity. At minimum, promote patient's normal sleep habits.	3. Sleep helps to restore energy levels. Prolonged napping during the day may interfere with sleep habits.	
4. During active treatment, rearrange daily schedule and organize activities to conserve energy expenditure; encourage patient to ask for others' assistance with	4. Reorganization of activities can reduce energy losses and stressors.	

necessary chores, such as housework, child care, shopping, and cooking. During periods of profound fatigue, consider reduced job workload, if necessary and possible, by reducing number of hours worked per week. 5. Encourage protein, fat, and calorie intake at least equal to that recommended for the general public. 6. Encourage the use of relaxation techniques and guided imagery. 7. Encourage participation in planned exercise programs involving aerobic, resistance, and flexibility training based on individual limitations and safety measures. a. Minimum exercise for survivors depending on individual capabilities ranges from 10 minutes of light exercise, yoga, or stretching daily to 30 minutes of moderate to vigorous of activity	5. Protein and calorie depletion decreases activity tolerance; preventing malnutrition, achieving and maintaining recommended weight and body mass assist in management of fatigue. 6. Promotion of relaxation and psychological rest limits contribution to physical fatigue. 7. Various approaches to exercise programs have demonstrated increases in endurance and stamina and lower fatigue. 8. Many providers fail to discuss the role of exercise and healthy lifestyle practices for patients during and after cancer treatment. Patients may be more likely to utilize the benefits of exercise in addressing fatigue if they receive a formal prescription. 9. Creates community partnerships, a nonclinical environment of support, fosters increased awareness of survivorship needs, and provides referral sources that can reach more survivors. 10. A CET designs and administers fitness assessments and exercise programs specific to an	• Reports adequate sleep • Requests assistance with activities appropriately • Uses relaxation exercises and imagery to decrease anxiety and promote rest • Reports no breathlessness during activities • Reports improved ability to relax and rest • Exhibits improved mobility and decreased fatigue • Fatigue does not interfere with ability to participate in activities of daily living or pleasure

8.	Collaborate with other cancer providers to encourage them to give patients a prescription to exercise and explain role of exercise in cancer treatment.	individual's cancer diagnosis, treatment, current recovery status; possesses basic understanding of cancer diagnoses, treatments, and potential adverse effects.	
9.	Partner with community organizations (e.g., YMCA) to develop and offer cancer survivor specific rehab/exercise programs.		
10.	Collaborate with physical and occupational therapy or refer to American College of Sports Medicine (ACSM) Certified Cancer Exercise Trainer (CET) to identify safe and appropriate activities.		

NURSING DIAGNOSIS: Chronic pain
GOAL: Relief of pain and discomfort

Nursing Intervention	Rationale	Expected Outcomes
1. Use pain scale to assess pain and discomfort characteristics: location, quality, frequency, duration, etc., at baseline and on an ongoing basis. 2. Assure patient that you know the pain is real and will assist them in reducing it. 3. Assess prior pain experiences and previous management strategies the patient found successful. 4. Assess other factors contributing to patient's pain: fear, fatigue, other symptoms, psychosocial distress, etc. 5. Provide education to patient and family about prescribed analgesic regimen. 6. Address myths or misconceptions and lack of knowledge about the use of opioid analgesics.	1. Provides baseline for assessing changes in pain level and evaluation of interventions 2. Fear that pain will not be considered real increases anxiety and reduces pain tolerance. 3. Helps to individualize pain management approaches and identify potential challenges or approaches that should not be utilized because of safety or other issues 4. Provides data about factors that decrease the patient's ability to tolerate pain and increase pain level 5. Analgesics tend to be more effective when given early in pain cycle, around the clock at regular intervals, or when given in long-acting forms; breaks the pain cycle; premedication with analgesics is used for activities that cause increased pain or breakthrough pain. 6. Barriers to adequate pain management involve patients' fear of side effects, fatalism about the possibility of achieving pain control,	• Reports decreased level of pain and discomfort on pain scale • Reports less disruption in activity and quality of life from pain and discomfort • Reports decrease in other symptoms and psychosocial distress • Adheres to analgesic regimen as prescribed • Barriers to adequately addressing pain do not interfere with strategies for managing pain. • Takes an active role in administration of analgesia • Identifies additional effective pain-relief strategies • Uses previously employed successful pain-relief strategies appropriately • Identifies or utilizes nonpharmacologic pain-relief strategies and

7. Collaborate with patient, primary provider, and other health care team members when changes in pain management are necessary. 8. Consult with palliative care providers or team throughout the cancer continuum. 9. Explore nonpharmacologic and complementary strategies to relieve pain and discomfort: distraction, imagery, relaxation, cutaneous stimulation, acupuncture, etc.	fear of distracting providers from treating the cancer, belief that pain is indicative of progressive disease, and fears about addiction. Professional health providers also have demonstrated limited knowledge about evidence-based approaches to pain. 7. New methods of administering analgesia must be acceptable to patient, primary provider, and health care team to be effective; patient's participation decreases the sense of powerlessness. 8. Palliative care specialists provide expertise and contribute to symptom management regardless of stage of disease or treatment within the cancer continuum, not only during end-stage disease. Palliative care can improve quality of life, length of survival, symptom burden, mood, and efficient utilization of health services. 9. Increases the number of options and strategies available to patient that serve as adjuncts to pharmacologic interventions.	reports successful decrease in pain • Reports that decreased level of pain permits participation in other activities and events and quality of life

NURSING DIAGNOSIS: Grief associated with loss; altered role functioning
GOAL: Appropriate progression through grieving process

Nursing Intervention	Rationale	Expected Outcomes
1. Encourage verbalization of fears, concerns, and questions regarding disease, treatment, and future implications. 2. Explore previous successful coping strategies. 3. Encourage active participation of patient or family in care and treatment decisions. 4. Visit family and friends to establish and maintain relationships and physical closeness. 5. Encourage ventilation of negative feelings, including projected anger and hostility, within acceptable limits. 6. Allow for periods of crying and expression of sadness. 7. Involve spiritual advisor as desired by the patient and family. 8. Refer patient and family to professional counseling as indicated to alleviate	1. An increased and accurate knowledge base decreases anxiety and dispels misconceptions. 2. Provides frame of reference and examples of coping. 3. Active participation maintains patient independence and control. 4. Frequent contacts promote trust and security and reduce feelings of fear and isolation. 5. This allows for emotional expression without loss of self-esteem. 6. These feelings are necessary for separation and detachment to occur. 7. This facilitates the grief process and spiritual care. 8. Goal is to facilitate the grief process or adaptive methods of coping. 9. Grief work is variable. Not every person uses every phase of the grief process, and the time spent in dealing with each phase varies with every person. To complete grief work, this variability must be allowed.	The patient and family: • Progress through the phases of grief as evidenced by increased verbalization and expression of grief. • Identify resources available to aid coping strategies during grieving. • Use resources and supports appropriately. • Discuss the future openly with each other. • Discuss concerns and feelings openly with each other. • Use nonverbal expressions of concern for each other. • Develop positive or adaptive coping mechanisms for processing of grief.

pathologic or nonadaptive grieving.

9. Allow for progression through the grieving process at the individual pace of the patient and family.

NURSING DIAGNOSIS: Disturbed body image and situational low self-esteem associated with changes in appearance, function, and roles
GOAL: Improved body image and self-esteem

Nursing Intervention	Rationale	Expected Outcomes
1. Assess patient's feelings about body image and level of self-esteem. 2. Identify potential threats to patient's self-esteem (e.g., altered appearance, decreased sexual function, hair loss, decreased energy, role changes). Validate concerns with patient. 3. Encourage continued participation in activities and decision making. 4. Encourage patient to verbalize concerns. 5. Individualize care for the patient. 6. Assist patient in self-care when fatigue, lethargy, nausea, vomiting, and other symptoms prevent independence. 7. Assist patient in selecting and using cosmetics, scarves, hair pieces, hats, and clothing that increase their sense of attractiveness. 8. Encourage patient and partner to share	1. Provides baseline assessment for evaluating changes and assessing effectiveness of interventions. 2. Anticipates changes and permits patient to identify importance of these areas to them. 3. Encourages and permits continued control of events and self. 4. Identifying concerns is an important step in coping with them. 5. Prevents or reduces depersonalization and emphasizes patient's self-worth. 6. Physical well-being improves self-esteem. 7. Promotes positive body image. 8. Provides opportunity for expressing concern, intimacy, affection, and acceptance.	• Identifies concerns of importance • Takes active role in activities • Maintains participation in decision making • Verbalizes feelings and reactions to losses or threatened losses • Participates in self-care activities • Permits others to assist in care when they are unable to be independent • Exhibits interest in appearance, maintains grooming, and uses aids (cosmetics, scarves, etc.) appropriately if desired • Participates with others in conversations and social events and activities • Verbalizes concern about sexual partner or significant others • Explores alternative ways of expressing concern and affection • The patient and significant other can maintain level of intimacy and express affection and acceptance

concerns about altered sexuality and sexual function and to explore alternatives to their usual sexual expression. 9. Refer to collaborating specialists as needed.	9. Interdisciplinary collaboration is essential in meeting patient needs.	

COLLABORATIVE PROBLEM: Potential complication: risk for bleeding problems
GOAL: Prevention of bleeding

Nursing Intervention	Rationale	Expected Outcomes
1. Monitor for factors increasing risk of bleeding (thrombocytopenia, elevated INR/PT/PTT, decreased fibrinogen or other clotting factors, use of medications affecting platelets or other clotting indices) 2. Assess for and educate patient/family about signs and symptoms of bleeding: a. Petechiae or ecchymosis (bruising) b. Decrease in hemoglobin or hematocrit c. Prolonged bleeding from invasive procedures, venipunctures,	1. The underlying cancer, antineoplastic agents or other medications may interfere with normal mechanisms of clotting. 2. Early detection promotes early intervention. a. Petechiae and ecchymosis indicate injury to microcirculation and larger vessels. b. Decreased hemoglobin or hematocrit may indicate blood loss. c. Prolonged bleeding may indicate	• Signs and symptoms of bleeding are identified • Exhibits no blood in feces, urine, or emesis • Exhibits no bleeding of gums or injection/venipuncture sites • Exhibits no ecchymosis (bruising) or petechiae • Patient and family identify ways to prevent bleeding • Uses recommended measures to reduce risk of bleeding (uses soft toothbrush, shaves with electric razor only) • Exhibits normal vital signs • Reports that environmental hazards have been reduced or removed • Maintains hydration

minor cuts or scratches d. Frank or occult blood in any body fluids e. Bleeding from any body orifice f. Altered mental status g. Hypotension; tachycardia	abnormal clotting indices. d. Occult blood in body fluids indicates bleeding. e. Indicates blood loss f. Altered mental status may indicate decreased cerebral tissue oxygenation or bleeding. g. Hypotension or tachycardia may indicate blood loss.	• Reports absence of constipation • Avoids substances interfering with clotting • Absence of tissue destruction • Exhibits normal mental status and absence of signs of intracranial bleeding • Avoids medications that interfere with clotting (e.g., aspirin) • Absence of epistaxis and cerebral bleeding
3. Instruct patient and family about ways to minimize risk of bleeding. a. Use soft toothbrush for mouth care. b. Avoid commercial mouthwashes. c. Use electric razor for shaving. d. Use emery board for nail care. e. Avoid foods that are difficult to chew. f. Keep lips moisturized with water-based lubricant g. Maintain fluid intake of at least 3 L per 24 hours unless contraindicated h. Use stool softeners or increase bulk in diet. i. Recommend use of water-based lubricant before	3. Patient can participate in self-protection. a. Prevents trauma to oral tissues b. Contain high alcohol content that will dry oral tissues c. Prevents trauma to skin d. Reduces risk of trauma to nail beds e. Prevents oral tissue trauma f. Prevents skin from drying g. Prevents skin and oral tissue membranes from drying h. Prevents trauma to rectal	

sexual intercourse.

4. Initiate measures to minimize bleeding. Draw all blood for lab work with one daily venipuncture for hospitalized patients.
   a. Avoid taking temperature rectally or administering suppositories and enemas.
   b. Avoid intramuscular injections; use smallest needle possible.
   c. Apply direct pressure to injection and venipuncture sites for at least 5 minutes.
   d. Avoid bladder catheterizations; use smallest catheter if catheterization is necessary.
   e. Avoid medications that will interfere with clotting (e.g., aspirin).
   f. Recommend use of water-based lubricant before sexual intercourse.
   g. Platelet transfusions as prescribed; administer prescribed diphenhydramine

mucosa from straining
   i. Prevents friction and tissue trauma

4. Measures are taken to minimize bleeding
   a. Minimizes blood loss
   b. Bleeding may occur from intramuscular injection sites, particularly if large bore needles are used
   c. Bleeding may occur if direct pressure is not applied for a long enough time period
   d. Prevents trauma to urethra
   e. Minimizes risk of bleeding
   f. Helps prevent bleeding from small skin tears
   g. Platelet count <20,000/mm^3 (0.02 × 1012/L) is associated with increased risk of spontaneous bleeding. Allergic reactions to blood products are associated with antigen–

hydrochloride or hydrocortisone sodium succinate to prevent reaction to platelet transfusion. h. Supervise activity when out of bed. i. Caution against forceful nose blowing.	antibody reaction that causes platelet destruction h. Reduces risk of falls i. Prevents trauma to nasal mucosa and increased intracranial pressure

Radiation-Associated Impairment of Skin Integrity

Although advances in radiation therapy have resulted in decreased incidence and severity of skin impairments, patients may still develop radiodermatitis, formerly called radiation dermatitis, associated with pain, irritation, pruritus, burning, skin sloughing without drainage (dry desquamation) or with drainage (wet desquamation), and diminished quality of life (Gosselin, Beamer, Ciccolini, et al., 2017; Olsen et al., 2019). Nursing care for patients with radiodermatitis includes maintenance of skin integrity, cleansing, promotion of comfort, pain reduction, prevention of additional trauma, prevention and management of infection, and promotion of a moist wound-healing environment (Olsen et al., 2019). In order to prevent impaired skin integrity, patients are advised to use moisturizer on the skin, avoid sun exposure to the area of treatment, and avoid tape or bandages and other sources of irritation or trauma. Although a variety of methods and products are used in clinical practice for patients with radiation-induced skin impairment, there is

limited evidence to support their value (Gosselin et al., 2017). Patients with skin and tissue reactions to radiation therapy require careful skin care to prevent further skin irritation, drying, and damage, as discussed in the nursing care plan (see Chart 12-6, Risk for impaired skin integrity: erythematous and wet desquamation reactions to radiation therapy).

Alopecia

The temporary or permanent thinning or complete loss of hair is a potential adverse effect of whole brain radiation therapy, various chemotherapies and targeted agents. Alopecia usually begins 1 to 3 weeks after the initiation of chemotherapy and radiation therapy; regrowth most often begins within 8 weeks after the last treatment (Olsen et al., 2019). Some patients who undergo radiation to the head may sustain permanent hair loss. The onset of gradually progressing alopecia and body hair loss associated with targeted therapies generally occurs 1 to 3 months after the start of treatment and may be patchy appearing as temporal or frontal hair loss (Barton-Burke, Ciccolini, Mekas, et al., 2017). This type of hair loss is usually reversible after the end of therapy and in some cases beginning sooner. Several targeted agents are associated with changes in hair growth rate, curliness, texture, and pigmentation. Although health care providers may view hair loss as a minor issue, for many patients it is a major assault on body image, challenging to self-esteem, and resulting in psychosocial distress and depression. Despite the significant psychosocial impact of alopecia, few studies have addressed methods to prevent or minimize the impact of alopecia. The use of cryotherapy to the head (scalp cooling) has been shown to be effective in reducing alopecia during chemotherapy administration (Ross & Fischer-Cartlidge, 2017; Rugo, Melin, & Voigt, 2017). However, due to reports of scalp metastasis and a lack of safety data, cryotherapy is not recommended for use in patients with hematologic malignancies (Rugo et al., 2017). Nurses provide information about hair loss and support the patient and family in coping with changes in body image. Patients are assisted to identify proactive choices that may empower them to improve responses to cancer and perceived lack of control as discussed in the nursing care plan (see Chart 12-6, Impaired tissue integrity: alopecia).

Malignant Skin Lesions

Skin lesions may occur with local extension or metastasis of the tumor into the epithelium and its surrounding lymph and blood vessels. Either locally invasive or metastatic cancer to the skin may result in erythema, discolored nodules, or progression to wounds involving edema, exudates, and tissue necrosis. The most extensive lesions involve ulceration (referred to as fungating lesions) with an overgrowth of malodorous microorganisms. These lesions are a source of considerable pain, discomfort, and embarrassment. Although skin lesions occur in various malignancies, they are most commonly associated with breast cancer.

Ulcerating skin lesions usually indicate advanced or disseminated disease that is unlikely to be eradicated but may be controlled or palliated through systemic treatment (chemotherapy and targeted therapy) or radiation therapy. Local care of

these lesions is a nursing priority. Nurses carefully assess malignant skin lesions for the size, appearance, condition of surrounding tissue, odor, bleeding, drainage, and associated pain or other symptoms, including evidence of infection. The potential for serious complications such as hemorrhage, vessel compression/obstruction, or airway obstruction, especially in head and neck cancer, should be noted so that the caregiver can be instructed in palliative measures to maintain patient comfort.

Nursing care (see Chart 12-6) also includes wound cleansing, reduction of superficial bacteria, control of bleeding, odor reduction, protection from further skin trauma, and pain management. The patient and family require emotional support, assistance, and guidance in providing wound care and addressing comfort measures at home.

Promoting Nutrition

Most patients with cancer experience some weight loss during their illness. Thus nurses need to promote good nutrition throughout treatment.

Nutritional Impairment

Anorexia, malabsorption, and cancer-related anorexia-cachexia syndrome (CACS) are some common nutritional problems. Impaired nutritional status may contribute to both physical and psychosocial consequences (see Chart 12-7). Nutritional concerns include decreased protein and caloric intake, metabolic or mechanical effects of the cancer, systemic disease, side effects of the treatment, or the patient's emotional status.

Chart 12-7

Potential Consequences of Impaired Nutrition in Patients with Cancer

- Anemia
- Decreased survival
- Immune incompetence and increased incidence of infection
- Delayed tissue and wound healing
- Fatigue
- Diminished functional ability
- Decreased capacity to continue antineoplastic therapy
- Increased hospital admissions
- Increased length of hospital stay
- Impaired psychosocial functioning

Anorexia

Among the many causes of anorexia in patients with cancer are alterations in taste, manifested by increased salty, sour, and metallic taste sensations, and altered responses to sweet and bitter flavors. Taste changes contribute to decreased appetite and nutritional intake and subsequently protein–calorie malnutrition. Taste

alterations may result from mineral (e.g., zinc) deficiencies, increases in circulating amino acids and cellular metabolites, or the administration of chemotherapeutic agents. Patients undergoing radiation therapy to the head and neck may experience "mouth blindness," which is a severe impairment of taste.

Anorexia may occur because patients develop early satiety after eating only a small amount of food. This sense of fullness occurs secondary to a decrease in digestive enzymes, abnormalities in the metabolism of glucose and triglycerides, and prolonged stimulation of gastric volume receptors, which convey the feeling of being full. Psychological distress (e.g., fear, pain, depression, isolation) throughout illness may also have a negative impact on appetite. Patients may develop an aversion to food because of nausea and vomiting associated with treatment.

Malabsorption

Some patients with cancer are unable to absorb nutrients from the gastrointestinal system as a result of tumor activity, cancer treatments, or both. Malignancy can affect gastrointestinal activity in several ways (e.g., impaired enzyme production, interference with both protein and fat digestion) that can lead to increased gastrointestinal irritation, peptic ulcer disease, and fistula formation.

Chemotherapy and radiation associated with mucositis cause damage to mucosal cells of the bowel, resulting in impaired nutrient absorption. Abdominal irradiation has been associated with sclerosis of intestinal blood vessels and fibrotic changes in the gastrointestinal tissue, both impacting nutrient absorption. Surgical intervention may change peristaltic patterns, alter gastrointestinal secretions, and reduce the absorptive surfaces of gastrointestinal mucosa, all of which contribute to malabsorption.

Cancer-Related Anorexia-Cachexia Syndrome

CACS is a complex biologic process that results from a combination of increased energy expenditure and decreased intake (Mattox, 2017; Olsen et al., 2019). This syndrome can occur in both the curative and palliative stages of treatment and care. Combined immunologic, neuroendocrine, and metabolic processes give rise to anorexia, unintentional weight loss, and increased metabolic demand with impaired metabolism of glucose and lipids. As this syndrome continues, altered metabolic processes and tumor responses lead to cytokine release, causing generalized systemic inflammation. The patient experiences continued weight loss and malnutrition characterized by loss of adipose tissue, visceral protein, and skeletal muscle mass. Patients with CACS complain of loss of appetite, early satiety, and fatigue. It is estimated that 50% of patients with cancer experience anorexia and cachexia; this percentage increases to as high as 86% in patients with advanced cancer at the end of life (Olsen et al., 2019). Protein losses are associated with the development of anemia, peripheral edema, and progressive debilitation. The signs and symptoms of cancer cachexia and progressive debilitation result in decreased quality of life, psychological distress, and anxiety for both patient and family as they respond to actual and perceived impending losses, fear, lack of control, and helplessness.

Nursing care is integral to an interdisciplinary approach that addresses the multiple factors contributing to impaired nutritional status in patients with cancer (see Chart 12-6).

General Nutrition Considerations

Assessment of the patient's nutritional status is conducted at diagnosis and monitored throughout the course of treatment and follow-up. Early identification of patients at risk for problems with intake, absorption, and cachexia, particularly during the early stages of disease, can facilitate timely implementation of specifically targeted interventions that attempt to improve quality of life, treatment outcomes, and survival (Krishnasamy, Yoong, Chan, et al., 2017). Current weight, weight loss, diet and medication history, patterns of anorexia, nausea and vomiting, diarrhea, and situations and foods that aggravate or relieve symptoms are assessed and addressed.

The type of cancer, stage, and treatment approaches are considered so that proactive measures to support nutrition can be identified. For example, patients with head and neck cancers who are treated with radiation therapy, or some combination of surgery, radiation, chemotherapy or targeted agents, are at high risk for inadequate oral intake and nutritional deficits. In many centers, these patients have a percutaneous endoscopic gastrostomy (PEG) tube placed for enteral nutrition prior to initiation of treatment and the onset of mucositis, weight loss, and other consequences of impaired oral intake. A speech therapy consult may be helpful for patients with oropharyngeal or laryngeal tumors or surgical interventions that are anticipated to effect swallowing, secretion management, speech, or respiratory function.

Whenever possible, every effort is made to maintain adequate nutrition through the oral route. Prokinetic agents such as metoclopramide are used to increase gastric emptying in patients with early satiety and delayed gastric emptying. Other pharmacologic interventions such as megestrol acetate or corticosteroids (on a short-term basis) may be used to improve appetite. Oral nutritional supplements are encouraged to meet nutritional needs and to maintain or improve weight gain and physical functioning. Approaches incorporate nutritional counseling, exercise, pharmacologic interventions to combat anorexia, and symptom management when feasible (NCCN, 2019g). If adequate nutrition cannot be maintained by oral intake, nutritional support via the enteral route may be necessary as discussed previously. When needed, the patient and family are taught to administer enteral nutrition in the home. Home health nurses assist with patient education and monitor the patient's symptoms and response to enteral nutrition.

When malabsorption is a problem, enzyme and vitamin replacement may be instituted. Additional strategies include changing the feeding schedule, using simple diets, and relieving diarrhea. If malabsorption is severe, or the cancer involves the upper gastrointestinal tract, parenteral nutrition may be necessary. However, patients receiving parenteral nutrition are at increased risk for complications, including catheter-related and systemic infection. The use of parenteral nutrition in patients with advanced or end-stage cancer is seldom used and controversial (Jatoi & Kelly, 2019). Parenteral nutrition can be given in several ways: by a long-term

venous access device such as a right atrial catheter (see Fig. 12-3), implanted venous port (see Fig. 12-4), or PICC (see Fig. 12-6). The nurse educates the patient and family to care for the venous access device and to administer parenteral nutrition. Home health nurses provide education and assist with or supervise parenteral nutrition administration in the home.

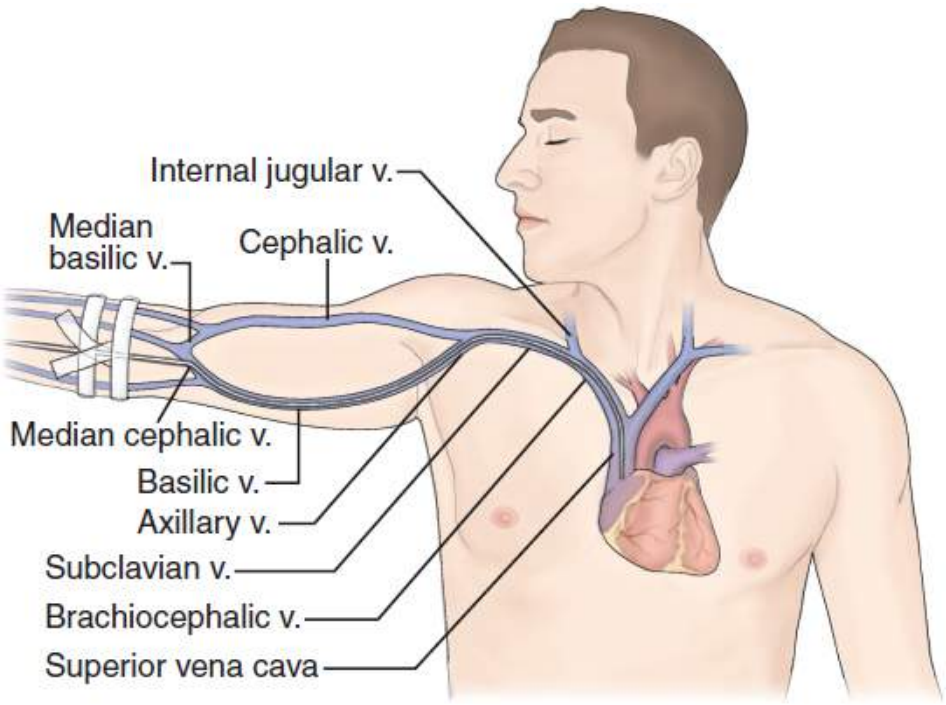

Figure 12-6 • A peripherally inserted central catheter is advanced through the cephalic or basilic vein to the axillary, subclavian, or brachiocephalic vein or the superior vena cava.

Relieving Pain

More than half of patients with cancer experience pain throughout the cancer trajectory. Moderate to severe pain is reported by approximately 28% of patients with cancer during treatment and as many as 52% of those with advanced disease (van den Beuken-van Everdingen, Hochstenbach, Joosten, et al., 2016). Although cancer pain may be acute, it is more frequently characterized as chronic. (See Chapter 9 for more information on pain.) As in other situations involving pain, the experience of cancer pain is influenced by physical, psychosocial, cultural, and spiritual factors.

Cancer can cause pain in various ways (see Table 12-9). Initially, pain is most often related to the underlying cancer process. Pain is also associated with various cancer treatments. Acute pain is linked with trauma from surgery. Occasionally, chronic pain syndromes, such as postsurgical neuropathies (pain related to nerve tissue injury), occur. Some chemotherapeutic agents cause tissue necrosis, peripheral neuropathies, and stomatitis—all potential sources of pain—whereas radiation therapy can cause pain secondary to skin, nervous tissue, or organ

inflammation. Patients with cancer may have other sources of pain, such as arthritis or migraine headaches, that are unrelated to the underlying cancer or its treatment.

The nurse assesses the patient for the source and site of pain as well as those factors that influence the patient's perception and experience of pain, such as fear and apprehension, fatigue, anger, and social isolation. Pain assessment scales are useful for assessing the patient's pain before and after pain-relieving interventions are instituted to assess the effectiveness of interventions. Other symptoms that contribute to the pain experience, such as nausea and fatigue, are assessed and addressed as well.

TABLE 12-9 Examples of Sources of Cancer Pain

Source	Descriptions	Underlying Cancer
Bone metastasis	Throbbing, aching	Breast, prostate, myeloma
Ischemia	Sharp, throbbing	Kaposi sarcoma
Lymphatic or venous obstruction	Dull, aching, tightness	Lymphoma, breast, Kaposi sarcoma
Nerve compression, infiltration	Burning, sharp, tingling	Breast, prostate, lymphoma
Organ obstruction	Dull, crampy, gnawing	Colon, gastric
Organ infiltration	Distention, crampy	Liver, pancreatic
Skin inflammation, ulceration, infection, necrosis	Burning, sharp	Breast, head and neck, Kaposi sarcoma

Adapted from van den Beuken-van Everdingen, M. H., Hochstenbach, L. M., Joosten, E. A., et al. (2016). Update on prevalence of pain in patients with cancer: Systematic review and meta-analysis. *Journal of Pain and Symptom Management*, *51*(6), 1070–1090; Yarbro, C. H., Wujcik, D., & Gobel, B. H. (2018). *Cancer nursing: Principles and practice*. Burlington, MA: Jones & Bartlett Publishers.

Today, most people expect pain to disappear or resolve quickly. Although it is often controllable, advanced cancer pain is commonly irreversible and not quickly resolved. For many patients, pain is often seen as a signal that cancer is advancing, and that death is approaching. As patients anticipate pain and anxiety increases, pain perception heightens, producing fear and further pain. Thus, chronic cancer pain can lead to a cycle progressing from pain to anxiety to fear and back to pain, especially when the pain is not adequately managed. Inadequate pain management is most often the result of misconceptions and insufficient knowledge about pain assessment and management on the part of patients, families, and health care providers (Scarborough & Smith, 2018). Chapter 9 provides information regarding factors contributing to the pain experience, pain perception, and tolerance as well as pharmacologic and nonpharmacologic nursing interventions addressing pain. The nursing care plan (see Chart 12-6) also provides strategies for nursing assessment and management of chronic pain. Analgesics are administered based on the patient's reported level of pain. A cancer pain algorithm, developed as a set of analgesic guiding principles, is given in Figure 12-7.

Pharmacologic and nonpharmacologic approaches, even those that may be invasive, are considered in managing cancer-related pain regardless of the patient's status along the cancer trajectory. The nurse assists the patient and family to take an active role in managing pain. The nurse provides education and support to correct fears and misconceptions about opioid use. Inadequate pain management leads to a diminished quality of life characterized by distress, suffering, anxiety, fear, immobility, isolation, and depression.

Decreasing Fatigue

Fatigue is one of the most frequent and distressing symptoms experienced by patients receiving cancer therapy. Patients report that fatigue persists and interferes with activities of daily living for months to years after the completion of treatment (Wang, Yang, Miao, et al., 2018). Fatigue rarely exists in isolation; patients typically experience other symptoms concurrently, such as pain, dyspnea, anemia, sleep disturbances, or depression. The relationship between sleep disturbances, fatigue, and depression (as well as other clinical factors) in older adults with cancer is an active area of research.

In assessing fatigue, the nurse distinguishes between *acute fatigue,* which occurs after an energy-demanding experience, and *cancer-related fatigue,* which is defined as "a distressing persistent, subjective sense of physical, emotional or cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and interferes with usual functioning" (NCCN, 2019h). Acute fatigue serves a protective function, whereas cancer-related fatigue does not. The exact mechanisms of fatigue are not well understood and are multifactorial in nature.

Despite the commonly occurring experience of fatigue in patients with cancer, a reliable assessment tool has not been identified. The experience of fatigue is highly subjective, with patient descriptors varying greatly (NCCN, 2019h). The nurse assesses physiologic and psychological factors that can contribute to fatigue (see Chart 12-8).

Exercise is an effective approach to the management of cancer-related fatigue (Mitchell, Albrecht, Omar Alkaiyat, et al., 2017). Psychoeducational approaches, cognitive-behavioral therapy to address sleep, progressive muscle relaxation, yoga, and mindfulness meditation may be effective measures to facilitate fatigue management (Mitchell et al., 2017). Nurses assist patients with strategies to minimize fatigue or help the patient cope with fatigue as described in the nursing care plan (see Chart 12-6, Fatigue). Occasionally, pharmacologic interventions are utilized, including antidepressants for patients with depression, anxiolytics for those with anxiety, hypnotics for patients with sleep disturbances, and psychostimulants for some patients with advanced cancer or fatigue that does not respond to other interventions (NCCN, 2019h; Mitchell et al., 2017). See the Nursing Research profile in Chart 12-9.

Chart 12-8

Sources of Fatigue in Patients with Cancer

- Anxiety associated with fear, diagnosis, role changes, uncertainty of future
- Disturbed sleep pattern related to cancer therapies, anxiety, and pain
- Electrolyte imbalances due to vomiting, diarrhea
- Risk for impaired nutritional intake due to nausea, vomiting, cancer-related anorexia-cachexia syndrome
- Impaired physical mobility due to neurologic impairments, surgery, bone metastasis, pain, and analgesic use
- Impaired tissue integrity due to stomatitis, mucositis
- Ineffective breathing associated with cough and dyspnea
- Ineffective protection secondary to neutropenia, thrombocytopenia, anemia
- Pain, pruritus
- Uncertainty and education needs related to disease process, treatment

Chart 12-9 NURSING RESEARCH PROFILE

Poor Sleep and Fatigue in Women with Breast Cancer

Overcash, J., Tan, A., & Noonan, A. (2018). Factors associated with poor sleep in older women diagnosed with breast cancer. *Oncology Nursing Forum, 45*(3), 359–371.

Purpose

Breast cancer is the most common form of cancer in women. The risk for developing breast cancer increases with age, as does the incidence of poor quality of sleep. The purpose of this study was to determine the relationship among poor sleep and gait, grip (hand) strength, cognitive status, and symptoms (depression, pain, fatigue).

Design

Women with breast cancer (any stage) aged 69 years or older were recruited to participate in this descriptive, cross-sectional study for an outpatient cancer clinic in the midwestern region of the United States. Instruments used to collect data in this study included: the Timed Up and Go Test (gait), Jamar Hydraulic Hand Dynamometer (grip strength), the Mini-Cog (cognitive status), the Geriatric Depression Scale (depression), Numeric Pain Scale (pain), the Brief Fatigue Inventory (fatigue), and the Pittsburgh Sleep Quality Index (sleep).

Findings

Sixty women with breast cancer, with a mean age of 77.6 (range 69.0 to 93.0) years, participated in this study. Strong to moderate relationships were found between pain and fatigue (r = 0.58, p = 0.001); pain and depression (r = 0.40, p = 0.002); and depression and fatigue (r = 0.66, p = 0.001). Patients with greater severity of fatigue (OR = 1.57, 95% CI = 1.32 – 2.16]), depression (OR = 1.46, 95% CI = 1.07 – 1.99]), and pain (OR = 1.41, 95% CI = 1.04 – 1.92]) were found to be at significantly higher risk of having poor sleep. Fatigue was found to have the strongest association with poor sleep. Poor sleep was not significantly related to gait, grip strength, or cognitive status in this study (all p-values > 0.05).

Nursing Implications

Nurses need to be aware of the symptoms that can affect sleep in older women with breast cancer, both during and following treatment. In this study, fatigue was found to strongly relate to poor sleep, which suggests that nurses must assess for and develop strategies to address both symptom concerns. Nurses should encourage older women with breast cancer to engage in physical activity (exercise) as part of their daily routine, to decrease fatigue and enhance sleep. Given that fatigue, depression, pain, and poor sleep may contribute to an increased risk for falls in older adults, nurses must pay particular attention to safety when caring for women with breast cancer and their families.

Improving Body Image and Self-Esteem

The nurse identifies potential threats to the patient's body image and assesses the patient's ability to cope with the many bodily changes that may be experienced throughout the course of disease and treatment. Entry into the health care system

may be accompanied by depersonalization. Threats to self-concept occur as the patient faces the realization of illness, disfigurement, possible disability, and death. To accommodate treatments or because of the disease, many patients with cancer are forced to alter their lifestyles. Priorities and values change when body image is threatened. Disfiguring surgery, hair loss, cachexia, skin changes, altered communication patterns, and sexual dysfunction can threaten the patient's self-esteem and body image.

A creative and positive approach is essential when caring for patients with altered body image. Nursing strategies for addressing issues related to body image and self-esteem are included in the nursing care plan (see Chart 12-6). The nurse serves as an active listener and counselor to both the patient and the family. Possible influences of the patient's culture and age are considered when discussing concerns and potential interventions.

Addressing Sexuality

The physiologic processes associated with cancer; potential short- and long-term effects of cancer treatments; and psychosocial, emotional, and spiritual responses to the entire experience may lead patients to confront a variety of sexuality-based issues. Patients at the greatest risk of sexual dysfunction are those with tumors that involve the sexual or pelvic organs and those whose treatment affects the hormonal systems mediating sexual function (Olsen et al., 2019). Although sexuality is an important component of overall health, many nurses and other health professionals are hesitant to include sexuality in their discussions with patients (Almont, Farsi, Krakowski, et al., 2019). In offering a holistic approach to the care of patients with cancer, nurses should initiate discussions about sexuality and assess sexual health.

Infertility, a common consequence of cancer and cancer treatments, can be of concern to patients and their partners. The potential for impaired fertility is discussed and options reviewed for fertility preservation (Olsen et al., 2019). Fertility plans are discussed and determined prior to the initiation of any therapy that may compromise reproductive abilities.

Referrals are made as needed for specialized evaluation and interventions that are beyond the scope of nursing intervention.

Assisting in the Grieving Process

A cancer diagnosis need not indicate a fatal outcome. Many forms of cancer are curable, and others may be controlled for long periods of time similar to the course of other chronic diseases. Despite the tremendous advances in cancer treatment, many patients and their families still view cancer as a fatal disease that is inevitably accompanied by pain, suffering, debilitation, and emaciation. Grieving is a normal response to these fears and to actual or potential losses: loss of health, normal sensations, body image, social interaction, intimacy, independence, and usual social roles. Patients, families, and friends may grieve for the loss of quality time to spend with others, the loss of future and unfulfilled plans, and the loss of control over the patient's body and emotional reactions. Nurses continue to assess the patient and

family for positive or maladaptive coping behaviors, interpersonal communication, and evidence of the need for additional psychosocial support or interventions such as referral for professional counseling.

If the patient enters the terminal phase of disease, the nurse may assess that the patient and family members are at different stages of grief. In such cases, the nurse assists the patient and family to acknowledge and cope with their reactions and feelings. The nurse also empowers the patient and family to explore preferences for issues related to end-of-life care, such as withdrawal of active disease treatment, desire for the use of life-support measures, and symptom management approaches. Oncology nurses respectfully support the patient's spiritual or religious views and facilitate contact with their preferred clergy member, if desired. In addition, nurses consider the patient's cultural beliefs and practices when addressing issues related to grief. After the death of a patient with cancer, home health or hospice nurses follow up with surviving family members for bereavement counseling to facilitate expression and coping with feelings of loss and grief. (See Chapter 13 for further discussion of end-of-life issues.)

Management of Psychosocial Distress

Despite advances in cancer care, patients experience varying levels of psychosocial distress related to actual or potential losses, fear of the unknown, symptoms due to cancer or cancer treatments, changes in usual family and social roles, financial concerns, and a sense of loss of control. Psychosocial distress is defined as a multifactorial unpleasant emotional experience of a psychological (cognitive, behavioral, emotional), social, or spiritual nature that may interfere with the ability to cope effectively with cancer, its physical symptoms and its treatment (NCCN, 2019i). Distress occurs along a continuum, ranging from common normal feelings of vulnerability, sadness, and fears to problems that can become disabling, such as depression, anxiety, panic, social isolation, and existential and spiritual crisis. Distress that is not addressed can have a significant impact on the overall well-being, interpersonal relationships, cognitive abilities, and adherence to treatment regimens, leading to poor outcomes.

Nurses need to screen patients for psychosocial distress during the cancer experience. Patients are supported in managing various sources and levels of distress. Referral to mental health providers may be helpful to address specific concerns (NCCN, 2019i).

Monitoring and Managing Potential Complications

Nurses need to pay particular attention to monitoring for and helping manage complications such as infection, septic shock, bleeding, and thrombocytopenia.

Infection

For patients in all stages of cancer, the nurse assesses factors associated with the development of infection. Although infection-associated morbidity and mortality have greatly decreased, prevention and prompt treatment of infection are essential

in patients with cancer (Olsen et al., 2019). Often, more than one predisposing factor is present in patients with cancer. The nurse monitors laboratory studies to detect early changes in WBC counts. Common sites of infection, such as the pharynx, skin, perianal area, urinary, and respiratory tracts, are assessed on a regular basis. However, the typical signs of infection (swelling, redness, drainage, and pain) may not occur in myelosuppressed patients because of decreased circulating WBCs and a diminished local inflammatory response. Fever may be the only sign of infection (NCCN, 2019j). The nurse monitors the patient for sepsis, particularly if invasive catheters or long-term IV catheters are in place.

WBC function is often impaired in patients with cancer. Among the five types of WBCs (neutrophils [granulocytes], lymphocytes, monocytes, basophils, and eosinophils), neutrophils serve as the body's primary initial defense against invading organisms. Comprising 60% to 70% of the body's WBCs, neutrophils act by engulfing and destroying infective organisms through phagocytosis. Both the total WBC count and the concentration of neutrophils are important in determining the patient's ability to fight infection. A decrease in circulating WBCs is referred to as leukopenia. The terms granulocytopenia and neutropenia refer to a decrease in neutrophils.

A differential WBC count identifies the relative numbers of WBCs and permits tabulation of polymorphonuclear neutrophils (PMNs) or segmented neutrophils (mature neutrophils, reported as "polys," PMNs, or "segs") and immature forms of neutrophils (reported as bands, metamyelocytes, and "stabs"). The absolute neutrophil count (ANC) is calculated by the following formula:

$$\text{ANC} = (\text{segmented neutrophils [\%]} + \text{band [\%]}) \times \text{WBC count (cell/mm}^3\text{)}$$

$$\text{Example: } (25\% \text{ seg} + 25\% \text{ bands}) \times 6000 \text{ WBC cell/mm}^3 = 3000 \text{ ANC}$$

Neutropenia, an abnormally low ANC, is associated with an increased risk of infection. The risk of infection rises as the ANC decreases. As the ANC declines below 1500 cells/mm^3, the risk of infection rises. An ANC less than 500 cells/mm^3 reflects a severe risk of infection (NCCN, 2019j). The ***nadir*** is the lowest ANC following chemotherapy, targeted therapy, or radiation therapy that suppresses bone marrow function. Severe neutropenia may necessitate delays in administration of myelosuppressive therapies or treatment dose adjustments, although the use of the hematopoietic growth factors (e.g., colony-stimulating factors; see previous discussion) has reduced the severity and duration of treatment-associated neutropenia as well as infection-related morbidity and early death (NCCN, 2019j). The administration of these growth factors assists in maintaining treatment schedules, drug dosages, treatment effectiveness, and quality of life.

Patients with febrile neutropenia are assessed for factors that increase the risk of infection and for sources of infection through cultures of blood, sputum, urine, stool, IV and urinary or other catheters, and wounds, if appropriate (see Table 12-10). In addition, a chest x-ray is usually obtained to assess for pulmonary infection.

Defense against infection is compromised in many ways. The integrity of the skin and mucous membranes is challenged by multiple invasive diagnostic procedures, by the adverse effects of all cancer treatment modalities, and by the detrimental effects of immobility. Impaired nutrition as a result of CACS, nausea, vomiting, diarrhea, and the underlying disease alters the body's ability to combat invading organisms. Medications such as antibiotics disturb the balance of normal flora, allowing the overgrowth of normal flora and pathogenic organisms. Other medications can also alter the immune response (see Chapter 31). Cancer itself may lead to defects in cellular and humoral immunity. Advanced cancer may cause obstruction of hollow viscera (e.g., intestines), blood, and lymphatic vessels, creating a favorable environment for proliferation of pathogenic organisms. In some patients, tumor cells infiltrate bone marrow and prevent normal production of WBCs.

TABLE 12-10 Assessment of Neutropenic Fever in Patients with Cancer

Fever Criteria	Neutropenia Criteria
• Any one-time temperature of 38.3°C (101°F) or • Any temperature of ≥38°C (100.4°F) or ≥1 h	• <500 neutrophils/mcL or • <1000 neutrophils/mcL and predicted to decline to ≤500 neutrophils/mcL over the next 48 h

Assessment Targets for Neutropenic Fever Evaluation

Infection Risk Factors	Physical Assessment	Diagnostic Procedures	Microbiologic Cultures
• Chronic comorbid illnesses • Underlying hematologic malignancies • Immunosuppression related to factors other than neutropenia (e.g., immunosuppressive therapy following allogeneic HSCT or hypogammaglobulinemia [decreased gammaglobulin production]) • Solid tumors causing obstructions of the bronchial tree, ureters, colon, or biliary ducts • Advanced or refractory underlying malignancy • Prolonged duration of neutropenia • Age ≥65 yrs • Limited mobility or debilitation • Medications (e.g., corticosteroids such as prednisone) • Antibiotic therapy or prophylaxis • Recent surgery for diagnosis or treatment • Chemotherapy or targeted therapy received within the last 7–10 days • Prior treatment with multiple types of chemotherapy regimens • Recent radiation therapy; especially to areas	• Skin, pressure points, wounds • Surgical or biopsy incision sites • IV access or reservoir sites • Drainage catheter sites • Tracheostomy site • Lungs and sinuses • Perivaginal and perirectal area • Alimentary canal, abdomen • Neurologic assessment • Vital signs	• Diagnostic imaging as appropriate to identify abscesses, fistulas, pneumonia, obstruction, etc. • Complete blood count/differential • Serum chemistries, liver function tests • Renal function tests • Pulse oximetry or arterial blood gases • Lumbar puncture for CSF analysis	• Blood (peripheral and central venous access if applicable) • Urine (especially with indwelling catheter) • Skin wounds, lesions, incision sites, catheter exit sites • Catheter tips when feasible • Drainage from catheters • Stool, diarrhea • Sputum • CSF

associated with bone marrow reserves • Prior documented infections • Impaired skin integrity • Invasive drainage or urinary catheters • Peripheral or central venous access devices • Exposures (travel, others with infection, blood administration, pets) • Diarrhea • Poor nutritional status • Recent lumbar puncture or indwelling Ommaya reservoir™ (long-term intraventricular catheter for administration of chemotherapy into CSF and ventricles)	

CSF, cerebrospinal fluid; HSCT, hematopoietic stem cell transplantation; IV, intravenous.
Adapted from National Comprehensive Cancer Network (NCCN). (2019j). NCCN clinical practice guidelines in oncology: Prevention and treatment of cancer-related infection—version 1.2019. Retrieved on 7/14/2019 at: www.nccn.org/professionals/physician_gls/pdf/infections.pdf; Palmore, T. N., Parta, M., Cuellar-Rodriguez, J., et al. (2018). Infections in the cancer patient. In DeVita, V. T., Lawrence, T. S., Rosenberg, S. A. (Eds.). *Cancer: Principles & practice of oncology* (11th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Nurses are in a key position to assist in preventing and identifying symptoms of infection, as discussed in the nursing care plan (see Chart 12-6). Clinical practice guidelines developed by the ONS, the Infusion Nurses Society (INS), the NCCN, and the ASCO are used to guide prevention and management of infection. Interventions to prevent infection and alternative patient education formats for infection-related instruction are high nursing research priorities.

Gram-positive bacteria (*Streptococcus,* enterococci, and *Staphylococcus* species) and gram-negative organisms (*Escherichia coli, Klebsiella pneumoniae, Enterobacter,* and *Pseudomonas aeruginosa*) are the most frequently isolated causes of infection. Fungal organisms, such as *Candida albicans,* also contribute to the incidence of serious infection. Viral infections in immunocompromised patients are caused most often by herpes simplex, respiratory syncytial, parainfluenza, and influenza A and B viruses.

Fever is reported promptly as it is an important sign of infection in patients when associated with neutropenia (Olsen et al., 2019). Patients with neutropenic fever (see Table 12-10) are assessed for infection and reported promptly (NCCN, 2019j). Antibiotics may be prescribed after cultures of wound drainage, exudates, sputum, urine, stool, or blood are obtained. Careful consideration is given to the underlying malignancy, prior antineoplastic treatment, ANC, comorbidities, and other patient-

related factors prior to the identification of the most appropriate antibiotic therapy. Evidence-based guidelines are available for prevention and treatment of cancer-related infections (NCCN, 2019j). Patients with neutropenia are treated with broad-spectrum antibiotics before the infecting organism is identified because of the increased risk of mortality associated with untreated infection. Broad-spectrum antibiotic therapy targets the most likely major pathogenic organisms. It is important for these medications to be given and taken promptly as scheduled to achieve adequate blood levels. Once the offending organism is identified, more specific antimicrobial therapy is prescribed as appropriate. Nurses provide education for patients and families regarding prevention of infection, signs and symptoms to report, and the importance of adherence to prescribed antimicrobial therapy.

Septic Shock

The nurse assesses the patient frequently for signs and symptoms of infection and inflammation throughout the trajectory of cancer care. Sepsis and septic shock are life-threatening complications that must be prevented or detected and treated promptly. Although all patients with cancer are at risk, patients who are neutropenic or who have hematologic malignancies are at the greatest risk. Patients with signs and symptoms of impending sepsis and septic shock require immediate hospitalization and aggressive treatment in the intensive care setting. See Chapter 11 for discussion of sepsis and septic shock.

Bleeding and Thrombocytopenia

Platelets are essential for normal blood clotting and coagulation (hemostasis). **Thrombocytopenia**, a decrease in the circulating platelet count, is the most common cause of bleeding in patients with cancer and is usually defined as a platelet count less than 100,000/mm^3 (0.1×10^{12}/L). The risk of bleeding increases when the platelet count decreases below 50,000/mm^3 (0.05×10^{12}/L). At platelet counts lower than 10,000/mm^3 (0.02×10^{12}/L), the risk for spontaneous bleeding is increased (Olsen et al., 2019).

Thrombocytopenia often results from bone marrow depression after certain types of chemotherapy and radiation therapy and with tumor infiltration of the bone marrow. In some cases, platelet destruction is associated with hypersplenism (enlarged spleen) and abnormal antibody function, which occur with leukemia and lymphoma. Bacterial and viral infections may lead to early platelet destruction or impaired bone marrow production of platelets and subsequent thrombocytopenia. Some medications (e.g., heparin, vancomycin) may cause bone marrow toxicity leading to decreases in circulating platelets. Less commonly, posttransfusion complications may lead to antibody destruction of platelets causing profound thrombocytopenia (Mones & Soff, 2019). The nursing care plan addresses nursing assessment parameters and interventions for patients at risk for bleeding (see Chart 12-6).

Quality and Safety Nursing Alert

Although laboratory test results confirm the diagnosis of thrombocytopenia, the patient who is developing thrombocytopenia may display early signs and symptoms. Thus, nurses need to observe keenly for petechiae and ecchymoses, which are early indicators of decreasing platelet levels. Early detection promotes early intervention.

Additional medications may be prescribed to address bleeding or thrombocytopenia based on the underlying etiology. See Chapter 29 for further discussion of assessment and treatment of thrombocytopenia and coagulopathies.

VTE, a common problem for patients with cancer, includes deep venous thrombosis (DVT), pulmonary embolism (PE), superficial venous thrombosis (SVT), and thrombosis in other abdominal or thoracic venous tributaries such as the mesenteric veins or the superior vena cava. The incidence of VTE has been linked to an increased likelihood of death in patients with cancer (NCCN, 2019k). Factors associated with risk for VTEs in cancer patients include preexisting underlying or cancer-related coagulopathies, medications including chemotherapy, hospitalizations, surgical procedures, increased age, debilitation, immobility, infection, and peripheral and central venous catheters (NCCN, 2019k). Patients with cancer are monitored for associated risk factors and are assessed on an ongoing basis for VTE. Nurses provide patient and family education regarding symptoms of VTE to report to the provider. Recommendations for prophylaxis are based on national guidelines and patient risk factors. Nursing assessment findings associated with VTE are reported promptly so that VTE evaluation and treatment can be initiated expeditiously.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Most commonly, patients with cancer are diagnosed and treated in the outpatient setting. Nurses in outpatient settings often have the responsibility for patient education and helping coordinate care in the home (see Chart 12-10). The shift of care from acute care facilities to the home or outpatient settings as well as the increasing use of oral antineoplastic agents places significant responsibility for care on the patient and family. In order to maintain optimal patient outcomes and quality of life, patients and families require support and information that will prepare them to engage in self-care. Education initially focuses on the most immediate care needs likely to be encountered at home.

Approaches to preparing patients for self-care responsibilities are chosen with consideration of the patient's preferred learning strategies, level of education, and health literacy (Howell, Harth, Brown, et al., 2017). Nurses are in a prime role to

promote self-care by ensuring that the educational needs of patients and families are met across time points of the cancer continuum (Eller, Lev, Yuan, et al., 2018; White, Cohen, Berger, et al., 2017). Easily understood, concrete, objective information that assists patients to understand what to expect and includes sensory and temporal components is important. Symptoms, side effects of treatment, and changes in the patient's status that should be reported are discussed and reinforced with printed materials that can be referred to in the home. Nurses help to empower patients by sharing strategies to manage side effects or other symptoms. Additional learning needs are based on the priorities conveyed by the patient and family as well as on the complexity of care required (Howell et al., 2017).

Chart 12-10 **HOME CARE CHECKLIST**

The Patient Receiving Care for an Oncologic Disorder

At the completion of education, the patient or caregiver will be able to:

- State the impact of cancer treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in lifestyle (e.g., diet, activity) necessary to maintain health.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Demonstrate how to administer the chemotherapy agent in the home:
  - Describe safe storage and handling of oral chemotherapy/immunotherapy/targeted therapy agents in the home.
  - Demonstrate safe disposal of needles, syringes, IV supplies, or unused chemotherapy medications.
  - List possible side effects of chemotherapy/immunotherapy/targeted therapy agents and suggested management approaches.
- List possible side effects of radiation therapy and suggested management approaches.
- List complications of medications/therapeutic regimen necessitating a call to the nurse or primary provider.
- List complications of medications/therapeutic regimen necessitating a visit to the emergency department.
- Locate list of names and contact details of resource personnel involved in care (e.g., home health nurse, infusion services, IV vendor, equipment company, radiation therapy department).
- Explain treatment plan and importance of upcoming visits to the primary provider.
- State how to obtain medical supplies after discharge.
- Identify durable medical equipment needs, proper usage, and maintenance necessary for safe utilization.
- Demonstrate usage of adaptive equipment for ADLs.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community)
  - Identify phone numbers of support groups for people with cancer and their caregivers/families
  - State meeting locations and times
- Identify the need for health promotion, disease prevention, and screening activities

ADL, activities of daily living; IADL, independent activities of daily living.

Technologic advances allow home administration of IV chemotherapy, blood products, and antibiotics; enteral or parenteral nutrition; and parenteral analgesics. Patients and families are taught to care for vascular access devices, infusion pumps, various types of drainage catheters, and on occasion complex wounds. The importance of patient safety and infection control is included in patient and family education. Although nurses are often available to provide some assistance with

cancer care in the home, patients and families need to acquire the requisite knowledge and skills that will enable them to develop a strong sense of self-efficacy to not only foster self-care, but also to promote a more positive health status and better quality of life (Eller et al., 2018; White et al., 2017).

Continuing and Transitional Care

Referral for home or transitional care is often indicated for patients with cancer. The responsibilities of the nurse include assessing the home environment and suggesting modifications in the home or in care to help address the patient's physical and safety needs. Home health nurses also assess the psychosocial impact of cancer on the patient and family so that appropriate interventions can be identified or referrals for support services are instituted.

Ongoing nursing visits or phone contact from the home or transitional care nurse assist in prevention, early identification, prompt reporting, and management of patient problems. Timely modifications in therapy to manage symptoms and adverse effects of treatment may decrease patient suffering and decrease emergency department visits or hospital admissions. Continued contact facilitates evaluation of the patient's progress, responses to treatment, and assessment of the ongoing needs of the patient and family. It is necessary to assess the patient's and family's understanding of the treatment plan and management strategies and to reinforce previous education. The nurse facilitates coordination of patient care by maintaining close communication with all involved health care providers. The nurse may make referrals and coordinate available community resources (e.g., local office of the ACS, home aides, church groups, faith community nurses, support groups) to assist patients and caregivers.

Gerontologic Considerations

Approximately 55% of cancer incidence and 70% of cancer deaths occur in persons aged 65 years or older (ACS, 2019a). The rising number of individuals over age 65 with cancer has led to the emergence of geriatric oncology, a multidimensional and multidisciplinary approach to treating growing numbers of older adults with cancer.

Nurses working with older adults must understand the normal physiologic changes that occur with aging and the implications for the patient with cancer (see Table 12-11). These changes that affect all body systems may ultimately influence older patients' responses to cancer treatment. In addition, many older patients have other chronic diseases requiring multiple medications. The existence of comorbidities and multiple medications may contribute to drug interactions and toxicities in older patients.

The understanding of the effects and tolerance of chemotherapy, immunotherapy, targeted therapies, and radiation in the older adult is limited, as older adults have been underrepresented in oncology clinical trials. Potential chemotherapy-related toxicities, such as renal impairment, myelosuppression, fatigue, and cardiomyopathy, may increase as a result of declining organ function and diminished physiologic reserves. The recovery of normal tissues after radiation

therapy may be delayed, and older adult patients may experience more severe adverse effects, such as mucositis, nausea and vomiting, and myelosuppression. Because of impaired healing and declining pulmonary and cardiovascular functioning, older patients are slower to recover from surgery. Older patients are also at increased risk for complications, such as atelectasis, pneumonia, and wound infections.

TABLE 12-11 Age-Related Changes and Their Effects on Patients with Cancer

Age-Related Changes	Implications
Impaired immune system	Use special precautions to avoid infection; monitor for atypical signs and symptoms of infection.
Altered drug absorption, distribution, metabolism, and elimination	Mandates careful calculation of chemotherapy and frequent assessment for drug response and side effects; dose adjustments may be necessary.
Increased prevalence of other chronic diseases	Monitor for effect of cancer or its treatment on patient's other chronic diseases; monitor patient's tolerance for cancer treatment; monitor for interactions with medications used to treat chronic diseases.
Diminished renal, respiratory, and cardiac reserve	Be proactive in prevention of decreased renal function, atelectasis, pneumonia, and cardiovascular compromise; monitor for side effects of cancer treatment.
Decreased skin and tissue integrity; reduction in body mass; delayed healing	Prevent pressure ulcers secondary to immobility; monitor skin and mucous membranes for changes related to radiation or chemotherapy; monitor nutritional status.
Decreased musculoskeletal strength	Prevent falls; assess support for performing activities of daily living in home setting; encourage safe use of assistive mobility devices.
Decreased neurosensory functioning: loss of vision, hearing, and distal extremity tactile senses	Provide instruction modified for patient's hearing and vision changes; provide instruction concerning safety and skin care for distal extremities; assess home for safety.
Altered social and economic resources	Assess for financial concerns, living conditions, and resources for support.
Potential changes in cognitive and emotional capacity	Provide education and support modified for patient's level of functioning and safety.

Adapted from Eliopoulos, C. (2018). *Gerontological nursing* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Cancer Survivorship

In the United States, there are currently an estimated 16.9 million adult cancer survivors; by 2030, that number is estimated to be 22.1 million (ACS, 2019f). Advances in cancer screening, treatment, and management of complications have contributed to a lengthened survival period for many, with long-term survival

becoming possible for many patients. *Cancer survivorship* has been defined as the period from cancer diagnosis through the remaining years of life and focuses on the health and life of a person beyond diagnostic and treatment phases. Although individuals vary and many types of cancers and treatments exist, the acute, long-term, and late effects of cancer and its treatment may have multiple long-term physical, cognitive, psychological, social, and financial consequences that can impact activities of daily living, ultimately affecting quality of life (ACS, 2019f).

Survivorship care is often based on expert opinion and experience rather than on evidence-based practices. Knowledge regarding survivorship concerns continues to evolve. The Institute of Medicine has identified four components of survivorship care, the period that follows primary treatment for cancer and lasts until end of life. In addition to a summary of prior diagnosis and treatment, survivorship care includes monitoring and treatment for late effects related to disease and prior treatments, physical and vocational rehabilitation, psychosocial support and counseling as necessary, surveillance and screening for new and recurrent cancer, and coordination between specialists and primary care providers to ensure that all of the survivor's needs are met (Hewitt, Greenfield, & Stovall, 2006) (see Table 12-12). Advocacy organizations across the country have recommended that a survivorship care plan be provided to all patients with cancer and their primary provider at the completion of treatment. The survivorship care plan includes a summary of cancer diagnosis, treatment, recommendations for follow-up care, including approaches to treat symptoms, rehabilitative needs, monitoring for late effects, and surveillance and screening for new and recurrent cancer. Referrals for specific services such as lymphedema therapy, chronic pain management, and genetic counseling are also provided. Nurses assist in the development of the survivorship care plan and provide education and care for cancer survivors. Nurses, other health care providers, public health professionals, and patient advocates design and conduct research to identify needs of cancer survivors and evidence-based approaches to care.

TABLE 12-12 Components of Survivorship Care

Component	Examples of Care
Prevention and detection of new and recurrent cancer	Mammography (per ACS guidelines) Papanicolaou (Pap) smears (per ACS guidelines) Smoking cessation programs Nutrition counseling
Surveillance for cancer spread, recurrence, or second cancers	Colonoscopy post colon cancer Mammography post breast cancer Liver function tests post colon cancer Prostate-specific antigen post prostate cancer
Intervention for consequences of cancer and its treatments	Lymphedema therapy Pain management Enterostomal therapy Fertility care Psychosocial support or counseling Reconstructive surgery
Coordination between specialists and primary providers to meet health needs	Care for comorbidities (e.g., diabetes) Influenza vaccination Bone densitometry Monitoring for chemotherapy induced cardiotoxicity

ACS, American Cancer Society.

Washington, DC: Institute of Medicine and National Research Council, National Academies Press. Components of survivorship care provided by the Institute of Medicine report on cancer survivorship.

Providing Care to the Patient with Advanced Cancer

The patient with advanced cancer needs to be monitored for oncologic emergencies and have appropriate treatment should emergencies occur. These patients may have end-of-life and palliative care needs that must be addressed.

Providing Care in Oncologic Emergencies

Table 12-13 discusses select nursing and medical care of oncologic emergencies.

As a result of advances in all aspects of cancer care, it is more common that individuals are living with cancer that has advanced beyond the original site of development to regional or distant sites. Patients with advanced cancer are likely to experience many of the problems described previously, although more often and to a greater degree. Symptoms of pain, anorexia, weight loss, CACS, fatigue, and impaired functional status and mobility make patients more susceptible to depressive symptoms, skin breakdown, fluid and electrolyte imbalances, and infection.

Treatment for the patient with advanced cancer is likely to be palliative rather than curative, with an emphasis on prevention and appropriate management of pain.

The use of long-acting analgesic agents at set intervals, rather than on an "as needed" basis, is recommended in addressing pain management. Working with the patient and family, as well as with other health care providers, to manage pain is essential to increase the patient's comfort and offer some sense of control. Other medications (e.g., sedatives, tranquilizers, muscle relaxants, antiemetics) are added to assist in palliating additional symptoms and promoting quality of life.

TABLE 12-13 Oncologic Emergencies: Manifestations and Management

Oncologic Emergency	Clinical Manifestations and Diagnostic Findings	Medical and Nursing Management
Superior Vena Cava Syndrome (SVCS) Compression or invasion of the superior vena cava by tumor; enlarged lymph nodes; intraluminal thrombus that obstructs venous circulation; or drainage of the head, neck, arms, and thorax. Most often associated with lung cancer, SVCS is also associated with lymphoma, thymoma, and testicular cancers and mediastinal metastases from breast cancer. If untreated, SVCS may lead to cerebral anoxia (because not enough oxygen reaches the brain), laryngeal edema, bronchial obstruction, and death.	**Clinical Manifestations:** Gradually or suddenly impaired venous drainage giving rise to: progressive dyspnea (shortness of breath), cough, hoarseness, chest pain, and facial swelling Edema of the neck, arms, hands, and thorax and reported sensation of skin tightness, difficulty swallowing, and stridor. Possibly engorged and distended jugular, temporal, and arm veins. Dilated thoracic vessels causing prominent venous patterns on the chest wall. Increased intracranial pressure, associated visual disturbances, headache, and altered mental status **Diagnostic Findings:** Diagnosis confirmed by: Clinical findings Chest x-ray Thoracic CT scan Thoracic MRI	**Medical Management:** Radiation therapy to shrink tumor or enlarged lymph nodes and relieve symptoms. Chemotherapy for sensitive cancers (e.g., lymphoma, small cell lung cancer) or when the mediastinum has been irradiated to maximum tolerance. Anticoagulant or thrombolytic therapy for central venous catheter–related intraluminal thrombosis. Percutaneously placed intravascular stents may be priority consideration rather than surgery unless symptoms are rapidly progressing. Supportive measures such as oxygen therapy, corticosteroids, and diuretics (in cases of fluid overload). **Nursing Management:** Identify patients at risk for SVCS. Provide patient and family education regarding signs and symptoms to report. Monitor and report clinical manifestations of SVCS. Monitor cardiopulmonary and neurologic status.

	Venogram if intraluminal thrombosis is suspected	Avoid upper extremity venipuncture and blood pressure measurement; instruct patient to avoid tight or restrictive clothing and jewelry on fingers, wrist, and neck. Facilitate breathing and drainage from upper portion of body by instructing patient to maintain some elevation of head and upper body with semi-Fowler position; avoid completely supine or prone position (this helps to promote comfort and reduce anxiety associated with dependent and progressive edema). Promote energy conservation to minimize dyspnea. Monitor the patient's fluid volume status; administer fluids cautiously to minimize edema. Assess for thoracic radiation-related problems such as mucositis with resultant dysphagia (difficulty swallowing) and esophagitis. Monitor for chemotherapy-related problems, such as myelosuppression. Provide postoperative care as appropriate.
Spinal Cord Compression Most commonly caused by compression of the cord and its nerve roots by a metastatic paravertebral tumor that extends into the epidural space; vertebral bone metastasis leading to bone collapse and displacement impinging on the spinal cord or nerve roots; and less commonly, primary malignancy of the cord. May potentially lead to significant and permanent neurologic impairment associated with multiple physical, psychosocial consequences. Most often associated with cancers that metastasize to the bone such as breast, lung, and prostate cancers and lymphoma. Also seen in nasopharyngeal cancer and multiple myeloma.	**Clinical Manifestations:** Local inflammation, edema, venous stasis, and impaired blood supply to nerve tissues. Local or radicular back or neck pain along the dermatomal areas innervated by the affected nerve root (e.g., thoracic radicular pain extends in a band around the chest or abdomen). Pain exacerbated by movement, supine recumbent position, coughing, sneezing, or the	**Medical Management:** Radiation therapy to reduce tumor size and halt progression; corticosteroid therapy to decrease inflammation and swelling at the compression site. Surgery to debulk tumor and stabilize the spine if symptoms progress despite radiation therapy or if vertebral fracture or bone fragments lead to additional nerve damage; surgery is also an option when the tumor is not radiosensitive or is located in an area that was previously irradiated. Minimally invasive surgical procedures, referred to as vertebral augmentation, may be used for patients with vertebral fractures to attain stability of the bone, prevent nerve compression, and decrease pain. Procedures include: Vertebroplasty: involves percutaneous injection of polymethyl methacrylate (PMMA), a bone cement filler, into the vertebral body. Kyphoplasty: a balloon is inserted into the damaged vertebral body and then inflated to create a cavity within the bone that can be filled with bone cement. The balloon

About 60% of spinal cord compressions occur at the thoracic level, 30% in the lumbosacral level, and 10% in the cervical and sacral regions. The prognosis depends on the severity and rapidity of onset.	Valsalva maneuver. Neurologic dysfunction and related motor and sensory deficits (numbness, tingling, feelings of coldness in the affected area, inability to detect vibration, loss of positional sense). Motor loss ranging from subtle weakness to flaccid paralysis. Bladder or bowel dysfunction depending on level of compression (above S2, overflow incontinence; from S3 to S5, flaccid sphincter tone and bowel incontinence).	helps to compress the fracture fragments together as the cavity is created.
	Diagnostic Findings: Percussion tenderness at the level of compression; abnormal reflexes; and sensory and motor abnormalities. MRI is a preferred diagnostic tool; may also utilize x-rays, bone scans, and CT scan.	Radiofrequency vertebral augmentation: similar to kyphoplasty; instead of the balloon, a small navigational cannula is inserted into the vertebra to create small pathways for cement. The cement is heated with radiofrequency to create an ultra-high viscosity that is thought to promote bone stability. Chemotherapy as adjuvant to other local therapies for patients with chemosensitive cancers, such as lymphoma or small cell lung cancer. *Note:* Despite treatment, patients with poor neurologic function before treatment are less likely to regain complete motor and sensory function; patients who develop complete paralysis usually do not regain all neurologic function. **Nursing Management:** Perform ongoing assessment of neurologic function to identify existing and progressing dysfunction. Control pain with pharmacologic and nonpharmacologic measures.

		Prevent complications of immobility resulting from pain and decreased function (e.g., skin breakdown, urinary stasis, thrombophlebitis, decreased clearance of pulmonary secretions). Maintain muscle tone by assisting with range-of-motion exercises in collaboration with physical and occupational therapists; patients with unstable vertebral fractures do not initiate physical therapy until spine stabilization procedures have been completed. Institute intermittent urinary catheterization and bowel training programs for patients with bladder or bowel dysfunction. Provide encouragement and support to the patient and family coping with pain and altered functioning, lifestyle, roles, and independence. Institute appropriate referrals for home care and physical and occupational therapy. Provide patient and family education about pharmacologic and nonpharmacologic interventions
Hypercalcemia Hypercalcemia is a potentially life-threatening metabolic abnormality resulting when the calcium released from the bones is more than the kidneys can excrete or the bones can reabsorb. It may result from production of cytokines, hormonal substances, and growth factors by cancer cells, or by the body in response to biochemical mediators produced by cancer cells, which lead to bone breakdown and calcium release. Occurs in about 20% of patients with cancer; most commonly seen in patients with multiple myeloma and cancers of the lung and breast.	**Clinical Manifestations:** Fatigue, weakness, confusion, decreased level of responsiveness, hyporeflexia, nausea, vomiting, constipation, ileus, polyuria (excessive urination), polydipsia (excessive thirst), dehydration, and arrhythmias. **Diagnostic Findings:** Total serum calcium level >10.4 mg/dL (2.6 mmol/L) Ionized serum calcium >1.29 mmol/L	**Medical Management:** Identify patients at risk for hypercalcemia and assess for signs and symptoms of hypercalcemia. Treatment of the underlying malignancy (e.g., chemotherapy, radiation therapy, hormone therapy, immunotherapy or targeted therapy). Reduce serum calcium levels: Oral hydration (3–4 L of fluid daily unless contraindicated by existing renal or cardiac disease) or IV hydration followed by diuretics (forced diuresis). Avoid dietary supplements and medications that can increase serum calcium levels (e.g., thiazide diuretics, nonsteroidal anti-inflammatory drugs; and vitamins A and D, and calcium supplements). Bisphosphonate therapy may be indicated for the long-term management. Maintenance of nutritional intake without restricting normal calcium intake. Dietary and pharmacologic interventions such as stool softeners and laxatives for constipation. Antiemetic therapy for nausea and vomiting. **Nursing Management:** Monitor closely for changes in mental status; fluid and electrolyte imbalances;

		and renal, gastrointestinal, cardiac dysfunction. Monitor treatment effectiveness and for the presence of side effects. Ensure proper hydration and monitor fluid and electrolyte balance closely. Educate patients who are at-risk and their families to recognize and report signs and symptoms of hypercalcemia. Encourage mobilization / weight-bearing activities, as tolerated, to limit bone resorption. Maintain patient safety and ensure comfort. Educate patient and families about prescribed management strategies.
Tumor Lysis Syndrome (TLS) Potentially fatal complication that occurs spontaneously or more commonly following radiation, immunotherapy, targeted therapy, or chemotherapy-induced cell destruction of large or rapidly growing cancers such as leukemia, lymphoma, and small cell lung cancer. The release of tumor intracellular contents (nuclei acids, electrolytes, and debris) leads to rapidly induced electrolyte imbalances—hyperkalemia, hyperphosphatemia (leading to hypocalcemia), and hyperuricemia—that can have life-threatening end-organ effects on the myocardium, kidneys, and central nervous system.	**Clinical Manifestations:** Clinical manifestations depend on the extent of metabolic abnormalities. *Neurologic:* Fatigue, weakness, memory loss, altered mental status, muscle cramps, tetany, paresthesias (numbness and tingling), and seizures. *Cardiac:* Elevated blood pressure, shortened QT complexes, widened QRS waves, altered T waves, arrhythmias, and cardiac arrest. *Gastrointestinal*: Anorexia, nausea, vomiting, abdominal cramps, diarrhea, and increased bowel sounds *Renal*: Flank pain, oliguria, anuria, kidney injury, and acidic urine pH.	**Medical Management:** To prevent kidney injury and restore electrolyte balance. Aggressive fluid hydration is initiated 24–48 h before and after the initiation of cytotoxic therapy to increase urine volume and eliminate uric acid and electrolytes. Diuresis with a loop diuretic or osmotic diuretic, if urine output is inadequate. Allopurinol therapy to inhibit the conversion of nucleic acids to uric acid (oral or IV). Rasburicase may be used to convert already formed uric acid to allantoin, which is highly water soluble and eliminated in urine. Administration of a cation-exchange resin, such as sodium polystyrene sulfonate to treat hyperkalemia by binding and eliminating potassium through the bowel. Administration of IV sodium bicarbonate, hypertonic dextrose, and regular insulin temporarily shifts potassium into cells and lowers serum potassium levels if a rapid decrease in potassium is necessary. Administration of phosphate-binding gels, such as aluminum hydroxide, to treat hyperphosphatemia by promoting phosphate excretion in the feces. Hemodialysis when patients are unresponsive to the standard approaches for managing uric acid and electrolyte abnormalities. Identify at-risk patients. Institute essential preventive measures (e.g., fluid hydration, medications) as prescribed. Assess patient for signs and symptoms of electrolyte imbalances.

	Other: Gout, malaise, and pruritis. **Diagnostic Findings:** Electrolyte imbalances identified by serum electrolyte measurement and urinalysis (see Chapter 10); electrocardiogram to detect cardiac arrhythmias. Clinical TLS is diagnosed when ≥1 of 3 conditions arise either 3 days prior to or 7 days after cytotoxic cancer therapy: acute kidney injury (defined as a rise in creatinine to ≥1.5 times the upper limit of normal that is not attributable to medications, arrhythmias, and seizures).	**Nursing Management:** Monitor for signs and symptoms of TLS in patients who are at-risk (e.g., those with hematologic malignancies). Monitor vital signs, laboratory values (i.e., electrolyte), fluid balance closely (i.e., daily weights, intakes and outputs), and cardiac status closely. Educate patients and families about risk factors for TLS; teach about current treatments (e.g., hydration, dietary restrictions [e.g., potassium and phosphorous], and pharmacologic therapy); signs and symptoms of complications; and when to report symptoms indicating electrolyte disturbances to the provider.

CT, computed tomography; IV, intravenous; MRI, magnetic resonance imaging.

Superior vena cava syndrome. In DeVita, V. T., Lawrence, T. S., Rosenberg, S. A. (Eds.). *Cancer: Principles & practice of oncology* (11th ed.). Philadelphia, PA: Lippincott Williams & Wilkins; Stein, S., & Deshpande, H. A. (2018). Metabolic emergencies. In DeVita, V. T., Lawrence, T. S., Rosenberg, S. A. (Eds.). *Cancer: Principles & practice of oncology* (11th ed.). Philadelphia, PA: Lippincott Williams & Wilkins; and Szerlip, N., Beeler, W. H., & Spratt, D. E. (2018). Spinal cord compression. In DeVita, V.T., Lawrence, T. S., Rosenberg, S. A. (Eds.). *Cancer: Principles & practice of oncology* (11th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

If the patient is a candidate for radiation therapy or surgical interventions to relieve pain or other symptoms, the potential benefits and risks of these procedures (e.g., percutaneous nerve block, cordotomy) are explained to the patient and family. Measures are taken to prevent complications that result from altered sensation, immobility, and changes in bowel and bladder function.

Weakness, altered mobility, fatigue, and inactivity typically increase with advanced cancer as a result of the disease, treatment, inadequate nutritional intake,

or dyspnea. The nurse works with the patient and family to identify realistic goals and promote comfort. Measures include use of energy conservation methods to accomplish tasks and activities that the patient values most.

Efforts are made to provide the patient with as much control and independence as desired but with assurance that support and assistance are available when needed. In addition, health care teams work with the patient and family to ascertain and comply with the patient's wishes about treatment methods and care as the terminal phase of illness and death approach.

Hospice

The needs of patients with end-stage illness are best met by a comprehensive interdisciplinary specialty program that focuses on quality of life; palliation of symptoms; and provision of physical, psychosocial, and spiritual support for patients and families when cure and control of the disease are no longer possible. The concept of hospice best addresses these needs.

Hospice care is often delivered through coordination of specialty services provided by hospitals, home care programs, and the community. Patients need to be referred to hospice services in a timely fashion so that complex patient and family needs can be addressed. See Chapter 13 for detailed discussion of end-of-life care.

CRITICAL THINKING EXERCISES

1 ebp A 38-year-old man with early-onset colorectal cancer completed his first cycle of chemotherapy 2 days ago. He is now being admitted to the inpatient oncology unit with febrile neutropenia. What interventions and education should be considered for febrile neutropenia? What is the evidence for these interventions and education that you identified for febrile neutropenia? How strong is that evidence, and what criteria will you use to assess the strength of that evidence?

2 pq A 76-year-old woman, with a past medical history that is significant for cataracts, arthritis, and hypertension, was recently diagnosed with stage II breast cancer. She is being discharged today from the hospital following a bilateral mastectomy with several surgical drains in place. What are the priorities for the assessment of this patient to ensure her readiness for discharge to home? What will be your priorities when educating this patient for self-care?

3 ipc You are caring for a 53-year-old man with diffuse large B-cell lymphoma who received CAR T–cell therapy 2 days ago. How does CAR T–cell therapy differ from conventional chemotherapy? What type of referrals might be appropriate for this patient? What members of the interprofessional health care team do you anticipate as being integral to the care of this patient?

13 Palliative and End-of-Life Care

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Compare and contrast the settings where palliative care and end-of-life care are provided.
2. Describe the principles and components of hospice care in the United States, including the Medicare hospice benefit.
3. Apply skills for communicating with patients who are seriously ill and their families in order to provide culturally and spiritually sensitive care.
4. Identify components of uncomplicated grief and mourning and implement nursing measures to support patients and families.

NURSING CONCEPTS

Assessment
Comfort
End-of-Life
Ethics
Grief and Loss
Palliative Care

GLOSSARY

autonomy: self-determination; in the health care context, the right of the person to make choices about the use and discontinuation of medical interventions

bereavement: period during which mourning for a loss takes place

grief: personal feelings that accompany an anticipated or actual loss

hospice: a coordinated program of interdisciplinary care and services for terminally ill patients and their families

interdisciplinary collaboration: communication and cooperation among members of diverse health care disciplines jointly to plan, implement, and evaluate care

Medicare Hospice Benefit: a Medicare Part A entitlement that provides for comprehensive, interdisciplinary palliative care and services for eligible beneficiaries who have a terminal illness and a life expectancy of less than 6 months

mourning: individual, family, group, and cultural expressions of grief and associated behaviors

palliative care: a patient/person and family-centered approach to care that attends to the physical, functional, psychological, spiritual, and existential aspects of a serious illness

palliative sedation: controlled and monitored use of certain sedatives and nonopioid medications with the intention of reducing the patient's level of consciousness for the relief of refractory pain and symptoms that have not responded to other management measures; the purpose is not to hasten the patient's death but to relieve intractable symptoms

prognosis: the expected course of an illness and the chance for recovery

spirituality: personal belief systems that focus on a search for meaning and purpose in life, intangible elements that impart meaning and vitality to life, and a connectedness to a higher or transcendent dimension

terminal illness: progressive, irreversible illness that despite cure-focused medical treatment will result in the patient's death

Nurses have a significant and lasting effect on the way patients live until they die, the manner in which death occurs, and the enduring memories of that death for patients' families. The contemporary definition of nursing includes "…the diagnosis and treatment of human responses, and advocacy in the care of individuals, families, groups, communities, and populations" (American Nurses Association [ANA], 2015, p. 1). There may be no group more important than seriously ill and dying patients.

Knowledge about palliative and end-of-life principles of care and the ability to recognize the unique response of each patient and family to a given illness

are essential components required to support the unique values, preferences, and goals of a person's care. Nurses have an opportunity to bring research, education, and practice together to impact the culture of dying, allowing for much-needed improvement to care that is relevant across practice settings, age groups, cultural backgrounds, and illnesses. Nurses in all settings are likely to encounter patients who are seriously ill and families who can benefit from palliative care during advanced illness and at end-of-life. This chapter presents concepts about death and dying in the United States, settings for end-of-life care of the dying, and ways that nurses can address the health issues of patients who are terminally ill.

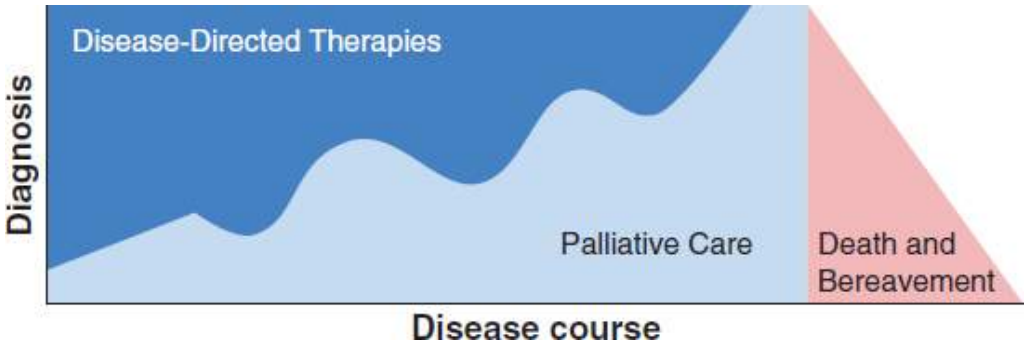

Figure 13-1 • This model shows the intersection of disease-directed therapies and palliative care beginning at diagnosis and continuing to death and bereavement. Adapted from Ferrell, B. R., Twaddle, M. L., Melnick., A., et al. (2018). National consensus project clinical practice guidelines for quality palliative care guidelines, 4th edition. *Journal of Palliative Medicine*, *21*(12), 1684–1689.

Palliative Care and End-of-Life Care

Palliative care uses an interdisciplinary model of care, focusing on symptom management and psychosocial/spiritual support for those with serious, life-limiting illnesses. Palliative care aims to improve quality of life for people and families through early integration into the plan of care strategies for managing pain and symptoms and for reducing burdensome care transitions through interdisciplinary teamwork, care coordination, clinician–patient communication, and decisional support. It is appropriate for patients at any age and at any stage in a serious illness, even while pursuing disease-directed or curative therapies, and extending into bereavement for families (Fig. 13-1). Palliative care can be viewed as both an approach to care and as a structured system for care delivery that aims to optimize quality of life by anticipating, preventing, and treating suffering (National Consensus Project for Quality Palliative Care [NCP], 2018). **Interdisciplinary collaboration** is an essential

component which is rooted in communication and cooperation among the various disciplines, with each member of the team contributing to a single integrated care plan that addresses the needs of the patient and the family. In contrast, multidisciplinary care refers to participation of clinicians with varied backgrounds and skill sets but without coordination and integration of care into a unified plan.

Hospice is a type of palliative care, focusing on comfort at the end-of-life. When patients enroll in hospice, they have made the decision to forego disease-directed therapies and focus solely on the relief of symptoms associated with their illness and the dying process. Both palliative care and hospice clinicians are skilled in the delivery of end-of-life care (which may include the months or weeks prior to death), expert pain and symptom management, life review and bereavement support. Focus on care of the dying is motivated by the aging of the population, the prevalence of and publicity surrounding life-threatening illnesses, and the increasing likelihood of a prolonged period of chronic illness prior to death. Figure 13-2 depicts four illness trajectories: sudden death, terminal illness, organ failure, and frailty. Sudden death is unexpected and accounts for the minority of deaths in this day and age. The other trajectories depict a common course in three types of chronic life-limiting illness: (1) terminal illness (e.g., cancer) is generally diagnosed when one is highly functioning, with a short steady decline before death; (2) organ failure (e.g., heart failure, end-stage kidney disease, or chronic lung disease) usually follows a slow decline after diagnosis, with episodic illnesses, perhaps exacerbation or hospitalization, where one has difficulty returning back to functional baseline; and (3) frailty (e.g., dementia) is typically diagnosed when one is already frail, with a slow decline over years. With the exception of sudden death, functional status can be a good prognostic indication; one such scale, the Palliative Performance Scale, is based on ambulation, activity, outward evidence of disease, self-care, intake, and level of consciousness (10-point increments, with 100% being fully functional and independent) (Hui, Park, Liu, et al., 2016).

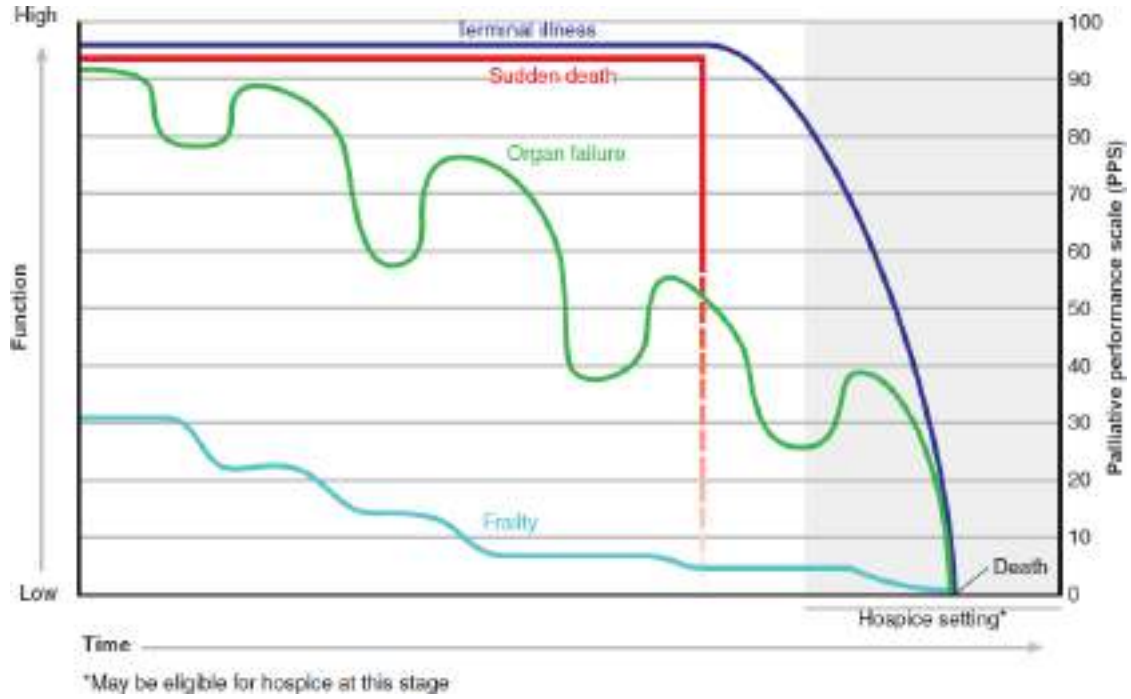

Figure 13-2 • The four trajectories of illness.

The Evolution of End-of-Life Care

In the 20th century, chronic, degenerative diseases replaced communicable diseases as the major causes of death. In the earlier part of the 20th century, most deaths occurred at home and most families had direct experience with death, through providing care to family members at the end-of-life and then mourning their losses together as a family unit. As the place of death shifted from home to hospitals, families became increasingly distanced from the death experience, placing the care of the patient into the health care provider's hands.

In the latter half of the 20th century, a technologic imperative practice pattern among health care professionals emerged, along with an expectation among patients and families that every available means to extend life must be tried. In the 21st century, technologic intervention at the end-of-life continues to have profound implications, affecting how clinicians care for the dying, how family and friends participate in care, how patients and families understand and choose among end-of-life care options, how families prepare for **terminal illness** (a progressive, irreversible illness that despite medical treatment will result in the patient's death) and death, and how they heal after the death of a loved one. Palliative and end-of-life care continues to evolve with the technology and medical interventions that are used to care for the seriously ill.

Between 2000 and 2050, the number of people older than 85 years is expected to quadruple (West, Cole, Goodkind, et al., 2014). More than half of the aged population has one or more chronic, serious illness (West et al.,

2014). The incidence of life-limiting illness is expected to continue to rise. Numerous initiatives aimed at improving end-of-life care have been launched in recent years, spurred by a widespread call for substantive change in the way Americans deal with death. In 2014, the Institute of Medicine (IOM) released a consensus report titled *Dying in America: Improving Quality and Honoring Individual Preferences Near the End of Life.* The report presented a summary of findings from a review of the evidence and provided recommendations for improving palliative and end-of-life care. The authors noted that patients experienced many transitions in settings, frequent and potentially avoidable hospital readmission, and inconsistent referral to palliative care. Recommendations include widespread and timely access to, and comprehensive coverage for palliative care services, improved clinician–patient communication, greater emphasis on advance care planning, professional education and development, and stronger public education and engagement (IOM, 2014).

The NCP identified eight key domains that underline a more comprehensive and humane approach to the care of the seriously ill patient at any stage, age, setting or prognosis, with the most recent update released in 2018 and outlined in Chart 13-1 (NCP, 2018). These practice guidelines have been endorsed by more than 80 national organizations, such as the Institute for Healthcare Improvement (IHI), American Cancer Society (ACS), Hospice and Palliative Nurses Association (HPNA), and the National Hospice and Palliative Care Organization (NHPCO), to structure and evaluate quality palliative and end-of-life programs for all those with serious illness at any stage, age, setting or prognosis.

In 2017, the ANA in collaboration with HPNA developed a *Call for Action —Nurses Lead and Transform Palliative Care,* which outlined the five areas of palliative nursing care: clinical practice, education, policy, research, and administration. In the document, the ANA and HPNA outline ways that nurses can transform palliative care, both as primary and specialty palliative care clinicians (ANA, 2017a). Primary palliative care is defined as the fundamental palliative care skills that all health care providers should have, including basic symptom assessment and management and the ability to explore goals of care through therapeutic communication. In contrast, the palliative care specialist addresses complex symptoms and navigates difficult goals of care conversations and family conflict. As a measure to better incorporate primary palliative care into nursing education, the American Association of Colleges of Nursing (AACN) recommended a new curriculum for palliative education for undergraduate nurses, including developing an online version of the End-of-Life Nursing Education Consortium (ELNEC) (Ferrell, Malloy, Mazanec, et al., 2016). See Resources section at end of chapter.

Settings for Palliative Care and End-of-Life Care

As the landscape of care at the end-of-life moved from the home to a more institutionalized death, the models of palliative care delivery changed as well. At hospice's inception, end-of-life care was home based or at a free-standing hospice. Palliative care was largely hospital based; it was born out of academic medical centers, where some health care providers felt that everyone deserves to receive treatment based on the tenets of hospice care throughout the progression of serious illness (Morrison, 2013). Current models for palliative and end-of-life care delivery will be described in greater detail in the following sections and include (NCP, 2018):

- Institution-based palliative care programs (e.g., programs within hospitals or long-term care facilities)
- Outpatient-based palliative care programs (e.g., outpatient clinics, ambulatory settings)
- Community-based palliative care program (consultative teams collaborate with hospice or home health agencies, to support patients not yet receiving hospice care in their place of residence)
- Hospice care (under Medicare Part A)

As our population ages and is expected to develop multiple comorbidities, the need for a palliative care workforce also grows. Yet, experts project a workforce shortage of all palliative clinicians that may not recover for nearly three decades. Proposed policy changes include (Kamal, Wolf, Troy, et al., 2019):

Chart 13-1

Overview of National Consensus Project Guidelines, Fourth Edition

Domain 1: Structure and Processes of Care

- *Overview:* Palliative care is based on a comprehensive interdisciplinary assessment of the patient and the family, by all clinicians with assistance from palliative care specialists as needed.
- *Clinical Implications:* Palliative care may improve quality of life for patients and families when well-trained interdisciplinary clinicians create care plans based on patient-stated values and preferences.

Domain 2: Physical Aspects of Care

- *Overview:* Pain, other symptoms, and side effects are managed based on the best available evidence, with attention to disease-specific pain and symptoms, which is skillfully and systematically applied.
- *Clinical Implications:* Interdisciplinary teams treat physical symptoms through recognition that physical symptoms impact a patient's emotional and spiritual well-being. Clinicians also consider goals, cultural, and developmental needs when choosing pharmacologic and nonpharmacologic treatments.

Domain 3: Psychological and Psychiatric Aspects of Care

- *Overview:* Psychological status, including need for assistance with distress, coping, family conflict, grief support and resources is assessed and managed based on the best available evidence, which is skillfully and systematically applied. When necessary, psychiatric issues are addressed and treated.
- *Clinical Implications:* Initial assessment is usually performed by social workers with assistance from psychologists and psychiatrists as needed.

Domain 4: Social Aspects of Care

- *Overview:* Comprehensive interdisciplinary assessment identifies the environmental and social factors that may impact the patient's and family members' quality of life, and a plan of care is developed to respond to these needs as effectively as possible.
- *Clinical Implications:* Coordination of care to address social and environmental vulnerabilities.

Domain 5: Spiritual, Religious, and Existential Aspects of Care

- *Overview:* Spiritual and existential dimensions are assessed and responded to based on the best available evidence, which is skillfully and systematically applied.
- *Clinical Implications:* The interdisciplinary team assesses each patient's sources of meaning and purpose, while respecting patient-specific beliefs, values, and traditions.

Domain 6: Cultural Aspects of Care

- *Overview:* Palliative care team members assess and attempt to meet the needs of the patient, family, and community in a culturally sensitive manner.
- *Clinical Implications:* Health care providers must examine their own biases to work to avoid judgment and provide culturally sensitive care.

Domain 7: Care of the Patient Nearing the End-of-Life

- *Overview:* Care is provided by interdisciplinary team members skilled in end-of-life care domains including expert symptom management, skilled communication, and grief/bereavement support.
- *Clinical Implications:* Signs and symptoms of impending death are recognized and communicated in developmentally appropriate language for the patient, family, and children, if applicable, with respect to information preferences.

Domain 8: Ethical and Legal Aspects of Care

- *Overview:* The patient's goals, preferences, and choices are respected within the limits of applicable state and federal law, within current accepted standards of medical care, and form the basis for the plan of care.
- *Clinical Implications:* Knowledge of ethical principles (beneficence, nonmaleficence, justice, self-determination) as well as pertinent health care laws is required. Clinicians must determine moral agency and understand when to engage surrogate decision makers to employ substituted judgment.

Adapted from Ferrell, B. R., Twaddle, M. L., Melnick., A., et al. (2018). National consensus project clinical practice guidelines for quality palliative care guidelines, 4th edition. *Journal of Palliative Medicine*, *21*(12), 1684–1689.

- The adoption of the Palliative Care and Hospice Education and Training Act (PCHETA), which if passed would increase the field by over 9000 practitioners.
- Policy to financially support palliative fellowship training across disciplines.
- Further research defining nonphysician palliative care specialist clinicians (nurses, social workers, chaplaincy).
- Creative reimbursement models that support the full interdisciplinary team.
- Policy to promote resiliency and, in turn, prevent burnout. (For more on burnout see later section entitled "Professional Caregiver Issues.")

Institution-Based Palliative Care

The landmark Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) documented troubling deficiencies in the care of the dying in hospital settings (SUPPORT Principal Investigators, 1995). Subsequently, the IOM's *Dying in America* (2014), the NCP *Clinical Practice Guidelines* (2018), and the ANA-HPNA *Call for Action* (2017a) have been shaping palliative and end-of-life care through developing and encouraging adherence to standards of care for patients with advanced illness and at end-of-life that will apply regardless of where the patients are receiving care (ANA, 2017a; IOM, 2014; NCP, 2018). There has been a steady increase in American hospital-based palliative care, with reportedly 90% of hospitals with 300 beds or more offering palliative care, compared to 56% of hospitals with fewer than 300 beds (Dumanovsky, Augustin, Rogers, et al., 2016).

In the hospital, the delivery of palliative care is typically through an interdisciplinary consultation service where primary teams consult specialists for one or more of the following reasons:

- Pain management
- Symptom management
- Goals of care discussions
- End-of-life issues
- Psychosocial distress
- Spiritual or existential distress

The core interdisciplinary team usually consists of physicians, nurses, advanced practice nurses, social workers, and chaplains (National Palliative Care Registry, 2017). Additional team members may include pharmacists, nutritionists, music or art therapists, ethicists, and psychologists. Occasionally, institutions have palliative care units where palliative care clinicians oversee a patient's care when palliative care needs supersede other hospital conditions. The most common reason for palliative care consultation in the hospital setting is goals of care discussion; those referred for care planning are most often older with a serious illness other than cancer and typically have a full code status (Bischoff, O'Riordan, Marks, et al., 2017).

In 2011, The Joint Commission launched an advanced certification program for palliative care to recognize hospitals that provide exceptional patient and family-centered care (The Joint Commission, 2018). The Center to Advance Palliative Care (CAPC) has a plethora of institutional resources for developing hospital–hospice partnerships to provide high-quality palliative care for hospitalized patients and for addressing the palliative care needs of other specialized populations. See Resources section at the end of the chapter.

According to the National Palliative Care Registry in 2017, the most common primary diagnoses seen by palliative care specialists included cancer (26%), cardiac diseases (15%), pulmonary conditions (9%), neurologic diagnoses (9%), and infectious causes (7%). For patients with diagnoses for

which palliative care specialists have rarely been consulted, the efficacy of palliative care has been demonstrated. In one study, for example, patients undergoing stem cell transplant at an academic medical center reported better quality of life during transplant hospitalization after palliative care intervention (El-Jawahri, LeBlanc, VanDusen, et al., 2016).

Researchers have reported that seriously ill hospitalized patients who receive palliative care consultations for goals of care have lower future health care utilization and cost (O'Connor, Junker, Appel, et al., 2018). Despite the growth of palliative care, many believe that palliative care resources are still lacking; in a survey of administrators and clinicians, respondents felt that 60% of patients who may benefit from palliative or end-of-life care do not receive this type of support (Compton-Phillips & Mohta, 2019). Additionally, there is ample room for improvement in end-of-life care delivery. Hospital end-of-life care has been found to be of higher quality in hospitals with better rated nurse practice environments (as measured by the Practice Environment Scale of the Nursing Work Index survey, where nurse workload, autonomy, and interdisciplinary collaboration are favored); however, the majority of nurses rated overall end-of-life care in hospitals unfavorably (Lasater, Sloane, McHugh, et al., 2019).

Experts estimate that the number of people who will need some form of short- or long-term skilled nursing care in their lifetimes, whether in the community or in a residential care facility, is likely to increase exponentially (West et al., 2014). As a result, the likely place of death for a growing number of Americans after the age of 65 years will be a skilled nursing facility. A 2018 study by Teno and colleagues found that, among Medicare fee-for-service beneficiaries, the proportion of death in acute care hospitals has decreased, yet one in five beneficiaries continues to die in acute care settings. More than one in four (29%) fee-for-service beneficiaries are admitted to intensive care units in the last 30 days of their life. Based on recent trends, about two in five (40%) of fee-for-service beneficiaries die at home and community settings, including assisted living facilities. Nursing homes remain the site of death for 25% of Medicare beneficiaries. Thus, while dying at home has increased for those older than age 65 in recent years, deaths in other locations still exceed the number of deaths occurring at home (Teno, Gozalo, Trivedi, et al., 2018).

Residents of skilled nursing facilities typically have poor access to palliative care. Regulations that govern how care in these facilities is organized and reimbursed tend to emphasize restorative measures and serve as a disincentive to palliative care. Since 1989, home hospice programs have been permitted to enroll long-term care facility residents in hospice programs and to provide interdisciplinary services to residents who qualify for hospice care. Of over one million Medicare beneficiaries who received hospice services in 2016, close to a third resided in long-term care facilities, an increase from 14.5% in 2013 to 32.8% (NHPCO, 2018). Because hospices provide some

services that may overlap with services provided by the skilled nursing provider, payment models have been developed to define and reconcile duplication of services. In 1997, the Office of Inspector General (OIG), an oversight arm of the federal government, questioned whether hospice services in nursing homes were an unnecessary duplication of services already provided by long-term care facility staff. Hospice/skilled nursing facility contracts continue to be scrutinized by federal regulators. More recently, facilities are under increasing public pressure to improve care of the dying and are beginning to develop palliative care units or services; continuing to contract with home hospice programs to provide palliative care consultations and hospice care in the facilities; and to educate staff, residents, and their families about pain and symptom management and end-of-life care. Many skilled nursing providers have implemented culture change innovations such as resident-centered care plans and consistent staff assignments to change the experience of long-term skilled nursing care. In nursing homes, "comfort measures" are used to identify residents who do not wish to receive life-sustaining interventions. Nevertheless, hospitalizations continue to occur and research reports that 77% of events (i.e., fall, change in mental status, or development of a new symptom) are unavoidable, yet opportunities exist for improvement in communication and monitoring (Unroe, O'Kelly Phillips, Effler, et al., 2019). Palliative care education and training for nursing home staff may improve the quality of care residents receive at the end-of-life.

Outpatient-Based Palliative Care

As palliative care has become more prevalent in hospitals, skilled nursing settings, and in home hospice programs, outpatient palliative care has emerged as an approach to providing services and support to patients and families who opt not to, or are not eligible for, home hospice but could benefit from comprehensive palliative care in the community. Outpatient palliative care benefits both patients and their families and other providers by providing expert consultation and management of symptoms and other needs. A growing body of evidence supports the role of palliative care that is delivered *concurrently* with standard medical treatment. For example, in a landmark study of outpatient referral to palliative care for patients newly diagnosed with metastatic non–small cell lung carcinoma (a disease with very poor prognosis), researchers found that those patients randomized to the palliative care plus standard oncology care arm of the trial not only showed improved quality of life and mood, but also had longer median survival than those who received standard oncology care alone (Temel, Greer, Muzikansky, et al., 2010). Such studies underscore the value of palliative care.

Models for palliative care in ambulatory clinics vary and include independent clinics, colocated clinics and embedded practices (Finlay,

Newport, Sivendran, et al., 2019). Each model differs in the referral process, financial makeup, staffing and population served (Finlay et al., 2019). In addition, clinics may follow a consultative only, comanagement with one or shared opioid prescribing (Finlay et al., 2019). Although many outpatient palliative care clinics start with oncology patients, as palliative care has gained traction in many disease states in the hospital, other medical specialties (cardiologists, pulmonologist, nephrologists, etc.) are lacking proper palliative care follow-up and requesting nononcology palliative care clinics.

Community-Based Palliative Care

Home-based primary care has become more common due to the aging of society and a desire for people to remain at home rather than live in an institution (Schuchman, Fain, & Cornwell, 2018). Home-based primary care incorporates palliative care skills, and specialty palliative care home programs have developed with the goal of managing symptoms and providing support in the home. The Affordable Care Act, passed in 2010, also included new payment models for home-based palliative care in an effort to reduce hospital readmissions and mortality (Morrison, 2013).

Hospice Care

The broadening of the application of palliative care in the United States actually *followed* the development of hospice programs. All hospice care is palliative care; however, not all palliative care is hospice care. The difference is that hospice care is an application of palliative care delivered at the end-of-life. Hospice care focuses on quality of life, and by necessity, it usually includes realistic emotional, social, spiritual, and financial preparation for death. Hospice in the United States is not a *place* but a philosophy of care in which the end-of-life is viewed as a developmental stage.

Originally, the concept of hospice care as an alternative to depersonalized death in institutions began in the early 1970s as a volunteer-based, grassroots, and spiritually centered movement (Meghani, 2004). In 2016, there were 4382 hospice programs in operation across all 50 states (as well as Washington, DC and Puerto Rico), serving an estimated 1.43 million patients (NHPCO, 2018). Currently the most common diagnosis for hospice patients in the United States is cancer (Table 13-1). While median length of hospice stay in 2016 was approximately 24 days across diagnoses, for patients with dementia, the average length of stay was 104 days (NHPCO, 2018).

TABLE 13-1 Hospice Admission Diagnosis Prevalence

Diagnosis	Percent of Hospice Patients (%)
Cancer	27.2
Cardiac/circulatory	18.7
Dementia	18.0
Respiratory	11.0
Stroke	9.5
Other	15.6

Adapted from National Hospice and Palliative Care Organization (NHPCO). (2018). *NHPCO facts and figures: Hospice care in America*. Alexandria, VA: Author.

After hospice care was recognized as a distinct program of services under Medicare in early 1983, organizations providing hospice care were able to receive Medicare reimbursement if they could demonstrate that the hospice program met the Medicare conditions of participation, or regulations for hospice providers as enforced by the Centers for Medicare & Medicaid Services (CMS, 2019). In many aspects, Medicare standards have come to largely define hospice philosophy and services. State Medical Assistance (Medicaid) also provides coverage for hospice care, as do most commercial insurers.

Hospice is a coordinated program of interdisciplinary services provided by professional caregivers and trained volunteers to patients with serious, progressive illnesses that are not responsive to cure. The root of the word *hospice* is *hospes,* meaning "host." According to Cicely Saunders, who founded the world-renowned St. Christopher's Hospice in London, the principles underlying hospice are as follows:

- Death must be accepted.
- The patient's total care is best managed by an interdisciplinary team whose members communicate regularly with one another.
- Pain and other symptoms of terminal illness must be managed.
- The patient and the family should be viewed as a single unit of care.
- Home care of the dying is necessary.
- Bereavement care must be provided to family members.
- Research and education should be ongoing.

The goal of hospice is to enable the patient to remain at home, surrounded by the people and objects that have been important to them throughout life. The patient and the family comprise the unit of care. Hospice care does not seek to hasten death or encourage the prolongation of life through artificial means.

Despite more than 45 years of existence in the United States and the early calls for its concurrent integration with disease-modifying treatments

(Meghani, 2004), hospice remains an option for end-of-life care that has not been fully integrated into mainstream health care. Reasons include the difficulties in making a terminal prognosis (especially for those patients with noncancer diagnoses), the strong association of hospice with death, advances in "curative" treatment options in late-stage illness, and financial pressures on health care providers that may cause them to retain rather than refer patients who are eligible for hospice. Moreover, there are significant racial differences in the utilization of hospice care; for example, Asian Americans tend to have shorter lengths of hospice stay, and non-White patients have a higher incidence of revoking hospice when compared to White patients (Wang, Hsu, Aldridge, et al., 2019).

The Medicare-certified hospice is paid a predetermined dollar amount for each day of hospice care that each patient receives. Four levels of hospice care are covered under Medicare and Medicaid hospice benefits: (1) routine care, (2) continuous care, (3) respite care, and (4) general inpatient hospice care. Most hospice care is provided at the "routine home care" level; routine and continuous care are outlined in greater detail in Chart 13-2. According to federal guidelines, hospices may provide no more than 20% of the aggregate annual patient-days at the inpatient level. Respite care allows primary caregivers a break through admission of the patient to an inpatient unit or nursing facility.

Federal rules for hospices require that eligibility be reviewed periodically. Patients who live longer than 6 months under hospice care are *not* discharged, provided that their primary provider and the hospice medical director continue to certify that they are terminally ill with a life expectancy of 6 months or less (assuming that the disease continues its expected course). Thus, the patient is re-certified and continues to receive hospice benefits. Once a patient meets eligibility criteria and elects to use the benefit, the Medicare-certified hospice program assumes responsibility for providing and paying for the care and treatment to palliate the terminal illness for which hospice care was elected. Patients may revoke their hospice benefits at any time, resuming traditional coverage under Medicare or Medicaid for the terminal illness. Those who revoke their benefits may also reelect to use them at a later time.

The **Medicare Hospice Benefit** requirement that beneficiaries make a choice between palliative care (to enroll in hospice) and cure-focused treatment has long been a barrier to earlier hospice enrollment. A Medicare beneficiary could not receive BOTH palliative care and cure-focused care under their hospice benefit. The Affordable Care Act authorized a study of concurrent palliative and curative care services. Under this federally funded study, titled Medicare Care Choices, CMS is evaluating whether beneficiaries would choose palliative care under hospice guidelines while they *continue to receive* cure-focused care (CMS, 2018). The model is being tested with 104 hospices currently participating and 1092 Medicare patients receiving this

concurrent care, with a hope to reach 150,000 in the coming years (CMS, 2018).

Veterans Considerations

The Veterans Administration (VA) offers concurrent care, whereby a veteran has the option to receive disease-directed therapy, such as radiation or chemotherapy, while receiving hospice care. The VA reported that veterans with cancer at the end-of-life received radiation and chemotherapy at the same rate as before concurrent care was offered, but the utilization of hospice increased, thus allowing patients to receive significant support in the last weeks of life (Mor, Joyce, Cote, et al., 2016).

Chart 13-2

Eligibility Criteria for Hospice Care

Who? A Patient with a Serious, Progressive Life-Limiting Illness Must Meet Two Criteria:

- Two primary providers certify that prognosis is less than 6 mo if the disease runs usual course
- Patient and family agree with comfort as the goal of care

When? The patient wishes to pursue comfort-focused care and prognosis is believed to be months. If a patient survives >6 mo they may be re-enrolled in hospice care.

What? Medicare and Medicaid Hospice Benefits

- Medicare Part A; Medical Assistance eligibility
- Waiver of traditional Medicare/Medicaid benefits for the terminal illness (e.g., surgery, skilled nursing care, hospital stay)
- Care must be provided by a Medicare-certified hospice program

Where? Hospice settings vary depending on a person's care needs and may include:

- Home (*Routine Hospice Care,* delivered in a private residence, nursing home)
  - The majority of patients receive hospice at home
  - Care is primarily delivered by family and friends
  - Hospice staff (nurses, aides, social workers and chaplains) provide additional support as needed
  - All services (staff visits, medications, durable medical equipment) provided are included in the daily rate to the hospice
  - Phone hotline available for caregivers to reach a hospice nurse 24 hours a day
  - *Continuous care:* This is a temporary level of care provided in the patient's home where continuous nursing care is provided in the home for the management of a medical crisis (e.g., the hospice patient seizes and a hospice nurse comes to the home to monitor the patient and administer medications; nursing need is reevaluated every shift). Care reverts to the routine home care level after the crisis is resolved
- Long-term care facility
  - Hospice staff is added as additional layer of support for established residents
  - Facility staff continue to provide 24-h care
  - Facility room and board paid separately from hospice care
- Residential hospice
  - Residences for long-term stay

- Payment is typically prorated based on income
- Not many exist and travel may be prohibitive for family or friends

- General inpatient hospice
  - Indicated for acute pain or symptom management requiring 24-h care
  - Usually in a free-standing inpatient hospice unit or in a Medicare certified hospital

Communication in Palliative Care

Expert communication is a tenet of palliative and end-of-life care. Historically, communication was thought of as an innate art. Experts now view communication as a set of skills that can be taught, practiced, and built upon. Nurses need to develop skill and comfort in assessing patients' and families' responses to serious illness and planning interventions that support their values and choices throughout the continuum of care (Wittenberg-Lyles, Goldsmith, Ferrell, et al., 2013). To develop a level of comfort and expertise in communicating with seriously and terminally ill patients and their families, nurses must first consider their own experiences with and values concerning illness and death through reflection, discussion with colleagues, reading, and self-discovery.

Skills for Communicating with the Seriously Ill

Throughout the course of a serious illness, patients and their families encounter complicated treatment options and bad news about disease progression. They may have to make difficult decisions at the time of diagnosis, when disease-focused treatment fails, when the effectiveness of a particular intervention is being discussed, and when decisions about hospice care are presented. These critical points on the treatment continuum demand patience, empathy, and honesty from nurses. Over the years, many communication training models have been developed to improve goals of care and end-of-life conversations (Table 13-2). One such program, the Serious Illness Conversation Project (SICP) communication guide, has helped clinicians have earlier, more thorough, and more accessible conversations around patients' values, worries, and preferences (Paladino, Bernacki, Neville, et al., 2019).

Therapeutic communication can be learned and, like other skills, must be practiced to gain expertise. Like other skills, communication should be practiced in a safe setting, such as a classroom or clinical skills laboratory with other students and clinicians. One skill that nurses have the opportunity to master is responding to emotion. Nurses often meet patients in vulnerable states experiencing strong emotions such as anxiety, anger, fear, and sadness. The NURSE framework (Table 13-3) should be considered when a patient

expresses an emotion. Typically, the nurse would choose one response listed at a time.

Patients often direct questions or concerns to nurses before they have been able to fully discuss the details of their diagnosis and prognosis with their primary providers or the entire health care team. Using open-ended questions allows the nurse to elicit the patient's and family's concerns, explore misconceptions and needs for information, and form the basis for collaboration with primary providers and other team members. Chart 13-3 provides sample language for exploring a patient's values and preferences. In practice, communication with each patient and family should be tailored to their particular level of understanding and values concerning disclosure.

TABLE 13-2 Interdisciplinary Communication Training Models

Model Name	Target Clinicians	Format	Curriculum	Considerations
Center to Advance Palliative Care Continuing Medical Education modules[a]	All disciplines	Online, case-based, open-ended answers	Five modules on foundational communication skills. Additional PC modules available	Included in institutional CAPC membership
Education on Palliative and End-of-Life Care[b]	All disciplines	Classroom didactic	Overview of communication skills embedded in PC curriculum	A separate 2-d facilitator training is available
End-of-Life Nursing Education Consortium (ELNEC)[c]	RN, NP	Classroom didactic	Communication is focus during 1 h of a 2-d course. Various tracks including: ELNEC-Core, ELNEC-APRN, ELNEC Critical Care, ELNEC-Geriatrics	"Train-the-trainer" model. ELNEC added a communication-only course called COMFORT
Respecting Choices	RN, SW, APP, MD	Classroom didactic	First steps (RN/SW focused), next steps (RN/SW focused), last steps (MD focused). From advanced care planning to decision making	Usually paired with system implementation
Serious Illness Care Program at Ariadne Labs[d]	All disciplines	3-h workshop with didactic and roleplay	Training on the Serious Illness Conversation Guide (see Chart 13-3) with scripted exploratory questions	Usually paired with system implementation. Faculty members have 2+ d training
ViralTalk[e]	MD, APP, and ICU RN	Online video, Smartphone application, small-group workshop (0.5–2 d) with simulated patient actors	Content across disease continuum customized to learner needs organized by clinical task. Includes five-step talking map	Core workshop with actors, constructive feedback, and opportunity to replay

Chart 13-3 **ASSESSMENT**

Preferred Language for Assessing Goals of Care

Assess understanding of diagnosis and prognosis: Seek patient's knowledge of illness.

- What is your understanding of your condition?
- What did your provider say about your illness?
- How have things been going with your treatment?
- What is the plan moving forward?

Exploratory questions: Ask for clarifications and allow patient the space to tell narrative.

- Tell me more.
- Can you say more about that?
- I heard you say [x], can we go back to that?
- Will you tell me more about how you are feeling about [x]?

Ask about patient's values, preferences, and concerns: These questions allow health care providers to match patient values to treatment options, often called goals of care.

- What is most important to you?
- What are you hoping for, in terms of your illness?
- What you hoping from this treatment?
- What concerns you when you think about the future?
- What is most important to you?

Assess coping and support system: In learning more about how a person has coped in the past, you can incorporate appropriate supports (e.g., social work, chaplain)

- How have you coped with challenges in the past?
- What gives you strength?
- What gives you meaning and purpose?
- Is there anything we should consider or anyone we should include when making decisions about your care?
- If you cannot participate in health care decisions, with whom should we speak?

Important questions for family members when patient is unable to participate in conversation.

- Tell me about your loved one.
- What did they value?
- Did they ever talk about what they would or would not want if they were in a situation like this?

- Did they ever discuss states of living that would not be acceptable (e.g., being bedbound, unable to toilet, inability to speak)?

Adapted from Peereboom, K., & Coyle, N. (2012). Facilitating goals-of-care discussions for patients with life-limiting disease—Communication strategies for nurses. *Journal of Hospice and Palliative Nursing, 14*(4), 251–258.

The Role of the Nurse in Family Meetings

Family meetings, prompted by either the patient and family or the care team, are often held to clarify goals, address concerns, and formulate a plan. The objectives of a family meeting are to both gather information and share information. Family meetings may be held at any time during a serious illness and should especially be arranged when new diagnostic information is available. More often than not, difficult news is shared at a family meeting. As such, patient and family members may become emotional and the nurse has the unique opportunity to offer support (see Table 13-3).

TABLE 13-3 Responding to Emotions

Patient Statement: "I just can't handle any more setbacks."		
	Empathic Response	Sample Language
N	NAME the emotion	It sounds like you are worried about the future.
U	UNDERSTAND the emotion	You have been through so much already.
R	RESPECT (or praise) the patient	I am so impressed with how you have dealt with so many ups and downs.
S	SUPPORT the patient	I hope you don't have any more setbacks and I'm here for you no matter what the future holds.
E	EXPLORE the emotion	You seem more worried than usual; can you tell me more about what's different about today than yesterday?

Adapted from Back, A., Arnold, R., Tulsky, J. (2009). *Mastering communication with seriously ill patients: Balancing empathy and hope*. New York: Cambridge University Press.

Before a family meeting, the nurse in collaboration with the primary team can perform a stakeholder analysis to ensure that important people are present. The nurse can ask the patient who helps them make decisions and help arrange for their presence. Engaging integral medical team members and consults is important to ensure that experts can answer all patient and family questions.

The nurse can assure the patient that they will be present at the meeting to support the patient. The nurse can also ensure the setting is right—free from disturbances, private, ample seating. Additional roles for the nurse in a family meeting are listed in Chart 13-4.

Advanced Care Planning

The process of thinking through, and possibly documenting, the medical interventions that one would or would not want in the case one is no longer able to voice one's own decisions is called advanced care planning (ACP). Nurses play an integral role in ACP. With the proper training and understanding of ACP, nurses should feel empowered to engage with patients about their goals of care and, when applicable, assist patients with completion of ACP documentation (Izumi, 2017). Two components of ACP are designating a health care surrogate and documenting end-of-life preferences (Chart 13-5).

Chart 13-4

The Role of the Nurse in a Family Meeting

- Advocate for patient based on values shared by patient and family.
- Act as interpreter when medical jargon is not clearly understood by patient and family.
- Respond to emotion expressed in meeting.
- Prior to meeting, encourage and assist patient and family with developing questions to ask of interdisciplinary teams during meeting.
- Express concerns.
- Share clinical nursing updates.

Integrating palliative nursing in the ICU: The nurse in a leading role. *Journal of Hospice and Palliative Nursing, 13*(2), 89–94; Wittenberg-Lyles, E., Goldsmith, J., Ferrell, B. R., et al. (2013). *Communication in palliative nursing*. New York: Oxford.

Chart 13-5

Methods of Stating End-of-Life Preferences

Advance directives: written documents that allow the person of sound mind to document preferences regarding end-of-life care that should be followed when the signer is terminally ill and unable to verbally communicate their wishes. The documents are generally completed in advance of serious illness but may be completed after a diagnosis of serious illness if the signer is still of sound mind. The most common types are the durable power of attorney for health care and the living will.

Do not resuscitate: a medical order to withhold cardiopulmonary resuscitation (CPR) in the event of cardiac arrest. In some settings, the term "allow natural death" (AND) is used in place of "do not resuscitate" (DNR).

Durable power of attorney for health care: a legal document through which the signer appoints and authorizes another person to make medical decisions on their behalf when they are no longer able to speak for themselves. This is also known as a health care power of attorney, medical power of attorney, or a proxy directive.

Living will: a type of advance directive in which the individual documents treatment preferences. It provides instructions for care in the event that the signer is terminally ill and not able to communicate their wishes directly and often is accompanied by a durable power of attorney for health care. This is also known as a medical directive or treatment directive.

Physician orders for life-sustaining treatment (POLST): a form that translates patient preferences expressed in advance directives to medical "orders" that are transferable across settings and readily available to all health care providers, including emergency medical personnel. The POLST form is a brightly colored form that specifies preferences related to CPR, intubation, artificial nutrition and hydration, antibiotics, and other medical interventions. The form is signed by the patient or surrogate and the primary provider, advanced practice nurse, or physician assistant. The use of the POLST is subject to state laws and regulations. Numerous states have endorsed the POLST or a similar form and some states have implemented electronic registries and electronic versions of POLST forms (e.g., New York's e-MOLST program).

Information about the advance care planning and state-specific advance directive documents and instructions is available at www.caringinfo.org. Information about the POLST is available at www.polst.org

Now legally sanctioned in every state and federally sanctioned through the Patient Self-Determination Act of 1991, advance directives are written documents that allow competent people to document their preferences regarding the use or abatement of medical treatment at the end-of-life, specify their preferred setting for care, and communicate other valuable insights into their values and beliefs. These documents are widely available from health care providers, community organizations, bookstores, and from trusted Web sites. Unfortunately, ACP documents remain underutilized, as a systematic review found that only one in three Americans have completed any advanced

directive (Yadav, Gabler, Cooney, et al., 2017). Data was similar for those with chronic illnesses and healthy adults in this study. The underuse of advanced directives may reflect society's continued discomfort with openly confronting the subject of death. Furthermore, the existence of a properly executed advance directive does not reduce the complexity of end-of-life decisions.

The Patient Self-Determination Act requires that health care entities receiving Medicare or Medicaid reimbursement must ask whether patients have advance directives, provide information about advance directives, and incorporate advance directives into the medical record. However, advance directives should not be considered a substitute for ongoing communication among the health care provider, patient, and family as the end-of-life approaches.

Concept Mastery Alert

An advance directive states a patient's wishes for treatment. A proxy directive appoints another person to make medical decisions on behalf of the patient and is added to the advance directive.

Symptom Assessment and Management

Expected Physiologic Changes

Patients approaching the end-of-life experience many of the same symptoms, regardless of their underlying disease processes. Symptoms in terminal illness may be caused by the disease, either directly (e.g., dyspnea owing to chronic obstructive lung disease) or indirectly (e.g., nausea and vomiting related to pressure in the gastric area), by the treatment for the disease, or by a coexisting disorder that is unrelated to the disease. Symptoms should be carefully and systematically assessed and managed. Pharmacologic and nonpharmacologic methods of symptom management may be used in combination with medical interventions to modify the physiologic causes of symptoms. The principles of pharmacologic symptom management are the use of the smallest dose of the medication to achieve the desired effect, avoidance of polypharmacy, anticipation and management of adverse effects, and creation of a therapeutic regimen that is acceptable to the patient based on the patient's goals for maximizing quality of life.

The patient's goals should guide symptom management. The clinician should help the patient and the family weigh the benefits and risks of continued diagnostic testing and disease-focused medical treatment in the context of their goals for care. The patient and the family may be extremely

reluctant to forego monitoring that has become routine throughout the illness (e.g., blood testing, x-rays) but that may contribute little to a primary focus on comfort. Medical interventions may be aimed at treating the underlying causes of the symptoms or reducing the impact of symptoms. For example, a medical intervention such as thoracentesis (an invasive procedure in which fluid is drained from the pleural space) may be performed to temporarily relieve dyspnea in a patient with pleural effusion secondary to lung cancer.

For the procedural guidelines for assisting the patient undergoing thoracentesis, go to **thepoint.lww.com/Brunner15e**.

Anticipating and planning interventions for symptoms is a cornerstone of both palliative and end-of-life care. Patients and family members cope more effectively with new symptoms and exacerbations of existing symptoms when they know what to expect and how to manage them. At the end-of-life, hospice programs typically provide a *comfort kit* which contains ready-to-administer doses of various medications that are useful to treat symptoms in advanced illness. For example, a kit might contain small doses of oral morphine liquid for pain or shortness of breath, a benzodiazepine for anxiety, and an acetaminophen suppository for fever. Family members can be instructed to administer a prescribed dose from the emergency kit, often avoiding prolonged suffering for the patient.

Although clinicians may believe that symptoms must be completely relieved whenever possible, the patient might choose instead to decrease symptoms to a tolerable level rather than to relieve them completely if the side effects of medications are unacceptable to them. This often allows the patient to have greater independence, mobility, and alertness and to devote attention to issues that they consider of higher priority and greater importance. For instance, a mother may choose to wait to take pain medication until bedtime so that she can be awake and engaged when her children return home from school.

TABLE 13-4 Stages of the Dying Process

Time Frame	Symptoms: *How the patient is feeling*	Nursing Interventions: *What you can do*
Months before death	• Gradual generalized weakness • Fatigue • Social isolation • Decreased appetite	• Provide education to patient and family that symptoms are expected. • Allow patient choice in activity level and sleep schedule. • Assist with life review. Provide support to family who are distressed by patient's withdrawal. • Educate patient/family on eating for comfort.
Weeks before death	• Neurologic: ↑ sleepiness, possible delirium, dulled senses (except hearing) • Cardiopulmonary: ↑ pulse and ↑ RR, ↓ BP, Periodic apnea or agonal breathing, inability to clear secretions • Renal: ↓ urinary output + incontinence or retention • Skin: feverish or cold, possible perspiration, pallor	• Provide education on terminal delirium. Engage family in periods of lucidity. Talk to patient even when appears to be sleepy (to avoid leaving anything unsaid). • Assess and treat dyspnea as appropriate. Cluster care. Assess if ANH is contributing to pulmonary congestion. Position patient in side-lying position with HOB elevated. • Insert urinary catheter for comfort if indicated. Use absorbent pads and change as needed. Consider retention if patient is restless. • Bath and change linens as needed. Engage family in scheduling.
Days before death	• Neurologic: somnolence, restlessness, further dulled senses (except hearing), possible "rally" in energy • Cardiopulmonary: ↑ pulse and ↑ or ↓ RR, ↓ BP, more frequent periods of apnea or agonal breathing, inability to clear secretions • Renal: ↓ urinary output +	• Normalize the dying process for family. If patient has a "rally" in energy, guide family to take patient's lead in preference for this time (e.g., a favorite meal). • Assess and treat dyspnea as appropriate. Cluster care. Position patient in side-lying position with HOB elevated. Avoid suctioning; administer anticholinergics for impaired secretions as prescribed. • Provide education to family. Use absorbent pads and change as needed. Consider retention if patient is restless. • Change linens as needed. Bed bath for comfort.

	incontinence or retention • Skin: feverish or cold, mottling of extremities, pallor	
Hours before death (or *actively dying* phase)	• Neurologic: obtunded, nonresponsive, hearing may remain • Cardiopulmonary: ↑ pulse (may be irregular or difficult to palpate) and ↑or ↓ RR, ↓ BP, periods of apnea (>40 s) or agonal breathing • Renal: oliguria/anuria • Skin: worsening mottling of extremities	Interventions as above. Continue to provide education that these signs and symptoms are a normal part of the dying process. If certain family wishes to be present at the time of death, alert them of prognosis. Encourage family self-care during vigil. Additionally, the nurse may engage in conversation with family around funeral/burial preferences and cultural rituals at the end-of-life. Offer chaplaincy support if helpful to family.

ANH, artificial nutrition and hydration; BP, blood pressure; ↓, decreased; HOB, head of bed; ↑, increased; +, plus; RR, respiratory rate.

Adapted from Berry, P., & Griffie, J. (2019). Planning for the actual death. In B. R. Ferrell, N. Coyle, & J. Paice (Eds.). *Oxford textbook of palliative nursing* (5th ed.). New York: Oxford.

As death approaches and organ systems begin to fail, observable, expected changes in the body take place (Table 13-4). The nurse should prepare the family for the normal, expected changes that accompany the period immediately preceding death. Although the exact time of death cannot be predicted, it is often possible to identify when the patient is very close to death. When death is imminent, patients may become increasingly somnolent and unable to clear sputum or oral secretions, which may lead to further impairment of breathing from pooled secretions. The sound and appearance of the secretions are often more distressing to family members than is the presence of the secretions to the patient. Family distress over the changes in the patient's condition may be eased by supportive nursing care. Continuation of comfort-focused interventions and reassurance that the patient is not in any distress can do much to ease family concerns. Hospice programs frequently provide written information for families so that they know what to expect and what to do as death nears.

Pain

In the final stages of illnesses such as cancer, heart disease, chronic obstructive pulmonary disease (COPD), and renal disease, pain is a common symptom. Pain results from the disease state as well as the modalities used to treat them. The Worldwide Palliative Care Alliance, World Health Organization (2014) called attention to the continuing, worldwide high prevalence of pain at the end-of-life and the inadequate supply of opioids, particularly in developing nations. A primary role for nurses in end-of-life care is to ensure that pain is assessed, prevented where possible, and managed. Chapter 9 presents the importance of pain assessment, assessment principles for pain that include identifying the effect of the pain on the patient's life, and the importance of believing the patient's report of the pain and its effect. Poorly managed pain affects the psychological, emotional, social, and financial well-being of patients. Every clinician should be able to assess and oversee the basic management of pain (IOM, 2014).

Management of moderate to severe pain in the United States is complicated by public policy and legal challenges due to an opioid crisis (Foxwell, Uritsky, & Meghani, 2019) and federal prescribing guidelines aimed at reducing opioid use (Centers for Disease Control and Prevention [CDC], 2016). While patients receiving palliative care are exempt from the opioid guidelines, there are reports of the misapplication of the guidelines for patients with serious illnesses (Dowell, Haegerich, & Chou, 2019). The current context of pain management is also feared to worsen the widely documented disparities in pain treatment in the United States (Meghani & Vapiwala, 2018). Simultaneously, there are concerns about opioid misuse in the palliative care setting (Hui, Arthur, & Bruera, 2019). Thus, palliative care clinicians are also challenged with the imperative to provide effective pain relief while balancing societal risks.

All patients on opioid therapy and their family caregivers should receive comprehensive education and support to ensure safe use of opioids while addressing fears and concerns about opioid use. Personalized treatment plans should include longitudinal assessment and documentation of pain management goals and needs, management of treatment side effects, use of integrative therapies and interventional techniques when appropriate, monitoring risk of opioid misuse, and longitudinal counseling.

In their recent position statement, the American Society for Pain Management Nursing (ASPMN) and HPNA maintain that nurses and other health care professionals "must advocate for effective, efficient, and safe pain and symptom management to alleviate suffering for every patient receiving end-of-life care regardless of their age, diseases, history of substance misuse, or site of care" (Coyne, Mulvenon, & Paice, 2018). The statement underscores the indispensable role of comprehensive and continuous pain and symptom management in all patients and, specifically, in the patient who is nonverbal during the dying phase (Coyne et al., 2018).

The nurse educates the family caregivers about continuation of comfort measures as the patient approaches the end-of-life, how to administer antispasmodic agents via alternative routes, and how to assess for pain when the patient cannot verbally report pain intensity. Short-acting antispasmodic agents are most effective for uncontrolled pain. At the end-of-life, patients may receive frequent dosing. There is always a strong possibility that a patient approaching the end-of-life will die in close proximity to the time of analgesic administration. If the patient is at home, family members administering antispasmodic agents should be prepared for this possibility. They need reassurance that they did not cause the death of the patient by administering a dose of analgesic medication. In the hospital, nurses need to understand that there is always a last dose of medication in a patient who is dying, but the last dose does not cause death.

Dyspnea

Dyspnea, an uncomfortable awareness of breathing, is one of the most prevalent symptoms at the end-of-life and can be challenging to manage. A highly subjective symptom, dyspnea often is not associated with visible signs of distress, such as tachypnea, diaphoresis, or cyanosis. Although the underlying cause of the dyspnea can be identified and treated in some cases, the burdens of additional diagnostic evaluation and treatment aimed at the physiologic problem may outweigh the benefits. The treatment of dyspnea varies depending on the underlying cause, the patient's general physical condition, and imminence of death. For example, a blood transfusion may provide temporary symptom relief for a patient with anemia earlier in the disease process; however, as the patient approaches the end-of-life, the benefits are typically short-lived or absent.

Similar to the assessment of pain, reports of dyspnea are typically a subjective report. Also, as is true for physical pain, the meaning of dyspnea to an individual patient may increase their suffering. For example, the patient may interpret increasing dyspnea as a sign that death is approaching. For some patients, sensations of breathlessness may invoke frightening images of drowning or suffocation, and the resulting cycle of fear and anxiety may increase the sensation of breathlessness. Therefore, the nurse should conduct a careful assessment of the psychosocial and spiritual components of the dyspnea. Physical assessment parameters include symptom intensity, distress, and interference with activities; auscultation of lung sounds; assessment of fluid balance, including measurement of dependent edema (circumference of lower extremities) and abdominal girth; temperature; skin color; sputum quantity and character; and cough.

To determine the intensity of dyspnea and its interference with daily activities, the patient can be asked to report the severity of the dyspnea using a scale of 0 to 10 (similar to the pain scale), where 0 is no dyspnea and 10 is the

worst imaginable dyspnea. There is new evidence that the use of the Respiratory Distress Observation Scale may be effective as well (Birkholz & Haney, 2018) (see the Nursing Research Profile in Chart 13-6). The nurse should assess the patient's baseline rating before treatment and should elicit subsequent measurements taken during exacerbation of the symptom, periodically during treatment, and whenever the treatment plan changes; these parameters provide ongoing objective evidence for the efficacy of the treatment plan. In addition, physical assessment findings may assist in locating the source of the dyspnea and selecting nursing interventions to relieve the symptom. The components of the assessment change as the patient's condition changes. Like other symptoms at the end-of-life, dyspnea can be managed effectively in the absence of assessment and diagnostic data (e.g., arterial blood gases) that are standard when a patient's illness or symptom is acute and considered reversible.

Nursing management of dyspnea at the end-of-life is directed toward administering medical treatment for the underlying pathology, monitoring the patient's response to treatment, helping the patient and the family manage anxiety (which exacerbates dyspnea), altering the perception of the symptom, and conserving energy (Chart 13-7). Pharmacologic intervention is aimed at modifying lung physiology and improving performance as well as altering the perception of the symptom. Bronchodilators and corticosteroids are used to treat underlying obstructive pathology, thereby improving overall lung function. Low doses of opioids effectively relieve dyspnea, although the mechanism of relief is not entirely clear. Although dyspnea in terminal illness is typically not associated with diminished blood oxygen saturation, low-flow oxygen often provides psychological comfort to both patients and families, particularly in the home setting.

Chart 13-6 **NURSING RESEARCH PROFILE**

Comparison of Dyspnea Assessment Tools

Birkholz, L., & Haney, T. (2018). Using a dyspnea assessment tool to improve care at the end of life. *Journal of Hospice and Palliative Nursing, 20*(3), 219–227.

Purpose

There is no standard for the assessment of dyspnea, the subjective sensation of breathlessness. Generally, patients experiencing shortness of breath tell providers. However, when a person is no longer able to report symptoms at the end-of-life, nurses rely on experiential practice to guide dyspnea management. The purpose of this study was to compare end-of-life dyspnea assessment and management before and after educational implementation of Respiratory Distress Observation Scale (RDOS).

Design

This was a pre-experimental study which used a pretest/posttest format to examine the use of the RDOS. Nurses (n = 39) who provide end-of-life care where there is no standardized dyspnea assessment tool were recruited from centers: (1) a hospice agency in the Northeastern region of United States with both home hospice and an inpatient hospice unit, and (2) a medical-surgical unit in a community hospital in the Rural Western United States. RDOS was taught by video where standardized patients simulated mild, moderate, and severe levels of dyspnea in six scenarios. Nurses watched the simulated scenarios and recorded a dyspnea assessment based on experiential knowledge, in a pretest. Then, RDOS education was provided by a palliative nurse educator. Finally, the nurses rewatched the video of simulated scenarios and documented a dyspnea assessment using the RDOS in a posttest.

Findings

Researchers found a statistically significant difference in both the nurse's ability to accurately assess level of dyspnea ($p < 0.001$) and the nurse's ability to choose the most appropriate treatment ($p = 0.021$), after RDOS education. There was no statistically significant difference after education in the nurses' determination of overall comfort. The final research question addressed the nurse's evaluation of the RDOS education, where almost all agreed that the RDOS was easy to use with strong recommendation to use in end-of-life dyspnea assessment.

Nursing Implications

Nurses working in end-of-life care treat dyspnea frequently and tend to rely on previous experiences for assessment and management of dyspnea. The RDOS is a validated dyspnea assessment tool which helps nurses to systematically assess dyspnea. When nurses used the RDOS, there was a significant improvement in both the ability to assess degree of dyspnea and select the appropriate treatment.

Chart 13-7

Palliative Nursing Interventions for Dyspnea

Treat Underlying Cause

- Administer prescribed bronchodilators and corticosteroids (obstructive pathology).
- Administer blood products as prescribed for anemia.
- Administer prescribed diuretics and monitor fluid balance.

Interdisciplinary Resources

- Respiratory Therapists: pulmonary rehabilitation, noninvasive ventilation, chest wall vibration
- Physical and Occupational Therapists: energy conservation techniques, walking aids (rolling walker, cane), exercise
- Social Work or Psychologists: cognitive-behavioral therapy, meditation/mindfulness training
- Integrative Medicine Treatments: Biofeedback, Reiki, Chiropractic, Acupuncture, Yoga, T'ai Chi, and Qi gong

Self-Management (Nursing Role: Provide Education and Foster Practices)

- Forward-leaning posture
- Pursed lips or abdominal accessory muscle breathing
- Cool air movement: portable fan, air-conditioning unit, opening window in fall/winter
- Lifestyle changes: adapting socialization practices and/or accepting limitations

As mentioned previously, dyspnea may be exacerbated by anxiety, and anxiety may trigger episodes of dyspnea, setting off a respiratory crisis in which the patient and the family may panic. For patients receiving care at home, patient and family education should include anticipation and management of crisis situations and a clearly communicated emergency plan. The patient and the family should be educated about medication administration, condition changes that should be reported to the primary provider and the nurse, and strategies for coping with diminished reserves and increasing symptomatology as the disease progresses. The patient on hospice and their family require reassurance that the symptom can be effectively managed at home without the need for activation of the emergency medical services or hospitalization and that a nurse will be available at all times via telephone and to make a visit.

Impaired Secretions at the End-of-Life

In the last stage of dying, patients typically experience impaired secretions. This may be manifested by noisy, gurgling breathing or moaning. In most cases, the sounds of breathing at the end-of-life are related to oropharyngeal relaxation with inability to clear secretions through cough or swallowing due to somnolence. Treatment of impaired secretions in the actively dying is usually achieved with the use of anticholinergic medications to dry secretions (Table 13-5). Sounds caused by impaired secretions are generally most distressing to family members. Nurses need to educate family members about impaired secretions, provide assurance on the normalcy of the symptom, and distinguish it from dyspnea.

TABLE 13-5 Medications to Control Secretions and Terminal Respiratory Congestion

Medication	Suggested Initial Dosing
Atropine 1% ophthalmic	1–2 drops PO/SL every 4 h, scheduled or PRN
Atropine injection	0.4 mg IV/SC/IM every 4 h, scheduled or PRN
Glycopyrrolate	1 mg PO TID, scheduled or PRN, up to 6 mg/day or 0.1 mg SC/IM/IV TID or PRN
Hyoscyamine	0.125 mg PO/SL every 4 h PRN, up to 1.5 mg/day
Hyoscyamine extended-release	0.375 mg PO every 12 h, up to 1.5 mg/day
Scopolamine transdermal	Apply 1 patch topically behind the ear every 72 h, up to 3 patches/72 h

IM, intramuscularly; IV, intravenously; PO, by mouth; PRN, as needed; SC, subcutaneously; SL, sublingually; TID, twice a day.

Anorexia and Cachexia at the End-of-Life

Anorexia and cachexia are common in the seriously ill. The profound changes in the patient's appearance and a lack of interest in the socially important rituals of mealtime are particularly disturbing to families. The approach to the problem varies depending on the patient's stage of illness, level of disability associated with the illness, and desires. The anorexia–cachexia syndrome (Table 13-6) is characterized by disturbances in carbohydrate, protein, and fat metabolism; endocrine dysfunction; and anemia. The syndrome results in severe asthenia (loss of energy).

Anorexia and cachexia differ from starvation (simple food deprivation) in several important ways. Anorexia is defined as inadequate nutritional intake,

while cachexia refers to severe lean muscle loss. In chronic illness, appetite is lost early in the process, the body becomes catabolic in a dysfunctional way, and supplementation by enteral feeding or parenteral nutrition in advanced disease does not replenish lean body mass that has been lost. Similarly, appetite stimulants are ineffective at this stage. Cachexia is associated with anabolic and catabolic changes in metabolism that relate to activity of neurohormones and proinflammatory cytokines, resulting in profound protein loss.

Near the end-of-life, the body's nutritional needs change, and the desire for food and fluid may diminish. People may no longer be able to use, eliminate, or store nutrients and fluids adequately. Eating and sharing meals are important social activities in families and communities, and food preparation and enjoyment are linked to happy memories, strong emotions, and hope for survival. For patients with serious illness, food preparation and mealtimes often become a constant struggle in which well-meaning family members argue, plead, and cajole to encourage ill people to eat. Patients who are seriously ill often lose their appetites entirely, develop strong aversions to foods that they have enjoyed in the past, or crave a particular food to the exclusion of all other foods.

TABLE 13-6 Anorexia/Cachexia Syndrome

Mechanism	Effect
Loss of appetite	• Generalized tissue wasting • Queasiness • Decreased pleasure at meals yielding decreased socialization
Reduced voluntary motor activity	• Sarcopenia (muscle wasting) • Skeletal muscle fatigue
Reduced rate of muscle protein synthesis	• Sarcopenia • Skeletal muscle weakness
Decreased immune response	• Increased risk of infection
Decreased response or intolerability to treatments	• Increased morbidity • Increased mortality

Nursing Interventions for Anorexia/Cachexia Syndrome:
Assess the impact of current medications (e.g., chemotherapy, antiretroviral).
Consider impact of additional therapies on appetite (e.g., radiation, dialysis).
Assess for concomitant symptoms including nausea, anxiety, depression, constipation, and diarrhea.
Perform oral assessment (e.g., presence of ulcers or thrush); administer and monitor effects of topical and systemic treatment for oropharyngeal pain.
Ensure that dentures fit properly, if applicable.
Administer antiemetics or laxatives when appropriate.
Explore barriers to eating with patient and develop plan.
Remove unpleasant odors including soiled tissues, bedpans, and emesis basin.
Position to enhance gastric emptying.
Provide frequent mouth care, especially after eating.

Adapted from Schack, E. E., & Wholihan, D. (2019). Anorexia and cachexia. In B. R. Ferrell, N. Coyle, & J. Paice (Eds.). *Oxford textbook of palliative nursing* (5th ed.). New York: Oxford.

As the patient approaches the end-of-life, the family and the health care providers should offer the patient what they prefer and can most easily tolerate. The nurse should educate the family about ways to separate feeding from caring and how to demonstrate love, sharing, and caring by being with the loved one in other ways. Preoccupation with appetite, feeding, and weight loss diverts energy and time that the patient and the family could use in other meaningful activities. Encourage patients to eat what brings them joy. For family members who are struggling with seeing their loved one eat less, the nurse ensures they understand that patients are allowed to refuse foods and

fluids. The nurse may also instruct family members how to make ice cubes from frozen fruit juices or smoothies and to offer these to the patient.

Anxiety and Depression

Almost half of patients in hospice experience significant anxiety and/or depression at the end-of-life as reported by proxy (Kozlov, Phongtankuel, Prigerson, et al., 2019). Anxiety may be exacerbated by other symptoms such as pain or dyspnea, as well as anticipating symptoms at the end-of-life. A systematic approach to anxiety involves treating the underlying cause, providing psychosocial support, referral to counseling as needed, and administering medications as prescribed.

Clinical depression should neither be accepted as an inevitable consequence of dying nor confused with sadness and anticipatory grieving, which are normal reactions to the losses associated with impending death. Emotional and spiritual support and control of disturbing physical symptoms are appropriate interventions for situational depression associated with terminal illness. Patients and their families must be given space and time to experience sadness and to grieve; however, patients should not have to endure untreated depression at the end of their lives. An effective approach to clinical depression includes relief of physical symptoms, attention to emotional and spiritual distress, psychotherapy, and pharmacologic intervention with antidepressants.

Delirium

Many patients remain alert, arousable, and able to communicate until very close to death. Others sleep for long intervals and awaken only intermittently, with eventual somnolence until death. Delirium refers to concurrent disturbances in the level of consciousness, attention, awareness, and cognitive capability that develop over a relatively short period of time (Bush, Tierney, & Lawlor, 2017). Confusion may be related to underlying, treatable conditions such as medication side effects or interactions, pain or discomfort, hypoxia or dyspnea, or a full bladder or impacted stool. In patients with cancer, confusion may be secondary to brain metastases. Delirium may also be related to metabolic changes, infection, and organ failure. In some patients, a period of agitated delirium precedes death, sometimes causing families to be hopeful that suddenly active patients may be getting better.

Nursing interventions are aimed at identifying the underlying causes of delirium; acknowledging the family's distress over its occurrence; reassuring family members about what is normal; educating family members how to interact with and ensure safety for the patient with delirium; and monitoring the effects of medications used to treat severe agitation, paranoia, and fear. Confusion may mask the patient's unmet spiritual needs and fears about dying.

Spiritual intervention, music therapy, gentle massage, and therapeutic touch may provide some relief. Reduction of environmental stimuli, avoidance of harsh lighting or very dim lighting (which may produce disturbing shadows), presence of familiar faces, and gentle reorientation and reassurance are also helpful.

Patients with delirium may become hypoactive and/or hyperactive, restless, irritable, and fearful. Sleep deprivation and hallucinations may occur. When treating delirium, it is important to attempt to treat underlying factors contributing to symptoms first. Much controversy remains on the pharmacologic treatment of delirium at the end-of-life. One study compared the use of haloperidol plus lorazepam to haloperidol alone and found improved relief of symptoms with the medication combination (Hui, Frisbee-Hume, Wilson, et al., 2017). Unfortunately, delirium is a common symptom at the end-of-life; providing education on this may be the most reassuring intervention for family members.

Additional Common Symptoms

Patients may experience other common symptoms. Progressive fatigue occurs in most chronic, progressive illnesses, worsening in the last weeks and months of life. At the end-of-life, many patients suffer from constipation as a side effect of medications, such as opioids, as well as the sedentary nature of advanced chronic illness. Nurses should be performing a physical assessment including abdominal examination and last bowel movement. The nurse can administer laxatives (either by mouth or per rectum) as prescribed if patients show signs of constipation.

Nausea and vomiting may be common at the end-of-life, especially in patients who experienced nausea during disease progression. Patients with malignant bowel obstructions may experience refractory nausea at the end-of-life requiring antiemetics to target multiple hormone receptors or decompression via a gastric tube. Further, skin breakdown occurs as the organs, including skin begin to fail. Diligent nursing care of wounds includes assessment, treatment of pain, dressing changes for comfort, and consultation with wound care specialists.

Time of Death

For patients who have received adequate management of symptoms and for families who have received adequate preparation and support, the actual time of death is commonly peaceful and occurs without struggle. Nurses may or may not be present at the time of a patient's death. In many states, nurses are authorized to make the pronouncement of death and sign the death certificate when death is expected. The determination of death is made through a physical examination that includes auscultation for the absence of breathing and heart

sounds. Home care or hospice programs in which nurses make the time-of-death visit and pronounce death have policies and procedures to guide the nurse's actions during this visit. Immediately on cessation of vital functions, the body begins to change. It becomes dusky or bluish, waxen appearing, and cool; blood darkens and pools in dependent areas of the body (e.g., the back and the sacrum if the body is in a supine position); and urine and stool may be evacuated.

Immediately after death, family members should be allowed and encouraged to spend time with the deceased. Normal responses of family members at the time of death vary widely and range from quiet expressions of grief to overt expressions that include wailing and prostration. The family members' desire for privacy during their time with the deceased should be honored. Family members may wish to independently manage or assist with care of the body after death. In the home, after-death care of the body frequently includes culturally specific rituals such as bathing the body. Home care agencies and hospices vary in the policies surrounding removal of tubes. In the absence of specific guidance from the organization, the nurse should shut off infusions of any kind (intravenous or tube feeding) and leave intravenous access devices, feeding tubes, catheters, and wound dressings in place. When an expected death occurs in the home setting, the family generally will have received assistance with funeral arrangements in advance of the death. The funeral home should be called and the funeral director will transport the body directly to the funeral home. In the hospital or long-term care facility, nurses follow the respective facility's procedure for preparation of the body and transportation to the facility's morgue. However, the needs of families to remain with the deceased, to wait until other family members arrive before the body is moved, and to perform after-death rituals should be honored.

Some patients may have elected to donate tissue such as corneas, bone, veins, or heart valves for transplant. Typically, this information would be known to the care team before the patient dies. In some cases, such as late referral or an unexpectedly rapid progression, the patient's wishes with respect to donation might be unknown. If the patient died at home or in a nursing home and the deceased's wishes are known, a team member should contact the organ procurement organization through which the deceased had arranged to donate tissue. That organization will ordinarily transport the body for tissue procurement and to the funeral home.

Providing Psychosocial and Spiritual Support

Many patients suffer unnecessarily when they do not receive adequate attention for the symptoms accompanying serious illness. Careful evaluation of

the patient should include not only the physical problems but also the psychosocial and spiritual dimensions of the patient's and family's experience of serious illness. This approach contributes to a more comprehensive understanding of how the patient's and family's life has been affected by illness and leads to nursing care that addresses their needs in every dimension.

Hope and Meaning in Illness

Clinicians and researchers have observed that although specific hopes may change over time, hope generally persists in some form across every stage of illness. In terminal illness, hope represents the patient's imagined future, forming the basis of a positive, accepting attitude and providing the patient's life with meaning, direction, and optimism. When hope is viewed in this way, it is not limited to cure of the disease; instead, it focuses on what is achievable in the time remaining. Many patients find hope in working on important relationships and creating legacies. Patients who are terminally ill can be extremely resilient, reconceptualizing hope repeatedly as they approach the end-of-life.

Numerous nurse researchers have studied the concept of hope, and they have related its presence to spirituality, quality of life, and transcendence (Tarbi & Meghani, 2019). Hope is a multidimensional construct that provides comfort as a person endures life threats and personal challenges. The following are hope-fostering and hope-hindering activities among patients who are terminally ill and in hospice with various diagnoses:

- *Hope-fostering categories:* Love of family and friends, spirituality/faith, setting goals and maintaining independence, positive relationships with clinicians, humor, personal characteristics, and uplifting memories
- *Hope-hindering categories:* Abandonment and isolation, uncontrollable pain/discomfort, and devaluation of personhood

Nurses can support hope for the patient and the family by using effective listening and communication skills, thus encouraging realistic hope that is specific to their needs for information, expectations for the future, and values and preferences concerning the end-of-life. Nurses must engage in self-reflection and identify their own biases and fears concerning illness, life, and death. As nurses become more skilled in working with patients who are seriously ill, they can become less determined to *fix* and more willing to listen; more comfortable with silence, grief, anger, and sadness; and more fully present with patients and their families.

Nursing interventions for enabling and supporting hope include the following:

- Answering questions about illness in terms the patient understands

- Listening attentively
- Encouraging sharing of feelings
- Providing accurate information
- Encouraging and supporting patients' control over their circumstances, choices, and environment whenever possible
- Assisting patients to explore ways for finding meaning in their lives
- Facilitating effective communication within families
- Making referrals for psychosocial and spiritual counseling
- Assisting with the development of supports in the home or community when none exist

Providing Culturally Sensitive Care at the End-of-Life

Nurses are responsible for educating patients and their caregivers and for supporting them as they adapt to life with the illness. Nurses can assist patients and families with life review, values clarification, treatment decision making, and end-of-life goals. The only way to do this effectively is to try to appreciate and understand the illness from the patient's perspective.

The nurse's role is to assess the values, preferences, and practices of every patient, regardless of ethnicity, gender identity, socioeconomic status, or background. The nurse can share knowledge about a patient's and family's cultural beliefs and practices with the health care team and facilitate the adaptation of the care plan to accommodate these practices.

Although death, grief, and mourning are universally accepted aspects of living, the values, expectations, and practices during serious illness as death approaches and after death are culturally bound and expressed. Health care providers may share similar values concerning end-of-life care and may find that they are inadequately prepared to assess for and implement care plans that support culturally diverse perspectives. Historical mistrust of the health care system and unequal access to even basic medical care may underlie the beliefs and attitudes among ethnically diverse populations. In addition, lack of education or knowledge about end-of-life care treatment options and language barriers may influence decisions among many socioeconomically disadvantaged groups.

Nurses should be both culturally aware and sensitive in their approaches to communication with patients and families about death. To provide effective patient- and family-centered care at the end-of-life, nurses must be willing to set aside their own assumptions and attitudes so that they can discover what type and amount of disclosure is most meaningful to each patient and family within their unique belief systems. For example, a nurse may find that a female patient prefers to have her eldest son make all of her care decisions. Institutional practices and laws governing informed consent are also rooted in

the Western notion of autonomous decision making and informed consent. If a patient wishes to defer decisions to her son, the nurse can work with the team to negotiate informed consent, respecting the patient's right not to participate in decision making and honoring her family's cultural practice.

Every person has unique needs at the end-of-life and deserves to be respected as a person. Those who identify as lesbian, gay, bisexual, transgender, and queer may need special attention to psychological stressors of serious illness and ACP to designate a preferred surrogate, as this may be outside of the biologic family. An additional concern for some transgender patients is loss of identity after death; for instance, not being buried in clothes of their preferred gender or honored with the name they chose (Higgins & Hynes, 2019).

The nurse should assess and document the patient's and family's specific beliefs, preferences, and practices regarding end-of-life care, preparation for death, and after-death rituals. Chart 13-8 identifies suggested language for cultural and spiritual assessment. The discomfort of novice nurses with asking questions and discussing this type of sensitive content can be reduced by prior practice in a classroom or clinical skills laboratory, observation of interviews conducted by experienced nurses, and partnering with experienced nurses during the first few assessments.

Spiritual Care

Attention to the spiritual component of the illness experienced by the patient and the family is not new within the context of nursing care, yet many nurses lack the comfort or skills to assess and intervene in this dimension. Spirituality contains features of religiosity; however, the two concepts are not interchangeable. **Spirituality** includes domains such as how a person derives meaning and purpose from life, one's beliefs and faith, sources of hope, and attitudes toward death (Puchalski, 2015).

The spiritual assessment is a key component of comprehensive nursing assessment for patients who are terminally ill and their families. While the nursing assessment should include religious affiliation, the nurse keeps in mind that spirituality is a broader concept than just religion (see Chart 13-8). In addition to the assessment of the role of religious faith and practices, important religious rituals, and connection to a religious community, the nurse should further explore:

- The harmony or discord between the patient's and the family's beliefs
- Other sources of meaning, hope, and comfort
- The presence or absence of a sense of peace of mind and purpose in life

- Spiritual or religious beliefs about illness, medical treatment, and care of the sick

A four-step spiritual assessment process using the acronym FICA involves asking the following questions (Puchalski & Romer, 2000):

- *F*aith and belief: Do you consider yourself to be a spiritual or religious person? What is your *faith* or belief? What gives your life meaning?

Chart 13-8 **ASSESSMENT**

Cultural and Spiritual Issues at the End-of-Life

Cultural Assessment

- Tell me more about yourself and your family.
- How are decisions made in your family?
- In order to provide you with the best care, are there any customs or practices important to you that should be included in your care plan?

Spiritual Assessment

- How is your spirit?
- Are you at peace?
- What gives you meaning and purpose?
- What are you most hoping for?
- Is anything worrying you?
- Is there anything you have not done that you wish/need to do?

Assessing Cultural and Spiritual Practices Surrounding Death

- What do you believe happens after death?
- Would you like your family to be involved in the care of your body?
- Are there certain people you would like to care for your body after death (e.g., women only or spiritual care provider)?
- Immediately after death are there any rituals, practices, or ceremonies that should be performed? Are there ways that we can help facilitate these?

Culturally Competent Communication Skills

- Respect uniqueness of each patient.
- Listen attentively to patient's narratives.
- Assess values and preferences for care.
- Address concerns.
- Anticipate when communication may be difficult and engage interdisciplinary team to provide support.

Adapted from Cormack, C., Mazanec, P., & Panke, J. T. (2019). Cultural considerations in palliative care. In B. R. Ferrell, N. Coyle, & J. Paice (Eds.). *Oxford textbook of palliative nursing* (5th ed.). New York: Oxford; Taylor, E. J. (2019). Spiritual screening, history, and assessment. In B. R. Ferrell, N. Coyle, & J. Paice (Eds.). *Oxford textbook of palliative nursing* (5th ed.). New York: Oxford.

- *I*mportance and *I*nfluence: What *importance* does faith have in your life? Have your beliefs *influenced* the way you take care of yourself

and your illness? What role do your beliefs play in regaining your health?

- *C*ommunity: Are you a part of a spiritual or religious *community*? Is this of support to you and how? Is there a group of people you really love or who are important to you?
- *A*ddress in care: How would you like me to *address* these issues in your health care?

For most people, contemplating one's own death raises many issues, such as the meaning of existence, the purpose of suffering, and the existence of an afterlife. When faced with a grave prognosis, many patients experience spiritual or existential distress where a sense of meaning or purpose is lost. Other manifestations of spiritual distress include questioning or blaming their god. Nurses may identify distress when patients ask questions like, "Why me?" or "Why is God punishing me?" When hearing such questions, nurses should engage a spiritual care provider. Near the end-of-life, many draw strength from religion and spirituality and may turn to spiritual care providers for support; however, one study showed that 75% of clergy want more education surrounding end-of-life issues (Sanders, Chow, Enzinger, et al., 2017). Nurses may be perfectly poised to deliver point-of-care education to spiritual care providers. Further, the interdisciplinary team can organize a debriefing session to enrich education for all disciplines.

Another phenomenon associated with spirituality at the end-of-life is spiritual pain, defined as a pain deep in one's soul not manifested as physical symptoms, which may be experienced in the seriously ill. Although prevalence is not known in all illnesses, in those with advanced cancer as many as 67% of patients may experience spiritual pain, which is correlated with lower quality of life (Perez-Cruz, Langer, Carrasco, et al., 2019).

Grief, Mourning, and Bereavement

A wide range of feelings and behaviors are normal, adaptive, and healthy reactions to the loss of a loved one. **Grief** refers to the personal feelings that accompany an anticipated or actual loss; see Table 13-7 for types of grief. **Mourning** refers to individual, family, group, and cultural expressions of grief and associated behaviors. **Bereavement** refers to the period of time during which mourning for a loss takes place. Both grief reactions and mourning behaviors change over time as people learn to live with the loss. Although the pain of the loss may be tempered by the passage of time, loss is an ongoing developmental process, and time does not heal the bereaved person completely. That is, the bereaved do not get over a loss entirely, nor do they return to who they were before the loss. Rather, they develop a new sense of who they are and where they fit in a world that has changed dramatically and permanently.

TABLE 13-7 Characteristics of Types of Grief and Nursing Interventions

Type of Grief	Characteristics
Anticipatory	Unconsciously preparing for what might happen *Examples:* Grief at diagnosis at loss of "normal" life; preparing for the loss of a limb for amputation
Uncomplicated	Range of emotions experienced after a loss moving toward adjustment; brief periods of relapse common *Examples:* Missing a deceased grandparent during holidays
Complicated or Prolonged	Intense response after loss where profound emotions persist usually >1 y *Example:* Widow who stops caring for herself after the death of her husband and sobs at any mention of his name a year later
Disenfranchised	Grieving person feels that society does not acknowledge or support person's right to grieve *Examples:* Mistress, homosexual partner, colleagues
Unresolved	Traumatic or unexpected losses *Examples:* Death of a child; suicide; disaster-related death
Nursing Interventions: Assessment of self-care and social supports. Employ assessment tools, such as the Inventory of Complicated Grief. Referral to professional counseling services.	

Adapted from Corless, I. B., & Meisenh, J. B. (2019). Bereavement. In B. R. Ferrell, N. Coyle, & J. Paice (Eds.). *Oxford textbook of palliative nursing* (5th ed.). New York: Oxford; Limbo, R., Kobler, K., & Davies, B. (2019). Grief and bereavement in perinatal and pediatric palliative care. In B. R. Ferrell, N. Coyle, & J. Paice (Eds.). *Oxford textbook of palliative nursing* (5th ed.). New York: Oxford.

Anticipatory Grief and Mourning

People experience grief in different ways. Kübler-Ross (1969) originally described five stages of grief including (1) denial, (2) anger, (3) bargaining, (4) depression, and (5) acceptance. Newer models of grief acknowledge that grieving is not a linear process and many more emotions may be present than originally identified by Kübler-Ross. Additionally, people many feel conflicting emotions, such as hope and guilt when thinking about the future, at the same time. The Dual Process Model (Fig. 13-3) of coping with bereavement allows oscillation between the loss-oriented process and the restoration-oriented process (Stroebe & Schut, 1999). The Dual Process Model assumes fluidity in bereavement and normalizes the individual experience by offering that people will experience competing and complicated emotions after the death of a loved one.

Individual and family coping with the anticipation of death is complicated by the varied and conflicting trajectories that grief and mourning may assume in families. For example, the patient may be experiencing sadness while contemplating role changes that have been brought about by the illness, and the patient's spouse or partner may be expressing or suppressing feelings of anger about the current changes in role and impending loss of the relationship.

Others in the family may cope with fear using withdrawal. Each person copes in their own way as there is no *right* way to cope.

The nurse should assess the characteristics of the family system and intervene in a manner that supports and enhances the cohesion of the family unit. The nurse can suggest that family members talk about their feelings and understand them in the broader context of anticipatory grief and mourning. Acknowledging and expressing feelings, continuing to interact with the patient in meaningful ways, and planning for the time of death and bereavement are adaptive family behaviors. Professional support provided by grief counselors, whether in the community, at a local hospital, in the long-term care facility, or associated with a hospice program, can help both the patient and the family sort out and acknowledge feelings and make the end-of-life as meaningful as possible.

Grief and Mourning After Death

When a loved one dies, family members enter a new phase of grief and mourning as they begin to accept the loss, feel the pain of permanent separation, and prepare to live a life without the deceased. Even if the loved one dies after a long illness, preparatory grief experienced during the terminal illness does not preclude the grief and mourning that follow the death. With a death after a long or difficult illness, family members may experience conflicting feelings of relief that the loved one's suffering has ended, compounded by guilt and grief related to unresolved issues or the circumstances of death. Grief work may be especially difficult if a patient's death was painful, prolonged, accompanied by unwanted interventions, or unattended. Families that had no preparation or support during the period of imminent death may have a more difficult time finding a place for the painful memories.

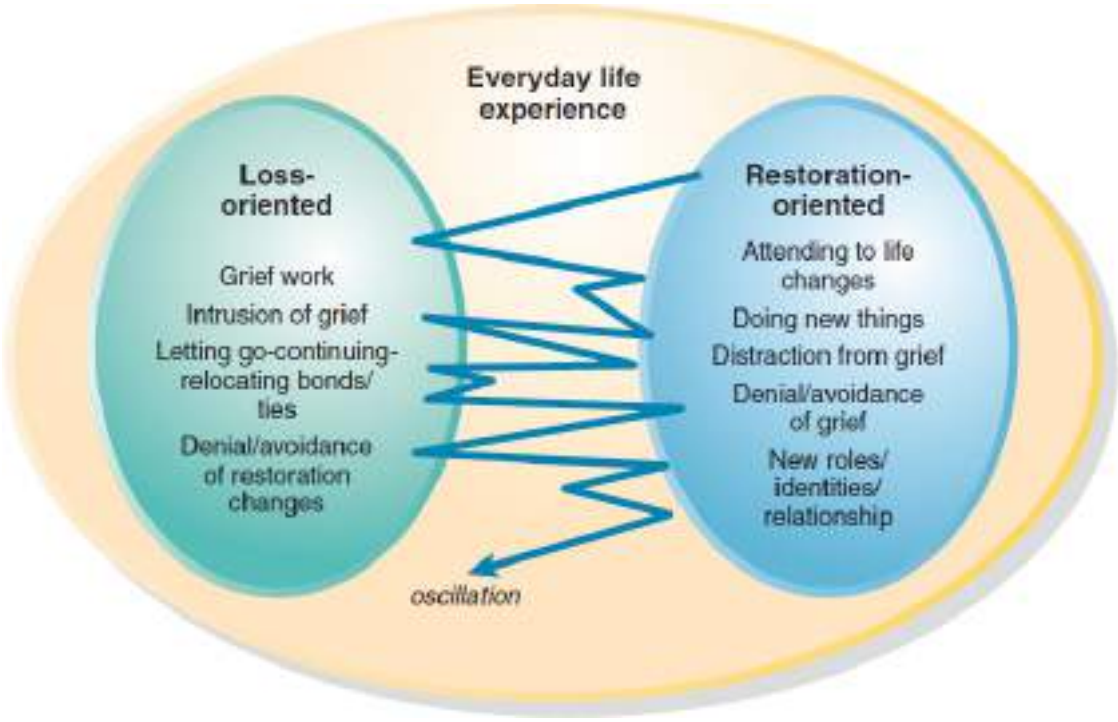

Figure 13-3 • The Dual Process Model of coping with bereavement. Adapted with permission from Stroebe, M. S., & Schut, H. (1999). The Dual Process Model of coping with bereavement: Rationale and description. *Death Studies*, *23*, 197–224, by permission of Taylor & Francis Ltd (http://www.tandfonline.com) and Stroebe MS & Schut H. doi: 10.1080/074811899201046.

Feelings of grief are often profound; however, bereaved people eventually reconcile the loss and find a way to reengage with their lives. Grief and mourning are affected by several factors, including individual characteristics, coping skills, and experiences with illness and death; the nature of the relationship to the deceased; factors surrounding the illness and the death; family dynamics; social support; and cultural expectations and norms.

After-death rituals, including preparation of the body, funeral practices, and burial rituals, are socially and culturally significant ways in which family members begin to accept the reality and finality of death. Preplanning of funerals is common, and hospice professionals, in particular, help the family make plans for death, often involving the patient, who may wish to play an active role. Preplanning of the funeral relieves the family of the burden of making decisions in the intensely emotional period after a death.

In general, the period of mourning is an adaptive response to loss during which mourners come to accept the loss as real and permanent, acknowledge and experience the painful emotions that accompany the loss, experience life without the deceased, overcome impediments to adjustment, and find a new way of living in a world without the loved one. Particularly immediately after

the death, mourners begin to recognize the reality and permanence of the loss by talking about the deceased in past terms and telling and retelling the story of the illness and death. Societal norms in the United States are frequently at odds with the normal grieving processes of people; time excused from work obligations is typically measured in days, and mourners are often expected to get over the loss quickly and get on with life.

In reality, the work of grief and mourning takes time, and avoiding grief work after the death often leads to long-term adjustment difficulties. According to Rando (2000), mourning for a loss involves the "undoing" of psychosocial ties that bind mourners to the deceased, personal adaptation to the loss, and learning to live in the world without the deceased. Six key processes of mourning allow people to accommodate to the loss in a healthy way (Rando, 2000):

- Recognition of the loss
- Reaction to the separation and experiencing and expressing the pain of the loss
- Recollection and reexperiencing the deceased, the relationship, and the associated feelings
- Relinquishing old attachments to the deceased
- Readjustment to adapt to the new world without forgetting the old
- Reinvestment

Although many people complete the work of mourning with the informal support of families and friends, many find that talking with others who have had a similar experience, such as in formal support groups, normalizes the feelings and experiences and provides a framework for learning new skills to cope with the loss and create a new life. Hospitals, hospices, religious organizations, and other community organizations often sponsor bereavement support groups. When a person dies while enrolled in hospice, families receive proactive bereavement from the hospice agency for an average of 13 months after the death. Hospice bereavement programs vary, yet bereavement support usually starts with scheduled calls to deceased primary contact. Bereavement may then be set up as individual counseling or group sessions, such as widow or parents support groups. Hospices may offer specialized child bereavement support services. Bereavement staff may consist of specially trained nurses, child psychologists, counselors, child life specialists, and/or music or art therapists. If a person dies and is not enrolled in hospice, some palliative care teams offer bereavement or help to connect families with a hospice for bereavement resources. When one cancer center implemented a bereavement program, surveyed bereaved family members felt that acknowledgment of their loved one through a formal condolence letter had a positive impact (Morris & Block, 2015).

Complicated Grief and Mourning

Complicated grief and mourning are characterized by prolonged feelings of sadness and feelings of general worthlessness or hopelessness that persist long after the death, prolonged symptoms (depression, anxiety, insomnia, fatigue) that interfere with activities of daily living, or self-destructive behaviors such as alcohol or substance abuse and suicidal ideation or attempts (Mason & Duffy, 2019). Certain risk factors that increase the likelihood of complicated grief include death of a child or spouse, multiple losses, and history of trauma (Tofthagen, Kip, Witt, et al., 2017). Complicated grief and mourning require professional assessment and can be treated with psychological interventions and, in some cases, with medications.

Special Issues for the Nurse in End-of-Life Care

Nursing care often intersects with moral and ethical dilemmas (see Chapter 1 for further discussion of ethics). Nurses are encouraged to personally examine their respective moral compasses in order to provide the best, unbiased care for patients and families. In caring for patients at the end-of-life, questions of *right* and *wrong* may arise in relation to treatment options. The ANA's *Code of Ethics for Nurses* provides a framework for the nurse to support patients, with guiding principles being the patient's right to self-determination and the nurse's adherence to professional nursing standards (ANA, 2015). When approaching an ethical dilemma, the nurse should take the following steps: define the problem, clarify facts and assumptions, compile a list of all options, evaluate options with interdisciplinary team input, and choose the most appropriate option and implement the plan (Prince-Paul & Daly, 2019). The most common ethical dilemmas a nurse will encounter are determining decisional capacity, withholding or withdrawing life-prolonging measures—including, but not limited to, ventilator support, dialysis, artificial nutrition and hydration—requests for hastening death, and concerns related to proxy decision making. Select ethical issues are discussed in greater detail in the following sections.

Medically Administered Nutrition and Hydration

Although nutritional supplementation may be an important part of the treatment plan in early or chronic illness, unintended weight loss and dehydration are expected characteristics of progressive illness. As illness progresses, patients, families, and clinicians may believe that without artificial nutrition and hydration, patients who are terminally ill will *starve,* causing profound suffering and hastened death. The use of artificial nutrition and hydration (tube and intravenous fluids and feeding) carries considerable risks

and generally does not contribute to comfort at the end-of-life (Casarett, Kapo, & Kaplan, 2005; Marcolini, Putnam, & Aydin, 2018). Similarly, survival is not increased when patients who are terminally ill with advanced dementia receive enteral feeding, and no data support an association between tube feeding and improved quality of life in these patients (De & Thomas, 2019). Furthermore, in patients who are close to death, symptoms associated with dehydration such as dry mouth, confusion, and diminished alertness are common and typically do not respond to artificial nutrition and hydration (Danis, Arnold, & Savarese, 2018). Dry mouth can generally be managed through nursing measures such as mouth care, and environmental changes with medications can help to diminish confusion.

Palliative Sedation at the End-of-Life

Effective control of symptoms can be achieved under most conditions; however, some patients may experience distressing, intractable symptoms. Although **palliative sedation** remains controversial, it is offered in some settings to patients who are close to death or who have symptoms that do not respond to conventional pharmacologic and nonpharmacologic approaches, resulting in unrelieved suffering. Palliative sedation is distinguished from euthanasia and physician-assisted suicide (PAS) in that the intent of palliative sedation is to relieve symptoms, not to hasten death (see Chart 13-9). Proportionate palliative sedation uses the minimum drug necessary to relieve the symptom while preserving consciousness, whereas palliative sedation induces unconsciousness, which is more controversial (Quill, Lo, Brock, et al., 2009). Palliative sedation is most commonly used when the patient exhibits intractable pain, dyspnea, seizures, or delirium, and it is generally considered appropriate in only the most difficult situations. Palliative sedation is accomplished through an infusion of one or more pharmacologic agents in doses adequate to eliminate signs of discomfort. Before implementing palliative sedation, the health care team should assess for the presence of underlying and treatable causes of suffering, such as depression or spiritual distress. Finally, the patient and the family should be fully informed about the use of this treatment and alternatives. A retrospective study of Italian hospice patients reported that palliative sedation was documented as discussed in only half of the cases where it was implemented (Ingravallo, de Nooijer, Pucci, et al., 2018).

Published guidelines for pharmacologic management of palliative sedation vary widely internationally (Abarshi, Rietjens, Robijn, et al., 2017) but most mention the use of midazolam, a short-acting benzodiazepine (Lux, Protus, Kimbrel, et al., 2017). Nurses act as collaborating members of the interdisciplinary health care team, providing emotional support to patients and families, facilitating clarification of values and preferences, and providing

comfort-focused physical care. Once sedation has been induced, the nurse should continue to comfort the patient, monitor the physiologic effects of the sedation, support the family during the final hours or days of their loved one's life, and ensure communication within the health care team and between the team and the family.

Requests for Assistance in Dying

A major debate in palliative and end-of-life care is the acceptability of a patient's requests to hasten death. Health care recognizes the right to choose for or against medical treatments when a patient is of sound mind and can relay a rationale for or against treatments. Further, patients may choose to withdraw or withhold life-sustaining treatments and allow natural death if such therapies are not aligned with their wishes. When faced with a progressive life-limiting illness, some cannot fathom suffering at the end-of-life and explore options to hasten death. Language around assistance in dying has evolved over the years and it is important to recognize the following terms:

Chart 13-9 **ETHICAL DILEMMA**

Does Intent Matter When Palliative Care Leads to Death?

Case Scenario

You are a staff nurse working for an outpatient home hospice service. G.R. is a 68-year-old man admitted to home hospice service two months ago with advanced multiple myeloma. As a consequence of his disease he also has extensive destruction of bony matrix resulting in widespread pain, numerous vertebral fractures, and spinal cord compression. For the first six weeks that G.R. was managed in hospice, you and the hospice staff have successfully kept his pain and other symptoms under reasonable control. However, over the past two weeks his pain has been more difficult to control, despite escalating dosages of opioids. He has not been able to sleep, and is restless, dyspneic, and anxious. The hospice physician was consulted, and G.R. and his husband agreed to intravenous opioids, sedatives, and anxiolytics to relieve G.R.'s suffering, knowing that he would also lose consciousness as a consequence of this treatment. However, they stated that though they were not pleased that G.R. would never regain consciousness, that result was offset by their hope was the G.R. might die peacefully. You administer the prescribed intravenous medications, and slowly administer the minimum dosages of these medications to relieve symptoms. G.R. loses consciousness and dies peacefully 48 hours later with his husband holding his hand at his bedside.

Discussion

There is a great deal of apprehension among both clinicians and laypersons around what constitutes comfort care (i.e., palliative care) at end-of-life and what may constitute either assisted suicide or euthanasia. The premise is that palliative care should ameliorate pain and suffering in the patient who is terminally ill, but it should not significantly shorten the patient's life.

The principle of double-effect highlights that some actions have two effects - one good, the other evil. The good and evil consequences are not considered in terms of proportions; if they were, and the evil outcome is death, then the good outcome could never be considered sufficient to justify the action. Rather, the intention behind the action is given paramount consideration. If the intention is to cause death, then the act is not morally justifiable. However, if the intention is to relieve suffering, then the act might be sanctioned.

Analysis

- Describe how the ethical principles of autonomy, beneficence, and nonmaleficence may intersect or be at odds with each other in this case. Discuss how palliative sedation meets the moral justification of the four criteria for the principle of double effect (see Chapter 1, Chart 1-7).

- Would you describe your role in this case as complicit in assisted suicide, euthanasia, or providing palliation? What distinction, if any, might there be among these three acts?
- Note that the ANA (2015) *Code of Ethics* clearly states that nurses should not *intentionally* cause a patient's death. What were your "intentions" in this case? How might intentionality be instrumental in making this act of titrating medications that provided palliation morally defensible? Are there resources you could identify that might be of assistance to you if you were to feel moral distress about your actions?

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

- *Physician aid in dying (PAD), medical aid in dying (MAD), and physician-assisted dying:* A physician prescribes a lethal dose of oral medication that the patient self-administers, for the purpose of ending someone's life.
- *PAS:* A physician prescribes medications, that the patient self-administers, to end their life at the person's voluntary and competent request.
- *Euthanasia:* Greek for "good death"; has evolved to mean the intentional killing by act or omission of a dependent human being for their alleged benefit.

Although assisted suicide is expressly prohibited under statutory or common law in the majority of states, calls for legalized aid in dying have highlighted inadequacies in end-of-life care. In 1994, Oregon voters approved the Oregon Death with Dignity Act, the first and—until 2009 only such legislative initiative to pass. This law provides for access to PAS by terminally ill patients under very controlled circumstances. After numerous challenges, the law was enacted in 1997. Of 2127 Oregonians who have received written prescriptions under the terms of the law since it was passed in 1997, 1459 have self-administered physician-prescribed lethal medication and have died (Oregon Public Health Division, 2018).

In recent years, additional states have adopted MAD laws, and Montana's Supreme Court has ruled that PAD is not a crime. International MAD is legal in Canada, the Netherlands, Belgium, Luxembourg, Switzerland, Columbia, and Victoria in Australia. Proponents of PAS argue that people who are terminally ill should have a legally sanctioned right to make independent decisions about the value of their lives and the timing and circumstances of their deaths, and its opponents argue for greater access to symptom management and psychosocial support for people approaching the end-of-life.

In its 2013 position statement on *Euthanasia, Assisted Suicide, and Aid in Dying,* the ANA acknowledged the complexity of the assisted suicide debate but clearly stated that nursing participation in assisted suicide is a violation of the Code for Nurses. The ANA position statement further stressed the important role of the nurse in supporting effective symptom management, contributing to the creation of environments for care that honor the patient's and family's wishes, as well as identifying their concerns and fears (ANA, 2013). Per the ANA, "Nurses have an obligation to provide humane, comprehensive, and compassionate care that respects the rights of patients but upholds the standards of the profession in the presence of chronic, debilitating illness and at end-of-life" (ANA, 2013, p. 1).

Similarly, the HPNA favors the value of comprehensive end-of-life care, as opposed to physician-assisted death (HPNA, 2017). The HPNA acknowledges that nurses may care for patients exploring or choosing physician-assisted death and thus concludes that nurses must be able to provide unbiased education yet not take an active role in this end-of-life option. American Academy of Hospice and Palliative Medicine (AAHPM, 2016) has taken a position of "studied neutrality" on assisted death, recommending that clinicians carefully assess the fear and suffering that have led patients to request assisted suicide and to address these without hastening death.

The International Association for Hospice and Palliative Care (IAHPC) released a position statement on euthanasia and PAS, in which they recommend access to palliative care and medication, such as opioids, prior to the legalization of both euthanasia and/or PAS. Further, they recommend that these acts should not be carried out on palliative care units (De Lima, Woodruff, Pettus, et al., 2017).

Voluntary Stopping of Eating and Drinking

Another potential, however quite controversial, option of last resort is voluntary stopping of eating and drinking (VSED) when a person cannot imagine prolonged dying and suffering for a life-limiting illness. Patient inquiry about VSED should be met with thorough assessment of both decisional capacity and presence of mental illness (Quill, Ganzini, Troug, et al., 2018; Wax, An, Koiser, et al., 2018). Aggressive palliative treatments for all types of suffering—physical, psychological, social, spiritual, and existential

—should be explored and offered before pursing VSED. Typically, a person will die 10 to 14 days after starting VSED during which the most distressing symptoms include thirst and delirium (Quill et al., 2018; Wax et al., 2018). Given this expected prognosis, patients may have the opportunity to complete legacy work prior to initiating VSED.

The ANA included VSED in a 2017 position statement on *Nutrition and Hydration at the End of Life* in which the organization upholds respect for autonomy, relief of suffering, and expert care at the end of life. Nurses involved in the care of a patient who self-initiates VSED should support the family while providing expert symptom assessment and management. One example of a patient who may choose to pursue VSED is a patient who has been diagnosed with a progressive disease, such as ALS, and who finds a slow decline intolerable.

COVID-19 Considerations

The coronavirus disease 2019 (COVID-19) pandemic has altered the delivery of palliative and end-of-life care. Patients with severe COVID-19 pneumonia are managed with endotracheal intubation and mechanical ventilation and have a high case fatality rate (see Chapter 19) (Bajwah, Wilcock, Towers, et al., 2020; Richardson, Hirsch, Narasimhan, et al., 2020). Common end-of-life symptoms for those with severe COVID-19 include dyspnea, cough, anxiety, and delirium (Bajwah et al., 2020). During the pandemic, symptom management at the end-of-life has required revisions due to logistical challenges such as medication shortages and preservation of personal protective equipment (Chidiac, Feuer, Naismith, et al., 2020). Due to high risk of infectious transmission, family members may not be permitted to see loved ones at the end-of-life (Richardson et al., 2020; Wakam, Montgomery, Biesterveld, et al., 2020). Furthermore, family meetings are primarily virtual, where proxies must make difficult decisions such as resuscitation and intubation, and even removal of life support (Richardson et al., 2020). Communication guides for proactive goals of care discussions related to possible COVID-19 infection (Back, Tulsky, & Arnold, 2020), recommendations for "webside" manner (Chua, Jackson, & Kamdar, 2020), innovative use of virtual reality to stimulate previously unachieved dreams or allow families to virtually share one last moment together (Wang, Teo, Teo, et al., 2020). Meanwhile, health care providers are struggling from high physical workload demands while simultaneously experiencing moral and psychological distress (Adams & Walls, 2020). Clinicians working with patients with COVID-19 voice concerns about the risk of infecting self and family and stress due to constant change as health care systems evolve to meet patient needs during a pandemic situation (Foxwell, 2020). Health systems have developed innovative processes to support staff at the front lines of

working with patients with COVID-19 and at end-of-life, such as a 24-hour hotlines and pet therapy.

Clinicians' Attitudes toward Death

Clinicians' attitudes toward the terminally ill and dying remain the greatest barrier to improving care at the end-of-life. Kübler-Ross illuminated the concerns of the seriously ill and dying in her seminal work, *On Death and Dying,* first published in 1969. At that time, it was common for patients to be kept uninformed about life-threatening diagnoses, particularly cancer, and for primary providers and nurses to avoid open discussion of death and dying with their patients. Kübler-Ross's work revealed that, given open discussion, adequate time, and some help in working through the process, patients could reach a stage of acceptance in which they were neither angry nor depressed about their fate.

The growth of palliative and hospice care programs has led to greater numbers of health care providers becoming comfortable with and skilled in assessing patients' and families' information needs and disclosing honest information about the seriousness of illness (Brighton & Bristowe, 2016). However, in many settings, clinicians still avoid the topic of death in the hope that patients will ask or find out on their own. Despite progress on many health care fronts, many who work with patients who are seriously ill and dying recognize a persistent conspiracy of silence about dying.

How to communicate truthfully with patients and encourage patient **autonomy** (the right of the person to make choices) in a way that acknowledges where they are on the continuum of acceptance is a challenge. Despite continued reluctance of health care providers to engage in open discussion about end-of-life issues, patients want information about their illness and end-of-life choices and are not harmed by open discussion about death (Hamel, Wu, & Brodie, 2017; The Conversation Project National Survey, 2018). Timing of sensitive discussion takes experience, but speaking the truth can be a relief to patients and families, enhancing their autonomy by making way for truly informed consent as the basis for decision making.

Patient and Family Concerns

Terminal illness is experienced uniquely by each person and their loved ones. Family members are key stakeholders in honoring patients' wishes, caring for patients, and engaging in care planning. Family members are impacted by a loved one's illness and require support throughout the course of caregiving. Recognizing maladaptive coping in family members and providing resources for the family whether through social work staff or palliative care specialists is key to preventing worsening distress at the time of death. Palliative care

interventions have been reported to improve communication, improve person-centeredness and decrease length of ICU stay without significantly impacting caregiver psychological distress (White, Angus, Shields, et al., 2018).

Patient and family awareness of **prognosis** is a key factor in acceptance of and planning for death. For patients who have been informed about terminal illness, their understanding of treatment goals and prognosis is dynamic and may sometimes require reinforcement. Even when patients have been told that the intent of a therapy is palliative, they may think *I'll be the one to beat the odds.* As many as 37% of patients with metastatic cancer receiving palliative therapies misperceive their cancer as potentially curable (Yennurajalingam, Lu, Prado, et al., 2018). Just as patients and families may have differing perspectives on prognosis, they may also have different perceptions of severity of symptoms. Family caregivers tend to report distress and quality of life as worse than patient reports at the end-of-life (Hack, McClement, Chochinov, et al., 2018). This may be due to the family member's distress or anticipatory grief.

Historically, the approach in the United States to serious illness has been described as *death denying*—that is, the health care system has been built on management of acute illness and the use of technology to cure (when possible) and to extend life. As a result, life-threatening illness, life-sustaining treatment decisions, dying, and death occur in a social environment in which illness is largely considered an enemy. Many common expressions reflect this dominant sociocultural view. For example, people talk about the *war* against cancer or *fighting* illness, and when patients choose not to pursue the most aggressive course of medical treatment available, many health care providers and indeed patients and families perceive this as *giving up*. A care/cure dichotomy has persisted in which health care providers may view cure as the ultimate good and care as second best, a good only when cure is no longer possible. In such a model, alleviating suffering is not as valued as curing disease. Patients who cannot be cured feel distanced from the health care team, and when curative treatments have failed, they may feel that they too have failed. Patients and families may fear that any shift from curative goals to comfort-focused care will result in no care or lower-quality care, and that the clinicians on whom they have come to rely will abandon them if they withdraw from a focus on cure.

The statement in late-stage illness that exemplifies this care versus cure dichotomy is *nothing more can be done*. This all-too-frequently used statement communicates the belief of many clinicians that there is nothing of value to offer patients beyond cure; however, in a care-focused perspective, there is always more that can be done. This expanded notion of healing implies that healing can take place throughout life. There are many opportunities for physical, spiritual, emotional, and social healing, even as body systems begin to fail at the end-of-life.

TABLE 13-8 Select Resiliency Skills

Individual Skills	System Level Opportunities

Adapted from Back, A. L., Stienhauser, K. E., Kamal, A. H., et al. (2017). Why burnout is so hard to fix. *Journal of Oncology Practice*, *13*(6), 348–351.

Professional Caregiver Issues

Issues of importance to professional caregivers include burnout, promoting resiliency, and nurses supporting themselves.

Burnout and Promoting Resiliency

Burnout is defined as the triad of emotional exhaustion, cynicism, and ineffectiveness at work. By the time one notices burnout it is usually too late. In order to prevent burnout, there is a body of work to promote resilience, thereby providing clinicians with the skills needed to have work–life balance and the opportunity to remain productive and satisfied with their career (Back, Steinhauser, Kamal, et al., 2017). See Table 13-8 for select resiliency skills and workplace factors to prevent burnout.

While the prevalence of burnout among nurses working in palliative care and hospice is unknown, researchers have attempted to assess the prevalence of burnout among all clinicians working in palliative care. One study found that physicians were more likely to exhibit signs of burnout; however, factors for both physicians and clinicians from other disciplines (advanced practice provider, nurse, chaplain, social worker) that contributed to burnout are younger age, working weekends or overtime, and feeling isolated (Kamal, Bull, Wolf, et al., 2020). Overall, hospice and palliative clinicians were found to have a burnout rate of approximately 39% (Kamal et al., 2020).

The ANA (2017a) published *A Call to Action: Exploring Moral Resilience toward a Culture of Ethical Practice,* which highlights potential for burnout among nurses and makes recommendations for both individuals and institutions to foster resilience, as well as recommendations for research. This

document also contains a toolkit for resources for the nurse and proposed actions.

Supporting Ourselves

In addition to healthy work environments that promote resiliency, nurses are often encouraged to develop self-care practices. Self-care can be any number of activities or practices that a person maintains while not at work; examples include practicing yoga or meditation, engaging in hobbies, or simply not checking email when away from work. A recent qualitative study found palliative care clinicians (primary providers and nurses) seek practices that promote well-being and allow restoration of self so as to better care for patients (Mills, Wand, & Fraser, 2018). The palliative care clinicians sought meaning through work–life balance and building relationships; they sought self-care during work (such as establishing boundaries, negotiating workload, and reflecting on practice) and outside of work (such as meditation, rest, separating self from work, and positive social relationships) (Mills et al., 2018).

Whether practicing in a trauma center, ICU, or other acute care setting, home care, hospice, long-term care, or the many locations where patients and their families receive ambulatory services, nurses are closely involved with complex and emotionally laden issues surrounding loss of life. To be most effective and satisfied with the care they provide, nurses should attend to their own emotional responses to the losses witnessed every day. In hospice settings, where death, grief, and loss are expected outcomes of patient care, interdisciplinary colleagues rely on one another for support by learning coping skills from one another and speaking about how they were affected by the lives of those patients who have died. In many settings, staff members organize periodic memorial services to support bereaved families and other caregivers, who find comfort in joining one another to remember and celebrate the lives of patients.

CRITICAL THINKING EXERCISES

1 ipc Your patient is a 60-year-old woman with lung cancer who is hospitalized with increasing shortness of breath. She is currently receiving second-line chemotherapy treatment and recently completed palliative radiation to rib metastases. She lives with her husband and has two adult children who live out of state. As you are administering her morning medications, she asks, "Why did God do this to me? What did I do to deserve this?" How will you facilitate an interprofessional discussion to address the patient's spiritual concerns? What members of the interdisciplinary team are essential to include?

2 ebp Your patient is a 52-year-old man with idiopathic pulmonary fibrosis who is being evaluated for a lung transplant. He arrives at the lung transplant clinic with his friend from work. He is a security guard, but has been calling out frequently as he can't make hourly rounds. He lives alone in a two-story home with one bathroom on the second floor. Due to dyspnea on exertion, he has not been able to go upstairs and now sleeps on a recliner and hasn't showered in weeks. He has an estranged daughter whom he has not spoken to in over 10 years. Dyspnea also interferes with his appetite and he has been drinking sports drinks and eats fast food when his friends bring it over. How would you complete an evidence-based symptom assessment? What interventions would you consider to treat his dyspnea based on the evidence?

3 pq You are a new hospice nurse in your third month making home hospice visits. Your patient is a 73-year-old woman who has had multiple strokes. She previously expressed to her family that she would not want to live on prolonged life support. She has four devoted children who have set up a schedule so that someone will be with her 24 hours a day. When you enter the room, the patient is somnolent with periods of apnea. Her daughter at the bedside tells you that her mother was screaming out last night, calling for her parents and trying to get out of bed. The daughter feels that her mother is more comfortable now. She is intermittently tearful as she talks with you. At one point she asks, "Do you think she's angry with us? That must be why she was agitated last night. . . . I knew I shouldn't have listened to my siblings—My mom wants to live!" What stage of dying is this patient experiencing? How would you educate the daughter about stages of dying? How would you assess for bereavement needs?

UNIT 3 Perioperative Concepts and Nursing Management

Case Study

MAINTAINING A CULTURE OF SAFETY USING THE SURGICAL SAFETY CHECKLIST

A 32-year-old woman is admitted to the hospital with nausea, vomiting, and right upper quadrant pain. She is diagnosed with acute cholecystitis and is scheduled for a laparoscopic procedure to remove her gallbladder. After completing the preoperative procedures and preprocedure verification, the patient is brought to the operating room (OR) where you work. The surgical safety checklist involves members of the team including the surgeon, anesthesia provider, circulating nurse, and OR technician. Prior to induction of anesthesia the team confirms the patient's identity, procedure, and consent. In addition, the incision site is marked, the anesthesia machine and medication check is completed, and the pulse oximeter is placed on the patient and is confirmed to be working. The team also checks if the patient has a known allergy, if there are any airway or aspiration risks, and whether there is risk of a >500 mL blood loss.

QSEN Competency Focus: Safety

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Safety Definition: Minimizes risk of harm to patients and providers through both system effectiveness and individual performance.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Describe factors that create a culture of safety (such as, open communication strategies and organizational error reporting systems)	Describe your role in participating in a surgical safety checklist. Identify the additional checks that need to be conducted before the surgical skin incision is made and further safety measures that must be addressed before the patient leaves the OR to help facilitate a culture of safety.
Skills	
Communicate observations or concerns related to hazards and errors to patients, families, and the health care team	Identify your role in communicating to the members of the OR team important assessments, potential hazards, and errors that may occur because of surgery.
Attitudes	
Value relationship between national safety campaigns and implementation in local practices and practice settings	A goal of the Joint Commission is to ensure the safety of patients by eliminating potential errors. The surgical safety checklist is supported by accrediting bodies such as the Joint Commission and the World Health Organization. What other practices can you implement to ensure safety in the OR setting?

14 Preoperative Nursing Management

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Define the phases of perioperative patient care.
2. Perform a comprehensive preoperative assessment to identify pertinent health and surgical risk factors.
3. Describe considerations related to preoperative nursing care of older adult patients, patients with obesity, and patients with disability.
4. Identify the regulatory documents that are required prior to a patient entering surgery.
5. Initiate the immediate preoperative preparation and education of the patient.

NURSING CONCEPTS

Communication
Managing Care
Mobility

GLOSSARY

ambulatory surgery: includes outpatient, same-day, or short-stay surgery that does not require an overnight hospital stay

bariatrics: having to do with patients with obesity

history and physical: mandatory form completed by the surgeon that gives a comprehensive overview of the patient's history, current physical status, and plan of care

informed consent: the patient's autonomous decision about whether to undergo a surgical procedure, based on the nature of the condition, the treatment options, and the risks and benefits involved

intraoperative phase: period of time that begins with transfer of the patient to the operating room area and continues until the patient is admitted to the postanesthesia care unit

minimally invasive surgery: surgical procedures that use specialized instruments inserted into the body either through natural orifices or through small incisions

perioperative phase: period of time that constitutes the surgical experience; includes the preoperative, intraoperative, and postoperative phases of nursing care

postoperative phase: period of time that begins with the admission of the patient to the postanesthesia care unit and ends after follow-up evaluation in the clinical setting or home

preadmission testing: diagnostic testing performed before admission to the hospital

preoperative phase: period of time from when the decision for surgical intervention is made to when the patient is transferred to the operating room table

As techniques to perform surgery have evolved with improved technology and expertise, surgery has become less invasive and less debilitating. The increased use of **minimally invasive surgery** (procedures that use specialized instruments inserted into the body either through natural orifices or through small incisions) enables many procedures to be performed on an outpatient basis. Surgery remains a complex, stressful experience, whether minimally invasive, elective, or emergent. Even healthy patients having elective outpatient surgery may experience unanticipated complications during otherwise benign procedures. Many patients enter the hospital 90 minutes prior to surgery and have necessary medical assessments and analyses preceding the surgical intervention. The surgery is followed by a recovery period in the postanesthesia care unit (PACU). Later that day the patient goes home. When comorbidities exist or procedures are more complex, the patient may have laboratory studies completed prior to admission, and may be admitted to the hospital for postoperative recovery.

Traumatic and emergency surgery most often results in prolonged hospital stays. Patients who are acutely ill or undergoing major surgery and patients with concurrent medical disorders may require supportive supplementary care from other medical disciplines, which can be coordinated more easily within the hospital setting. The high acuity level of surgical inpatients and the greater complexity of procedures have placed greater demands on the practice of nursing in this setting.

Although each setting (ambulatory, outpatient, or inpatient) offers its own unique advantages for the delivery of patient care, all patients require a comprehensive preoperative nursing assessment, patient education, and nursing interventions to prepare for surgery.

Perioperative Nursing

Communication, teamwork, and patient assessment are crucial to ensure good patient outcomes in the perioperative setting. Professional perioperative and perianesthesia nursing standards encompass the domains of behavioral response, physiologic response, and patient safety and are used as guides toward development of nursing diagnoses, interventions, and plans. Perioperative nursing, which spans the entire surgical experience, consists of three phases that begin and end at particular points in the sequence of surgical experience events. The **preoperative phase** begins when the decision to proceed with surgical intervention is made and ends with the transfer of the patient onto the operating room (OR) bed. The **intraoperative phase** begins when the patient is transferred onto the OR bed and ends with admission to the PACU. Intraoperative nursing responsibilities involve acting as scrub nurse, circulating nurse, or registered nurse first assistant (see Chapter 15 for the description of these roles). The **postoperative phase** begins with the admission of the patient to the PACU and ends with a follow-up evaluation in the clinical setting or home (see Chapter 16).

Each **perioperative phase** includes the many diverse activities a nurse performs, using the nursing process, and is based on the recommended practice standards of the Association of periOperative Registered Nurses (AORN), formerly known as the Association of Operating Room Nurses (AORN, 2019) and the American Society of PeriAnesthesia Nurses (ASPAN, 2019). Chart 14-1 presents examples of nursing activities characteristic of the three perioperative phases of care. The phases of the surgical experience are reviewed in more detail in this chapter and in the other chapters in this unit.

A conceptual model of patient care, published by AORN, helps delineate the relationships between various components of nursing practice and patient outcomes into four domains: safety, physiologic responses, behavioral responses, and health care systems. The first three domains reflect phenomena

of concern to perioperative nurses and are composed of nursing diagnoses, interventions, and outcomes. The fourth domain—the health care system—consists of structural data elements and focuses on clinical processes and outcomes. The model is used to depict the relationship of nursing process components to the achievement of optimal patient outcomes (Rothrock, 2019).

Advances in Surgical and Anesthesia Approaches

Technologic advancements continue to lead health care industry providers toward performing more complex procedures that are less invasive, and therefore cause less morbidity during the recovery phase of surgery (Rothrock, 2019). Minimally invasive and robotic surgeries are continuing to replace traditional surgical procedures. Advancements in surgical technology allow for shorter hospital stays and promote patient comfort (Sadler, 2017).

The fastest growing trend in recent years is the use of robotic surgery (see Fig. 14-1). Robotic surgery offers many advantages over laparoscopic surgery including more precise accuracy for dissecting and suturing, better range of motion of the instruments, enhanced ability to access deep structures, and attain three-dimensional visual feedback (Rothrock, 2019). Robotic surgery is used in a wide variety of surgical specialties such as cardiac; gastrointestinal; urologic; gynecologic; ear, nose, and throat (ENT); thoracic; and orthopedic.

Enhanced anesthesia methodology complements advances in surgical technology. Modern methods of achieving airway patency, sophisticated monitoring devices, and new pharmacologic agents, such as short-acting anesthetics, have created a safer atmosphere in which to operate. Effective antiemetics have reduced postoperative nausea and vomiting (PONV). Improved postoperative pain management and shortened procedure and recovery times have improved the operative experience for surgical patients.

Surgical Classifications

The decision to perform surgery may be based on facilitating a diagnosis (a diagnostic procedure such as biopsy, exploratory laparotomy, or laparoscopy), a cure (e.g., excision of a tumor or an inflamed appendix), or repair (e.g., multiple wound repair). It may be reconstructive or cosmetic (such as mammoplasty or a facelift) or palliative (to relieve pain or correct a problem—such as debulking a tumor to achieve comfort, or removal of a dysfunctional gallbladder). In addition, surgery might be rehabilitative (e.g., total joint replacement surgery to correct crippling pain or progression of degenerative osteoarthritis). Surgery can also be classified based upon the degree of urgency involved: emergent, urgent, required, elective, and optional (see Table 14-1).

Preadmission Testing

Concurrent with the increase in **ambulatory surgeries** (surgery that does not require an overnight hospital stay) have been changes in the delivery of and payment for health care. Incentives to reduce hospital stays and contain costs have resulted in diagnostic **preadmission testing** (PAT) and preoperative preparation prior to admission. Many facilities have a presurgical services department to facilitate PAT and to initiate the nursing assessment process, which focuses on admission data such as patient demographics, health history, and other information pertinent to the surgical procedure (i.e., appropriate consent forms, diagnostic and laboratory tests) (Rothrock, 2019). During the PAT visit, patients learn what to expect on the day of surgery and receive answers to questions they may have. Nurses in the PAT department are responsible for communicating information related to the surgical procedure and the effect that the surgical procedure and anesthetic may have on the patient's health status, functional status, and family dynamics (Malley, Kenner, Kim, et al., 2015).

Chart 14-1

Examples of Nursing Activities in the Perioperative Phases of Care

Preoperative Phase

Preadmission Testing

1. Performs initial preoperative assessment
2. Initiates education appropriate to patient's needs
3. Involves family in interview
4. Verifies completion of preoperative diagnostic testing according to patient's needs
5. Confirms understanding of surgeon-specific preoperative prescribed therapies (e.g., bowel preparation, preoperative shower)
6. Discusses and reviews advance directive document
7. Begins discharge planning by assessing patient's need for postoperative transportation and care

Admission to Surgical Center

1. Completes preoperative assessment
2. Assesses for risks for postoperative complications
3. Reports unexpected findings or any deviations from normal
4. Verifies that operative consent has been signed
5. Coordinates patient education and plan of care with nursing staff and other health team members
6. Reinforces previous education
7. Explains phases in perioperative period and expectations
8. Answers patient's and family's questions

In the Preoperative Area

1. Identifies patient
2. Assesses patient's physical and emotional status, baseline pain, and nutritional status
3. Reviews medical record
4. Verifies surgical site and that it has been marked per institutional policy
5. Establishes IV line
6. Administers medications if prescribed
7. Takes measures to ensure patient's comfort
8. Provides psychological support
9. Communicates patient and family's needs to other appropriate members of the health care team

Intraoperative Phase

Maintenance of Safety

1. Maintains aseptic, controlled environment

2. Effectively manages human resources, equipment, and supplies for individualized patient care
3. Transfers patient to operating room bed or table
4. Positions patient based on functional alignment and exposure of surgical site
5. Applies grounding device to patient
6. Ensures that the sponge, needle, and instrument counts are correct
7. Completes intraoperative documentation

Physiologic Monitoring

1. Communicates amount of fluid instillation and blood loss
2. Distinguishes normal from abnormal cardiovascular data
3. Reports changes in patient's vital signs
4. Institutes measures to promote normothermia

Psychological Support (Before Induction and When Patient is Conscious)

1. Provides emotional support to patient
2. Stands near or touches patient during procedures and induction
3. Continues to assess patient's emotional status
4. Notifies the patient's family or significant others of updates throughout the procedure

Postoperative Phase

Transfer of Patient to Postanesthesia Care Unit

1. Communicates intraoperative information:
   a. Identifies patient by name
   b. States type of surgery performed
   c. Identifies type and amounts of anesthetic and analgesic agents used
   d. Reports patient's vital signs and response to surgical procedure and anesthesia
   e. Describes intraoperative factors (e.g., insertion of drains or catheters, administration of blood, medications during surgery, or occurrence of unexpected events)
   f. Describes physical limitations
   g. Reports patient's preoperative level of consciousness
   h. Communicates necessary equipment needs
   i. Communicates presence of family or significant others

Postoperative Assessment Recovery Area

1. Determines patient's immediate response to surgical intervention
2. Monitors patient's vital signs and physiologic status
3. Assesses patient's pain level and administers appropriate pain-relief measures
4. Maintains patient's safety (airway, circulation, prevention of injury)

5. Administers medications, fluid, and blood component therapy, if prescribed
6. Provides oral fluids if prescribed for ambulatory surgery patient
7. Assesses patient's readiness for transfer to inhospital unit or for discharge home based on institutional policy (e.g., Aldrete score, see Chapter 16)

Surgical Nursing Unit

1. Continues close monitoring of patient's physical and psychological response to surgical intervention
2. Assesses patient's pain level and administers appropriate pain-relief measures
3. Provides education to patient during immediate recovery period
4. Assists patient in recovery and preparation for discharge home
5. Determines patient's psychological status
6. Assists with discharge planning

Home or Clinic

1. Provides follow-up care during office or clinic visit or by telephone contact
2. Reinforces previous education and answers patient's and family's questions about surgery and follow-up care
3. Assesses patient's response to surgery and anesthesia and their effects on body image and function
4. Determines family's perception of surgery and its outcome

Figure 14-1 • The daVinci surgical system. Reprinted with permission from ©2022 Intuitive Surgical, Inc.

Special Considerations during the Perioperative Period

In an effort to reduce surgical complications, The Joint Commission and the Centers for Medicare and Medicaid Services (CMS) developed National Patient Safety Goals. The goals are updated yearly and identify performance measures aimed at preventing surgical complications, including venous thromboembolism (VTE), surgical site infections (SSIs), and wrong-site surgery related to positive patient identification (Joint Commission, 2019). On the day of surgery, the preoperative nurse should verify the list of home medications with the patient and, if applicable, confirm which medications the patient discontinued and when they were last taken. This information assists providers in understanding the patient's medical conditions and helps to avoid medication interactions between what patients take at home and what is administered to them during surgery (Ubaldi, 2019). For example, particular beta-blockers taken within 24 hours of surgery are associated with improved perioperative cardiovascular outcomes. If the patient has not taken the usual dosage of this medication, the anesthesiologist or certified registered nurse anesthetist (CRNA) must evaluate whether or not it should be administered prior to surgery or during the perioperative period. The nurse in the perioperative area needs to be alert for appropriate preoperative prescriptions aimed at preventing VTE and SSIs. If these prescriptions are not present, they should be requested so that appropriate treatment begins before the start of surgery.

TABLE 14-1 Categories of Surgery Based on Urgency

Classification	Indications for Surgery	Examples
I. Emergent—Patient requires immediate attention; disorder may be life-threatening	Without delay	Severe bleeding Bladder or intestinal obstruction Fractured skull Gunshot or stab wounds Extensive burns
II. Urgent—Patient requires prompt attention	Within 24–30 h	Closed fractures Infected wound exploration/irrigation
III. Required—Patient needs to have surgery	Plan within a few weeks or months	Prostatic hyperplasia Thyroid disorders Cataracts
IV. Elective—Patient should have surgery	Failure to have surgery not catastrophic	Repair of scars Simple hernia Vaginal repair
V. Optional—Decision rests with patient	Personal preference	Cosmetic surgery

Gerontologic Considerations

The hazards of surgery for older adults are proportional to the number and severity of comorbidities and the nature and duration of the operative procedure. Anesthesia associated with these surgeries can precipitate the dysregulation of older adult physiology. Identification of at-risk older adult patients is important in determining the appropriate operative risk and management (Vernon, Rice, Titch, et al., 2019). Cardiac reserves are lower, renal and hepatic functions are depressed, and gastrointestinal activity is likely to be reduced. Therefore, a comprehensive assessment that focuses on the cardiovascular, respiratory, and renal systems may help improve immediate perioperative outcomes (Odom-Forren, 2018). See Chapter 8, Table 8-1 for additional age-related changes.

In the preoperative period, the nurse pays careful attention to the integumentary system of the patient as it can reveal pertinent data about the patient's health status. Assessment includes the overall condition of the skin, and determination of any bruises, abrasions, and discolorations (Phillips, 2017). Precautions are taken when moving an older adult. Decreased subcutaneous fat makes older adults more susceptible to temperature changes. A lightweight cotton blanket is an appropriate cover when an older patient is moved to and from the OR but never replaces asking patients if they feel sufficiently warm and attending to their needs.

The older adult is at a higher risk of cardiovascular complications. Of all the body systems, the cardiovascular system exerts the most influence on anesthesia. The older adult patient usually has decreased or slow circulation to the rest of the body. A preoperative assessment, including blood tests, blood pressure, and EKG, can identify potential risks including anemia, hypertension, and arrhythmias (Phillips, 2017).

In addition to physical risks, the older adult should be assessed for poor memory and cognition. When older adults are in a vulnerable and stressful state, such as preparing for surgery, they may show poor concentration, confusion, and disorganized thought patterns (Odom-Forren, 2018). Nurses must educate patients and caregivers about appropriate pain management and encourage good communication to obtain greater postoperative pain relief. Older adults may need multiple education formats (verbal and print) along with extra time in order to understand and retain what is communicated (see Providing Patient Education section).

Bariatric Patients

Bariatrics is a specialty that revolves around diagnosing, treating, and managing patients with obesity. The prevalence of obesity is approximately

39.8% and affects about 93.3 million adults in the United States (Centers for Disease Control and Prevention [CDC], 2018). Obesity increases the risk and severity of complications associated with surgery. Preoperative assessment of the patient with obesity should pay careful attention to pulmonary, cardiovascular, psychological, and integumentary systems.

Patients with obesity have more subcutaneous fat. The increase in adipose tissue can result in difficult intravenous (IV) access and delayed wound healing at the incision site (Odom-Forren, 2018). Obesity is also associated with increased SSIs and joint replacement failure. Patients with a body mass index (BMI) of greater than 45 are at a significantly increased risk for total joint replacement failure and postoperative infection (Boudreaux & Simmons, 2019).

The patient with obesity tends to have shallow respirations when supine, increasing the risk of hypoventilation and postoperative pulmonary complications. Additionally, diagnosed and undiagnosed obstructive sleep apnea (OSA) is common among patients with obesity. Since these apnea and hypopnea events occur during sleep, most patients with OSA may not be aware that they have the condition. It has been estimated that up to 80% of individuals with moderate to severe OSA may remain undiagnosed and untreated (Chung, Abdullah, & Liao, 2016). Positive identification of OSA and OSA risks can dramatically reduce intubation and postoperative complications (see Chapter 18).

Patients with Disability

Special considerations for patients with mental or physical disability include the need for appropriate assistive devices, modifications in preoperative education, and additional assistance with and attention to positioning or transferring. Assistive devices include hearing aids, eyeglasses, braces, prostheses, and other devices. People who are hearing impaired may need and are entitled by law to a sign interpreter or some alternative communication system perioperatively. If the patient relies on signing or speech (lip) reading and their eyeglasses or contact lenses are removed or the health care staff wears surgical masks, an alternative method of communication will be needed. These needs must be identified in the preoperative evaluation and clearly communicated to personnel. Specific strategies for accommodating the patient's needs must be identified in advance. Ensuring the security of assistive devices is important, because these devices are expensive and require time to replace if lost.

Nurses in the preoperative area report that patients with mobility limitations have difficulty transferring from a standing position to the transport gurney and then, once on the gurney, to reposition themselves (Link, 2018). Therefore, the surgical team should incorporate a plan of care that ensures safe patient

movement and handling. The patient with a disability that affects body position (e.g., cerebral palsy, postpolio syndrome, and other neuromuscular disorders) may need special positioning during surgery to prevent pain and injury. Patients with disability may be unable to sense painful positioning if their extremities are incorrectly adjusted, or they may be unable to communicate their discomfort. A comprehensive care plan should be developed preoperatively addressing the type of disability and patient specific needs.

Patients with respiratory problems related to a disability (e.g., multiple sclerosis, muscular dystrophy) may experience difficulties unless the problems are made known to the anesthesiologist or CRNA and adjustments are made (Barash, Cullen, Stoelting, et al., 2017). These factors need to be clearly identified in the preoperative period and communicated to the appropriate personnel.

Patients Undergoing Ambulatory Surgery

Ambulatory surgery includes outpatient, same-day, or short-stay surgery not requiring admission for an overnight hospital stay but may entail observation in a hospital setting for 23 hours or less. During the brief time the patient and family spend in the ambulatory setting, the nurse must quickly and comprehensively assess and anticipate the needs of the patient and at the same time begin planning for discharge and follow-up home care.

The nurse needs to be sure that the patient and family understand that the patient will first go to the preoperative area before going to the OR for the surgical procedure and then will spend some time in the PACU before being discharged home with the family member later that day. Other preoperative education content should also be verified and reinforced as needed (see later discussion). The nurse should ensure that any plans for follow-up home care or new assistive devices are in place if needed.

Patients Undergoing Emergency Surgery

Emergency surgeries are unplanned and occur with little time for preparation of the patient or the perioperative team. The unpredictable nature of trauma and emergency surgery poses unique challenges throughout the perioperative period. It is important for the nurse to communicate with the patient and team members as calmly and effectively as possible in these situations. (See Chapter 15 for the duties of the members of the perioperative team.)

Factors that affect patients preparing to undergo surgery also apply to patients undergoing emergency surgery, although usually in a very condensed time frame. The only opportunity for preoperative assessment may take place at the same time as resuscitation in the emergency department. A quick visual

survey of the patient is essential to identify all sites of injury if the emergency surgery is due to trauma (see Chapter 67 for more information). The patient, who may have undergone a traumatic experience, may need extra support and explanation of the surgery. For the patient who is unconscious, essential information, such as pertinent past medical history and allergies, need to be obtained from a family member, if one is available.

Required Preoperative Documents

Informed consent is the patient's autonomous decision about whether to undergo a surgical procedure. Voluntary and written informed consent from the patient is necessary before nonemergent surgery can be performed to protect the patient from unsanctioned surgery and protect the surgeon from claims of an unauthorized operation or battery. Consent is a legal mandate, but it also helps the patient to prepare psychologically, because it helps to ensure that the patient understands the surgery to be performed (Rothrock, 2019).

It is the surgeon's and the anesthesiologist's responsibility to provide a clear and simple explanation of what the surgery will entail prior to the patient giving consent. The surgeon must also inform the patient of the benefits, alternatives, possible risks, complications, disfigurement, disability, and removal of body parts as well as what to expect in the early and late postoperative periods. The nurse clarifies the information provided, verifies the presence of the patient's or designee's signature, and may be asked to sign as a witness. If at any point the patient requests additional information, or if the nurse feels that the patient may not understand, the nurse notifies the physician. The nurse ascertains that the consent form has been signed before administering psychoactive premedication, because consent is not valid if it is obtained while the patient is under the influence of medications that can affect judgment and decision making capacity.

Quality and Safety Nursing Alert

Any signed form required for surgery is placed in a prominent place on the patient's medical record and accompanies the patient to the OR.

Many ethical principles are integral to informed consent. Informed consent is necessary in the following circumstances:

- Invasive procedures, such as a surgical incision, a biopsy, a cystoscopy, or paracentesis

- Procedures requiring sedation or anesthesia (see Chapter 15 for a discussion of anesthesia)
- A nonsurgical procedure, such as an arteriography, that carries more than a slight risk to the patient
- Procedures involving radiation
- Blood product administration

The patient personally signs the consent if of legal age and mentally capable. Permission is otherwise obtained from a surrogate, who most often is a responsible family member (preferably next of kin) or legal guardian (see Chart 14-2 for criteria for valid informed consent). State regulations and agency policy must be followed. In an emergency, it may be necessary for the surgeon to operate as a lifesaving measure without the patient's informed consent. However, every effort must be made to contact the patient's family. In such a situation, contact can be made by telephone, fax, or other electronic means and consent obtained.

Chart 14-2

Valid Informed Consent

Voluntary Consent

Valid consent must be freely given, without coercion. Patient must be at least 18 years of age (unless an emancipated minor), a physician must obtain consent, and a professional staff member must witness patient's signature.

Patient Who Is Incompetent

Legal definition: individual who is *not* autonomous and cannot give or withhold consent (e.g., individuals who are cognitively impaired, mentally ill, or neurologically incapacitated).

Informed Subject

Informed consent should be in writing. It should contain the following:

- Explanation of procedure and its risks
- Description of benefits and alternatives
- An offer to answer questions about procedure
- Instructions that the patient may withdraw consent
- A statement informing the patient if the protocol differs from customary procedure

Patient Able to Comprehend

If the patient is non-English speaking, it is necessary to provide consent (written and verbal) in a language that is understandable to the patient. A trained medical interpreter may be consulted. Alternative formats of communication (e.g., Braille, large print, sign interpreter) may be needed if the patient has a disability that affects vision or hearing. Questions must be answered to facilitate comprehension if material is confusing.

If the patient has doubts and has not had the opportunity to investigate alternative treatments, a second opinion may be requested. No patient should be urged or coerced to give informed consent. Refusing to undergo a surgical procedure is a person's legal right and privilege. Such information must be documented and relayed to the surgeon so that other arrangements can be made. Additional explanations may be provided to the patient and family, or the surgery may be rescheduled. Consents for specific procedures such as sterilization, therapeutic abortion, disposal of severed body parts, organ donation, and blood product administration provide additional protection for the patient (Rothrock, 2019). States and regions may vary in their mandates.

Discussion with patients and their family members may be supplemented with audiovisual materials. Consent forms should be written in easily understandable words and concepts to facilitate the consent process and should use other strategies and resources as needed to help the patient understand the

content (see Chart 14-2). Asking patients to describe in their own words the surgery they are about to have promotes nurses' understanding of patients' comprehension.

A completed, updated and signed **History and Physical** must be present prior to the patient entering the OR. Not more than 30 days before the date of the scheduled surgery, each patient must have a comprehensive medical history and physical assessment. The primary provider is required to update the form within 24 hours of scheduled surgery on all non-inpatient clients (Joint Commission, 2019). The History and Physical consists of the history of present illness; surgical, medical, social, and family histories; allergies; current medications; and plan of care. It is the surgical team's responsibility to make sure the presence of these forms and all other supporting documentation (medication reconciliation, Power of Attorney form, etc.) are current and accurate in the preoperative area.

Preoperative Assessment

The goal in the preoperative period is for the patient to be as healthy as possible. Every attempt is made to assess for and address risk factors that may contribute to postoperative complications and delay recovery (see Chart 14-3). The preoperative assessment provides information regarding underlying conditions that may affect the patient's response to surgery techniques and anesthesia (AORN, 2019). During the physical examination, many factors that have the potential to affect the patient undergoing surgery are considered, such as joint mobility. Genetic considerations are also taken into account during assessment to prevent complications with anesthesia (see Chart 14-4).

Chart 14-3 **SELECT RISK FACTORS**

Surgical Complications

- Arthritis
- Cardiovascular disease:
  - Coronary artery disease or previous myocardial infarction
  - Cardiac failure
  - Cerebrovascular disease
  - Arrhythmias
  - Hemorrhagic disorders
  - Hypertension
  - Prosthetic heart valve
  - Venous thromboembolism (VTE)
- Dehydration or electrolyte imbalance
- Endocrine dysfunction:
  - Adrenal disorders
  - Diabetes
  - Thyroid malfunction
- Extremes of age (very young, very old)
- Extremes of weight (underweight, obese)
- Hepatic disease:
  - Cirrhosis
  - Hepatitis
- Hypovolemia
- Immunologic abnormalities
- Infection and sepsis
- Low socioeconomic status
- Medications
- Nicotine use
- Nutritional deficits
- Pregnancy:
  - Diminished maternal physiologic reserve
- Preexisting cognitive, developmental, intellectual, physical, or sensory disability
- Pulmonary disease:
  - Obstructive disease
  - Restrictive disorder
  - Respiratory infection
- Renal or urinary tract disease:
  - Decreased kidney function
  - Urinary tract infection
  - Obstruction
  - Toxic conditions

Asking the patient about use of prescription and over-the-counter (OTC) medications, including herbal and other supplements, provides useful information. Activity and functional levels should be determined, including that involving regular aerobic exercise. Known allergies and sensitivities to drugs, foods, adhesives, and latex could avert an anaphylactic response (Barash et al., 2017). Patients may have early manifestations of a latex allergy and be unaware of this. If a patient states that he or she is allergic to kiwi, avocado, or banana, or cannot blow up balloons, there may be an association with an allergy to latex.

The patient should be assessed for latex allergy and sensitivities. Latex is found in some food (such as bananas and kiwi) as well as in some hospital materials and equipment. Most hospital products today are latex-free, especially in ORs; however, special precautions are still taken to eliminate the risk of exposure to the patient. These precautions include thorough cleaning of the surgical areas between cases, awareness of allergy among surgical team members, ensuring the materials used are latex-free, and eliminating the use of latex powdered gloves during the case (Mendez, Martinez, Lopez, et al., 2018).

Quality and Safety Nursing Alert

A latex allergy can manifest as a rash, asthma, or anaphylactic shock.

The preoperative assessment should pay attention to the possible presence of undiagnosed OSA. The STOP-Bang is one assessment that may be performed (*S*noring, *T*ired, *O*bserved, *P*ressure, *B*MI, *A*ge, *N*eck, *G*ender) to assess for the presence of OSA (Chung et al., 2016).

Health care providers also should be alert for signs of interpersonal violence, including intimate partner violence, which can occur at any age, in either sex, and in any socioeconomic, ethnic, and cultural group. Findings need to be reported accordingly (see Chapter 4 for further discussion of signs of interpersonal violence). Laboratory tests and other diagnostic tests are prescribed when indicated by information obtained from the history and physical examination. Autologous blood donation or patient self-donation is discussed as needed for the type of surgical procedure planned. See Chapter 28 for further discussion of autologous blood donation.

Nutritional and Fluid Status

Optimal nutrition is an essential factor in promoting healing and resisting infection and other surgical complications. Assessment of a patient's nutritional status identifies factors that can affect the patient's surgical course, such as obesity, weight loss, malnutrition, deficiencies in specific nutrients, metabolic abnormalities, and the effects of medications on nutrition. Nutritional needs may be determined by measurement of BMI and waist circumference. (See Chapter 4 for further discussion of nutritional assessment.)

Any nutritional deficiency should be corrected before surgery to provide adequate protein for tissue repair. The nutrients needed for wound healing are summarized in Table 14-2.

Assessment of a patient's hydration status is also essential. The patient's NPO (Nothing by Mouth or *nil per os*) status should be confirmed preoperatively. Preoperative fasting helps prevent the risk of aspiration but it also induces stress on the body, including the loss of glycogen stores, and the body sacrifices lean muscle to meet the energy needs of the surgery. This may lead to dehydration, which may be exhibited day of surgery by low blood pressure or blood tests revealing fluid and electrolyte imbalances. The depletion of fluids and electrolytes following bowel preparation, especially when combined with prolonged fasting, can result in dehydration and chemical imbalances, even among healthy surgical patients.

Chart 14-4 **GENETICS IN NURSING PRACTICE**

Genetics Concepts and Perioperative Nursing

Nurses who are caring for patients undergoing surgery need to take various genetic considerations into account when assessing patients throughout the operative experience. Genetic disorders can impact pre-, intra-, and postoperative surgical outcomes. In particular, consideration must be given to genetic disorders associated with the delivery of anesthesia as well as other genetic disorders that may increase the risk of postoperative complications. Examples of genetic conditions that may cause complications with anesthesia include the following:

Autosomal Dominant

- Central core disease
- Hyperkalemic periodic paralysis
- Malignant hyperthermia

Examples of other genetic conditions that must be evaluated and are associated with perioperative risks include the following:

- Cystic fibrosis (autosomal recessive)
- Duchenne muscular dystrophy (X-linked recessive)
- Ehlers–Danlos syndrome
- Factor V Leiden (autosomal dominant)
- Hemophilia (X-linked)
- Scleroderma

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Genetics and Perioperative Nursing

- Obtain a thorough assessment of personal and family history for three generations, inquiring about prior problems with surgery or anesthesia with specific attention to complications, such as fever, rigidity, dark urine, and unexpected reactions.
- Inquire about any history of musculoskeletal complaints, history of heat intolerance, fevers of unknown origin, or unusual drug reactions.
- Assess for family history of any sudden or unexplained death, especially during participation in athletic events.
- Assess whether any family members have been diagnosed with King–Denborough syndrome, as this is a form of congenital myopathy that places the patient at risk for malignant hyperthermia.

Patient Assessment Specific to Genetics and Perioperative Nursing

- Identify the presence of other inherited genetic disorders that may impact surgical outcomes (e.g., inherited connective tissue, metabolic, bleeding, or neurologic disorders).

- Assess for subclinical muscle weakness.
- Assess for other physical features suggestive of an underlying genetic condition, such as contractures, kyphoscoliosis, and pterygium with progressive weakness.

Management Issues Specific to Genetics and Perioperative Nursing

- Inquire as to whether DNA mutation or other genetic testing has been performed on an affected family member.
- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, and availability of diagnostic/genetic testing.
- Provide support to families of patients with newly diagnosed malignant hyperthermia.
- Participate in management and coordination of care of patients with genetic conditions and individuals predisposed to develop or pass on a genetic condition.

Genetics Resources

Malignant Hyperthermia Association, www.mhaus.org

See Chapter 6, Chart 6-7: Components of Genetic Counseling for genetics resources.

Dentition

The condition of the mouth is an important health factor to assess. Dental caries, dentures, and partial plates are particularly significant to the anesthesiologist or CRNA, because decayed teeth or dental prostheses may become dislodged during intubation and occlude the airway. This is especially important for older patients as well as those who may not have regular dental care. The condition of the mouth is also important because any bodily infection, even in the mouth, can be a source of postoperative infection.

Drug or Alcohol Use

Excessive alcohol consumption can cause arrhythmias, infections, and withdrawal. These factors can lead to extended hospital stays and increased complications. Identifying patients who have excessive alcohol use presurgically and implementing interventions can reduce the incidence of complications by about 50% (Cuomo, Abate, Springer, et al., 2018). In addition, the use of illicit drugs and alcohol may impede the effectiveness of some medications. Because acutely intoxicated people are susceptible to injury, surgery is postponed if possible. If surgery is required, local, spinal, or regional block anesthesia is used for minor surgery (Norris, 2019). In an

emergency, to prevent vomiting and potential aspiration, a nasogastric tube is inserted before general anesthesia is given.

The person with a history of alcohol abuse often suffers from malnutrition and other systemic problems or metabolic imbalances that increase surgical risk. People who have a substance abuse problem may deny or attempt to hide it. In such situations, the nurse who is obtaining the patient's health history needs to ask frank questions with patience, care, and a nonjudgmental attitude. Such questions should include asking whether the patient has had two drinks per day or more on a regular basis in the 2 weeks prior to surgery (see Chapter 4 for an assessment of alcohol and drug use).

TABLE 14-2 Nutrients Important for Wound Healing

Nutrient	Rationale for Increased Need	Possible Deficiency Outcome
Protein	Allows collagen deposition and wound healing to occur	Collagen deposition leading to impaired/delayed wound healing Decreased skin and wound strength Increased wound infection rates
Arginine (amino acid)	Provides necessary substrate for collagen synthesis and nitric oxide (crucial for wound healing) at wound site Increases wound strength and collagen deposition Stimulates T-cell response Associated with various essential reactions of intermediary metabolism	Impaired wound healing
Carbohydrates and fats	Primary source of energy in the body and consequently in the wound-healing process Meets demand for increased essential fatty acids needed for cellular function after an injury Spares protein Restores normal weight	Signs and symptoms of protein deficiency due to the use of protein to meet energy requirements Extensive weight loss
Water	Replaces fluid lost through vomiting, hemorrhage, exudates, fever, drainage, diuresis Helps maintain homeostasis	Signs, symptoms, and complications of dehydration, such as poor skin turgor, dry mucous membranes, oliguria, anuria, weight loss, increased pulse rate, decreased central venous pressure
Vitamin C	Important for capillary formation, tissue synthesis, and wound healing through collagen formation Needed for antibody formation	Impaired/delayed wound healing related to impaired collagen formation and increased capillary fragility and permeability Increased risk for infection related to decreased antibodies
Vitamin B complex	Indirect role in wound healing through their influence on host resistance	Decreased enzymes available for energy metabolism

Vitamin A	Increases inflammatory response in wounds, reduces anti-inflammatory effects of corticosteroids on wound healing	Impaired/delayed wound healing related to decreased collagen synthesis; impaired immune function Increased risk for infection
Vitamin K	Important for normal blood clotting Impaired intestinal synthesis associated with the use of antibiotics	Prolonged prothrombin time Hematomas contributing to impaired healing and predisposition to wound infections
Magnesium	Essential cofactor for many enzymes that are involved in the process of protein synthesis and wound repair	Impaired/delayed wound healing (impaired collagen production)
Copper	Required cofactor in the development of connective tissue	Impaired wound healing
Zinc	Involved in DNA synthesis, protein synthesis, cellular proliferation needed for wound healing Essential to immune function	Impaired immune response

DNA, deoxyribonucleic acid.

Adapted from Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Respiratory Status

The patient is educated about breathing exercises and the use of an incentive spirometer, if indicated, to achieve optimal respiratory function prior to surgery. The potential compromise of ventilation during all phases of surgical treatment necessitates a proactive response to respiratory infections. Surgery is usually postponed for elective cases if the patient has a respiratory infection. Patients with underlying respiratory disease (e.g., asthma, chronic obstructive pulmonary disease) are assessed carefully for current threats to their pulmonary status.

Preoperative smoking cessation interventions can be effective in changing smoking behavior and reducing the incidence of postoperative complications. Patients who smoke are more likely to experience poor wound healing, a higher incidence of SSI, and complications that include VTE and pneumonia.

During the preoperative assessment, patients should be asked about current and previous tobacco use. The PAT visit is an optimal time to advocate for smoking cessation (Cuomo et al., 2018). Patients undergoing elective cases may have their surgery delayed or cancelled due to the potential complications associated with smoking. Those at highest risk of complications are patients scheduled to receive artificial implants such as grafts, total joint replacements, or breast enhancements (Devlin & Smeltzer, 2017).

Cardiovascular Status

Patient preparation for surgical intervention includes ensuring that the cardiovascular system can support the oxygen, fluid, and nutritional needs of the perioperative period. Patients are assessed for cardiac comorbidities including congestive heart failure, shortness of breath upon movement, and arrhythmias (Clifford, 2018). Preoperatively, patients may receive a chest x-ray and electrocardiogram (ECG) to rule out any undiagnosed cardiac condition. Before surgery, the patient's baseline vital signs and blood pressure are taken. In elective situations, surgery may be postponed if there is evidence of cardiac decomposition or unexplained elevated blood pressure (Phillips, 2017).

Hepatic and Renal Function

The presurgical goal is optimal function of the liver and urinary systems so that medications, anesthetic agents, body wastes, and toxins are adequately metabolized and removed from the body. The liver, lungs, and kidneys are the routes for elimination of drugs and toxins.

The liver is important in the biotransformation of anesthetic compounds. Disorders of the liver may substantially affect how anesthetic agents are metabolized. Acute liver disease is associated with high surgical mortality; preoperative improvement in liver function is a goal. Careful assessment may include various liver function tests (see Chapter 43).

The kidneys are involved in excreting anesthetic medications and their metabolites; therefore, surgery is contraindicated if a patient has acute nephritis, acute renal insufficiency with oliguria or anuria, or other acute renal problems (see Chapter 48). Exceptions include surgeries performed as lifesaving measures, surgery to enable easier access for dialysis, or those necessary to improve urinary function (e.g., obstructive uropathy or hydronephrosis).

Endocrine Function

Dysfunction of the endocrine system is associated with overproduction or underproduction of a hormone or hormones. This dysfunction may be the primary reason for surgery or it may coexist in patients who need surgery on other organ systems (Odom-Forren, 2018). Patients who have received corticosteroids are at risk for adrenal insufficiency. The use of corticosteroids for any purpose during the preceding year must be reported to the anesthesiologist or CRNA and surgeon. The patient is monitored for signs of adrenal insufficiency (see Chapter 45).

Patients with uncontrolled thyroid disorders are at risk for thyrotoxicosis (with hyperthyroid disorders) or respiratory failure (with hypothyroid disorders). The patient with an associated history of a thyroid disorder is assessed preoperatively (see Chapter 45).

The patient with diabetes who is undergoing surgery is at risk for both hypoglycemia and hyperglycemia. Hypoglycemia may develop during anesthesia or postoperatively from inadequate carbohydrates or excessive administration of insulin. Hyperglycemia, which can increase the risk of SSI, may result from the stress of surgery, which can trigger increased levels of catecholamine. Other risks are acidosis and glucosuria. Although the surgical risk in the patient with controlled diabetes is no greater than in the patient without diabetes, strict glycemic control leads to better outcomes (ASPAN, 2019). Frequent monitoring of blood glucose levels is important before, during, and after surgery. (See Chapter 46 for a discussion of the patient with diabetes.)

Immune Function

An important function of the preoperative assessment is to determine the presence of infection or allergies. Routine laboratory tests used to detect infection include the white blood cell (WBC) and the urinalysis. Surgery may be postponed in the presence of infection or elevated temperature.

It is important to identify and document any sensitivity to medications, solutions, adhesives, and past adverse reactions (ASPAN, 2019). The patient is asked to identify any substances that precipitated previous allergic reactions, including medications, blood transfusions, contrast agents, latex, and food products, and to describe the signs and symptoms produced by these substances. A sample latex allergy screening questionnaire is shown in Figure 14-2.

Latex Allergy Assessment

Ask the patient the following questions. Check "Yes" or "No" in the box.	YES	NO
1. Has a doctor ever told you that you are allergic to latex?		
2. Do you have on-the-job exposure to latex?		
3. Were you born with problems involving your spinal cord?		
4. Have you ever had allergies, asthma, hay fever, eczema, or problems with rashes?		
5. Have you ever had respiratory distress, rapid heart rate, or swelling?		
6. Have you ever had swelling, itching, hives, or other symptoms after contact with a balloon?		
7. Have you ever had swelling, itching, hives, or other symptoms after a dental examination or procedure?		
8. Have you ever had swelling, itching, hives, or other symptoms following a vaginal or rectal examination or after contact with a diaphragm or condom?		
9. Have you ever had swelling, itching, hives, or other symptoms during or within 1 hour after wearing rubber gloves?		
10. Have you ever had a rash on your hands that lasted longer than 1 week?		
11. Have you ever had swelling, itching, hives, runny nose, eye irritation, wheezing, or asthma after contact with any latex or rubber product?		
12. Have you ever had swelling, itching, hives, or other symptoms after being examined by someone wearing rubber or latex gloves?		
13. Are you allergic to bananas, avocados, kiwi, or chestnuts?		
14. Have you ever had an unexplained anaphylactic episode?

TABLE 14-3 Examples of Medications with the Potential to Affect the Surgical Experience

Agent	Effect of Interaction with Anesthetics
Corticosteroids	
Dexamethasone	Cardiovascular collapse can occur if discontinued suddenly. Therefore, a bolus of corticosteroids may be administered IV immediately before and after surgery.
Diuretics	
Hydrochlorothiazide	During anesthesia, may cause excessive respiratory depression resulting from an associated electrolyte imbalance.
Phenothiazines	
Chlorpromazine hydrochloride	May increase the hypotensive action of anesthetics.
Tranquilizers	
Diazepam	May cause anxiety, tension, and even seizures if withdrawn suddenly.
Insulins	
Insulin	Interaction between anesthetics and insulin must be considered when a patient with diabetes is undergoing surgery. IV insulin may need to be given to keep the blood glucose within the normal range.
Anticoagulants	
Warfarin	Can increase the risk of bleeding during the intraoperative and postoperative periods; should be discontinued in anticipation of elective surgery. The surgeon will determine how long before the elective surgery the patient should stop taking an anticoagulant, depending on the type of planned procedure and the medical condition of the patient.
Anticonvulsant Medications	
Carbamazepine	IV administration of medication may be needed to keep the patient seizure-free in the intraoperative and postoperative periods.
Thyroid Hormone	
Levothyroxine sodium	IV administration may be needed during the postoperative period to maintain thyroid levels.
Opioids	
Morphine sulfate	Long-term use of opioids for chronic pain (≥6 mo) in the preoperative period may alter the patient's response to analgesic agents.

IV, intravenous.

Adapted from Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer.

Immunosuppression is common with corticosteroid therapy, organ transplantation, radiation therapy, chemotherapy, and disorders affecting the immune system, such as acquired immunodeficiency syndrome and leukemia. The mildest symptoms or slightest temperature elevation must be investigated.

Previous Medication Use

A medication history is obtained because of the possible interactions with medications that might be given during surgery and the effects of any of these medications on the patient's perioperative course. Any medications the patient is using or has used in the past are documented, including OTC preparations and herbal agents, as well as the frequency with which they are used. Many medications have an effect on physiologic functions; interactions of such medications with anesthetic agents can cause serious problems, such as hypotension and circulatory collapse. Medications that cause particular concern are listed in Table 14-3.

Aspirin, clopidogrel, and other medications that inhibit platelet aggregation should be prudently discontinued 7 to 10 days before surgery; otherwise, the patient may be at increased risk for bleeding (Rothrock, 2019). Any use of aspirin or other OTC medications is noted in the patient's medical record and conveyed to the intraoperative team. The anesthesia provider evaluates the potential effects of prior medication therapy, considering the length of time the patient has used the medication, the physical condition of the patient, and the nature of the proposed surgery.

Quality and Safety Nursing Alert

The possible adverse interactions of some medications require the nurse to assess and document the patient's use of prescription medications, OTC medications (especially aspirin), herbal agents, and the frequency with which medications are used. The nurse must clearly communicate this information to the intraoperative team.

Preprocedure evaluation needs to include dietary and herbal supplements that may increase surgical risks (Odom-Forren, 2018). Commonly used herbal medications and supplements along with their indications for use and possible surgical risks can be found in Table 14-4. Additional herbal medications may include echinacea and licorice extract (*Glycyrrhizic acid*). Many patients fail to report the use of herbal medicines to health care service providers; therefore, the nurse must ask surgical patients specifically about the use of these agents. The American Society of Anesthesiologists (ASA) issued a statement cautioning patients who take herbal products to refrain from taking them for at

least 2 weeks before surgery (American Society of Anesthesiologists [ASA], 2017).

TABLE 14-4 Herbs or Supplements and Possible Surgical Risks

Herb or Supplement	Indication for Use	Possible Surgical Risk
Ephedra (Ma-Huang)	Appetite suppressant	May interact with medications to cause increased BP and HR
Garlic (*Allium sativum*)	Reported to lower BP and cholesterol levels	Can increase bleeding
Ginkgo biloba	Used to improve memory	Can increase bleeding
Ginseng	Used to increase concentration	Can increase HR and risk of bleeding
Kava kava (*Piper methysticum*)	Used to decrease anxiety	Can increase the effect of anesthesia
St. John's wort (*Hypericum perforatum*)	Used to decrease anxiety, help with depression and sleep problems	May prolong the effects of anesthesia
Valerian (*Valeriana officinalis*)	Used as a sleep aid	May prolong the effects of some types of anesthesia
Vitamin E	Thought to slow the aging process	Can increase bleeding and may cause BP problems

BP, blood pressure; HR, heart rate.

Psychosocial Factors

The nurse anticipates that most patients have emotional reactions prior to surgery—obvious or veiled, normal or abnormal. Fear may be related to the unknown, lack of control, or of death and may be influenced by anesthesia, pain, complications, cancer, or prior surgical experience. Preoperative anxiety can be a preemptive response to a threat to the patient's role in life, a permanent incapacity or body integrity, increased responsibilities or burden on family members, or life itself. Less obvious concerns may occur because of previous experiences with the health care system and people the patient has known with the same condition. Psychological distress directly influences body functioning. Identification of anxiety by the health care team using

supportive guidance at every juncture of the perioperative process helps to ease anxiety. Research suggests that negative postoperative outcomes can result from fear and anxiety preoperatively. Anxiety triggers a physical response, stimulating the release of epinephrine and norepinephrine, which in turn raises blood pressure and increases heart rate, cardiac output, and blood glucose levels. Therefore, overall healing may be impaired while pain and risk of infection may increase postoperatively (Bagheri, Ebrahimi, Abbasi, et al., 2019).

People express fear in different ways. Some patients may ask repeated questions, regardless of information already shared with them. Others may withdraw, deliberately avoiding communication by reading, watching television, or talking about trivialities. Consequently, the nurse must be empathetic, listen well, and provide information that helps alleviate concerns.

An important outcome of the psychosocial assessment is the determination of the extent and role of the patient's support network. The value and reliability of available support systems are assessed. Other information, such as knowledge of the usual level of functioning and typical daily activities, may assist in the patient's care and recovery. Assessing the patient's readiness to learn and determining the best approach to maximize comprehension provide the basis for preoperative patient education. This is of particular importance in patients who are developmentally delayed and those who are cognitively impaired, where the approach to patient education and consent will include the legal guardian.

Spiritual and Cultural Beliefs

Showing respect for a patient's cultural values and beliefs facilitates rapport and trust. Assessment includes identifying the ethnic group to which the patient relates and the customs and beliefs the patient holds about illness and health care providers. Knowledge of the patient's physiologic, psychosocial, cultural, spiritual, and educational needs allows the perioperative nurse to provide a holistic approach to care. A holistic picture of the patient allows the perioperative nurse the opportunity to identify patient care issues that extend beyond the medical diagnosis and planned surgical procedure and choose a nursing diagnosis based on key elements of the patient's needs and goals. The nurse advocates for the patient and develops a holistic care plan that is communicated to members of the intraoperative and postoperative team. Perioperative patient advocacy entails paying respect to other human beings, preserving the patient's expressed values, and treating all patients equally (Sundqvist, Holmefur, Nilsson, et al., 2016).

Certain ethnic groups are unaccustomed to expressing feelings openly with strangers, and nurses need to consider this pattern of communication when assessing pain. In some cultural groups, it is seen as impolite to make direct

eye contact with others and doing so is seen as disrespectful. The nurse should know that this lack of eye contact is not avoidance nor does it reflect a lack of interest. Other ethnicities view the top of the head as sacred; therefore, a nurse would not put the surgical cap on the patient but would ask the patient to don the cap.

Perhaps the most valuable skill at the nurse's disposal is listening carefully to the patient and observing body language, especially when obtaining the history. Invaluable information and insights may be gained through effective communication and interviewing skills. An unhurried, understanding, and caring nurse promotes confidence on the part of the patient.

Preoperative Nursing Interventions

A wide range of interventions are used to prepare the patient physically and psychologically and to maintain safety. Beginning with the nursing history and physical examination, listing of medications taken routinely, history of allergies, and surgical and anesthetic histories, the patient's overall health status and level of experience and understanding may be established.

Providing Patient Education

Nurses have long recognized the value of preoperative education (Rothrock, 2019). Each patient's education is individualized, with consideration for any unique concerns or learning needs. Multiple education strategies should be used (e.g., verbal, written, return demonstration), depending on the patient's needs and abilities.

Preoperative education is initiated as soon as possible, beginning in the physician's office, in the clinic, or at the time of PAT when diagnostic tests are performed. During PAT, the nurse or health care provider makes resources available related to patient education, such as written instructions (designed to be copied and given to patients), audiovisual and online resources, and telephone numbers, to ensure that education continues until the patient arrives for the surgical intervention. When possible, education is spaced over a period of time to allow the patient to assimilate information and ask questions as they arise.

Frequently, education sessions are combined with various preparation procedures to allow for an easy and timely flow of information. The nurse should guide the patient through the experience and allow ample time for questions. Education should go beyond descriptions of the procedure and should include explanations of the sensations the patient will experience. Telling the patient that a preoperative medication will cause relaxation before

the operation is not as effective as also noting that a medication will act quickly and may result in lightheadedness, dizziness, and drowsiness. Knowing what to expect will help the patient anticipate these reactions and attain a superior degree of relaxation. Overly detailed descriptions may increase anxiety in some patients; therefore, the nurse should be sensitive to this, by watching and listening, and provide less detail based on the individual patient's needs.

Unfolding Patient Stories: Vernon Watkins • Part 1

Vernon Watkins, a 69-year-old male, came to the emergency department with severe abdominal pain, and a bowel perforation was diagnosed. He is being prepared for surgery. Significant medical history includes controlled hypertension and smoking for 50 years. What preoperative education should the nurse discuss with Mr. Watkins prior to his emergent surgery? (Vernon Watkins' story continues in Chapter 58.)

Care for Vernon and other patients in a realistic virtual environment: vSim (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Deep Breathing, Coughing, and Incentive Spirometry

One goal of preoperative nursing care is to educate the patient how to promote optimal lung expansion and resulting blood oxygenation after anesthesia. The patient assumes a sitting position to enhance lung expansion. The nurse then demonstrates how to take a deep, slow breath and how to exhale slowly. After practicing deep breathing several times, the patient is instructed to breathe deeply, exhale through the mouth, take a short breath, and cough deeply in the lungs (see Chart 14-5). The nurse or respiratory therapist also demonstrates how to use an incentive spirometer, a device that provides measurement and feedback related to breathing effectiveness (see Chapter 19). In addition to enhancing respiration, these exercises may help the patient relax.

If a thoracic or abdominal incision is anticipated, the nurse demonstrates how to splint the incision to minimize pressure and control pain. The patient should put the palms of both hands together, interlacing the fingers snugly. Splinting or placing the hands across the incision site acts as an effective support when coughing. The patient is informed that medications are available to relieve pain and should be taken regularly for pain relief so that effective deep-breathing and coughing exercises can be performed comfortably. The goal in promoting coughing is to mobilize secretions so that they can be

removed. Deep breathing before coughing stimulates the cough reflex. If the patient does not cough effectively, atelectasis (collapse of the alveoli), pneumonia, or other lung complications may occur.

Mobility and Active Body Movement

The goals of promoting mobility postoperatively are to improve circulation, prevent venous stasis, and promote optimal respiratory function. The patient should be taught that early and frequent ambulation postoperatively, as tolerated, will help prevent complications.

The nurse explains the rationale for frequent position changes after surgery and then shows the patient how to turn from side to side and how to assume the lateral position without causing pain or disrupting IV lines, drainage tubes, or other equipment. Any special position the patient needs to maintain after surgery (e.g., adduction or elevation of an extremity) is discussed, as is the importance of maintaining as much mobility as possible despite restrictions. Reviewing the process before surgery is helpful, because the patient may be too uncomfortable or drowsy after surgery to absorb new information.

Exercise of the extremities includes extension and flexion of the knee and hip joints (similar to bicycle riding while lying on the side) unless contraindicated by type of surgical procedure (e.g., hip replacement). The great toe is pointed and rotated as though tracing a large circle (see Chart 14-5). The elbow and shoulder are also put through their range of motion. At first, the patient is assisted and reminded to perform these exercises. Later, the patient is encouraged to do them independently. Muscle tone is maintained so that ambulation will be easier. The nurse should remember to use proper body mechanics and to instruct the patient to do the same. Whenever the patient is positioned, their body needs to be properly aligned.

Chart 14-5 PATIENT EDUCATION

Diaphragmatic Breathing

Diaphragmatic breathing refers to a flattening of the dome of the diaphragm during inspiration, with resultant enlargement of the upper abdomen as air rushes in. During expiration, the abdominal muscles contract.

1. Practice in the same position you would assume in bed after surgery: a semi-Fowler position, propped in bed with the back and shoulders well supported with pillows.
2. Feel the movement with your hands resting lightly on the front of the lower ribs and fingertips against the lower chest.

Diaphragmatic breathing

3. Breathe out gently and fully as the ribs sink down and inward toward midline.
4. Then take a deep breath through your nose and mouth, letting the abdomen rise as the lungs fill with air.
5. Hold this breath for a count of five.
6. Exhale and let out *all* the air through your nose and mouth.
7. Repeat this exercise 15 times with a short rest after each group of five.
8. Practice this twice a day preoperatively.

Coughing

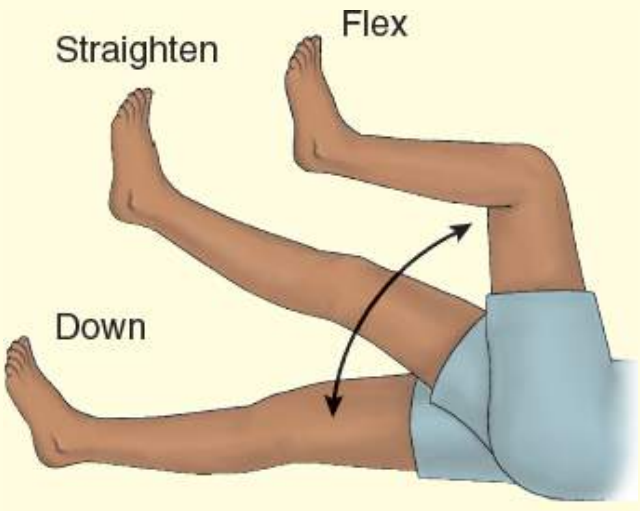
1. Lean forward slightly from a sitting position in bed, interlace your fingers together, and place your hands across the incision site to act as a splint for support when coughing.

Splinting of chest when coughing

2. Breathe with the diaphragm as described under “Diaphragmatic Breathing.”
3. With your mouth slightly open, breathe in fully.
4. “Hack” out sharply for three short breaths.
5. Then, keeping your mouth open, take in a quick deep breath and immediately give a strong cough once or twice. This helps clear secretions from your chest. It may cause some discomfort but will not harm your incision.

Leg Exercises

1. Lie in a semi-Fowler position and perform the following simple exercises to improve circulation.
2. Bend your knee and raise your foot—hold it a few seconds, then extend the leg and lower it to the bed.

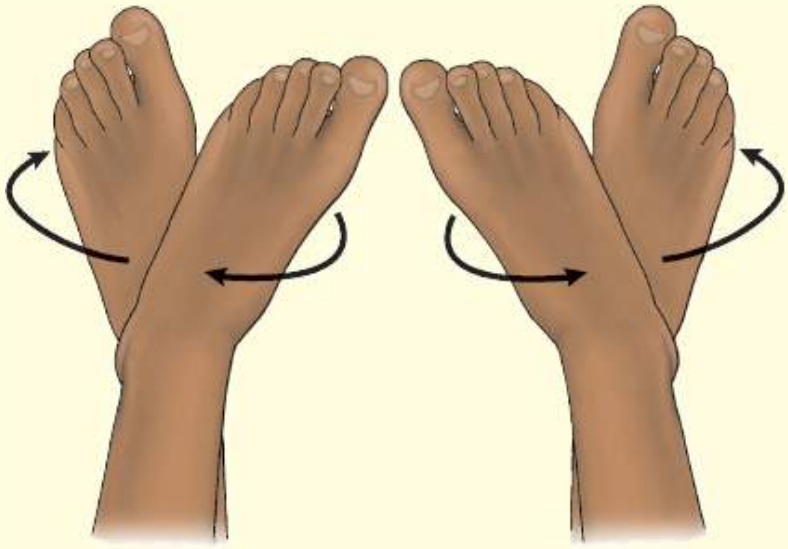


Leg exercises

3. Do this five times with one leg and then repeat with the other leg.
4. Then trace circles with the feet by bending them down, in toward each other, up, and then out.
5. Repeat these movements five times.

Turning to the Side

1. Turn on your side with the uppermost leg flexed most and supported on a pillow.
2. Grasp the side rail as an aid to maneuver to the side.
3. Practice diaphragmatic breathing and coughing while on your side.



Foot exercises

Getting Out of Bed

1. Turn on your side.
2. Push yourself up with one hand as you swing your legs out of bed.

Pain Management

A pain assessment should include differentiation between acute and chronic pain. A pain intensity scale should be introduced and explained to the patient to promote more effective postoperative pain management. (See Chapter 9 for examples of pain scales.) Preoperative patient education also needs to include the difference between acute and chronic pain so that the patient is prepared to differentiate acute postoperative pain from a chronic condition such as back pain. Preoperative pain assessment and education for the older patient may require additional attention (see Chart 14-6).

Chart 14-6

Preoperative Assessment and Education for Older Adults

Assessment

- Assess for allergies and medical comorbidities.
- Assess the patient's cognitive and sensory function before the surgeon begins the informed consent process.
- Perform a Fall Risk Assessment including the following factors:
  - History of previous falls
  - Medication use (e.g., preoperative sedatives)
  - Level of consciousness (e.g., alert, lethargic)
  - Ability to follow directions (e.g., cognitive impairment, language barrier)
  - Sensory impairments (e.g., vision, hearing)
  - Level of coordination or balance
  - Toileting needs (e.g., incontinence, frequency, need for assistance)
  - Presence of external devices (e.g., catheters, drains)
- Determine the need for a designated support person or power of attorney to complete the informed consent process.
- Review medications to identify potential polypharmaceutical risks to include the following:
  - Multiple medications
  - Multiple prescribers
  - Several filling pharmacies
  - Too many forms of medications
  - Over-the-counter medications
  - Multiple dosing schedules
- Document baseline physical assessment parameters, including pain, cardiac rhythm, and oxygen saturation level.
- Document a detailed skin assessment with notation of areas of dryness, lesions, or bruising.
- Document preoperative fasting status and assess for dehydration, malnutrition, and hypoglycemia.
- Perform a psychosocial assessment that addresses fears, anxiety, and feelings of loneliness.
- Identify social support to determine whether the patient has home assistance to complete ADLs.

Education

- Discuss advanced directives and code status to identify the patient's wishes.
- Educate the patient about the benefits of controlling pain.
- Be prepared to spend additional time, increase the amount of therapeutic touch utilized, and encourage family members to be present to decrease anxiety.

ADLs, activities of daily living.

Adapted from Ogg, M. (2018). Clinical issues. *AORN Journal, 108*(2), 195–203; Phillips, N. (2017). *Berry and Kohn's operating room technique*. St. Louis, MO: Elsevier.

Postoperatively, medications are given to relieve pain and maintain comfort without suppressing respiratory function. The patient is instructed to take the medication as frequently as prescribed during the initial postoperative period for pain relief. Anticipated methods of administration of analgesic agents for inpatients include patient-controlled analgesia (PCA), epidural catheter bolus or infusion, or patient-controlled epidural analgesia (PCEA; see Chapter 9 for discussion of PCA and PCEA). A patient who is expected to go home will likely receive oral analgesic agents. These methods are discussed with the patient before surgery, and the patient's interest and willingness to use them are assessed.

Cognitive Coping Strategies

Although some anxiety is common in the surgical setting, untreated or undertreated high preoperative anxiety can lead to complications. Tachycardia, arrhythmias, hypertension, and increased levels of pain have been reported postoperatively in patients with increased preoperative anxiety (Jaruzel, Gregoski, Mueller, et al., 2019). Cognitive strategies may be useful for relieving tension, overcoming anxiety, decreasing fear, and achieving relaxation. Examples of general strategies include:

- *Guided Imagery:* The patient concentrates on a pleasant experience or restful scene.
- *Distraction:* The patient thinks of an enjoyable story or recites a favorite poem or song.
- *Optimistic Self-Recitation:* The patient recites optimistic thoughts ("I know all will go well").
- *Music Therapy:* The patient listens to soothing music (an easy-to-administer, inexpensive, noninvasive intervention).
- *Aromatherapy:* The patient inhales aromatic oils to trigger emotional and physical relaxation responses through the olfactory system and brain.
- *Reiki:* The practitioner places hands over the patient to (theoretically) transfer energy to promote healing and relaxation.

Alternative interventions may include acupuncture, yoga therapy, muscle relaxation, and therapeutic touch.

Education for Patients Undergoing Ambulatory Surgery

Preoperative education for the same-day or ambulatory surgical patient comprises all previously discussed patient education as well as collaborative planning with the patient and family for discharge and follow-up home care. The major difference in outpatient preoperative education is the environment.

Preoperative education content may be presented in a group class, in a media presentation, at PAT, or by telephone in conjunction with the preoperative interview. In addition to answering questions and describing what to expect, the nurse tells the patient when and where to report, what to bring (insurance card, list of medications and allergies), what to leave at home (jewelry, watch, medications, contact lenses), and what to wear (loose-fitting, comfortable clothes; flat shoes). The nurse in the surgeon's office may initiate education before the perioperative telephone contact.

During the final preoperative telephone call, education is completed or reinforced as needed and last-minute instructions are given. The patient is reminded not to eat or drink for a specified period of time and about skin cleansing techniques prior to surgery (see later section on preparing the skin).

Providing Psychosocial Interventions

The nurse assesses for and provides interventions to enhance coping mechanisms to deal effectively with anxiety and fears, and thus provide emotional comfort (Phillips, 2017). Preoperatively, the nurse assesses any patient specific needs that may affect the emotional, psychosocial, or physical surgical experience.

Reducing Anxiety and Decreasing Fear

Perioperative nurses in the preoperative department have a limited amount of time to acquire information and establish trust. Nurses must introduce themselves, giving their title and a brief synopsis of their professional role and background. Each preoperative patient should be acknowledged as an individual, and each patient's needs and desires must be assessed. The patient should be thanked for choosing that particular hospital or surgical center. These methods facilitate establishing a positive nurse–patient relationship. Discussion of the surgical experience, its length, and explanation of what will happen may diminish the patient's anxiety.

During the preoperative assessment of psychological factors and spiritual and cultural beliefs, the nurse assists the patient to identify coping strategies that he or she has previously used to decrease fear. Discussions with the patient to help determine the source of fears can help with expression of concerns. The patient benefits from knowing when family and friends will be able to visit after surgery and that a spiritual advisor will be available if desired. Knowing ahead of time about the possible need for a ventilator, drainage tubes, or other types of equipment helps decrease anxiety related to the postoperative period.

Careful attention should be placed on patients who experience a delay in surgery as prolonged wait times in the preoperative area can lead to increased fear and anxiety.

Respecting Cultural, Spiritual, and Religious Beliefs

The nurse assesses for any patient specific needs that may affect the spiritual, emotional, or physical surgical experience. In some cultures, for example, people are stoic in regard to pain, whereas in others they are more expressive. These responses should be recognized as normal for those patients and families and should be respected by perioperative personnel. If patients decline blood transfusions for religious reasons (Jehovah's Witnesses), this information needs to be clearly identified in the preoperative period, documented, and communicated to the appropriate personnel. Although minimally invasive surgery has significantly lowered blood loss, any surgical procedure has the potential for hemorrhage.

Maintaining Patient Safety

Protecting patients from injury is one of the major roles of the perioperative nurse. Adherence to AORN-recommended practices and The Joint Commission's National Patient Safety Goals (see Chart 14-7) are crucial (Rothrock, 2019). These apply to hospitals as well as to ambulatory surgery centers and office-based surgery facilities (Joint Commission, 2019).

Chart 14-7

Summary of the 2019 National Patient Safety Goals

- Identify patients correctly
- Improve staff communication
- Use medicines safely
- Use alarms safely
- Prevent infection
- Identify patient safety risks
- Prevent mistakes in surgery

Adapted from Joint Commission (2019). 2019 National Patient Safety Goals. Retrieved on 5/22/19 at: www.jointcommission.org/assets/1/6/2019_HAP_NPSGs_final2.pdf

Managing Nutrition and Fluids

The purpose of withholding food and fluid before surgery is to prevent aspiration. Specific recommendations for restrictions depend on the age of the patient and the type of food eaten. For example, adults may be advised to fast for 8 hours after eating fatty food and 6 hours after ingesting milk products. Healthy patients are allowed clear liquids up to 2 hours before an elective procedure. New methods of "carbohydrate loading" have been implemented preoperatively in surgeries that do not involve the gastrointestinal system (i.e., thoracic, urologic, obstetric, orthopedic). A carbohydrate-rich drink has been used as a safe fasting process before surgery. It has been reported that these solutions do not pose a risk for aspiration and decrease insulin resistance when the duration of gastric emptying and the amount of liquid intake are controlled (Cakar, Yilmaz, Cakar, et al., 2017). Preoperative carbohydrate loading in patients undergoing surgery as part of an enhanced recovery after surgery protocol has demonstrated positive outcomes including decreased LOS, decreased incidence of PONV, and decreased pain (Pachella, Mehran, Curtin, et al., 2019).

Preparing the Bowel

Enemas are not commonly prescribed preoperatively unless the patient is undergoing abdominal or pelvic surgery. In this case, a cleansing enema or laxative may be prescribed the evening before surgery and may be repeated the morning of surgery. The goals of this preparation are to allow satisfactory visualization of the surgical site and to prevent trauma to the intestine or contamination of the peritoneum by fecal material. Unless the condition of the patient presents some contraindication, the toilet or bedside commode, rather than the bedpan, is used for evacuating the enema if the patient is hospitalized during this time. In addition, antibiotics may be prescribed to reduce intestinal flora.

Preparing the Skin

The goal of preoperative skin preparation is to decrease bacteria without injuring the skin. If the surgery is not performed as an emergency, most health care facilities and ambulatory surgical centers have implemented preoperative antiseptic skin cleansing protocols. At a minimum, preoperative bathing should consist of a full-body wash using antimicrobial soap the night before the planned surgery (Berríos-Torres, Umscheid, Bratzler, et al., 2018). Additional body cleansing with chlorhexidine wipes may occur in the preoperative area via the nurse or by the patient under the direction of the nurse. Surgical site hair removal should occur in the preoperative area. Electric clippers, not skin razors, are the preferred method for hair removal. Special consideration is given to those undergoing gynecologic, urologic, and cranial

surgeries. To ensure the correct site, the surgical site is typically marked by the patient and the surgeon prior to the procedure.

Immediate Preoperative Nursing Interventions

The nurse confirms the patient identity upon entry and dons "alert" bracelets on the patient when applicable: medication allergies, fall risk, extremity precautions (for needle sticks and blood pressures), and code status. The patient changes into a hospital gown, covers the head with a disposable bouffant, and nail polish is removed (if present) as it may interfere with hemodynamic monitoring. The mouth is inspected, and dentures or plates are removed. If left in the mouth, these items could easily fall to the back of the throat during induction of anesthesia and cause respiratory obstruction.

Jewelry is not worn to the OR; wedding rings and jewelry or body piercings should be removed to prevent injury. If a patient objects to removing jewelry, the patient must be notified of the risks associated with it. All articles of value, including assistive devices, dentures, glasses, and prosthetic devices, are given to family members or are labeled clearly with the patient's name and stored in a safe and secure place according to the institution's policy.

Preoperative Checklist

1. Patient's name: _____ Date: _____ Height: _____ Weight: _____
   Identification band present: _____
2. Informed consent signed: _____ Special permits signed: _____
3. Surgical site: _____ (Ex: Sterilization)
4. History & physical examination report present: _____ Date: _____
5. Laboratory records present: _____
   CBC: _____ Hgb: _____ Urinalysis: _____ Hct: _____
6. Traveled Outside of the United States in the last 14 days: Yes/No
7. NPO Status: Date/Time last liquid: _____ Date/Time last solid: _____
8.

Item	Present	Removed
a. Natural teeth		
Dentures: upper, lower, partial		
Bridge, fixed; crown		
b. Contact lenses		
c. Other prostheses—type: _____		
d. Jewelry:		
Wedding band (taped/tied)		
Rings		
Earrings: pierced, clip-on		
Neck chains		
Any other body piercings		
e. Make-up		
Nail polish		
9. Clothing		
a. Clean patient gown		
b. Cap		
c. Sanitary pad, etc.		

10. Family instructed where to wait? _____
11. Valuables secured? _____
12. Blood available? _____ Ordered? _____ Where? _____
13. Preanesthetic medication given: _____
    Type: _____ Time: _____
14. Voided: _____ Amount: _____ Time: _____ Catheter: _____
    Mouth care given: _____
15. Vital signs: Temperature: _____ Pulse: _____ Resp: _____ Blood Pressure: _____
16. Special problems/precautions: (Allergies, deafness, etc.): _____
17. Area of skin preparation: _____
18. _____ Date: _____ Time: _____
    Signature: Nurse releasing patient

Figure 14-3 • Example of a preoperative checklist.

All patients (except those with urologic disorders) should void immediately before going to the OR. This is particularly important in promoting visibility of anatomy and continence during low abdominal surgery. Urinary catheterization is performed in the OR only as necessary.

Administering Medication

The use of preanesthetic medication is minimal with ambulatory or outpatient surgery but may be used to help some patients remain calm and comfortable (Phillips, 2017). If a preanesthetic medication is given, the patient is kept in bed with the side rails raised, because the medication can cause lightheadedness or drowsiness. During this time, the nurse observes the patient for any untoward reaction to the medications.

Antibiotics are given preoperatively, as needed, to help reduce the risk of SSIs. The antibiotic is typically prescribed prior to the patient arriving and is prepared by the pharmacy so that it can be administered in a timely fashion

prior to surgery. Administration of the appropriate antibiotic should occur so that the peak efficacy of the medication is in the patient's tissues and bloodstream immediately before incision (Bashaw & Keister, 2018).

Maintaining the Preoperative Record

Preoperative checklists contain critical elements that must be checked and verified before the procedure (Rothrock, 2019). The nurse completes a preoperative checklist (see Fig. 14-3). The completed medical record (with the preoperative checklist and verification form) accompanies the patient to the OR with the surgical consent form attached, along with all laboratory reports and nurses' records. These documents may also be found in the patient's electronic health record; however, they must be easily accessed and verified by the surgical team. Any patient alerts (allergies, safety precautions) and individual needs are "flagged" on either the paper or electronic record.

Chart 14-8 **NURSING RESEARCH PROFILE**

The Efficacy of Prewarming in the Preoperative Setting

Rosenkilde, C., Vamosi, M., Lauridsen, J. T., et al. (2017). Efficacy of prewarming with a self-warming blanket for the prevention of unintended perioperative hypothermia in patients undergoing hip or knee arthroplasty. *Journal of PeriAnesthesia Nursing, 32*(5), 419–428.

Purpose

Unintended perioperative hypothermia (UPH) is defined as a core temperature of less than 36°C (96.8°F) in patients in the surgical setting when cooling is not associated with the procedure. Many risks are associated with UPH including increased wound infections, pain, coagulation disorders, and cardiac complications. The purpose of this study was to evaluate UPH rates when a self-warming blanket was utilized by patients undergoing hip or knee joint replacement surgeries.

Design

This was a secondary analysis of two cross-sectional studies. A control group of patients did not receive any warming methods, and another group of patients received a prewarming intervention. Core temperatures of both groups were taken preoperatively, every 30 minutes throughout the procedure, and postoperatively.

Findings

Sixty patients were included in the study, 30 in each group. The incidence of UPH was identified in 13% of the patients in the prewarmed group and 43% of the patients in the control group. Mean core temperature in the prewarmed group was significantly higher and remained above 36°C in the perioperative period.

Nursing Implications

Careful attention needs to be paid to maintaining normothermia in the patient throughout the entire perioperative phase of care. The findings of this study showed a reduction in UPH rates when patients were prewarmed with a self-warming blanket. Nurses at both outpatient and inpatient surgical settings could use this study to help develop interdisciplinary prewarming techniques and protocols.

Preoperative Patient Warming

Preoperative patient warming for a period of at least 30 minutes can be beneficial to prevent hypothermia development after anesthesia induction. Various techniques include warm blankets, forced air warming, and warmed IV fluid administration. Unintended hypothermia is associated with increased adverse patient outcomes, including bleeding, delayed surgical wound healing,

increased length of stay (LOS) in the PACU, cardiac dysfunction, and longer inpatient hospital stay (Williams, 2018). Patients should be educated about the purpose of the warming intervention and should be assessed for abnormal temperatures, profuse sweating, and discomfort (Williams, 2018). Research suggests that nurses play a crucial part in the reduction of unintended hypothermia, below 36°C (96.8°F), by applying prewarming techniques in the preoperative area (Rosenkilde, Vamosi, Lauridsen, et al., 2017). See the Nursing Research Profile in Chart 14-8.

The patient is taken to the preoperative area, greeted by name, and positioned comfortably on the stretcher or bed. The surrounding area should be kept quiet if the preoperative medication is to have maximal effect. Unpleasant sounds or conversation should be avoided, because a patient who is sedated may misinterpret them.

Attending to Family Needs

Most hospitals and ambulatory surgery centers have a waiting room where family members and significant others can wait while the patient is undergoing surgery. This room may be equipped with comfortable chairs, televisions, telephones, and light refreshments. Volunteers may remain with the family, offer them coffee, and keep them informed of the patient's progress. After surgery, the surgeon may meet the family in the waiting room and discuss the outcome.

The family and significant others should never judge the seriousness of an operation by the length of time the patient is in the OR. A patient may be in the OR much longer than the actual operating time for several reasons:

- Patients are routinely transported well in advance of the actual operating time.
- The anesthesiologist or CRNA often makes additional preparations that may take 30 to 60 minutes.
- The preceding case may take longer than expected, which delays the start of the next surgical procedure.

After surgery, the patient is taken to the PACU to ensure safe emergence from anesthesia. Family members and significant others waiting to see the patient after surgery should be informed that the patient may have certain equipment or devices (e.g., IV lines, indwelling urinary catheter, nasogastric tube, oxygen lines, monitoring equipment, blood transfusion lines) in place when he or she returns from surgery. When the patient returns to the room, the nurse provides explanations regarding the frequent postoperative observations that will be made. However, it is the responsibility of the surgeon, not the nurse, to relay the surgical findings and the prognosis, even when the findings are favorable.

Expected Patient Outcomes

Expected patient activities to decrease anxiety and fear, as well as increase knowledge in the preoperative phase of care are summarized in Chart 14-9. Nurse-sensitive outcomes often include central line–associated bloodstream infections (CLABSI), catheter-associated urinary tract infections (CAUTI), hospital-acquired pressure ulcers and unit-acquired pressure ulcers.

Chart 14-9

Expected Patient Activities in the Preoperative Phase of Care

Relief of anxiety, evidenced when the patient:

- Discusses with the anesthesiologist or CRNA concerns related to types of anesthesia and induction
- Verbalizes an understanding of the preanesthetic medication and general anesthesia
- Discusses last-minute concerns with the nurse or physician
- Discusses financial concerns with the social worker, when appropriate
- Requests visit with spiritual advisor, when appropriate
- Appears relaxed when visited by health care team members

Decreased fear, evidenced when the patient:

- Discusses fears with health care professionals or a spiritual advisor, or both
- Verbalizes an understanding of any expected bodily changes, including expected duration of bodily changes

Understanding of the surgical intervention, evidenced when the patient:

- Participates in preoperative preparation as appropriate (e.g., bowel preparation, shower)
- Demonstrates and describes exercises that he or she is expected to perform postoperatively
- Reviews information about postoperative care
- Accepts preanesthetic medication, if prescribed
- Remains in bed once premedicated
- Relaxes during transportation to the operating room or unit
- States rationale for use of side rails
- Discusses postoperative expectations

CRNA, certified registered nurse anesthetist.

CRITICAL THINKING EXERCISES

1 pq A 55-year-old man who is a patient on the surgical unit where you work is scheduled for a prostatectomy; he is showing signs of increased anxiety, fear, and insomnia. What are the priorities of the perioperative nurse? What further assessments are priorities? What are your priorities for nursing intervention?

2 ebp A 60-year-old woman with obesity has been admitted for a minimally invasive hysterectomy. She was diagnosed during her PAT visit with severe OSA. What resources would you use to identify evidence-based practices for prevention of complications during the perioperative period? Identify the evidence, as well as the criteria used to evaluate the strength of the evidence, for the practices identified.

3 ipc A 38-year-old man is admitted for knee surgery following a horse riding accident. He is in good physical condition but reports a family history of "problems with anesthesia." What are your immediate preoperative assessments? What should you include in the interprofessional handoff to the surgical team?

15 Intraoperative Nursing Management

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the roles of the surgical team members during the intraoperative phase of care.
2. Identify adverse effects of surgery and anesthesia.
3. Describe ways to decrease the risk of surgical site infections.
4. Compare types of anesthesia with regard to uses, advantages, disadvantages, and nursing responsibilities.
5. Use the nursing process to optimize patient outcomes during the intraoperative period.

NURSING CONCEPTS

Assessment
Comfort
Managing Care
Safety

GLOSSARY

anesthesia: a state of narcosis or severe central nervous system depression produced by pharmacologic agents

anesthesiologist: physician trained to deliver anesthesia and to monitor the patient's condition during surgery

anesthetic agent: the substance, such as a chemical or gas, used to induce anesthesia

certified registered nurse anesthetist (CRNA): advanced practice registered nurse who delivers anesthesia care under the direction of an anesthesiologist

circulating nurse : registered nurse who coordinates and documents patient care in the operating room (*synonym*: circulator)

laparoscope: a thin endoscope inserted through a small incision into a cavity or joint using fiber-optic technology to project live images of structures onto a video monitor; other small incisions allow additional instruments to be inserted to facilitate laparoscopic surgery

malignant hyperthermia: a rare life-threatening condition triggered by exposure to most anesthetic agents inducing a drastic and uncontrolled increase in skeletal muscle oxidative metabolism that can overwhelm the body's capacity to supply oxygen, remove carbon dioxide, and regulate body temperature, eventually leading to circulatory collapse and death if untreated; often inherited as an autosomal dominant disorder

moderate sedation: previously referred to as conscious sedation, involves the use of sedation to depress the level of consciousness without altering the patient's ability to maintain a patent airway and to respond to physical stimuli and verbal commands

monitored anesthesia care: moderate sedation given by an anesthesiologist or CRNA

multimodal anesthesia: the intentional practice of using a combination of nonopioid pharmaceuticals and regional anesthesia techniques

registered nurse first assistant: a member of the operating room team whose responsibilities may include handling tissue, providing exposure at the operative field, suturing, and maintaining hemostasis

restricted zone: area in the operating room where scrub attire and surgical masks are required; includes operating room and sterile core areas

scrub role: registered nurse, licensed practical nurse, or surgical technologist who scrubs and dons sterile surgical attire, prepares instruments and supplies, and hands instruments to the surgeon during the procedure

semirestricted zone: area in the operating room where scrub attire is required; may include areas where surgical instruments are processed

sterile technique: measures taken to maintain an area free from living microorganisms, including all spores

surgical asepsis: absence of microorganisms in the surgical environment to reduce the risk of infection

unrestricted zone: area in the operating room that interfaces with other departments; includes patient reception area and holding area

The intraoperative experience has undergone many changes and advances that make it safer and less disturbing to patients. Even with these advances, anesthesia and surgery still place the patient at risk for several complications or adverse events. Consciousness or full awareness, mobility, protective biologic functions, and personal control are totally or partially relinquished by the patient when entering the operating room (OR). Staff from the departments of anesthesia, nursing, and surgery work collaboratively to implement professional standards of care, to control iatrogenic and individual risks, to prevent complications, and to promote high-quality patient outcomes.

The Surgical Team

The surgical team consists of the patient, the anesthesiologist (physician) or certified registered nurse anesthetist (CRNA), the surgeon, nurses, surgical technicians, and registered nurse first assistants (RNFAs) or certified surgical technologists (assistants). The anesthesiologist or CRNA administers the **anesthetic agent** (substance used to induce anesthesia) and monitors the patient's physical status throughout the surgery. The surgeon, nurses, technicians, and assistants scrub and perform the surgery. The person in the scrub role, either a nurse or a surgical technician, provides sterile instruments and supplies to the surgeon during the procedure by anticipating the surgical needs as the surgical case progresses. The circulating nurse coordinates the care of the patient in the OR. Care provided by the circulating nurse includes planning for and assisting with patient positioning, preparing the site for surgery, managing surgical specimens, anticipating the needs of the surgical team, documenting intraoperative events, and updating the plan of care. Collaboration of the core surgical team using evidence-based practices tailored to the specific case results in optimum patient care and improved outcomes (see Chart 15-1).

Chart 15-1 ETHICAL DILEMMA

Can Lack of Civility in the OR Threaten Patient Safety?

Case Scenario

You are a registered nurse who has worked in the operating room (OR) for the past five years. You have enjoyed an ancillary role precepting students for the past two years. Recently, you volunteered to serve as a preceptor for a nurse who is transferring to the OR after working as a registered nurse on a general medical-surgical unit for the past two years since graduating from nursing school. The new nurse was accepted into the hospital's onsite perioperative nursing internship program three months ago and has completed most of the classroom portion of the program, reportedly receiving excellent test scores. Today, she is assigned to the role of scrub nurse. A staff nurse with 20 years of experience in the OR is the circulating nurse assigned to the OR suite where the new nurse is assigned. As you are preparing to enter the OR suite to check on the new nurse and to verify that she has setup the instruments properly, the circulating nurse storms angrily out of the room, rolls her eyes and tells you "that newbie badly bungled" and did not set up instruments correctly for the case. You immediately walk into the OR suite to investigate and find the surgeon and the CRNA are there, as well as the new nurse, who is blinking back tears. The new nurse tells you that the circulating nurse "chewed me out in front of everyone." The surgeon requests to have a different nurse assigned to be the scrub nurse.

Discussion

In the *Code of Ethics for Nurses*, the American Nurses Association (ANA; 2015) stresses that it is the responsibility of the nurse to treat colleagues with civility, dignity, and respect and that doing so creates an ethical work environment. By contrast, incivility, which can be evidenced by harassment, intimidation, and bullying, is considered morally unacceptable behaviors for the nurse to exhibit. Clark and Kenski (2017) take these tenets further, and note that incivility, which can consist of both overt behaviors (e.g., yelling, making disparaging remarks) as well as covert behaviors (e.g., eye rolling, withholding communication) can disrupt important professional transactions and communication, which may then threaten patient safety. They assert that "nurses have an ethical responsibility to foster healthy work environments in which conflict is managed in a respectful way and communication is clear, direct, and concise." (p. 62).

Analysis

- Identify the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Who are the stakeholders who might have been adversely affected by this event? Do nurses have a moral obligation to foster beneficent relationships? Can incivility threaten nonmaleficence?
- Describe how you would proceed and what you would say to the nurse you are precepting. Would your communication with her be different if you were to find that she had set up the instruments correctly or

incorrectly? Would you honor the surgeon's request and ask the charge nurse to change the new nurse's assignment?

- What resources might be of help to you so that a civil work environment may be cultivated? Should the nurse manager or other administrators be consulted to help resolve this conflict?

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

The Patient

As the patient enters the OR, they may feel either relaxed and prepared or fearful and highly stressed. These feelings depend to a large extent on the amount and timing of preoperative sedation, preoperative education, and the individual patient. Fears about loss of control, the unknown, pain, death, changes in body structure, appearance, or function, and disruption of lifestyle all contribute to anxiety. These fears can increase the amount of anesthetic medication needed, the level of postoperative pain, and overall recovery time (see Chapter 5 for more information on stress).

The patient is subject to several risks. Infection, failure of the surgery to relieve symptoms or correct a deformity, temporary or permanent complications related to the procedure or the anesthetic agent, and death are uncommon but potential outcomes of the surgical experience (see Chart 15-2). In addition to fears and risks, the patient undergoing sedation and anesthesia temporarily loses both cognitive function and biologic self-protective mechanisms. Loss of the sense of pain, reflexes, and the ability to communicate subjects the intraoperative patient to possible injury. The OR nurse is the patient's advocate while surgery proceeds.

Chart 15-2

Potential Adverse Effects of Surgery and Anesthesia

Anesthesia and surgery disrupt all major body systems. Although most patients can compensate for surgical trauma and the effects of anesthesia, all patients are at risk during the operative procedure. These risks include the following:

- Agitation or disorientation, especially in older adult patients
- Allergic reactions
- Anesthesia awareness
- Bleeding
- Cardiac arrhythmia from electrolyte imbalance or adverse effect of anesthetic agents
- Central nervous system agitation, seizures, and respiratory arrest
- Drug toxicity, faulty equipment, and other types of human error
- Electrical shock or burns
- Hypotension from blood loss or adverse effect of anesthesia
- Hypothermia from cool operating room temperatures, exposure of body cavities, and impaired thermoregulation secondary to anesthetic agents
- Hypoxemia or hypercarbia from hypoventilation and inadequate respiratory support during anesthesia
- Infection
- Laryngeal trauma, oral trauma, and broken teeth from difficult intubation
- Laser burns
- Malignant hyperthermia secondary to adverse effect of anesthesia
- Myocardial depression, bradycardia, and circulatory collapse
- Nerve damage and skin breakdown from prolonged or inappropriate positioning
- Oversedation or undersedation
- Retained foreign body or object
- Thrombosis from compression of blood vessels or stasis

Adapted from Association of PeriOperative Registered Nurses (AORN). (2019a). *Association of PeriOperative Registered Nurses (AORN) standards, recommended practice, and guidelines.* Denver, CO: Author.

Gerontologic Considerations

One in 10 patients undergoing surgery is age 65 or older (American Society of Anesthesiologists [ASA], 2019). Older adult patients are at higher risk for complications from anesthesia and surgery compared with younger adult patients due to several factors (Rothrock, 2019). One factor is age-related decline in physiologic reserve that weakens the normal response to stressors, acute illness, anesthesia, and surgery (Vernon, Rice, Titch, et al., 2019). Risks include delirium, hypothermia, positioning injury, deep vein thrombosis (DVT) formation, electrolyte imbalance, and circulatory compromise. Further discussion of age-related physiologic changes can be found in Chapter 8.

Biologic variations of particular importance include age-related cardiovascular and pulmonary changes. The aging heart and blood vessels have decreased ability to respond to stress. Cardiac output and pulmonary capacity diminish with age, with a decline in maximal oxygen uptake. Slow circulation and hypotension predispose the patient to thrombus formation and emboli (Phillips, 2017). Excessive or rapid administration of intravenous (IV) solutions can cause pulmonary edema. A sudden or prolonged decline in blood pressure may lead to cerebral ischemia, thrombosis, embolism, infarction, and anoxia. Reduced gas exchange can result in cerebral hypoxia.

Lower doses of anesthetic agents are required in older adults due to decreased tissue elasticity (lung and cardiovascular systems) and reduced lean tissue mass. Older patients often experience an increase in the duration of clinical effects of medications. With decreased plasma proteins, more of the anesthetic agent remains free or unbound, and the result is more potent action (Barash, Cullen, Stoelting, et al., 2017).

In addition, body tissues of the older adult are made up predominantly of water, and those tissues with a rich blood supply, such as skeletal muscle, liver, and kidneys, shrink as the body ages. Reduced liver size decreases the rate at which the liver can inactivate many anesthetic agents, and decreased kidney function slows the elimination of waste products and anesthetic agents. Nursing management for the older surgical patient in the intraoperative period includes the following (Phillips, 2017):

- Application of intraoperative warming techniques to reduce unintentional hypothermia
- Careful transfer and positioning on the OR bed. Protect pressure points and bony prominences with extra padding. Support the back and neck to prevent stiffness while maintaining respiratory and circulatory support
- Use of antiembolic stockings or a sequential compression device to prevent VTE formation
- Careful fluid and electrolyte monitoring via accurate blood loss measurement, urinary output, and blood gases

Nursing Care

Throughout surgery, nursing responsibilities include providing for the safety and well-being of the patient, coordinating the OR personnel, and performing scrub and circulating activities. Because the patient's emotional state remains a concern, the intraoperative nursing staff provides the patient with information and reassurance, continuing the care initiated by preoperative nurses. The nurse supports coping strategies and reinforces the patient's ability to influence outcomes by encouraging active participation in the plan of care, incorporating cultural, ethnic, and religious considerations as appropriate. The establishment of an environment of trust and relaxation through visualization techniques is

another method of patient reassurance that can be used as the patient is anesthetically induced.

As patient advocates, intraoperative nurses monitor factors that have the potential to cause injury, such as patient position, equipment malfunction, and environmental hazards. Nurses also protect the patient's dignity and interests while the patient is under anesthesia. Additional nursing responsibilities include maintaining surgical standards of care, identifying risks, and minimizing complications.

Cultural Diversity

Cultural, ethnic, and religious diversities are important considerations for all health care professionals. Nurses in the perioperative area should be aware of medications that may be prohibited by certain groups (e.g., Muslims and those of the Jewish faith may not wish to use porcine-based products [heparin (porcine or bovine)]; Buddhists may choose not to use bovine products). In certain cultures, the head is a sacred area, and staff should allow patients to apply their own surgical cap in this case. When English is the second language of the patient having surgery under local anesthesia, certified medical translators can be provided to maintain understanding and comprehension by the patient. Translator devices are also available at most hospitals. Family members may have the ability to translate but should not be used as medical translators, as they may wish to save the patient anxiety and not provide an accurate translation, resulting in the patient not receiving complete information.

The Circulating Nurse

The **circulating nurse (or circulator)**, a qualified registered nurse, works in collaboration with surgeons, anesthesia providers, and other health care providers to plan the best course of action for each patient (Rothrock, 2019). In this leadership role, the circulating nurse manages the OR and protects the patient's safety and health by monitoring the activities of the surgical team, checking the OR conditions, and continually assessing the patient for signs of injury and implementing appropriate interventions. A foremost responsibility includes verifying consent; if not obtained, surgery may not commence. The team is coordinated by the circulating nurse, who ensures cleanliness, proper temperature, humidity, appropriate lighting, safe function of equipment, and the availability of supplies and materials.

The circulating nurse monitors aseptic practices to avoid breaks in technique while coordinating the movement of related personnel (medical, x-ray, and laboratory), as well as implementing fire safety precautions. The circulating nurse also monitors the patient and documents specific activities throughout the operation to ensure the patient's safety and well-being.

In addition, the circulating nurse is responsible for ensuring that the second verification of the surgical procedure and site takes place and is documented (see Fig. 15-1). In some institutions, this is referred to as a time-out, surgical pause, or universal protocol that takes place among the surgical team prior to induction of anesthesia with a briefing about anticipated problems, potential complications, allergies, and comorbidities. Every member of the surgical team verifies the patient's name, procedure, and surgical site using objective documentation and data before beginning the surgery. Identifying patients correctly is a 2019 National Patient Safety Goal (see Chapter 14, Chart 14-7). The Surgical Safety Checklist (SSC) (see Fig. 15-1) has been adopted in ORs worldwide to reduce medical errors, increase patient safety, and improve interprofessional communication (Ziman, Espin, Grant, et al., 2018). A team debriefing session, led by the circulating nurse, often follows the completion of surgery to identify potential problems with the postsurgical care of the patient and potential areas for improvement (American Society of PeriAnesthesia Nurses [ASPAN], 2019).

Quality and Safety Nursing Alert

It is imperative that the correct patient identity, surgical procedure, and surgical site be verified prior to surgery. The surgical site should be marked by the physician and confirmed by the patient prior to coming to the OR suite during the consent process. The marking should be visible after the sterile drapes are applied and verified by the surgical team members during the time-out.

The Scrub Role

The registered nurse, licensed practical nurse, or surgical technologist (or assistant) performs the activities of the **scrub role**, including performing hand hygiene; setting up the sterile equipment, tables, and sterile field; preparing sutures, ligatures, and special equipment (e.g., a **laparoscope**, which is a thin endoscope inserted through a small incision into a cavity or joint using fiber-optic technology to project live images of structures onto a video monitor); and assisting the surgeon and the surgical assistants during the procedure by anticipating the instruments and supplies that will be required, such as sponges, drains, and other equipment. As the surgical incision is closed, the scrub person and the circulating nurse count all needles, sponges, and instruments to be sure that they are accounted for and not retained as a foreign body in the patient (Association of PeriOperative Registered Nurses [AORN], 2019a; Rothrock, 2019). Standards call for all sponges used in surgery to be visible on x-ray and for sponge counts to take place at the beginning of surgery and twice at the end (when wound closure begins and again as the skin is being closed). Tissue specimens obtained during surgery are labeled by the person in the scrub role

and sent to the laboratory by the circulating nurse. Medications and solutions are transferred to the sterile table by the circulating nurse and the name, strength, dosage, and expiration date are labeled by the person in the scrub role. Implants are handled in a similar fashion whereby the name, type, size, expiration date, and sterility are verified prior to handoff to the person in the scrub role.

The Surgeon

The surgeon performs the surgical procedure, heads the surgical team, and is a licensed physician (MD or DO), oral surgeon (DDS or DMD), or podiatrist (DPM) who is specially trained and qualified. Qualifications and training must adhere to The Joint Commission standards, hospital standards, and local and state admitting practices and procedures (Rothrock, 2019).

The Registered Nurse First Assistant

The **registered nurse first assistant (RNFA)** is another member of the OR team. Although the scope of practice of the RNFA depends on each state's nurse practice act, the RNFA practices under the direct supervision of the surgeon. RNFA responsibilities may include handling tissue, providing exposure at the operative field, suturing, and maintaining hemostasis (Rothrock, 2019). The role requires a thorough understanding of anatomy and physiology, tissue handling, and the principles of surgical asepsis. The RNFA must be aware of the objectives of the surgery, must have the knowledge and ability to anticipate needs and to work as a skilled member of a team, and must be able to handle any emergency situation in the OR.

The Anesthesiologist and CRNA

An **anesthesiologis**t is a physician specifically trained in the art and science of anesthesiology. A **certified registered nurse anesthetist (CRNA)** is a qualified and specifically trained health care professional who administers anesthetic agents, has graduated from an accredited nurse anesthesia program, and has passed examinations sponsored by the American Association of Nurse Anesthetists. The anesthesiologist or CRNA assesses the patient before surgery, selects the anesthesia, administers it, intubates the patient if necessary, manages any technical problems related to the administration of the anesthetic agent, and supervises the patient's condition throughout the surgical procedure. Before the patient enters the OR, often at preadmission testing, the anesthesiologist or CRNA visits the patient to perform an assessment, supply information, and answer questions. The type of anesthetic agent to be given, previous reactions to anesthetic medications, and known anatomic abnormalities that would make airway management difficult are among topics addressed.

The anesthesiologist or CRNA uses the American Society of Anesthesiologists (ASA) Physical Classification System to determine the patient's status. A patient who is classified as P2, P3, or P4 has a systemic disease that may or may not be related to the cause of surgery. If a patient with a classification of P1, P2, P3, P4, or P5 requires emergency surgery, an E is added to the physical status designation (e.g., P1E, P2E). P6 refers to a patient who is brain dead and is undergoing surgery as an organ donor. The abbreviations ASA1 through ASA6 are often used interchangeably with P1 to P6 to designate physical status (Rothrock, 2019).

When the patient arrives in the OR, the anesthesiologist or CRNA reassesses the patient's physical condition immediately prior to initiating anesthesia. The anesthetic agent is given, and the patient's airway is maintained through an intranasal intubation (if the surgeon is using an oral approach to surgery), intubation with an endotracheal tube (ET), or a laryngeal mask airway (LMA). During surgery, the anesthesiologist or CRNA monitors the patient's blood pressure, pulse, and respirations, as well as the electrocardiogram (ECG), blood oxygen saturation level, tidal volume, blood gas levels, blood pH, alveolar gas concentrations, and body temperature. End tidal CO_2 monitoring by electroencephalography (EEG) is sometimes required. Levels of anesthetic medications in the body can also be determined; a mass spectrometer can provide instant readouts of critical concentration levels on display terminals. This information is used to assess the patient's ability to breathe unassisted or the need for mechanical assistance if ventilation is poor and the patient is not breathing well independently.

Safety and Infection Prevention

Within the OR, many factors prevent the spread of microorganisms that may cause surgical site infections (SSIs). These factors involve a combination of facility structure and personnel practices, which are regulated by professional guidelines and overseen by facility members.

The Surgical Environment

The surgical suite is behind double doors, and access is limited to authorized, appropriately clad personnel. The OR is considered a restricted area where careful attention to infection prevention is at the highest standard. In the OR environment, microbial contamination can occur through an airborne or contact route; as a result, the OR has special air filtration devices to screen out contaminating particles, dust, and pollutants. ORs are designed with laminar flow ventilation to circulate particles away from the patient and surgical field. Personnel also follow strict aseptic practices, including hand scrubbing, machine and room cleaning, sterile supply and instrumentation use, and limited

movement. Reducing traffic and door openings has been linked to maintaining optimal airflow with minimal circulating particles and contaminants (Armellino, 2017). Policies governing this environment address such issues as the health of the staff; the cleanliness of the rooms; the sterility of equipment and surfaces; processes for scrubbing, gowning, and gloving; and OR attire (AORN, 2019a).

The surgical environment is known for its stark appearance and cool temperature. Therefore, it is important to maintain patient normothermia. Research supports warming the patient starting in the preoperative area, and throughout all perioperative phases of care. Examples of intraoperative warming techniques are raising room temperature, using forced-air warming blankets, and administering warmed irrigation and IV solutions (Phillips, 2017; Williams, 2018).

To provide the best possible conditions for surgery, the OR is situated in a location that is central to all supporting services (e.g., pathology, x-ray, and laboratory).

Many National Patient Safety Goals pertain to the perioperative areas (see Chapter 14, Chart 14-7); however, the one with the most direct relevance to the OR is to identify patient safety risks. A unique risk is the risk of fire in the OR due to three factors: a source of fuel, an oxygen source, and a mechanism to ignite a fire (AORN, 2019b; ASPAN, 2019).

Prevention of OR Fires

AORN recommends the use of the Fire Risk Assessment Tool to assess the dangers of fires for each surgical case (see Fig. 15-2). The fire risk is discussed during the surgical time-out, and an indication of whether or not the patient has a fire risk is placed on the team communication board in the OR. A regulatory requirement endorsed by The Joint Commission is that every OR perform an annual fire drill to ensure staff familiarity with evacuation plans and to test facility safeguards in the event of a fire (Joint Commission, 2019). To further improve safety, electrical hazards, emergency exit clearances, and storage of equipment and anesthetic gases are monitored periodically by official agencies, such as the respective state Department of Health and The Joint Commission.

Surgical Attire

To help decrease microbes, the surgical area is divided into three zones: the **unrestricted zone**, where street clothes are allowed; the **semirestricted zone**, where attire consists of scrub clothes and caps; and the **restricted zone**, where scrub clothes, shoe covers, caps, and masks are worn. The surgeons and other surgical team members wear additional sterile clothing and protective devices during surgery.

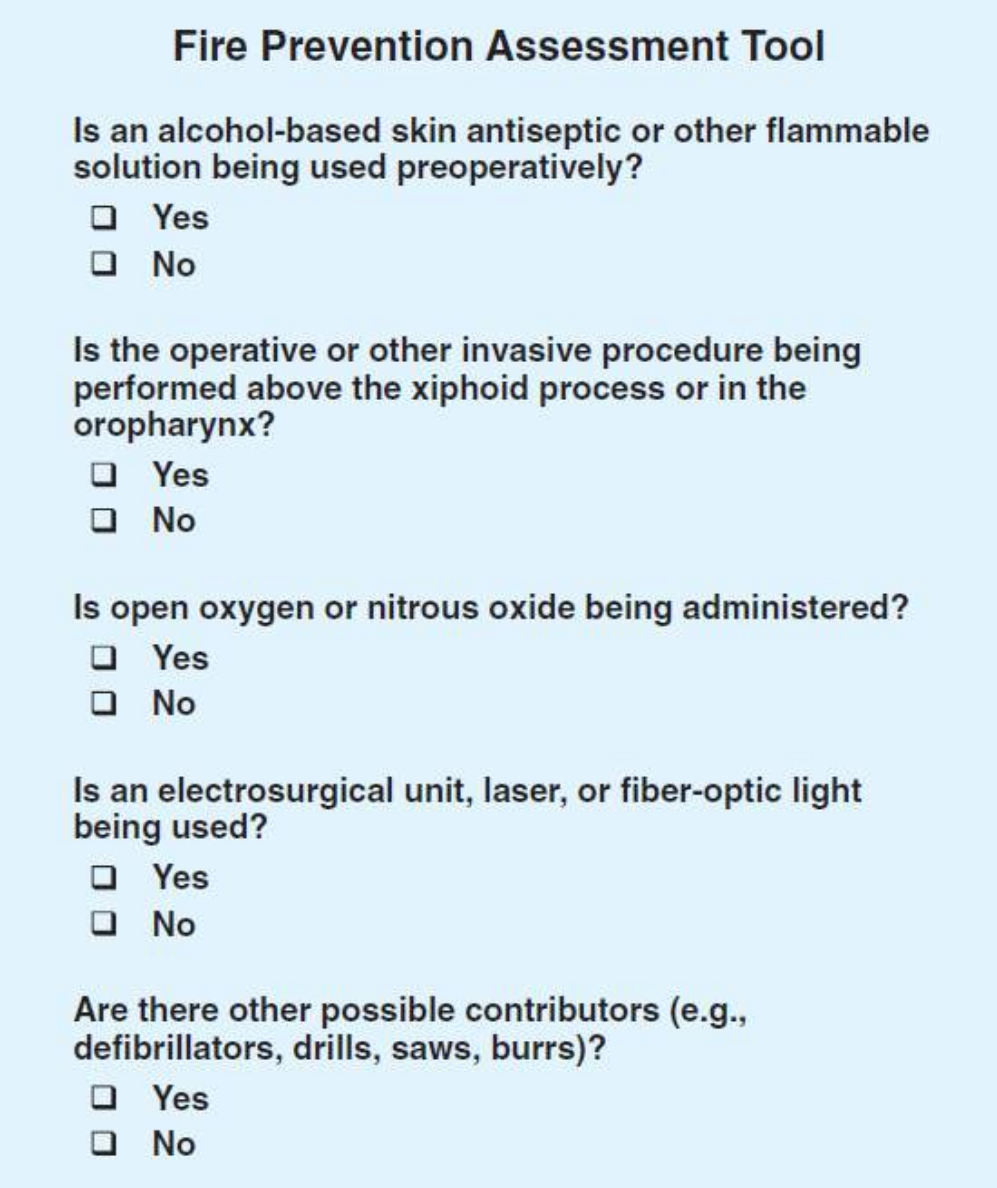

Figure 15-2 • AORN fire risk assessment tool. Reprinted with permission from Association of PeriOperative Registered Nurses (AORN). (2019b). Fire safety tool kit: Fire prevention assessment tool. Retrieved on 5/29/19 at: www.aorn.org/guidelines/clinical-resources/tool-kits/fire-safety-tool-kit

The AORN recommends specific practices for personnel wearing surgical attire to promote a high level of cleanliness in a particular practice setting (AORN, 2019a). OR attire includes close-fitting cotton scrub shirts and pants, gowns, and jackets. Knitted cuffs on sleeves prevent organisms from shedding and being released into the immediate surroundings. Shirts and waist drawstrings should be tucked inside the pants to prevent accidental contact with sterile areas and to contain skin shedding. Wet or soiled garments should be changed.

Masks are worn at all times in the restricted zone of the OR. High-filtration masks decrease the risk of postoperative wound infection by containing and

filtering microorganisms from the oropharynx and nasopharynx. Masks should fit tightly; should cover the nose and mouth completely; and should not interfere with breathing, speech, or vision. Masks must be adjusted to prevent venting from the sides. Disposable masks have a filtration efficiency exceeding 95%. Masks are changed between patients and should not be worn outside the surgical department. The mask must be either on or off; it must not be allowed to hang around the neck.

Headgear should completely cover the hair (head and neckline, including beard) so that hair, bobby pins, clips, and particles of dandruff or dust do not fall on the sterile field.

Shoes designated for use inside the OR (not worn home) should be comfortable and supportive. Shoe covers are used when spills or splashes are anticipated. If worn, the covers should be changed whenever they become wet, torn, or soiled (AORN 2019a; Rothrock, 2019).

Barriers such as scrub attire and masks do not entirely protect the patient from microorganisms. Upper respiratory tract infections, sore throats, and skin infections in staff and patients are sources of pathogens and must be reported.

Because artificial fingernails harbor microorganisms and can cause nosocomial infections, a ban on artificial nails by OR personnel is supported by the Centers for Disease Control and Prevention (CDC), AORN, and the Association for Professionals in Infection Control and Epidemiology (APIC). Research provides support for policies prohibiting artificial nails for health care workers (AORN, 2019a). Short, natural fingernails are encouraged.

Principles of Surgical Asepsis and Sterile Technique

Surgical asepsis prevents the contamination of surgical wounds. **Sterile technique** implies that the area is free of living microorganisms. The patient's natural skin flora or a previously existing infection may cause postoperative SSI. Rigorous adherence to the principles of sterility by OR personnel is basic to preventing SSIs.

All surgical supplies, instruments, needles, sutures, dressings, gloves, covers, and solutions that may come in contact with the surgical wound or exposed tissues must be sterilized before use (Rothrock, 2019). The surgeon, surgical assistants, scrub personnel, and nurses prepare themselves by scrubbing their hands and arms with antiseptic soap and water or alcohol-based (waterless) product. OR personnel must follow the product manufacturer's recommendations in order to achieve hand antisepsis (AORN, 2019a).

The skin of patients, OR team members, and visitors constitutes a microbiologic hazard. In an average individual, an estimated 4000 to 10,000 viable contaminated particles are shed by the skin each minute. *Staphylococcus aureus*, a bacterium, is the most common type of particle on dispersed skin cells (Phillips, 2017). Surgical team members wear long-sleeved, sterile gowns and gloves. Head and hair are covered with a cap, and a mask is worn over the nose

and mouth to minimize the possibility that bacteria from the upper respiratory tract will enter the wound. During surgery, only personnel who have scrubbed, gloved, and gowned touch sterilized objects. Nonscrubbed personnel refrain from touching or contaminating anything sterile.

An area of the patient's skin larger than that requiring exposure during the surgery is meticulously cleansed, and an antiseptic solution is applied (Rothrock, 2019). Close attention is paid to the application dry time of the agent, in particular chlorhexidine and other alcohol-based products. If hair removal needs to take place and this was unable to be performed before the patient arrived in the OR suite, this is done immediately before the procedure with electric clippers (not shaved) to minimize the risk of infection (AORN, 2019a). The remainder of the patient's body is covered with sterile drapes.

Environmental Controls

In addition to the protocols described previously, surgical asepsis requires meticulous cleaning and maintenance of the OR environment. Floors and horizontal surfaces are cleaned between cases with detergent, soap, and water or a detergent germicide. Sterilized equipment is inspected regularly to ensure optimal operation and performance.

All equipment that comes into direct contact with the patient must be sterile. Sterilized linens, drapes, and solutions are used. Instruments are cleaned and sterilized in a unit near the OR. Individually wrapped sterile items are used when additional individual items are needed.

Airborne bacteria are a concern. To decrease the amount of bacteria in the air, standard OR ventilation provides 15 air exchanges per hour, at least three of which are fresh air (AORN, 2019a; Rothrock, 2019). A room temperature of 20° to 24°C (68° to 73°F), humidity between 30% and 60%, and positive pressure relative to adjacent areas are maintained. With the standard air exchanges, air counts of bacteria are reduced to 50 to 150 colony-forming units (CFUs) per cubic foot per minute. Systems with high-efficiency particulate air (HEPA) filters are needed to remove particles larger than 0.3 μm (Rothrock, 2019). Unnecessary personnel and physical movement may be restricted to minimize bacteria in the air and achieve an OR infection rate no greater than 3% to 5% in clean, infection-prone surgery.

Some ORs have laminar airflow units. These units provide 400 to 500 air exchanges per hour (Rothrock, 2019). When used appropriately, laminar airflow units result in fewer than 10 CFUs per cubic foot per minute during surgery. The goal for a laminar airflow–equipped OR is an infection rate of less than 1%. An OR equipped with a laminar airflow unit is frequently used for total joint replacement or organ transplant surgery.

Even using all precautions, wound contamination may inadvertently occur. Constant surveillance and conscientious technique in carrying out aseptic practices are necessary to reduce the risk of contamination and infection.

Basic Guidelines for Maintaining Surgical Asepsis

All practitioners involved in the intraoperative phase have a responsibility to provide and maintain a safe environment. Adherence to aseptic practice is part of this responsibility. The basic principles of aseptic technique follow (AORN, 2019a):

- All materials in contact with the surgical wound or used within the sterile field must be sterile. Sterile surfaces or articles may touch other sterile surfaces or articles and remain sterile; contact with unsterile objects at any point renders a sterile area contaminated.
- Gowns of the surgical team are considered sterile in front from the chest to the level of the sterile field. The sleeves are also considered sterile from 2 inches above the elbow to the stockinette cuff.
- Sterile drapes are used to create a sterile field (see Fig. 15-3). Only the top surface of a draped table is considered sterile. During draping of a table or patient, the sterile drape is held well above the surface to be covered and is positioned from front to back.
- Items are dispensed to a sterile field by methods that preserve the sterility of the items and the integrity of the sterile field. After a sterile package is opened, the edges are considered unsterile. Sterile supplies, including solutions, are delivered to a sterile field or handed to a scrubbed person in such a way that the sterility of the object or fluid remains intact.

Figure 15-3 • Proper draping exposes only the surgical site, which decreases the risk of infection.

- The movements of the surgical team are from sterile to sterile areas and from unsterile to unsterile areas. Scrubbed people and sterile items contact only sterile areas; circulating nurses and unsterile items contact only unsterile areas.
- Movement around a sterile field must not cause contamination of the field. Sterile areas must be kept in view during movement around the area. At least a 1-ft distance from the sterile field must be maintained to prevent inadvertent contamination.
- Whenever a sterile barrier is breached, the area must be considered contaminated. A tear or puncture of the drape permitting access to an unsterile surface underneath renders the area unsterile. Such a drape must be replaced.
- Every sterile field is constantly monitored and maintained. Items of doubtful sterility are considered unsterile. Sterile fields are prepared as close as possible to the time of use.
- The routine administration of hyperoxia (high levels of oxygen) is *not* recommended to reduce SSIs.

Health Hazards Associated with the Surgical Environment

Faulty equipment, improper use of equipment, exposure to toxic substances, surgical plume (smoke generated by electrosurgical cautery), as well as infectious waste, cuts, needlestick injuries, and lasers are some of the associated hazards in the surgical environment (Rothrock, 2019). Internal monitoring of the OR includes the analysis of surface swipe samples and air samples for infectious and toxic agents. In addition, policies and procedures for minimizing exposure to body fluids and reducing the dangers associated with lasers and radiation are identified in AORN standards (AORN, 2019a).

Regardless of the size or location of an incision, unintentional retention of an object (e.g., sponge, instrument) can occur. A retained object can cause wound infection or disruption, an abscess can form, and fistulas may develop between organs (Rothrock, 2019). Safety measures should be in place to reduce the risk of a retained object. Best practices include minimized distractions during the counting process, radiofrequency (RF) technology, and clear communication that includes the willingness to raise concerns among the surgical team members. RF technology acts as a "back-up method" for sponge counting using low-frequency RF chips inside sponges that can be detected via a wand or other scanning detection device. The technology is used in many institutions and can increase patient safety by detecting retained sponges before the surgeon closes the incision (Steelman, Schaapveld, Storm, et al., 2019).

Laser Risks

The AORN has recommended practices for laser safety (AORN, 2019a). When lasers are in use, warning signs must be posted on the doors and safety goggles must be available for staff to don prior to room entry. Personnel must also wear a protective mask to prevent inhalation of the plume emitted from the laser. The type of laser in use and the safety precautions in place are verified by all team members during the time-out (Burlingame, 2017). Several types of lasers are available for clinical use; perioperative personnel should be familiar with the unique features, specific operation, and safety measures for each type of laser used in the practice setting and wear appropriate laser goggles for the type of laser beam in use. Registered nurses trained and certified in laser safety maintain the established standards in the OR (AORN, 2019a).

Surgical Smoke

Approximately 500,000 health care workers are exposed to surgical smoke each year. This smoke is created from thermal destruction of tissue. Smoke plumes may contain toxic gases and vapors such as benzene, hydrogen cyanide, formaldehyde, bioaerosols, dead and live cellular material, and viruses. It is estimated that in an average day, the effect of breathing surgical smoke could be comparable to smoking 30 unfiltered cigarettes. Perioperative nurses are twice as likely as the general population to report experiencing respiratory problems (Davis, 2018; US Department of Labor, Occupational Safety and Health Administration, 2018).

Smoke evacuators are used in some procedures to remove the plume from the operative field. If a smoke evacuator is not available, surgical team members should don an N95 respirator mask rather than a surgical mask, which does not prevent smoke from entering the airway orifices. In recent years, this technology has been extended to all surgical cases to protect the surgical team from the potential hazards associated with the generalized smoke plume generated by standard electric cautery units. Evacuating surgical smoke not only protects the perioperative team, but also patients (Spruce, 2018).

Exposure to Blood and Body Fluids

Basic scrub attire worn by sterile "scrubbed-in" OR personnel include double sterile gloves, eye protection, surgical mask, a sterile gown, and shoe covers. These help to protect against splashing, drilling, and blood loss exposure. In hospitals where numerous total joint procedures are performed, a complete bubble mask may be used. This mask provides full-barrier protection from bone fragments and splashes. Ventilation is accomplished through an accompanying hood with a separate air filtration system.

An estimated 380,000 sharps injuries occur in health care per year, and roughly one third of these occur in the OR setting. Interventions such as using sharps with safety engineered devices, passing sharps using a "neutral zone" or "safe zone," and placing used sharps in puncture-resistant containers can help to reduce these incidents (Davis, 2018). The "neutral zone" or "safe zone"

techniques are designated spaces established for sharps to be put down and picked up (AORN, 2019).

Robotics

Several types of surgical robots are used to facilitate the performance of minimally invasive procedures. These techniques were first introduced in the 1980s in an effort to overcome the disadvantages of traditional laparoscopic surgery, such as limited arm movement and view (Carlos & Saulan, 2018). Many surgical specialties have the ability to use robotic technology for surgical cases, particularly those in the cardiac, urologic, thoracic, and gynecologic specialties. Several types of robotic-driven tools assist in making surgery more precise and less invasive for patients. Technologic advancements of the robot include 3D high-definition imaging and better motion control of instrumentation. The articulated arms offer a 360-degree wristlike movement for precision grasping, manipulation, dissection, and suturing of tissue (Phillips, 2017).

The Surgical Experience

During the surgical procedure, the patient will need sedation, anesthesia, or some combination of these. There are many low-risk anesthesia agents to choose from.

Types of Anesthesia and Sedation

Research estimates anesthesia-related death rates in the United States to be less than 1 per 10,000 surgeries (Barash et al., 2017). For the patient, the anesthesia experience consists of having an IV line inserted, if it was not inserted earlier; receiving a sedating agent prior to induction with an anesthetic agent; losing consciousness; being intubated, if indicated; and then receiving a combination of anesthetic agents. Typically, the experience is a smooth one, and the patient has no recall of the events. The main types of anesthesia are general anesthesia (inhalation, IV), regional anesthesia (epidural, spinal, and local conduction blocks), moderate sedation (monitored anesthesia care [MAC]), and local anesthesia.

General Anesthesia

Anesthesia is a state of narcosis (severe central nervous system depression produced by pharmacologic agents), analgesia, relaxation, and reflex loss. Patients under general anesthesia are not arousable, not even to painful stimuli. They lose the ability to maintain ventilatory function and require assistance in maintaining a patent airway. Cardiovascular function may be impaired as well.

General anesthesia consists of four stages, each associated with specific clinical manifestations (Rothrock, 2019). Understanding of these stages is necessary for nurses because of the emotional support that the patient might need as anesthesia progresses. These stages occur in reverse as the patient wakes up at the end of surgery, so the nurse must be aware of the need for appropriate patient support.

- *Stage I: beginning anesthesia.* Dizziness and a feeling of detachment may be experienced during induction. The patient may have a ringing, roaring, or buzzing in the ears and, although still conscious, may sense an inability to move the extremities easily. These sensations can result in agitation. During this stage, noises are exaggerated; even low voices or minor sounds seem loud and unreal. For these reasons, unnecessary noises and motions are avoided when anesthesia begins.
- *Stage II: excitement.* The excitement stage, characterized variously by struggling, shouting, talking, singing, laughing, or crying, is often avoided if IV anesthetic agents are given smoothly and quickly. The pupils dilate, but they constrict if exposed to light; the pulse rate is rapid; and respirations may be irregular. Because of the possibility of uncontrolled movements of the patient during this stage, the anesthesiologist or CRNA must always be assisted by someone ready to help restrain the patient or to apply cricoid pressure in the case of vomiting to prevent aspiration. Manipulation increases circulation to the operative site and thereby increases the potential for bleeding.
- *Stage III: surgical anesthesia.* Surgical anesthesia is reached by administration of anesthetic vapor or gas and supported by IV agents as necessary. The patient is unconscious and lies quietly on the table. The pupils are small but constrict when exposed to light. Respirations are regular, the pulse rate and volume are normal, and the skin is pink or slightly flushed. With proper administration of the anesthetic agent, this stage may be maintained for hours in one of several planes, ranging from light (1) to deep (4), depending on the depth of anesthesia needed.
- *Stage IV: medullary depression.* This stage is reached if too much anesthesia has been given. Respirations become shallow, the pulse is weak and thready, and the pupils become widely dilated and no longer constrict when exposed to light. Cyanosis develops and, without prompt intervention, death rapidly follows. If this stage develops, the anesthetic agent is discontinued immediately and respiratory and circulatory support is initiated to prevent death. Stimulants, although rarely used, may be given; narcotic antagonists can be used if the overdose is due to opioids. It is not a planned stage of surgical anesthesia.

When opioid agents (narcotics) and neuromuscular blockers (relaxants) are given, several of the stages are absent. During smooth administration of an

anesthetic agent, there is no sharp division between stages. The patient passes gradually from one stage to another, and it is through close observation of the signs exhibited by the patient that an anesthesiologist or CRNA controls the situation. The responses of the pupils, the blood pressure, and the respiratory and cardiac rates are among the most reliable guides to the patient's condition.

Anesthetic medications produce anesthesia because they are delivered to the brain at a high partial pressure that enables them to cross the blood–brain barrier. Relatively large amounts of anesthetic medication must be given during induction and the early maintenance phases because the anesthetic agent is recirculated and deposited in body tissues. As these sites become saturated, smaller amounts of the anesthetic agent are required to maintain anesthesia because equilibrium or near-equilibrium has been achieved between brain, blood, and other tissues. When possible, the anesthesia induction (initiation) begins with IV anesthesia and is then maintained at the desired stage by inhalation methods, achieving a smooth transition and eliminating the obvious stages of anesthesia (see Table 15-1). All are given in combination with oxygen and usually nitrous oxide as well.

TABLE 15-1 Inhalation Anesthetic Agents

Agent	Administration	Advantages	Disadvantages	Implications/Considerations
Volatile Liquids				
Halothane	Inhalation; special vaporizer	Not explosive or flammable Induction rapid and smooth Useful in almost every type of surgery Low incidence of postoperative nausea and vomiting	Requires skillful administration to prevent overdose May cause liver damage May produce hypotension Requires special vaporizer for administration	In addition to observation of pulse and respiration postoperatively, blood pressure must be monitored frequently
Enflurane	Inhalation	Rapid induction and recovery Potent analgesic agent Not explosive or flammable	Respiratory depression may develop rapidly, along with electrocardiogram abnormalities Not compatible with epinephrine	Observe for possible respiratory depression. Administration with epinephrine may cause ventricular fibrillation
Isoflurane	Inhalation	Rapid induction and recovery Muscle relaxants are markedly potentiated	A profound respiratory depressant	Monitor respirations closely, support when necessary, and monitor for malignant hyperthermia
Sevoflurane[a]	Inhalation	Rapid induction and excretion; minimal side effects	Coughing and laryngospasm; trigger for malignant hyperthermia	Monitor for malignant hyperthermia
Desflurane	Inhalation	Rapid induction and emergence; rare organ toxicity	Respiratory irritation; trigger for malignant hyperthermia	Monitor for malignant hyperthermia and arrhythmias
Gases				
Nitrous oxide (N_2O)	Inhalation (semiclosed method)	Induction and recovery rapid Nonflammable Useful with oxygen for short procedures Useful with other agents for all types of surgery	Poor relaxant Weak anesthetic May produce hypoxia	Most useful in conjunction with other agents with longer action Monitor for chest pain, nausea and vomiting, hypertension, and stroke
Oxygen (O_2)	Inhalation	Can increase O_2 available to tissues	High concentrations are hazardous	Increased fire risk when used with lasers

[a]Currently most popular choice.
Adapted from Association of PeriOperative Registered Nurses (AORN). (2019a). *Association of PeriOperative Registered Nurses (AORN) standards, recommended practice, and guidelines*. Denver, CO: Author.

Any condition that diminishes peripheral blood flow, such as vasoconstriction or shock, may reduce the amount of anesthetic medication required. Conversely, when peripheral blood flow is unusually high, as in a muscularly active or apprehensive patient, induction is slower, and greater quantities of anesthetic agents are required because the brain receives a smaller quantity of anesthetic agent.

Inhalation

Inhaled anesthetic agents include volatile liquid agents and gases. Volatile liquid anesthetic agents produce anesthesia when their vapors are inhaled. Some commonly used inhalation agents are included in Table 15-1. All are given in combination with oxygen and usually nitrous oxide as well.

Gas anesthetic agents are given by inhalation and are always combined with oxygen. Nitrous oxide, sevoflurane, and desflurane are the most commonly used gas anesthetic agents. When inhaled, the anesthetic agents enter the blood through the pulmonary capillaries and act on cerebral centers to produce loss of consciousness and sensation. When anesthetic administration is discontinued, the vapor or gas is eliminated through the lungs.

The vapor from inhalation anesthetic agents can be given to the patient by several methods. The inhalation anesthetic agent may be given through an LMA—a flexible tube with an inflatable silicone ring and cuff that can be inserted into the larynx (see Fig. 15-4A). The endotracheal technique for administering anesthetic medications consists of introducing a soft rubber or plastic ET into the trachea, usually by means of a laryngoscope. The ET may be inserted through either the nose (see Fig. 15-4B) or mouth (see Fig. 15-4C). When in place, the tube seals off the lungs from the esophagus so that if the patient vomits, stomach contents do not enter the lungs.

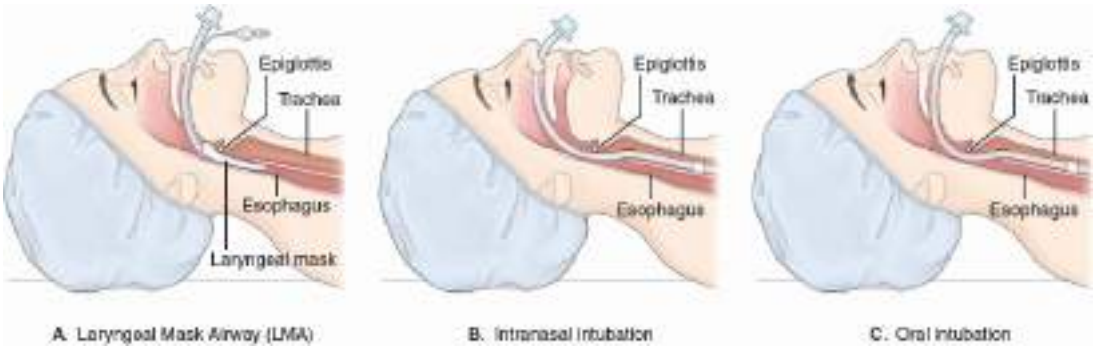

Figure 15-4 • Anesthetic delivery methods. **A.** Laryngeal mask airway (LMA). **B**. Nasal endotracheal catheter used when oral access will be required by the surgeon (in position with cuff inflated). **C.** Oral endotracheal intubation (tube is in position with cuff inflated).

Intravenous Administration

General anesthesia can also be produced by the IV administration of various anesthetic and analgesic agents, such as barbiturates, benzodiazepines, nonbarbiturate hypnotics, dissociative agents, and opioid agents. Table 15-2 lists commonly used IV anesthetic and analgesic agents, including IV medications used as muscle relaxants in the intraoperative period. These medications may be given to induce or maintain anesthesia. Although they are often used in combination with inhalation anesthetic agents, they may be used alone. They may also be used to produce moderate sedation, as discussed later in this chapter.

TABLE 15-2 Commonly Used Intravenous Medications

Medication	Common Usage	Advantages	Disadvantages	Comments
Opioid Analgesic Agents				
Alfentanil	Surgical analgesia in ambulatory patients	Ultra-short-acting (5–10 min) analgesic agent; duration of action 0.5 h; bolus or infusion	—	Potency: 750 μg half-life 1.6 h
Fentanyl	Surgical analgesia; epidural infusion for postoperative analgesia; add to SAB	Good cardiovascular stability; duration of action 0.5 h	May cause muscle or chest wall rigidity	Most commonly used opioid; potency: 100 μg = 10 mg morphine sulfate; elimination half-life 3.6 h
Morphine sulfate	Preoperative pain; premedication; postoperative pain	Inexpensive; duration of action 4–5 h; euphoria; good cardiovascular stability	Nausea and vomiting; histamine release; postural ↓ BP and ↓ SVR	Epidural and intrathecal administration for postoperative pain; elimination half-life 3 h
Remifentanil	IV infusion for surgical analgesia; small boluses for brief, intense pain	Easily titrated; very short duration; good cardiovascular stability. Ultiva is rapidly metabolized by hydrolysis of the propanoic acid–methyl ester linkage by nonspecific blood and tissue esterases	Expensive; requires nursing; may cause muscle rigidity	Potency: 25 μg = 10 mg morphine sulfate; 20–30 times potency of alfentanil; elimination half-life 3–10 min
Sufentanil	Surgical analgesia	Duration of action 0.5 h; prolonged analgesia exceptionally potent (5–10 times more than fentanyl); provides good stability in cardiovascular surgery	Prolonged respiratory depression	Potency: 15 μg = 10 mg morphine sulfate; elimination half-life 2.7 h
Depolarizing Muscle Relaxants				
Succinylcholine	Relax skeletal muscles for surgery and orthopedic manipulations; short procedures; intubation	Short duration; rapid onset	No known effect on consciousness, pain threshold, or cerebration; fasciculations, postoperative myalgias, arrhythmias, raises serum K^+ in tissue trauma, muscular disease, paralysis, burns; histamine release is slight; requires refrigeration	Prolonged muscle relaxation with serum cholinesterase deficiency and some antibiotics; may trigger malignant hyperthermia
Nondepolarizing Muscle Relaxants—Intermediate Onset and Duration				
Atracurium besylate	Intubation; maintenance of skeletal muscle relaxation	No significant cardiovascular or cumulative effects; good with kidney injury	Requires refrigeration; slight histamine release; pregnancy risk category C; do not mix with lactated Ringer's solution or alkaline solutions such as barbiturates	Rapid IV bolus; use cautiously with older adult patients and those who are debilitated
Cisatracurium besylate	Intubation; maintenance of skeletal muscle relaxation	Similar to atracurium	No histamine release	Similar to atracurium
Mivacurium	Intubation; maintenance of skeletal muscle relaxation	Short acting; rapid metabolism by plasma cholinesterase; used as bolus or infusion	Expensive in longer cases	Competes with acetylcholine for receptor sites at the motor end plate, blocking neuromuscular transmission; new; rarely need to reverse; prolonged effect with plasma cholinesterase deficiency
Rocuronium	Intubation; maintenance of relaxation	Rapid onset (dose dependent); elimination via kidney and liver	No known effect on consciousness, pain threshold, or cerebration; vagolytic; may ↑ HR	Duration similar to atracurium and vecuronium
Vecuronium	Intubation; maintenance of relaxation	No significant cardiovascular or cumulative effects; no histamine release	Requires mixing	Mostly eliminated in bile, some in urine

Nondepolarizing Muscle Relaxants—Longer Onset and Duration				
d-Tubocurarine	Adjunct to anesthetic maintenance of relaxation	—	No known effect on consciousness, pain threshold, or cerebration; might cause histamine release and transient ganglionic blockade	Mostly used for pretreatment with succinylcholine
Metocurine	Maintenance of relaxation	Good cardiovascular stability	Slight histamine release	Most commonly used opioid; potency: 100 µg = 10 mg morphine sulfate; elimination half-life 3.6 h
Pancuronium	Maintenance of relaxation	—	May cause ↑ HR and ↑ BP	Used intrathecally and epidurally for postoperative pain; elimination half-life 3 h
Intravenous Anesthetic Agents				
Diazepam	Amnesia; hypnotic; relieves anxiety; preoperative	Good sedation	Long acting	Residual effects for 20–90 h; increased effect with alcohol
Etomidate	Induction of general anesthesia; indicated to supplement low-potency anesthetic agents	Short-acting hypnotic; good cardiovascular stability; fast, smooth induction and recovery	May cause brief period of apnea; pain with injection and myotonic movements	—
Ketamine	Induction; occasional maintenance (IV or IM)	Short acting; profound analgesia; patient maintains airway; good in small children and burn patients	Large doses may cause hallucinations and respiratory depression; chest wall rigidity; laryngeal spasm	Need darkened, quiet room for recovery; often used in trauma cases
Midazolam	Hypnotic; anxiolytic; sedation; often used as adjunct to induction	Excellent amnesia; water soluble (no pain with IV injection); short acting	Slower induction than thiopental	Often used for amnesia with insertion of invasive monitors or regional anesthesia; depresses all levels of CNS, including limbic and reticular formation, probably through increased action of GABA, which is major inhibitory neurotransmitter in brain
Propofol	Induction and maintenance; sedation with regional anesthesia or MAC	Rapid onset; awakening in 4–8 min; produces sedation/hypnosis rapidly (within 40 s) and smoothly with minimal excitation; decreases intraocular pressure and systemic vascular resistance; rarely is associated with malignant hyperthermia and histamine release	May cause pain when injected; suppresses cardiac output and respiratory drive	Short elimination half-life (34–64 min)
Methohexital sodium	Induction; methohexital slows the activity of brain and nervous system	Ultra-short-acting barbiturate	May cause hiccups	Can be given rectally
Thiopental sodium	Induction; stops seizures	—	May cause laryngospasm	Large doses may cause apnea and cardiovascular depression; can be given rectally

BP, blood pressure; CNS, central nervous system; GABA, gamma-aminobutyric acid; HR, heart rate; IM, intramuscular; IV, intravenous; K^+, potassium; MAC, monitored anesthesia care; SAB, subarachnoid block; SVR, stroke volume rate.

Adapted from Association of PeriOperative Registered Nurses (AORN). (2018a). *Association of PeriOperative Registered Nurses (AORN) standards, recommended practice, and guidelines*. Denver, CO: Author.

An advantage of IV anesthesia is that the onset of anesthesia is pleasant; there is none of the buzzing, roaring, or dizziness known to follow administration of an inhalation anesthetic agent. The duration of action is brief, and the patient awakens with little nausea or vomiting.

The IV anesthetic agents are nonexplosive, require little equipment, and are easy to administer. The low incidence of postoperative nausea and vomiting (PONV) makes the method useful in eye surgery, because in this setting vomiting would increase intraocular pressure and endanger vision in the operated eye. IV anesthesia is useful for short procedures but is used less often for the longer procedures of abdominal surgery. It is not indicated for those who require intubation because of their susceptibility to respiratory obstruction. The combination of IV and inhaled anesthetic agents produces an effective and smooth experience for the patient, with a controlled emergence following surgery.

IV neuromuscular blockers (muscle relaxants) block the transmission of nerve impulses at the neuromuscular junction of skeletal muscles. Muscle relaxants are used to relax muscles in abdominal and thoracic surgery, relax eye muscles in

certain types of eye surgery, facilitate endotracheal intubation, treat laryngospasm, and assist in mechanical ventilation.

Multimodal Anesthesia

Multimodal analgesia regimens in surgical patients often use a combination of scheduled, nonopioid analgesic agents and regional anesthesia techniques (Wolfe, 2018). Multimodal analgesia aims to reduce opioid requirements and associated risks such as sedation, respiratory depression, nausea, vomiting, and potential of overuse of opioids. Multimodal anesthesia is a growing trend in the enhanced recovery after surgery (ERAS) pathways, as it decreases the risks of general anesthesia and aids in opioid reduction strategies. Analysis of opioid-naive surgical patients and opioid-naive nonsurgical patients found that those undergoing surgery had an increased risk of chronic opioid use during the first year after surgery (Sun, Darnall, Baker, et al., 2016). ERAS pathways are evidence based and facility specific; the patient follows these pathways from pre-, intra-, postoperative, and home phases of care. ERAS pathways are developed by multidisciplinary teams to optimize the recovery from surgery by reducing the patient's stress response. Instead of general anesthesia, regional/local anesthesia (LA) (discussed below) is administered. Nonopioid medications such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs), ketamine, and gabapentinoids are preferred pain control methods in ERAS pathways (American Association of Nurse Anesthetists [AANA], 2019b).

Regional Anesthesia

In regional anesthesia, an anesthetic agent is injected around nerves so that the region supplied by these nerves is anesthetized. The effect depends on the type of nerve involved. Motor fibers are the largest fibers and have the thickest myelin sheath. Sympathetic fibers are the smallest and have a minimal covering. Sensory fibers are intermediate. A local anesthetic agent blocks motor nerves least readily and sympathetic nerves most readily. An anesthetic agent is not considered metabolized until all three systems (motor, sensory, and autonomic) are no longer affected.

The patient receiving regional anesthesia is awake and aware of their surroundings unless medications are given to produce mild sedation or to relieve anxiety. The health care team must avoid careless conversation, unnecessary noise, and unpleasant odors; these may be noticed by the patient in the OR and may contribute to a negative response to the surgical experience. A quiet environment is therapeutic. The diagnosis must not be stated aloud if the patient is not to know it at this time.

Epidural Anesthesia

Epidural anesthesia is achieved by injecting a local anesthetic agent into the epidural space that surrounds the dura mater of the spinal cord (see Fig. 15-5).

The given medication diffuses across the layers of the spinal cord to provide anesthesia and pain relief (AORN, 2019; ASPAN, 2019). In contrast, spinal anesthesia involves injection through the dura mater into the subarachnoid space surrounding the spinal cord. Epidural anesthesia blocks sensory, motor, and autonomic functions; it differs from spinal anesthesia by the site of the injection and the amount of anesthetic agent used. Epidural doses are much higher because the epidural anesthetic agent does not make direct contact with the spinal cord or nerve roots (AORN, 2019a; ASPAN, 2019).

An advantage of epidural anesthesia is the absence of headache that can result from spinal anesthesia. A disadvantage is the greater technical challenge of introducing the anesthetic agent into the epidural space rather than the subarachnoid space. If inadvertent puncture of the dura occurs during epidural anesthesia and the anesthetic agent travels toward the head, high spinal anesthesia can result; this can produce severe hypotension and respiratory depression and arrest. Treatment of these complications includes airway support, IV fluids, and the use of vasopressors.

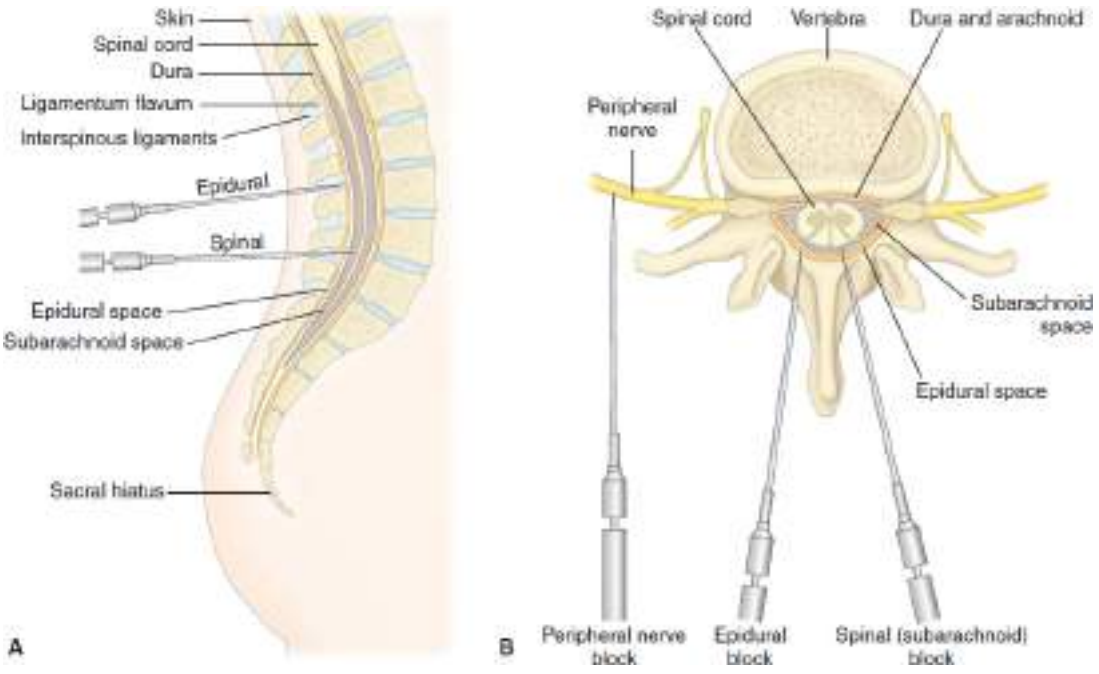

Figure 15-5 • **A.** Injection sites for spinal and epidural anesthesia. **B.** Cross-section of injection sites for peripheral nerve, epidural, and spinal blocks.

TABLE 15-3 Select Regional and Local Anesthetic Agents

Agent	Administration	Advantages	Disadvantages	Implications/Considerations
Lidocaine	Epidural, spinal, peripheral IV anesthesia, and local infiltration	Rapid Longer duration of action (compared with procaine) Free of local irritative effect	Occasional allergic reaction	Useful topically for cystoscopy Observe for untoward reactions—drowsiness, depressed respiration, seizures
Bupivacaine	Epidural, spinal, peripheral IV anesthesia, and local infiltration	Duration is 2–3 times longer than lidocaine	Use cautiously in patients with known drug allergies or sensitivities	A period of analgesia persists after return of sensation; therefore, the need for strong analgesic agents is reduced Greater potency and longer action than lidocaine
Tetracaine	Topical, infiltration, and nerve block	Long acting, produces good relaxation	Occasional allergic reaction	>10 times as potent as procaine
Procaine	Local infiltration	—	Occasional allergic reaction	Commonly used in oral or dental surgery

IV, intravenous.

Spinal Anesthesia

Spinal anesthesia is an extensive conduction nerve block that is produced when a local anesthetic agent is introduced into the subarachnoid space at the lumbar level, usually between L4 and L5 (see Fig. 15-5). It produces anesthesia of the lower extremities, perineum, and lower abdomen. For the lumbar puncture procedure, the patient usually lies on the side in a knee–chest position. Sterile technique is used as a spinal puncture is made and the medication is injected through the needle. As soon as the injection has been made, the patient is positioned on their back. If a relatively high level of block is sought, the head and shoulders are lowered.

The spread of the anesthetic agent and the level of anesthesia depend on the amount of agent injected, the speed with which it is injected, the positioning of the patient after the injection, and the specific gravity of the agent. If the specific gravity is greater than that of cerebrospinal fluid (CSF), the agent moves to the dependent position of the subarachnoid space. If the specific gravity is less than that of CSF, the anesthetic agent moves away from the dependent position. The anesthesiologist or CRNA controls the administration of the agent. Table 15-3 presents select regional anesthesia agents.

A few minutes after induction of a spinal anesthetic agent, anesthesia and paralysis affect the toes and perineum and then gradually the legs and abdomen.

Headache may be an aftereffect of spinal anesthesia. Several factors are related to the incidence of headache: the size of the spinal needle used, the leakage of fluid from the subarachnoid space through the puncture site, and the patient's hydration status. Measures that increase cerebrospinal pressure are helpful in relieving headache. These include maintaining a quiet environment, keeping the patient lying flat, and keeping the patient well hydrated.

In continuous spinal anesthesia, the tip of a plastic catheter remains in the subarachnoid space during the surgical procedure so that more anesthetic medication may be injected as needed. This technique allows greater control of the dosage; however, there is greater potential for postanesthetic headache because of the large-gauge needle used.

Peripheral Nerve Blocks

Peripheral nerve blocks (PNBs) are used in conjunction with general or MAC anesthesia, or as a stand-alone method. Instead of a single nerve being targeted, a bundle of nerves is located via ultrasound and injected with an anesthetic, opioid, or steroid. Traditionally, anesthesia would place the block in the OR setting. However, current research and best practices indicate that placing regional blocks in the preoperative department has greater efficacy. Patients emerge from anesthesia with less pain, decreasing the need for opioids. Research also suggests that patients spend less time in the postanesthesia care unit (PACU) and inpatients are discharged earlier (Gutierrez, Biehn, Eluna, et al., 2018).

Examples of common local conduction blocks include:

- Brachial plexus block, which produces anesthesia of the arm
- Paravertebral anesthesia, which produces anesthesia of the nerves supplying the chest, abdominal wall, and extremities
- Transsacral (caudal) block, which produces anesthesia of the perineum and, occasionally, the lower abdomen

Moderate Sedation

Moderate sedation, previously referred to as conscious sedation, is a form of anesthesia that involves the IV administration of sedatives or analgesic medications to reduce patient anxiety and control pain during diagnostic or therapeutic procedures. It is commonly used for many short-term surgical procedures in hospitals and ambulatory care centers (Rothrock, 2019). The goal is to depress a patient's level of consciousness to a moderate level to enable surgical, diagnostic, or therapeutic procedures to be performed while ensuring the patient's comfort during and cooperation with the procedures. With moderate sedation, the patient is able to maintain a patent airway, retain protective airway reflexes, and respond to verbal and physical stimuli.

Moderate sedation can be given by an anesthesiologist, CRNA, or other specially trained and credentialed physician or nurse. The practitioner who administers the sedation must be trained in resuscitative efforts as these patients are at risk for slipping into a deeper level of sedation (AORN, 2017). The continual assessment of the patient's vital signs, level of consciousness, and cardiac and respiratory function is an essential component of moderate sedation. Pulse oximetry, a continuous ECG monitor, and frequent measurement of vital signs are used to monitor the patient. Regulations for the use and administration of moderate sedation differ from state to state, and its administration is governed by standards issued by The Joint Commission and by institutional policies and nursing specialty organizations (AORN, 2017; ASPAN, 2018).

Monitored Anesthesia Care

Monitored anesthesia care (MAC), also referred to as monitored sedation, is moderate sedation given by an anesthesiologist or CRNA who must be prepared

and qualified to convert to general anesthesia if necessary. The skills of an anesthesiologist or CRNA may be necessary to manage the effects of a level of deeper sedation to return the patient to the appropriate level of sedation (Barash et al., 2017). MAC may be used for healthy patients undergoing relatively minor surgical procedures and for some critically ill patients who may be unable to tolerate anesthesia without extensive invasive monitoring and pharmacologic support (Rothrock, 2019).

Local Anesthesia

LA is the injection of a solution containing the anesthetic agent into the tissues at the planned incision site. Often it is combined with a local regional block by injecting around the nerves immediately supplying the area. A monitoring nurse (in addition to a circulating nurse) must be present during these cases. The monitoring nurse is responsible for documenting the patient's condition, pain level, level of consciousness, and vital signs throughout the procedure (AORN, 2019a). Advantages of LA are as follows:

- It is simple, economical, and nonexplosive.
- Equipment needed is minimal.
- Postoperative recovery is brief.
- Undesirable effects of general anesthesia are avoided.
- It is ideal for short and minor surgical procedures.

LA is often given in combination with epinephrine. Epinephrine constricts blood vessels, which prevents rapid absorption of the anesthetic agent and thus prolongs its local action and prevents seizures. Select local anesthetic agents are listed in Table 15-3; some of the same agents used in regional anesthesia are used as local anesthetic agents.

The skin is prepared as for any surgical procedure, and a small-gauge needle is used to inject a modest amount of the anesthetic medication into the skin layers. This produces blanching or a wheal. Additional anesthetic medication is then injected into the skin until an area surrounding the proposed incision is anesthetized. A larger, longer needle then is used to infiltrate deeper tissues with the anesthetic agent. The action of the agent is almost immediate, so surgery may begin shortly after the injection is complete. The anesthetic may be mixed with a fast-acting analgesic of short duration to circumvent the burning felt when the longer-acting anesthetics are injected.

Local Anesthetic Systemic Toxicity

Local Anesthetic Systemic Toxicity (LAST) is a potentially life-threatening event. LAST occurs when a bolus of LA is inadvertently injected into peripheral tissue or venous or arterial circulation during a PNB or spinal nerve block procedure and is rapidly absorbed into systemic circulation, resulting in cardiovascular or neurologic collapse (Ferguson, Coogle, Leppert, et al., 2019).

Signs and symptoms of LAST are:

- Metallic taste
- Oral numbness
- Auditory changes
- Slurred speech
- Arrhythmias
- Seizure
- Respiratory arrest

LAST is a rare event that occurs in approximately 1 of every 1000 patients (Wadlund, 2017). Early detection and treatment may prevent symptom progression and can lead to a better outcome for the patient. Initial treatment of LAST should focus on airway management. Hypoxemia and acidosis intensify the effects of LAST. The nurse calls for help and maintains the patient's airway while administering 100% oxygen and confirming IV access. Additional resources include members of the anesthesia team and critical-care nurses in the event that CPR or airway interventions take place. An IV infusion of lipid emulsions (an emulsion of soybean oil, egg phospholipids, and glycerin) can reverse the effects of LAST on the heart and central nervous system (AORN, 2019a; Wadlund, 2017).

Potential Intraoperative Complications

The surgical patient is subject to several risks. The major potential intraoperative complications include anesthesia awareness, nausea and vomiting, anaphylaxis, hypoxia, hypothermia, and malignant hyperthermia (MH). Targeted areas include SSIs as well as cardiac, respiratory, and venous thromboembolic complications (Joint Commission, 2019).

Anesthesia Awareness

It is important to discuss concerns about intraoperative awareness with patients preoperatively so that they realize that only general anesthesia is meant to create a state of oblivion. All other forms of anesthesia will eliminate pain, but sensation of pushing and pulling tissues may still be recognized and they may hear conversations among the operative team. In many cases, patients may be able to respond to questions and involve themselves in the discussion. This is normal and is not what is referred to as anesthesia awareness.

Unintended intraoperative awareness refers to a patient becoming cognizant of surgical interventions while under general anesthesia and then recalling the incident. Neuromuscular blocks, sometimes required for surgical muscle relaxation, intensify the fear of the patient experiencing awareness because they are then unable to communicate during the episode. Patients may or may not feel pain, and some patients experience a feeling of pressure. It has been estimated

that roughly 1 patient per 1000 receiving general anesthesia experiences some level of awareness that is most commonly fleeting (AANA, 2019a).

Indications of the occurrence of anesthesia awareness include an increase in the blood pressure, rapid heart rate, and patient movement. However, hemodynamic changes can be masked by paralytic medication, beta-blockers, and calcium channel blockers, thus the awareness may remain undetected. Premedication with amnesic agents and avoidance of muscle paralytics except when essential help to preclude its occurrence.

Nausea and Vomiting

Nausea and vomiting, or regurgitation, may affect patients during the intraoperative period. The patient should be assessed preoperatively for risk factors of PONV so that the surgical team can formulate a plan for intraoperative prevention. Risk factors include female gender, age less than 50 years, history of PONV, and opioid administration (Finch, Parkosewich, Perrone, et al., 2019).

If gagging occurs, the patient is turned to the side, the head of the table is lowered, and a basin is provided to collect the vomitus. Suction is used to remove saliva and vomited gastric contents. In some cases, the anesthesiologist or CRNA administers antiemetics preoperatively or intraoperatively to counteract possible aspiration. If the patient aspirates vomitus, an attack with severe bronchial spasms and wheezing is triggered. Pneumonitis and pulmonary edema can subsequently develop, leading to extreme hypoxia. Increasing medical attention is being paid to silent regurgitation of gastric contents (not related to preoperative fasting times), which occurs more frequently than previously realized. The volume and acidity of the aspirate determine the extent of damage to the lungs. Patients may be given citric acid and sodium citrate, a clear, nonparticulate antacid to increase gastric fluid pH or a histamine-2 (H_2) receptor antagonist such as cimetidine, or famotidine to decrease gastric acid production (Rothrock, 2019).

Anaphylaxis

Any time the patient comes into contact with a foreign substance, there is potential for an anaphylactic reaction. An anaphylactic reaction can occur in response to many medications, latex, or other substances. The reaction may be immediate or delayed. Anaphylaxis can be a life-threatening reaction.

Latex allergy—the sensitivity to natural rubber latex products—has become more prevalent, creating the need for alert responsiveness among health care professionals. If patients state that they have allergies to latex, even if they are wearing latex in their clothing, treatment must be latex free. In the OR, many products are latex free with the notable exception of softer latex catheters. Surgical cases should use latex-free gloves in anticipation of a possible allergy, and if no allergy is present, then personnel can switch to other gloves after the case starts if desired.

Fibrin sealants are used in various surgical procedures, and cyanoacrylate tissue adhesives are used to close wounds without the use of sutures. These sealants have been implicated in allergic reactions and anaphylaxis (Rothrock, 2019). Although these reactions are rare, the nurse must be alert to the possibility and observe the patient for changes in vital signs and symptoms of anaphylaxis when these products are used. In the OR, the team should remove potential causative agents promptly—within 3 minutes or less—of becoming aware of an anaphylactic reaction. The surgical team should be aware of the importance of prompt intervention to prevent cardiovascular and respiratory collapse (Seifert, 2017). (Chapters 11 and 33 provide more details about the signs, symptoms, and treatment of anaphylaxis and anaphylactic shock.)

Hypoxia and Other Respiratory Complications

Inadequate ventilation, occlusion of the airway, inadvertent intubation of the esophagus, and hypoxia are significant potential complications associated with general anesthesia. Many factors can contribute to inadequate ventilation. Respiratory depression caused by anesthetic agents, aspiration of respiratory tract secretions or vomitus, and the patient's position on the operating table can compromise the exchange of gases. Anatomic variation can make the trachea difficult to visualize and result in insertion of the artificial airway into the esophagus rather than into the trachea. In addition to these dangers, asphyxia caused by foreign bodies in the mouth; spasm of the vocal cords; relaxation of the tongue; or aspiration of vomitus, saliva, or blood can occur. Brain damage from hypoxia occurs within minutes; therefore, vigilant monitoring of the patient's oxygenation status is a primary function of the anesthesiologist or CRNA and the circulating nurse. Peripheral perfusion is checked frequently, and capnography readings are monitored continuously. Capnography provides instantaneous information about carbon dioxide production, pulmonary perfusion, and respiratory patterns that detect hypoventilation and apnea (Odom-Forren, 2018).

Hypothermia

During anesthesia, the patient's temperature may fall. Glucose metabolism is reduced, and as a result, metabolic acidosis may develop. This condition is called *hypothermia* and is indicated by a core body temperature that is lower than normal (36.6°C [98°F] or less). Risks of intraoperative hypothermia include cardiovascular events, SSIs, bleeding, and delayed arousal from anesthesia (Williams, 2018). Unintended hypothermia may occur as a result of a low temperature in the OR, infusion of cold fluids, inhalation of cold gases, open body wounds or cavities, decreased muscle activity, advanced age, or the pharmaceutical agents used (e.g., vasodilators, phenothiazines, general anesthetic medications). Hypothermia can depress neuronal activity and decrease cellular oxygen requirements below the minimum levels normally required for

continued cell viability. As a result, it is used to protect function during some surgical procedures (e.g., carotid endarterectomy, cardiopulmonary bypass) (Barash et al., 2017).

Unintended hypothermia needs to be avoided. If it occurs, it must be minimized or reversed. If hypothermia is intentional, the goal is safe return to normal body temperature. Environmental temperature in the OR can temporarily be set at 25° to 26.6°C (78° to 80°F). IV and irrigating fluids are warmed to 37°C (98.6°F). Wet gowns and drapes are removed promptly and replaced with dry materials, because wet materials promote heat loss. Warm air blankets and thermal blankets can also be used on the areas not exposed for surgery, and minimizing the area of the patient that is exposed will help maintain core temperature. Whatever methods are used to rewarm the patient, warming must be accomplished gradually, not rapidly. Conscientious monitoring of core temperature, urinary output, ECG, blood pressure, arterial blood gas levels, and serum electrolyte levels is required.

Malignant Hyperthermia

Malignant hyperthermia is a rare inherited muscle disorder that is chemically induced by anesthetic agents (Rothrock, 2019). This disorder can be triggered by myopathies, emotional stress, heatstroke, neuroleptic malignant syndrome, strenuous exercise exertion, and trauma. The incidence rate is 1 in every 170,698 general anesthetic cases (Phi, Carvalho, Sun, et al., 2018). MH occurs because of a genetic autosomal dominant disorder involving a mutation on the ryanodine receptor that causes an atypical increase in release of calcium in muscle cells (Mullins, 2018). Susceptible people include those with strong and bulky muscles, a history of muscle cramps or muscle weakness and unexplained temperature elevation, and an unexplained death of a family member during surgery that was accompanied by a febrile response (Ho, Carvalho, Sun, et al., 2018).

Pathophysiology

During anesthesia, potent agents such as inhalation anesthetic agents (i.e., halothane, enflurane, isoflurane) and muscle relaxants (succinylcholine) may trigger the symptoms of malignant hyperthermia (Rothrock, 2019). Stress and some medications, such as sympathomimetics (epinephrine), theophylline, aminophylline, anticholinergics (atropine), and cardiac glycosides (digitalis), can induce or intensify a reaction.

The pathophysiology of MH is related to a hypermetabolic condition that involves altered mechanisms of calcium function in skeletal muscle cells. This disruption of calcium causes clinical symptoms of hypermetabolism, which in turn increases muscle contraction (rigidity) and causes hyperthermia and subsequent damage to the central nervous system.

Clinical Manifestations

The initial symptoms of MH are often cardiovascular, respiratory, and abnormal musculoskeletal activity. Tachycardia (heart rate greater than 150 bpm) may be an early sign. Sympathetic nervous stimulation also leads to ventricular arrhythmia, hypotension, decreased cardiac output, oliguria, and, later, cardiac arrest. Hypercapnia, an increase in carbon dioxide (CO_2), may be an early respiratory sign. With the abnormal transport of calcium, rigidity or tetanuslike movements occur, often in the jaw. Generalized muscle rigidity is one of the earliest signs. The rise in temperature is actually a late sign that develops rapidly; body temperature can increase 1° to 2°C (2° to 4°F) every 5 minutes, and core body temperature can exceed 42°C (107°F) (Rothrock, 2019).

Medical Management

Goals of treatment are to decrease metabolism, reverse metabolic and respiratory acidosis, correct arrhythmias, decrease body temperature, provide oxygen and nutrition to tissues, and correct electrolyte imbalance. The treatment for MH is well known. Use of dantrolene has lowered mortality rates to 10% in current practice (Ho et al., 2018). The Malignant Hyperthermia Association of the United States (MHAUS) publishes a treatment protocol that should be posted in the OR and be readily available on a MH cart (see Resources section).

Anesthesia and surgery should be postponed. However, if end-tidal CO_2 monitoring and dantrolene sodium are available and the anesthesiologist is experienced in managing MH, the surgery may continue using a different anesthetic agent (Barash et al., 2017). Although MH usually manifests about 10 to 20 minutes after induction of anesthesia, it can also occur during the first 24 hours after surgery.

Nursing Management

Although MH is uncommon, the nurse must identify patients at risk, recognize the signs and symptoms, have the appropriate medication and equipment available, and be knowledgeable about the protocol to follow. Preparation and early intervention may be lifesaving for the patient.

NURSING PROCESS

The Patient during Surgery

Intraoperative nurses focus on nursing diagnoses, interventions, and outcomes that surgical patients and their families experience. Additional priorities include collaborative problems and expected goals.

Assessment

Nursing assessment of the intraoperative patient involves obtaining data from the patient and the patient's medical record to identify factors that can affect care. These serve as guidelines for an individualized plan of patient care. The intraoperative nurse uses the focused preoperative nursing assessment documented on the patient record. This includes assessment of physiologic status (e.g., health–illness level, level of consciousness), psychosocial status (e.g., anxiety level, verbal communication problems, coping mechanisms), physical status (e.g., surgical site, skin condition, and effectiveness of preparation; mobility of joints), and ethical concerns.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include the following:

- Anxiety associated with surgical or environmental concerns
- Risk for latex allergy
- Risk for perioperative positioning injury associated with positioning in the OR
- Risk for injury associated with anesthesia and surgical procedure
- Risk for compromised dignity associated with general anesthesia or sedation

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications may include the following:

- Anesthesia awareness
- Nausea and vomiting
- Anaphylaxis
- Hypoxia
- Unintentional hypothermia
- Malignant hyperthermia
- Infection

Planning and Goals

The major goals for care of the patient during surgery include reduced anxiety, absence of latex exposure, absence of positioning injuries, freedom

from injury, maintenance of the patient's dignity, and absence of complications.

Nursing Interventions

Reducing Anxiety

Preoperatively, the intraoperative nurse visiting the patient can help decrease anxiety and promote a relationship of communication and trust. The effect of familiarizing patients revealed significant decreased preoperative and postoperative anxiety (Bagheri, Ebrahimi, Abbasi, et al., 2019). The patient should be notified of what to expect when entering the operating room, and the nurse should inquire about any patient-specific relaxation preferences. The OR environment can seem cold, stark, and frightening to the patient, who may be feeling isolated and apprehensive. Introducing yourself, addressing the patient by name warmly and frequently, verifying details, providing explanations, and encouraging and answering questions provide a sense of professionalism and friendliness that can help the patient feel safe and secure. When discussing what the patient can expect in surgery, the nurse uses basic communication skills, such as touch and eye contact, to reduce anxiety. Attention to physical comfort (warm blankets, padding, position changes) helps the patient feel more comfortable. Telling the patient who else will be present in the OR, how long the procedure is expected to take, and other details helps the patient prepare for the experience and gain a sense of control.

The circulating nurse may assist to decrease anxiety during induction by using techniques such as guided imagery, decreasing room stimuli by dimming the lights, having the patient's favorite music playing, or by talking in a soft voice and using eye contact, if culturally appropriate.

Reducing Latex Exposure

Patients with latex allergies require early identification and communication to all personnel about the presence of the allergy according to standards of care for patients with latex allergy (AORN, 2019a). In most ORs, there are few latex items currently in use, but because there still remain some instances of latex use, maintenance of latex allergy precautions throughout the perioperative period must be observed. For safety, manufacturers and hospital materials managers need to take responsibility for identifying the latex content in items used by patients and health care personnel. (See Chapters 14 and 33 for assessment for latex allergy.)

Quality and Safety Nursing Alert

It is the responsibility of all nurses, and particularly perianesthesia and perioperative nurses, to be aware of latex allergies, necessary precautions, and products that are latex free. Hospital staff are also at risk for development of a latex allergy secondary to repeated exposure to latex products.

Preventing Perioperative Positioning Injury

The patient's position on the operating table depends on the surgical procedure to be performed as well as the patient's physical condition (see Fig. 15-6). One type of injury, peripheral nerve injury, is defined as the interruption of electrical activity that affects either the sensory, motor, or both nerve functions resulting in a deficit. Studies suggest a correlation between total OR time and tissue breakdown (Grap, Schubert, Munro, et al., 2019). See Chart 15-3 for a Nursing Research Profile that investigated these occurrences. The potential for transient discomfort or permanent injury is present because many surgical procedures require awkward anatomical positions. Hyperextending joints, compressing arteries, or pressing on nerves and bony prominences usually results in discomfort simply because the position must be sustained for a long period of time (Rothrock, 2019). Factors to consider include the following:

Chart 15-3 NURSING RESEARCH PROFILE

Sacral Tissue Pressure Injury Prevalence in Surgical Patients

Grap, M. J., Schubert, C., Munro, C. L., et al. (2019). OR time and sacral pressure injuries in critically ill surgical patients. *AORN Journal, 109*(2), 229–239.

Purpose

The ability to identify early changes associated with pressure injury and OR time may enhance pressure injury prevention strategies. The purpose of this study was to explore the relationship between OR time and sacral pressure injuries in critically ill patients using high-frequency ultrasound (HFU) to identify early tissue changes.

Design

A secondary analysis was used to evaluate the effect of backrest elevation on 150 ventilated patients in the ICU post surgery. All of the patients had recorded OR time and the Braden Score was collected to identify patients at risk for surgical pressure injury.

Findings

One hundred and fifty participants were enrolled and 132 had skin evaluations. The majority of participants were middle-aged White males (58%), overweight, and had a Braden Scale score showing moderate risk for pressure injury. Total OR time ranged from just under 1 hour to more than 13 hours, with an average time of more than 4 hours. For those participants who developed pressure injuries, time between the OR and injury observed was approximately 2 to 3 days on average. Approximately 63% of participants did not have sacral pressure injuries at any point during the observation period. Using multivariable models, the model containing OR bed time, BMI, and Braden Scale score produced the best prediction of pressure injury. A higher BMI, shorter OR bed time, and lower Braden Scale score were associated with a greater chance of pressure injury.

Nursing Implications

Preventing pressure injuries are a priority for nurses in all setting and is particularly challenging for critical-care patients. These preliminary results demonstrate that the use of HFU may help nurses identify the development of tissue changes before observable skin changes, leading to earlier pressure injury prevention strategies.

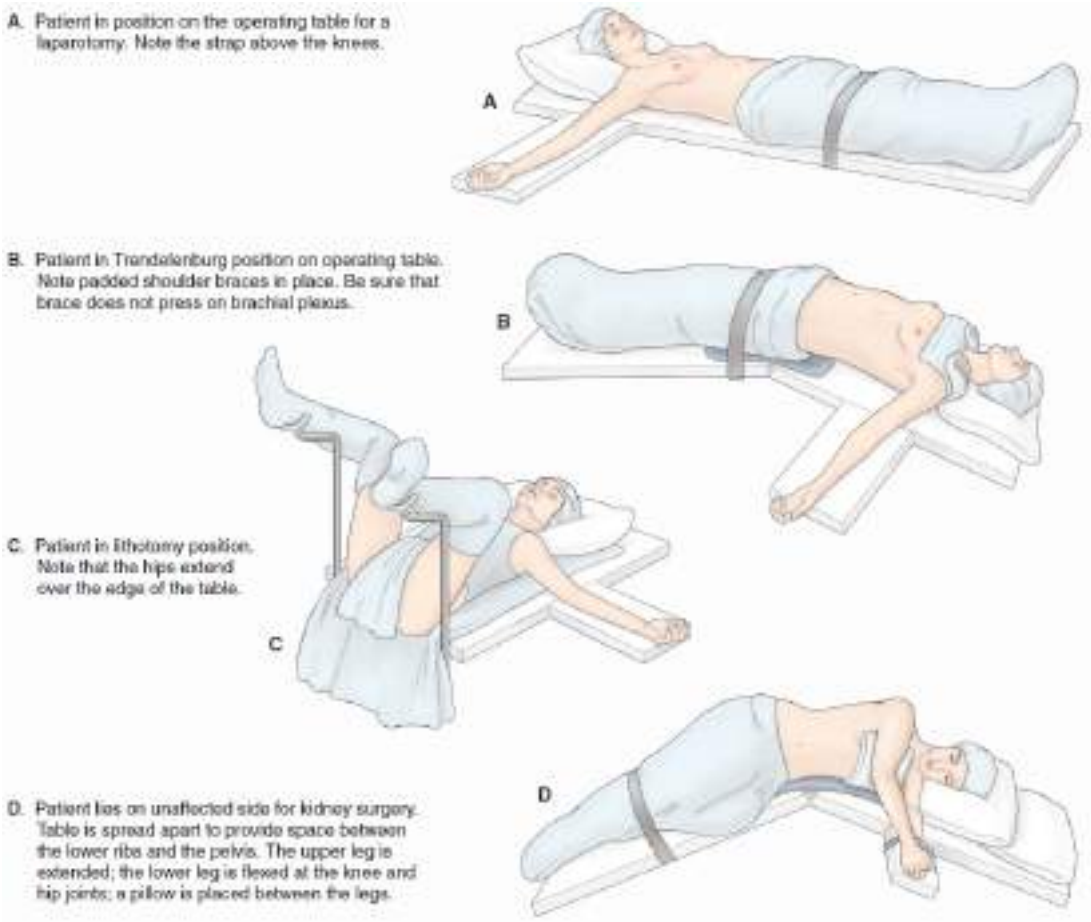

Figure 15-6 • Patient positions on the operating table. Captions call attention to safety and comfort features. All surgical patients wear caps to cover the hair completely.

- The patient should be in as comfortable a position as possible, whether conscious or unconscious.
- The operative field must be adequately exposed.
- An awkward anatomical position, undue pressure on a body part, or the use of stirrups or traction should not obstruct the vascular supply.
- Respiration should not be impeded by pressure of arms on the chest or by a gown that constricts the neck or chest.
- Nerves must be protected from undue pressure. Improper positioning of the arms, hands, legs, or feet can cause serious injury or paralysis. Shoulder braces must be well padded to prevent irreparable nerve injury, especially when the Trendelenburg position is necessary.
- Precautions for patient safety must be observed, particularly with older adults, patients who are thin or obese, and those with a physical deformity.
- The patient may need light restraint before induction in case of excitement.

The usual position for surgery, called the *dorsal recumbent position,* is flat on the back. Both arms are positioned at the side of the table: one with the hand placed palm down and the other carefully positioned on an armboard to facilitate IV infusion of fluids, blood, or medications. This position is used for most abdominal surgeries, except for surgery of the gallbladder or pelvis (see Fig. 15-6A).

The Trendelenburg position usually is used for surgery on the lower abdomen and pelvis to obtain good exposure by displacing the intestines into the upper abdomen. In this position, the head and body are lowered. The patient is supported in position by padded shoulder braces (see Fig. 15-6B), bean bags, and foam padding. Reverse Trendelenburg position provides the space to operate on the upper abdomen by shifting the intestines into the pelvis. A padded footboard and other supportive cushioning preserve a safe environment for the patient.

The lithotomy position is used for nearly all perineal, rectal, and vaginal surgical procedures (see Fig. 15-6C). The patient is positioned on the back with the legs and thighs flexed. The position is maintained by placing the feet in stirrups.

The Sims or lateral position is used for renal surgery. The patient is placed on the nonoperative side with an air pillow 12.5 to 15 cm (5 to 6 inches) thick under the loin, or on a table with a kidney or back lift (see Fig. 15-6D).

Protecting the Patient from Injury

Various activities are used to address the diverse patient safety issues that arise in the OR. The nurse protects the patient from injury by providing a safe environment. Verifying information, checking the medical record for completeness, and maintaining surgical asepsis and an optimal environment are critical nursing responsibilities. Verification that all the required documentation is completed is an important function of the intraoperative nurse. A surgical checklist is used prior to induction of anesthesia, before the skin incision is made, and before the patient leaves the OR (see Fig. 15-1). It is important to review the patient's record for the following:

- Allergies (including latex)
- Correct informed surgical consent, with patient's signature
- Completed records for health history and physical examination
- Results of diagnostic studies

In addition to checking that all necessary patient data are complete, the perioperative nurse obtains the necessary equipment specific to the procedure. The need for nonroutine medications, blood components, instruments, and other equipment and supplies is assessed, and the readiness of the room, completeness of physical setup, and completeness of instrument, suture, and dressing setups are determined. Any aspects of the OR environment that may negatively affect the patient are identified. These include physical features, such as room temperature and humidity; electrical

hazards; potential contaminants (dust, blood, and discharge on floor or surfaces; uncovered hair; nonsterile attire of personnel; jewelry worn by personnel; chipped or artificial fingernails); and unnecessary traffic. The circulating nurse also sets up and maintains suction equipment in working order, initiates appropriate physical comfort measures for the patient, and prepares any potential implantable devices and medications used at the surgical field.

Preventing physical injury includes using safety straps and side rails and not leaving the sedated patient unattended. Transferring the patient from the stretcher to the OR table requires safe transferring practices. Other safety measures include properly positioning a grounding pad under the patient to prevent electrical burns and shock, removing excess antiseptic solution from the patient's skin, and promptly and completely draping exposed areas after the sterile field has been created to decrease the risk of hypothermia.

Nursing measures to prevent injury from excessive blood loss include blood conservation using equipment such as a cell saver (a device for recirculating the patient's own blood cells) and administration of blood products (Rothrock, 2019). Fewer patients undergoing an elective procedure require blood transfusion, but those undergoing high-risk procedures (such as orthopedic or cardiac surgeries) may require an intraoperative transfusion. The circulating nurse anticipates this need, checks that blood has been cross-matched and held in reserve, and is prepared to administer blood.

Serving as Patient Advocate

The patient undergoing general anesthesia or moderate sedation experiences temporary sensory or perceptual alteration or loss, and has an increased need for protection and advocacy. Patient advocacy in the OR entails maintaining the patient's physical and emotional comfort, privacy, rights, and dignity. Patients, whether conscious or unconscious, should not be subjected to excess noise, inappropriate conversation, or, most of all, derogatory comments. Other advocacy activities include minimizing the clinical, dehumanizing aspects of being a surgical patient by making sure that the patient is treated as a person, respecting cultural and spiritual values, providing physical privacy, maintaining confidentiality, and contacting approved family or support personnel about updates throughout the procedure.

Preventing Retained Surgical Items

It is the entire surgical team's responsibility to provide vigilance and communication regarding items entering and leaving the surgical site. As part of their responsibilities, the circulating nurse and scrub personnel must account for items introduced to the sterile field. This includes sponges, needles, instruments, and access devices. Some of these items are radiopaque (visible under x-ray), others are not. All items must be accounted for at the beginning of surgery, prior to wound closure, and again at skin closure. The nurse serves as a patient advocate to alert the team of any missing items.

Technology can assist in surgical item identification; however, it should not be used as the primary source for counting.

Monitoring and Managing Potential Complications

It is the responsibility of the surgeon and the anesthesiologist or CRNA to monitor and manage complications. However, intraoperative nurses also play an important role. Being alert to and reporting changes in vital signs, cardiac arrhythmias, symptoms of nausea and vomiting, anaphylaxis, hypoxia, hypothermia, and MH and assisting with their management are important nursing functions. Each of these complications was discussed earlier. Maintaining asepsis and preventing infection are responsibilities of all members of the surgical team (Rothrock, 2019). Evidence-based interventions to decrease SSIs include appropriate skin preparation and antibiotic administration. These interventions are discussed by the surgical team and documented by the nurse in the intraoperative record.

Evaluation

Expected patient outcomes may include:

1. Exhibits low level of anxiety while awake during the intraoperative phase of care
2. Has no symptoms of latex allergy
3. Remains free of perioperative positioning injury
4. Experiences no unexpected threats to safety
5. Has dignity preserved throughout OR experience
6. Is free of complications (e.g., cardiac arrhythmias, nausea and vomiting, anaphylaxis, hypoxia, hypothermia, or MH or experiences successful management of adverse effects of surgery and anesthesia should they occur)

CRITICAL THINKING EXERCISES

1 ebp A 48-year-old man is scheduled to have robotic-assisted abdominal surgery. What is the best evidence for how his vital signs should be monitored? As the OR nurse, what best practices should you implement to support the patient and OR team during this minimally invasive surgery?

2 ipc A 66-year-old woman with chronic obstructive pulmonary disease (COPD) is scheduled for an elective procedure to remove a lipoma on her chest. She is having problems breathing, is agitated, and cannot lie flat on the surgical bed. How will you, as the circulating nurse, facilitate an interprofessional discussion to improve the patient's breathing and relieve her agitation? Which members of the surgical team are essential to include?

3 pq Identify the priorities, assessments, and nursing interventions you would implement for a 76-year-old female patient who is hard of hearing and is having spinal anesthesia for total knee replacement surgery. How would your priorities, approach, and techniques differ if the patient is having general anesthesia? What other risks should be considered based on this patient's age?

16 Postoperative Nursing Management

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the responsibilities of the postanesthesia care nurse in the prevention of immediate postoperative complications.
2. Identify common postoperative problems and their management.
3. Explain variables that affect wound healing and surgical site infections.
4. Implement nursing care to enhance recovery in the postoperative phase.
5. Use the nursing process as a framework for care of the hospitalized patient recovering from surgery.

NURSING CONCEPTS

Assessment
Infection
Managing Care

GLOSSARY

dehiscence: partial or complete separation of wound edges

evisceration: protrusion of organs through the surgical incision

first-intention healing: method of healing in which wound edges are surgically approximated and integumentary continuity is restored without granulation

phase I PACU: area designated for care of surgical patients immediately after surgery and for patients whose condition warrants close monitoring

phase II PACU: area designated for care of surgical patients who have been transferred from a phase I PACU because their condition no longer requires the close monitoring provided in a phase I PACU. The patient is prepared for transfer to an inpatient unit or for discharge from the facility

postanesthesia care unit (PACU): area where postoperative patients are monitored as they recover from anesthesia

second-intention healing: method of healing in which wound edges are not surgically approximated and integumentary continuity is restored by the process known as granulation

The postoperative period extends from the time the patient leaves the operating room (OR) until the last follow-up visit with the surgeon. This may be as short as a day or two or as long as several months. During the postoperative period, nursing care focuses on reestablishing the patient's physiologic equilibrium, alleviating pain, preventing complications, and educating the patient about self-care. Careful assessment and immediate intervention assist the patient in returning to optimal function quickly, safely, and as comfortable as possible. Ongoing care in the community through home care, clinic visits, office visits, or telephone follow-up facilitates an uncomplicated recovery.

Care of the Patient in the Postanesthesia Care Unit

The **postanesthesia care unit** (PACU) is located adjacent to the OR suite. Patients still under anesthesia or recovering from anesthesia are placed in this unit for easy access to experienced, highly skilled nurses, anesthesia providers, surgeons, advanced hemodynamic and pulmonary monitoring and support, special equipment, and medications.

Phases of Postanesthesia Care

In some hospitals and ambulatory surgical centers, postanesthesia care is divided into two phases (Rothrock, 2019). In the **phase I PACU**, used during

the immediate recovery phase, intensive nursing care is provided. After this phase, the patient transitions to the next phase of care as either an inpatient to a nursing unit or phase II PACU. In the **phase II PACU**, the patient is prepared for transfer to an inpatient nursing unit, an extended care setting, or discharge. Recliners rather than stretchers or beds are standard in many phase II units, which may also be referred to as step-down, sit-up, or progressive care units. Patients remain in PACU until they have met predetermined discharge criteria, depending on the type of surgery and any preexisting conditions or comorbidities. In facilities without separate phase I and II units, the patient remains in the PACU and may be discharged home directly from this unit.

Admitting the Patient to the Postanesthesia Care Unit

Transferring the postoperative patient from the OR to the PACU is the responsibility of the anesthesiologist or certified registered nurse anesthetist (CRNA) and other licensed members of the OR team. During transport from the OR to the PACU, the anesthesia provider remains at the head of the stretcher (to maintain the airway), and a surgical team member remains at the opposite end. Transporting the patient involves special consideration of the incision site, potential vascular changes, and exposure. The surgical incision is considered every time the postoperative patient is moved; many wounds are closed under considerable tension, and every effort is made to prevent further strain on the incision. The patient is positioned so that they are not lying on and obstructing drains or drainage tubes. Orthostatic hypotension may occur when a patient is moved too quickly from one position to another (e.g., from a lithotomy position to a horizontal position or from a lateral to a supine position), so the patient must be moved slowly and carefully. As soon as the patient is placed on the stretcher or bed, the soiled gown is removed and replaced with a dry gown. The patient is covered with lightweight blanket or a forced air warming blanket.

The nurse who admits the patient to the PACU reviews essential information with the anesthesiologist or CRNA (see Chart 16-1) and the circulating nurse. Oxygen is applied, monitoring equipment is attached, and an immediate physiologic assessment is conducted.

Chart 16-1

Anesthesia Provider-to-Nurse Report and Nurse-to-Nurse Report: Information to Convey

- Patient name, gender, age
- Allergies
- Surgical procedure
- Position during the procedure
- Length of time in the operating room
- Anesthetic agents and reversal agents used
- Estimated blood loss/fluid loss
- Fluid/blood replacement
- Last set of vital signs and any problems during the procedure (e.g., nausea and/or vomiting)
- Any complications encountered (anesthetic or surgical)
- Medical comorbidities (e.g., diabetes, hypertension)
- List of allergies and medications taken at home (including pain medications, antihypertensives, and anticoagulants)
- Considerations for immediate postoperative period (pain management, reversals, ventilator settings)
- Language barrier
- Location of patient's family

Ideally, the anesthesia provider should not leave the patient until the nurse is satisfied with the patient's airway and immediate condition.

Nursing Management in the Postanesthesia Care Unit

The nursing management objectives for the patient in the PACU are to provide care until the patient has recovered from the effects of anesthesia. PACU nurses have unique competencies as they care for patients who have undergone a wide range of surgical procedures. Recovery criteria include a return to baseline cognitive function, the airway is clear, nausea and vomiting is controlled, and vital signs are stabilized. The nurse in the PACU uses critical care skills and training to detect early subtle changes that could lead to complications (i.e., hemorrhage or respiratory distress) without intervention (American Society of PeriAnesthesia Nurses [ASPAN], 2019; Odom-Forren, 2018).

Some patients, particularly those who have had extensive or lengthy surgical procedures, may be transferred from the OR directly to the intensive care unit (ICU) or from the PACU to the ICU while still intubated and receiving mechanical ventilation. In most facilities, the patient is awakened and extubated in the OR (except in cases of trauma or critical illness) and arrives in the PACU breathing without ventilatory support.

Assessing the Patient

The nurse performs frequent, basic assessments of every postoperative patient. These assessments include airway, level of consciousness, cardiac, respiratory, wound, and pain. The patient's comorbidities and type of procedure will dictate additional assessments such as peripheral pulses, hemodynamics, and surgical drain placements (Odom-Forren, 2018). A baseline of any postanesthesia assessment scoring tool, such as the Aldrete score, is performed at this time as well (Aldrete & Wright, 1992). See discussion of this score later in this chapter.

The nurse performs and documents a baseline assessment, checks all drainage tubes, and verifies that monitoring lines are connected and functioning. IV fluids and medications currently infusing are checked, and the nurse verifies that they are infusing at the correct dosage and rate. Vital signs are assessed at time of arrival to PACU and repeated at intervals (i.e., every 5 or 15 minutes) per institutional protocol. The nurse must be aware of any pertinent information from the patient's history that may be significant (e.g., patient is deaf or hard of hearing, has a history of seizures, has diabetes, or is allergic to certain medications or to latex).

Concept Mastery Alert

Following surgery, patients who had ketamine as anesthesia must be placed in a quiet, darkened area of the PACU. See Chapter 15, Table 15-2 for more information about anesthetic agents.

Maintaining a Patent Airway

The primary objective in the immediate postoperative period is to maintain ventilation and thus prevent hypoxemia (reduced oxygen in the blood) and hypercapnia (excess carbon dioxide in the blood). Both can occur if the airway is obstructed and ventilation is reduced (hypoventilation). Besides administering supplemental oxygen as prescribed, the nurse assesses respiratory rate and depth, ease of respirations, oxygen saturation, and breath sounds.

Figure 16-1 • A. A hypopharyngeal obstruction occurs when neck flexion permits the chin to drop toward the chest; obstruction almost always occurs when the head is in the midposition. **B.** Tilting the head back to stretch the anterior neck structure lifts the base of the tongue off the posterior pharyngeal wall. The direction of the *arrows* indicates the pressure of the hands. **C.** Opening the mouth is necessary to correct a valvelike obstruction of the nasal passage during expiration, which occurs in about 30% of unconscious patients. Open the patient's mouth (separate lips and teeth) and move the lower jaw forward so that the lower teeth are in front of the upper teeth. To regain backward tilt of the neck, lift with both hands at the ascending rami of the mandible.

Patients who have experienced prolonged anesthesia usually are unconscious, with all muscles relaxed. This relaxation extends to the muscles of the pharynx. When the patient lies on the back, the lower jaw and the tongue fall backward and the air passages become obstructed (Fig. 16-1A). This is called *hypopharyngeal obstruction.* Signs of occlusion include choking; noisy and irregular respirations; decreased oxygen saturation scores; and, within minutes, a blue, dusky color (cyanosis) of the skin. Because movement of the thorax and the diaphragm does not necessarily indicate that the patient is breathing, the nurse needs to place the palm of the hand at the patient's nose and mouth to feel the exhaled breath.

Quality and Safety Nursing Alert

The treatment of hypopharyngeal obstruction involves tilting the head back and pushing forward on the angle of the lower jaw, as if to push the lower teeth in front of the upper teeth (see Fig. 16-1B,C). This maneuver pulls the tongue forward and opens the air passages.

The anesthesiologist or CRNA may place a temporary, hard rubber or plastic airway in the patient's mouth to maintain a patent airway (see Fig. 16-2). Such a device should not be removed until signs such as gagging indicate

that reflex action is returning. Alternatively, the patient may enter the PACU with an endotracheal tube still in place and may require continued mechanical ventilation. The nurse assists in initiating the use of the ventilator as well as the weaning and extubation processes.

If the teeth are clenched, the mouth may be opened manually but cautiously with a padded tongue depressor. The head of the bed is elevated 15 to 30 degrees unless contraindicated, and the patient is closely monitored to maintain the airway as well as to minimize the risk of aspiration. If vomiting occurs, the patient is turned to the side to prevent aspiration and the vomitus is collected in the emesis basin. Mucus or vomitus obstructing the pharynx or the trachea is suctioned with a pharyngeal suction tip or a nasal catheter introduced into the nasopharynx or oropharynx to a distance of 15 to 20 cm (6 to 8 inch). Caution is necessary in suctioning the throat of a patient who has had a tonsillectomy or other oral or laryngeal surgery because of the risk of bleeding and discomfort.

Maintaining Cardiovascular Stability

To monitor cardiovascular stability, the nurse assesses the patient's level of consciousness; vital signs; cardiac rhythm; skin temperature, color, and moisture; and urine output. The nurse also assesses the patency of all IV lines. The primary cardiovascular complications seen in the PACU include hypotension and shock, hemorrhage, hypertension, and arrhythmias.

In patients who are critically ill, have significant comorbidity, or have undergone riskier procedures, additional monitoring may have been done in the OR and will continue in the PACU. These may include central venous pressure, pulmonary artery pressure, pulmonary artery wedge pressure, and cardiac output.

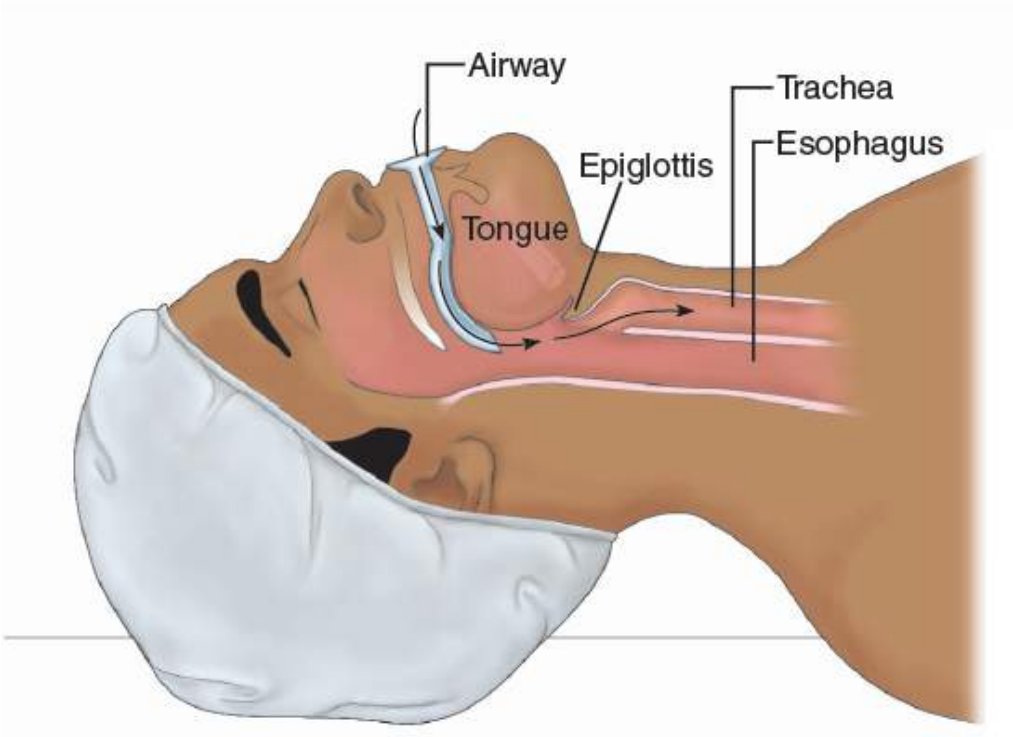

Figure 16-2 • The use of an airway to maintain a patent airway after anesthesia. The airway passes over the base of the tongue and permits air to pass into the pharynx in the region of the epiglottis. Patients often leave the operating room with an airway in place. The airway should remain in place until the patient recovers sufficiently to breathe normally. As the patient regains consciousness, the airway usually causes irritation and should be removed.

Hypotension and Shock

Hypotension can result from blood loss, hypoventilation, position changes, pooling of blood in the extremities, or side effects of medications and anesthetics. The most common cause is loss of circulating volume through blood and plasma loss. If the amount of blood loss exceeds 500 mL (especially if the loss is rapid), replacement may be considered.

Quality and Safety Nursing Alert

A systolic blood pressure of less than 90 mm Hg is usually considered immediately reportable. However, the patient's preoperative or baseline blood pressure is used to make informed postoperative comparisons. A previously stable blood pressure that shows a downward trend of 5 mm Hg at each 15-minute reading should also be reported.

Types of shock are classified as hypovolemic, cardiogenic, neurogenic, anaphylactic, and septic. The most common type of shock in the postoperative setting is hypovolemic and is associated with hemorrhage from the surgical site (Odom-Forren, 2018). The classic signs of hypovolemic shock are pallor; cool, moist skin; rapid breathing; cyanosis of the lips, gums, and tongue; rapid, weak, thready pulse; narrowing pulse pressure; low blood pressure; and concentrated urine (see Chapter 11 for a detailed discussion of shock).

Hypovolemic shock can be avoided largely by the timely administration of IV fluids, blood, blood products, and medications that elevate blood pressure. The primary intervention for hypovolemic shock is volume replacement, with an infusion of lactated Ringer solution, 0.9% sodium chloride solution, colloids, or blood component therapy (see Chapter 11, Table 11-3). Oxygen is given by nasal cannula, facemask, or mechanical ventilation. If fluid administration fails to reverse hypovolemic shock, then various cardiac, vasodilator, and corticosteroid medications may be prescribed to improve cardiac function and reduce peripheral vascular resistance.

The PACU bed can readily be positioned to facilitate the use of measures to counteract shock. The patient is placed flat with the legs elevated, usually with a pillow. Respiratory rate, pulse rate, blood pressure, blood oxygen concentration, urinary output, and level of consciousness are monitored to provide information on the patient's respiratory and cardiovascular status. Vital signs are monitored continuously until the patient's condition has stabilized.

Other factors can contribute to hemodynamic instability, such as body temperature and pain. The PACU nurse implements measures to manage these factors. The nurse keeps the patient warm (while avoiding overheating to prevent cutaneous vessels from dilating and depriving vital organs of blood), avoids exposure, and maintains normothermia (to prevent vasodilation). Pain control measures are implemented, as discussed later in this chapter.

Hemorrhage

Hemorrhage is an uncommon yet serious complication of surgery that can result in hypovolemic shock and death. It can present insidiously or emergently at any time in the immediate postoperative period or up to several days after surgery (see Table 16-1). The patient presents with hypotension; rapid, thready pulse; disorientation; restlessness; oliguria; and cold, pale skin. The early phase of shock will manifest in feelings of apprehension, decreased cardiac output, and vascular resistance. Breathing becomes labored, and "air hunger" will be exhibited; the patient will feel cold (hypothermia) and may experience tinnitus. Laboratory values may show a sharp drop in hemoglobin and hematocrit levels. If shock symptoms are left untreated, the patient will continually grow weaker but can remain conscious until near death (Rothrock, 2019).

TABLE 16-1 Types of Hemorrhage

Classification	Defining Characteristic
Time Frame	
Primary	Hemorrhage occurs at the time of surgery.
Intermediary	Hemorrhage occurs during the first few hours after surgery when the rise of blood pressure to its normal level dislodges insecure clots from nonanastomosed vessels.
Secondary	Hemorrhage may occur sometime after surgery if a suture slips because a blood vessel was not securely anastomosed, became infected, or was eroded by a drainage tube.
Type of Vessel	
Capillary	Hemorrhage is characterized by slow, general ooze.
Venous	Darkly colored blood flows quickly.
Arterial	Blood is bright red and appears in spurts with each heartbeat.
Visibility	
Evident	Hemorrhage is on the surface and can be seen.
Concealed	Hemorrhage is in a body cavity and cannot be seen.

Determining the cause of hemorrhage includes assessing the surgical site and incision for bleeding. If bleeding is evident, a sterile gauze pad and a pressure dressing are applied, and the site of the bleeding is elevated to heart level if possible. The patient is placed in the shock position (flat on back; legs elevated at a 20-degree angle; knees kept straight). Severe bleeding requires immediate action by the nurse. The surgeon is called and preparations are made to return the patient to the OR for ligation of bleeding veins and arteries, hematoma evacuation, or other necessary surgical interventions to stop the bleeding (Odom-Forren, 2018).

If hemorrhage is suspected, the nurse should be aware of any special considerations related to blood loss replacement. The treatment of hemorrhage is infusion of crystalloid and possibly blood product. Patients with blood loss of over 1500 mL should be considered for blood administration (Henry, 2018). Nurses in the PACU should be aware that patients may decline blood transfusions for religious or cultural reasons and may identify this request on their advance directives or living will.

Hypertension and Arrhythmias

Hypertension is common in the immediate postoperative period secondary to sympathetic nervous system stimulation from pain, hypoxia, or bladder distention. Arrhythmias are associated with electrolyte imbalance, altered respiratory function, pain, hypothermia, stress, and anesthetic agents. Both hypertension and arrhythmias are managed by treating the underlying causes.

Relieving Pain and Anxiety

The nurse in the PACU monitors the patient's physiologic status, manages pain, and provides psychological support in an effort to relieve the patient's fears and concerns. The nurse checks the electronic health record (EHR) for special needs and concerns of the patient. Opioid analgesic medications are given mostly by IV in the PACU (Rothrock, 2019). IV opioids provide immediate pain relief and are short acting, thus minimizing the potential for drug interactions or prolonged respiratory depression while anesthetics are still active in the patient's system (Barash, Cullen, Stoelting, et al., 2017). (See Chapter 9 for more information about pain management.) When the patient's condition permits, a close member of the family may visit in the PACU to decrease the family's anxiety and make the patient feel more secure. The nurse should consider providing nonpharmacologic, emotional, and psychological support to the patient. These include massage, acupuncture, heat or cold packs, relaxation and breathing techniques, guided imagery, and soothing music (Odom-Forren, 2018).

Controlling Nausea and Vomiting

Postoperative nausea and vomiting (PONV) occurs in about 30% to 50% of surgical patients (Thomas, Maple, Williams, et al., 2019). The nurse should intervene at the patient's first report of nausea to control the problem rather than wait for it to progress to vomiting.

Quality and Safety Nursing Alert

At the slightest indication of nausea, the patient is turned completely to one side to promote mouth drainage and prevent aspiration of vomitus, which can cause pneumonia, asphyxiation, and death.

PONV is controlled via medication administered intraoperatively and postoperatively. Table 16-2 contains select medications prescribed to control PONV. Studies suggest that nonpharmacologic measures, such as aromatherapy, may be effective for PONV prevention and treatment (Asay, Olson, Donnelly, et al., 2019). Aromatherapy inhalers with ginger, lavender, spearmint, and peppermint are a complementary, homeopathic, and a nonpharmacologic option (de la Vega, Gilliand, Martinez, et al., 2019).

Risk factors for PONV are female gender, age less than 50 years, history of nausea or vomiting after previous anesthesia, and opioid administration (Finch, Parkosewich, Perrone, et al., 2019). Surgical risks are increased with PONV due to an increase in intra-abdominal pressure, elevated central venous pressure, the potential for aspiration, increased heart rate, and systemic blood pressure, which increase the risk of myocardial ischemia and arrhythmias.

Aside from PONV as an unpleasant and uncomfortable experience, it may lead to dehydration, electrolyte imbalances, airway compromise, stress on suture lines or incision dehiscence, esophageal tears, hypotension, and increased length of stay in the recovery room (Asay et al., 2019). Chart 16-2 contains a Nursing Research Profile about PONV.

Gerontologic Considerations

The older patient, like all patients, is transferred from the OR table to the bed or stretcher slowly and gently. The effects of this action on blood pressure and ventilation are monitored. Special attention is given to keeping the patient warm, because older adults are more susceptible to hypothermia. The patient's position is changed frequently to stimulate respirations as well as promote circulation and comfort.

TABLE 16-2 Select Medications Used to Control Postoperative Nausea and Vomiting

Drug Classes	Name	Nursing Implications
GI stimulant	Metoclopramide	Acts by stimulating gastric emptying and increasing GI transit time. Administration recommended at the end of procedure. Available in oral, IM, and IV forms.
Phenothiazine antiemetic	Prochlorperazine	Indicated for control of severe nausea and vomiting. Available in oral, SR, rectal, IM, and IV forms.
Phenothiazine antiemetic antimotion sickness	Promethazine	Recommended every 4–6 h for nausea and vomiting associated with anesthesia and surgery. Available in oral, IM, and IV forms.
Antimotion sickness	Dimenhydrinate	Indicated for prevention of nausea, vomiting, or vertigo of motion sickness. Available in oral, IM, and IV forms.
Antiemetic	Hydroxyzine	Control of nausea and vomiting and as adjunct to analgesia preoperatively and postoperatively to allow decreased opioid dosage. Available in oral and IM forms.
Antiemetic antimotion sickness	Scopolamine	Used to prevent and control of nausea and vomiting associated with motion sickness and recovery from surgery. Available in oral, transdermal SC, and IM forms.
Antiemetic	Ondansetron	Prevention of postoperative nausea and vomiting. Available in oral, IM, and IV forms. With few side effects, frequently the drug of choice.

GI, gastrointestinal; IM, intramuscular; IV, intravenous; SR, sustained release; SC, subcutaneous.

Chart 16-2 NURSING RESEARCH PROFILE

An Investigation of PONV in Ambulatory Surgery

Finch, C., Parkosewich, J. A., Perrone, D., et al. (2019). Incidence, timing, and factors associated with postoperative nausea and vomiting in the ambulatory surgery setting. *Journal of PeriAnesthesia Nursing, 34*(6), 1146–1155.

Purpose

Postoperative nausea and vomiting (PONV) is a major concern for patients having surgery under general anesthesia. The purpose of this study was to investigate the incidence, timing, and factors associated with PONV in an ambulatory surgery PACU.

Design

The study used a prospective descriptive correlational, cross-sectional design. A random sample of 139 patients admitted to a 10-bed ambulatory PACU participated.

Findings

The mean age of participants was 50 years and 70% were female. Only 3 participants had nausea upon arrival to the PACU, but this number increased to 10 by 90 minutes in the PACU, and then went back down to 3 at 150 minutes in the PACU. A total of 4 participants vomited after reporting nausea. Participants with nausea had more hydration and longer PACU stays. Younger age and the presence of gastroesophageal reflux disease (GERD) were significantly associated with nausea.

Nursing Implications

Nurses working with postoperative patients should be aware that PONV can and does occur in both ambulatory and inpatient surgery settings. Nurses should take the age of patients into consideration with anticipating PONV. This study provides evidence that a history of GERD may be a risk factor and thus should be included in preoperative assessment.

Immediate postoperative care for the older adult is the same as for any surgical patient; however, additional support is given if cardiovascular, pulmonary, or renal function is impaired. With careful monitoring, it is possible to detect cardiopulmonary deficits before signs and symptoms are apparent. Changes associated with the aging process, the prevalence of chronic diseases, alteration in fluid and nutrition status, and the increased use of medications result in the need for postoperative vigilance. Nurses should keep in mind that older adults may have slower recovery from anesthesia due to the prolonged time it takes to eliminate sedatives and anesthetic agents. Thermoregulation is important to maintain immune function, adequate pain relief, and tissue oxygenation. Special care to maintain normothermia can

minimize the risk of postoperative ischemia and angina in older patients (Odom-Forren, 2018).

Postoperative confusion and delirium may occur in up to half of all older adult patients. Signs and symptoms include cognitive deficits, hallucinations, and fluctuating state of consciousness. It is important for the nurse to verify the preoperative psychological assessment as it can help differentiate between postoperative cognitive dysfunction (POCD) and postoperative delirium. With both conditions, patients exhibit signs of cognitive impairment; however, POCD is of sudden onset in the postsurgical period and is associated with the use of several anesthetic agents (Alalawi & Yasmeen, 2018). Providing adequate hydration, reorienting to the environment, and reassessing the doses of sedative, anesthetic, and analgesic agents may reduce the risk of confusion. Hypoxia can present as confusion and restlessness, as can blood loss and electrolyte imbalances. Exclusion of all other causes of confusion must precede the assumption that confusion is related to age, circumstances, and medications.

Maintaining a safe environment for older adults requires alertness and planning. Arthritis is a common condition among older patients, and it affects mobility, creating difficulty turning from one side to the other or ambulating without discomfort. The nurse provides mobility support and is vigilant for patients with an increased risk for falls. Fall prevention methods include using a fall risk identification method, providing assistance with ambulation, and allowing legs to dangle off of the stretcher prior to standing (DeSilva, Seabra, Thomas, et al., 2019).

Bariatric Considerations

Patients with obesity are seen in the PACU for a wide variety of conditions, including bariatric and nonbariatric procedures (Tjeertes, Hoeks, Beks, et al., 2015). Properly sized blood pressure cuffs, gowns, transfer devices, and wheelchairs may be needed for the recovery and transitioning care of these patients. Patients with obesity have unique postoperative risks including an increased risk of venous thromboembolism (VTE), deep vein thrombosis (DVT), and pulmonary embolus (PE).

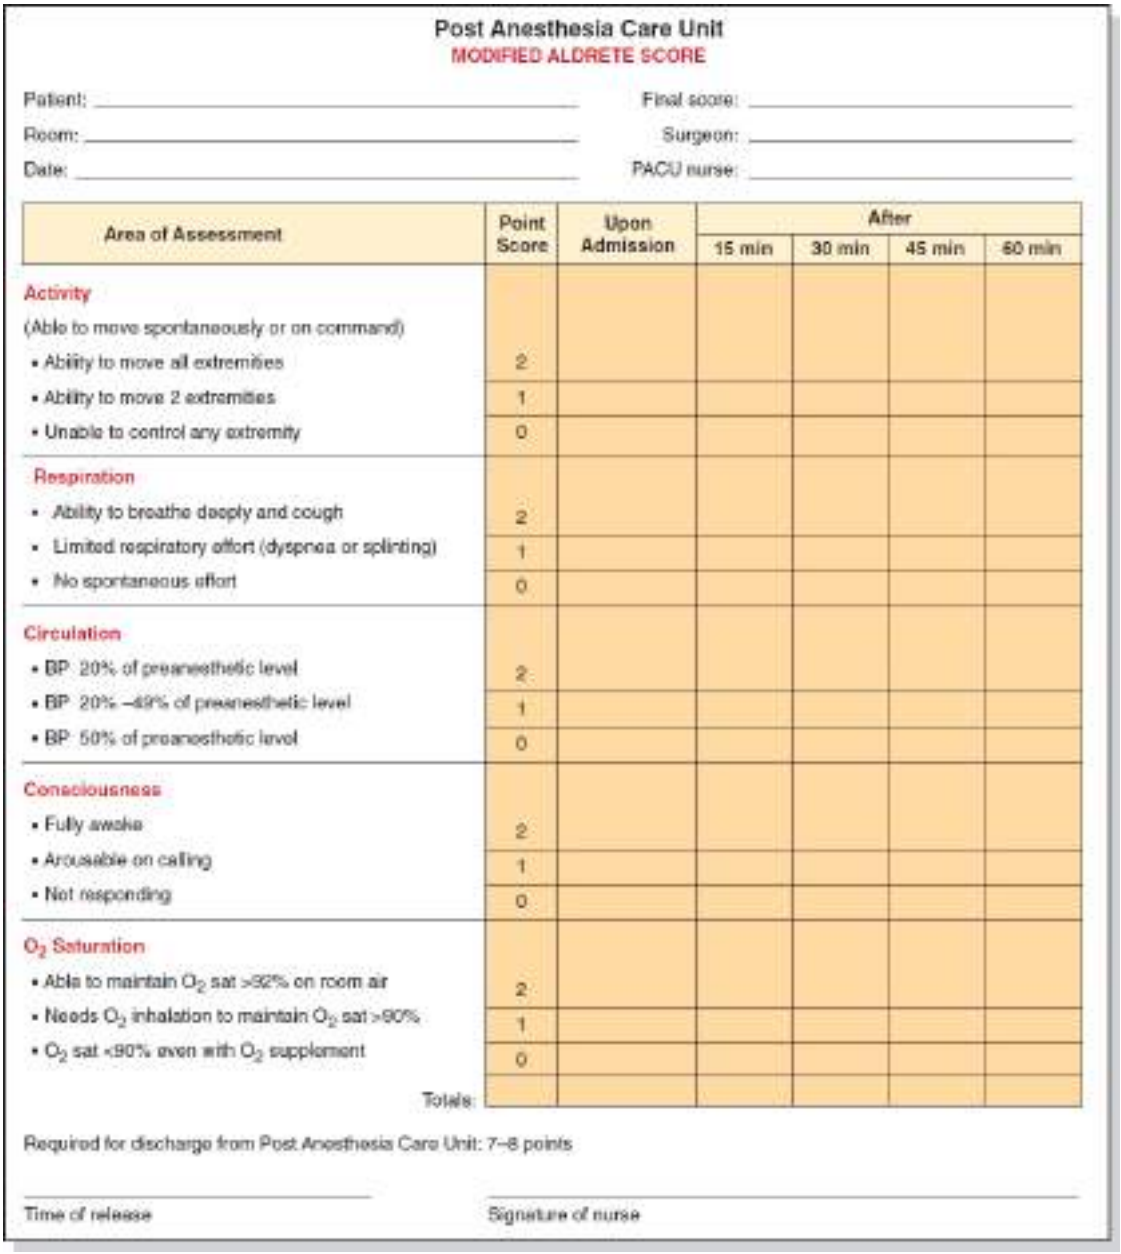
Patients with obesity are at particular risk for obstructive sleep apnea (OSA) in the postoperative period. A direct correlation exists between the incidence of pulmonary complications and the degree of obesity. The mortality rate after upper abdominal operations in patients with severe obesity is 2.5 times that of their normal weight counterparts (Odom-Forren, 2018). As discussed in Chapter 14, careful preoperative assessment for OSA should occur in patients with obesity in order to detect and manage the manifestations that may occur during the surgical stay. A combination of pulse oximetry and capnography should be utilized when patients are on supplemental oxygen therapy as

respiratory depression may be masked when measured only by pulse oximetry (Jungquist, Card, Charchaflieh, et al., 2018). Research suggests that the combination of continuous monitoring tools alerts PACU nurses to respiratory changes allowing for timely interventions (Wortham, Rice, Gupta, et al., 2019). Patients with OSA, many of whom also have obesity, are prone to hypoventilation and airway obstruction (ASPAN, 2019).

Determining Readiness for Postanesthesia Care Unit Discharge

A patient remains in the PACU until fully recovered from the anesthetic agent. Indicators of recovery include stable blood pressure, adequate respiratory function, and adequate oxygen saturation level compared with baseline.

The Aldrete score is used to determine the patient's general condition and readiness for transfer from the PACU (Aldrete & Wright, 1992). Throughout the recovery period, the patient's physical signs are observed and evaluated by means of a scoring system based on a set of objective criteria. This evaluation guide allows an objective assessment of the patient's condition in the PACU (see Fig. 16-3). The patient is assessed at regular intervals, and a total score is calculated and recorded on the assessment record. The Aldrete score is usually between 7 and 10 before discharge from the PACU. The unit policy and the established PACU discharge criteria determine appropriate postanesthesia recovery score parameters. Scores or conditions lower than the preestablished level necessitate evaluation by the anesthesia provider or surgeon and can result in an extension of the PACU stay or possible disposition to a special care or critical care unit (Odom-Forren, 2018).



Post Anesthesia Care Unit
MODIFIED ALDRETE SCORE

Patient: _____ Final score: _____
Room: _____ Surgeon: _____
Date: _____ PACU nurse: _____

Area of Assessment	Point Score	Upon Admission	After 15 min	After 30 min	After 45 min	After 60 min
Activity (Able to move spontaneously or on command)						
• Ability to move all extremities	2					
• Ability to move 2 extremities	1					
• Unable to control any extremity	0					
Respiration						
• Ability to breathe deeply and cough	2					
• Limited respiratory effort (dyspnea or splinting)	1					
• No spontaneous effort	0					
Circulation						
• BP 20% of preanesthetic level	2					
• BP 20%–49% of preanesthetic level	1					
• BP 50% of preanesthetic level	0					
Consciousness						
• Fully awake	2					
• Arousable on calling	1					
• Not responding	0					
O_2 Saturation						
• Able to maintain O_2 sat >92% on room air	2					
• Needs O_2 inhalation to maintain O_2 sat >90%	1					
• O_2 sat <90% even with O_2 supplement	0					
Totals:						

Required for discharge from Post Anesthesia Care Unit: 7–8 points

Time of release _____ Signature of nurse _____

Figure 16-3 • Postanesthesia care unit record; modified Aldrete score. O_2 sat, oxygen saturation; BP, blood pressure. Adapted from Aldrete, A., & Wright, A. (1992). Revised Aldrete score for discharge. *Anesthesiology News, 18*(1), 17.

The patient is discharged from the phase I PACU by the anesthesiologist or CRNA to the critical care unit, the medical-surgical unit, or the phase II PACU.

Preparing the Postoperative Patient for Direct Discharge

Ambulatory surgical centers frequently have a step-down PACU similar to a phase II PACU. Patients seen in this type of unit are usually healthy, and the plan is to discharge them directly to home. Prior to discharge, the patient will require verbal and written instructions and information about follow-up care.

Promoting Home, Community-Based, and Transitional Care

To ensure patient safety and recovery, expert patient education and discharge planning are necessary when a patient undergoes same-day or ambulatory surgery (Association of PeriOperative Registered Nurses [AORN], 2019; ASPAN, 2019). Because anesthetics cloud memory for concurrent events, verbal and written instructions should be given to both the patient and the adult who will be accompanying the patient home. Alternative formats (e.g., large print, Braille) of instructions or the use of a sign language interpreter may be required to ensure patient and family understanding. A translator may be required if the patient and family members do not understand English.

Discharge Preparation

The patient and caregiver (e.g., family member, friend) are informed about expected outcomes and immediate postoperative changes anticipated (AORN, 2019; ASPAN, 2019). Chart 16-3 identifies important educational points; before discharging the patient, the nurse provides written instructions covering each of those points. Prescriptions are given to the patient. Contact information for the hospital and surgeon's office are provided, and the patient and caregiver are encouraged to call with questions and to schedule follow-up appointments. A list of possible complications and how to manage them (e.g., call the surgeon's office, report to the emergency department [ED]), including elevated temperature, bleeding, and wound care instructions, are key focal points during discharge education.

Although recovery time varies depending on the type and extent of surgery and the patient's overall condition, instructions usually advise limited activity for 24 to 48 hours. During this time, the patient should not drive a vehicle, drink alcoholic beverages, or perform tasks that require high levels of energy or skill. Fluids may be consumed as desired and smaller than normal amounts may be eaten at mealtime. Patients are cautioned not to make important decisions at this time because the medications, anesthesia, and surgery may affect their decision-making ability. Follow-up phone calls from the nurse are also used to assess the patient's progress and to answer any questions.

Chart 16-3 **HOME CARE CHECKLIST**

Discharge After Surgery

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify interventions and strategies (e.g., durable medical equipment, adaptive equipment) used in adapting to any permanent change in structure or function.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., walking and breathing exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
- State the name, dose, side effects, frequency, and schedule for all medications.
- State how to obtain medical supplies and carry out dressing changes, wound care, and other prescribed regimens.
- Describe signs and symptoms of complications.
- State time and date of follow-up appointments.
- Relate how to reach health care provider with questions or complications.
- State understanding of community resources and referrals (if any).

Identify the need for health promotion (e.g., weight reduction, smoking cessation, stress management), disease prevention, and screening activities. ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Continuing and Transitional Care

Although most patients who undergo ambulatory surgery recover quickly and without complications, some patients require referral for some type of continuing or transitional care. These may be older or frail patients, those who live alone, and patients with other health care problems or disabilities that might interfere with self-care or resumption of usual activities. The home, community, or transitional care nurse assesses the patient's physical status (e.g., respiratory and cardiovascular status, adequacy of pain management, the surgical incision, surgical complications) and the patient's and family's ability to adhere to the recommendations given at the time of discharge. Previous education is reinforced as needed. Nursing interventions may include changing surgical dressings, monitoring the patency of a drainage system, or

administering medications. The patient and family are reminded about the importance of keeping follow-up appointments with the surgeon.

Care of the Hospitalized Postoperative Patient

The majority of surgical patients who require hospital stays are trauma patients, acutely ill patients, patients undergoing major surgery, patients who require emergency surgery, and patients with a concurrent medical disorder. Seriously ill patients and those who have undergone major cardiovascular, pulmonary, or neurologic surgery may be admitted to specialized ICUs for close monitoring and advanced interventions and support. The care required by these patients in the immediate postoperative period is discussed in specific chapters of this book.

Patients admitted to the clinical unit for postoperative care have multiple needs and require frequent assessment and care interventions by nursing staff. Postoperative care for those surgical patients returning to the general medical-surgical unit is discussed later in this chapter.

Receiving the Patient in the Clinical Unit

The patient's room is readied by assembling the necessary equipment and supplies: IV pumps, drainage receptacle holder, suction equipment, oxygen, emesis basin, tissues, disposable pads, blankets, and postoperative documentation forms. When the call comes to the unit about the patient's transfer from the PACU, the need for any additional items is communicated. The PACU nurse reports relevant data about the patient to the receiving nurse (see Chart 16-1).

Usually, the surgeon speaks to the family after surgery and relates the general condition of the patient. The receiving nurse gets a report about the patient's condition, reviews the postoperative orders, admits the patient to the unit, performs an initial assessment, and attends to the patient's immediate needs (see Chart 16-4).

Nursing Management After Surgery

During the first 24 hours after surgery, nursing care of the hospitalized patient on the medical-surgical unit involves continuing to help the patient recover from the effects of anesthesia (Barash et al., 2017), frequently assessing the patient's physiologic status, monitoring for complications, managing pain, and implementing measures designed to achieve the long-range goals of independence with self-care, successful management of the therapeutic regimen, discharge to home, and full recovery. In the initial hours after

admission to the clinical unit, adequate ventilation, hemodynamic stability, incisional pain, surgical site integrity, nausea and vomiting, neurologic status, and spontaneous voiding are primary concerns. The pulse rate, blood pressure, and respiration rate are assessed at intervals determined by the institution.

Patients usually begin to return to their usual state of health several hours after surgery or after awaking the next morning. Although pain may still be intense, many patients feel more alert, less nauseous, and less anxious. They have begun their breathing and leg exercises as appropriate for the type of surgery, and most will have dangled their legs over the edge of the bed, stood, and ambulated a few feet or been assisted out of bed to the chair at least once. Many will have tolerated a light meal and had IV fluids discontinued. The focus of care shifts from intense physiologic management and symptomatic relief of the adverse effects of anesthesia to regaining independence with self-care and preparing for discharge.

Chart 16-4

Immediate Postoperative Nursing Interventions

Nursing Interventions	Rationale
1. Assess breathing and administer supplemental oxygen, if prescribed.	**1.** Assessment provides a baseline and helps identify signs and symptoms of respiratory distress early.
2. Monitor vital signs and note skin warmth, moisture, and color.	**2.** A careful baseline assessment helps identify signs and symptoms of shock early.
3. Assess the surgical site and wound drainage systems. Connect all drainage tubes to gravity or suction as indicated and monitor closed drainage systems.	**3.** Assessment provides a baseline and helps identify signs and symptoms of hemorrhage early.
4. Assess level of consciousness, orientation, and ability to move extremities.	**4.** These parameters provide a baseline and help identify signs and symptoms of neurologic complications.
5. Assess pain level; pain characteristics (location, quality); and timing, type, and route of administration of the last dose of analgesic.	**5.** Assessment provides a baseline of current pain level and assesses effectiveness of pain management strategies.
6. Administer analgesic medications as prescribed and assess their effectiveness in relieving pain.	**6.** Administration of analgesic agents helps decrease pain.
7. Place the call light, emesis basin, ice chips (if allowed), and bedpan or urinal within reach.	**7.** Attending to these needs provides for comfort and safety.
8. Position the patient to enhance comfort, safety, and lung expansion.	**8.** This promotes safety and reduces risk of postoperative complications.
9. Assess IV sites for patency and infusions for correct rate and solution.	**9.** Assessing IV sites and infusions helps detect phlebitis and prevents errors in rate and solution type.
10. Assess urine output in closed drainage system or use bladder scanner to detect distention.	**10.** Assessment provides a baseline and helps identify signs of urinary retention.
11. Reinforce the need to begin deep breathing and leg exercises.	**11.** These activities help prevent complications related to immobility (e.g., atelectasis, VTE).
12. Provide information to the patient and family.	**12.** Patient education helps decrease the patient's and family's anxiety.

VTE, venous thromboembolism.

NURSING PROCESS

The Hospitalized Patient Recovering from Surgery

Nursing care of the hospitalized patient recovering from surgery takes place in a compressed time frame, with much of the healing and recovery occurring after the patient is discharged to home or to a rehabilitation center.

Assessment

Assessment of the hospitalized postoperative patient includes monitoring vital signs and completing a review of systems upon the patient's arrival to the clinical unit (see Chart 16-4) and at regular intervals thereafter.

Respiratory status is important because pulmonary complications are among the most frequent and serious problems encountered by the surgical patient. The nurse monitors for airway patency and any signs of laryngeal edema. The quality of respirations, including depth, rate, and sound, is assessed regularly. Chest auscultation verifies that breath sounds are normal (or abnormal) bilaterally, and the findings are documented as a baseline for later comparisons. Often, because of the effects of analgesic and anesthetic medications, respirations are slow. Shallow and rapid respirations may be caused by pain, constricting dressings, gastric dilation, abdominal distention, or obesity. Noisy breathing may be due to obstruction by secretions or the tongue. Another possible complication is flash pulmonary edema that occurs when protein and fluid accumulate in the alveoli unrelated to elevated pulmonary artery occlusive pressure. Signs and symptoms include agitation; tachypnea; tachycardia; decreased pulse oximetry readings; frothy, pink sputum; and crackles on auscultation.

The nurse assesses the patient's pain level using a verbal or visual analog scale and assesses the characteristics of the pain. The patient's appearance, pulse, respirations, blood pressure, skin color (adequate or cyanotic), and skin temperature (cold and clammy, warm and moist, or warm and dry) are clues to cardiovascular function. When the patient arrives in the clinical unit, the surgical site is assessed for bleeding, type and integrity of dressings, and drains.

The nurse also assesses the patient's mental status and level of consciousness, speech, and orientation and compares them with the preoperative baseline. Although a change in mental status or postoperative restlessness may be related to anxiety, pain, or medications, it may also be a symptom of oxygen deficit or hemorrhage. These serious causes must be investigated and excluded before other causes are pursued.

General discomfort that results from lying in one position on the operating table, the handling of tissues by the surgical team, the body's

reaction to anesthesia, and anxiety are also common causes of restlessness. These discomforts may be relieved by administering the prescribed analgesic medication, changing the patient's position frequently, and assessing and alleviating the cause of anxiety. If tight, drainage-soaked bandages are causing discomfort, reinforcing or changing the dressing completely as prescribed by the provider may make the patient more comfortable. The bladder is assessed for distention (usually with a bladder scanner) because urinary retention can also cause restlessness and change in mental status (AORN, 2019).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired airway clearance associated with to depressed respiratory function, pain, and bed rest
- Acute pain associated with surgical incision
- Impaired cardiac output associated with shock or hemorrhage
- Risk for activity intolerance associated with generalized weakness secondary to surgery
- Impaired skin integrity associated with surgical incision and drains
- Impaired thermoregulation associated with surgical environment and anesthetic agents
- Risk for impaired nutritional status associated with decreased intake and increased need for nutrients secondary to surgery
- Risk for constipation associated with effects of medications, surgery, dietary change, and immobility
- Impaired urinary system function associated with anesthetic agents
- Risk for injury associated with surgical procedure/positioning or anesthetic agents
- Anxiety associated with surgical procedure
- Lack of knowledge associated with wound care, dietary restrictions, activity recommendations, medications, follow-up care, or signs and symptoms of complications in preparation for discharge

Collaborative Problems or Potential Complications

Based on the assessment data, potential complications may include the following:

- Pulmonary infection/hypoxia
- Venous thromboembolism (VTE) (e.g., deep vein thrombosis [DVT], pulmonary embolism [PE])
- Hematoma or hemorrhage

- Infection
- Wound dehiscence or evisceration

Planning and Goals

The major goals for the patient include optimal respiratory function, relief of pain, optimal cardiovascular function, increased activity tolerance, unimpaired wound healing, maintenance of body temperature, and maintenance of nutritional balance (Dudek, 2017). Further goals include resumption of usual pattern of bowel and bladder elimination, identification of any perioperative positioning injury, acquisition of sufficient knowledge to manage self-care after discharge, and absence of complications.

Nursing Interventions

Preventing Respiratory Complications

Respiratory depressive effects of opioid medications, decreased lung expansion secondary to opioid pain medication, and decreased mobility combine to put the patient at risk for respiratory complications, particularly atelectasis (alveolar collapse; incomplete expansion of the lung), pneumonia, and hypoxemia (Rothrock, 2019). Atelectasis remains a risk for the patient who is not moving well or ambulating or who is not performing deep-breathing and coughing exercises or using an incentive spirometer. Signs and symptoms include decreased breath sounds over the affected area, crackles, and cough. Pneumonia is characterized by chills and fever, tachycardia, and tachypnea. Cough may or may not be present and may or may not be productive. Pulmonary congestion may occur if secretions are not cleared from the airway. The symptoms are often vague, with perhaps a slight elevation of temperature, pulse, and respiratory rate as well as a cough. Physical examination reveals dullness and crackles at the base of the lungs. If the condition progresses, the outcome may be fatal.

The types of hypoxemia that can affect postoperative patients are subacute and episodic. Subacute hypoxemia is a constant low level of oxygen saturation when breathing appears normal. Episodic hypoxemia develops suddenly, and the patient may be at risk for cerebral dysfunction, myocardial ischemia, and cardiac arrest. Risk for hypoxemia is increased in patients who have undergone major surgery (particularly abdominal), have obesity, or have preexisting pulmonary problems. Unidentified hypoxemia in the postanesthesia patient is not common since the advent of noninvasive oxygen saturation monitoring with pulse oximetry (Odom-Forren, 2018). Factors that may affect the accuracy of pulse oximetry readings include cold extremities, tremors, atrial fibrillation, acrylic nails, and nail polish.

Preventive measures and timely recognition of signs and symptoms help avert pulmonary complications. Crackles indicate static pulmonary secretions that need to be mobilized by coughing and deep-breathing

exercises. When a mucus plug obstructs one of the bronchi entirely, the pulmonary tissue beyond the plug collapses, resulting in atelectasis.

To clear secretions and prevent pneumonia, the nurse encourages the patient to turn frequently, take deep breaths, cough, and use the incentive spirometer at least every 2 hours. These pulmonary exercises should begin as soon as the patient arrives on the clinical unit and continue until the patient is discharged. Even if they are not fully awake from anesthesia, the patient can be asked to take several deep breaths. This helps expel residual anesthetic agents, mobilize secretions, and prevent atelectasis. Careful splinting of abdominal or thoracic incision sites helps the patient overcome the fear that the exertion of coughing might open the incision (see Chapter 14, Chart 14-5). Analgesic agents are given to permit more effective coughing, and oxygen is given as prescribed to prevent or relieve hypoxia. To encourage lung expansion, the patient is encouraged to yawn or take sustained maximal inspirations to create a negative intrathoracic pressure of −40 mm Hg and expand lung volume to total capacity. Chest physical therapy may be prescribed if indicated (see Chapter 19).

Coughing is contraindicated in patients who have head injuries or have undergone intracranial surgery (because of the risk for increasing intracranial pressure), as well as in patients who have undergone eye surgery (because of the risk for increasing intraocular pressure) or plastic surgery (because of the risk for increasing tension on delicate tissues).

Early ambulation increases metabolism and pulmonary aeration and, in general, improves all body functions. Assessment for readiness to ambulate as soon as the patient arrives in the PACU provides consistency and increased patient safety (Persico, Miller, Way, et al., 2019). Ambulation occurs as soon as the patient returns to a safe physical state and level of consciousness.

Relieving Pain

Most patients experience some pain after a surgical procedure. Complete absence of pain in the area of the surgical incision may not occur for a few weeks, depending on the site and nature of the surgery, but the intensity of postoperative pain gradually subsides on subsequent days. A comprehensive pain assessment provides the foundation of good pain control and includes obtaining information regarding the location, intensity, and quality (e.g., sharp, shooting) (Odom-Forren, 2018). Many patients are unable to accurately report their level of pain in the postoperative setting due to sedatives and other medications given during surgery. Nurses must be able to accurately assess other indicators such as behavior, vital signs, level of consciousness, and preoperative baseline pain report (see Chapter 9).

The degree and severity of postoperative pain and the patient's tolerance for pain depend on the incision site, the nature of the surgical procedure,

the extent of surgical trauma, the type of anesthesia, and the route of administration.

Intense pain stimulates the stress response, which adversely affects the cardiac and immune systems. When pain impulses are transmitted, both muscle tension and local vasoconstriction increase, further stimulating pain receptors. This increases myocardial demand and oxygen consumption. The hypothalamic stress response also results in an increase in blood viscosity and platelet aggregation, increasing the risk of thrombosis and PE.

In some states, providers may prescribe different medications or dosages to cover various levels of pain. After the medication is delivered, the nurse should periodically assess the patient's level of pain using a validated pain scale.

Opioid Analgesic Medications. Opioid analgesic agents are commonly prescribed for pain and immediate postoperative restlessness. A realistic goal for postoperative pain management is toleration rather than the elimination of pain. A preventive approach, rather than an "as needed" (PRN) approach, is more effective in relieving pain. With a preventive approach, the medication is given at prescribed intervals rather than when the pain becomes severe or unbearable. In the postoperative setting, intravenous (IV) route is the first-line route of administration for analgesia delivery (Odom-Forren, 2018).

Prior to opioid delivery, the nurse should assess the patient's level of sedation. Sedation assessment tools, such as the POSS (Pasero Opioid-Induced Sedation Scale), are used by the nurse to assess sedation level at frequent intervals to safely care for patients in the PACU. The POSS is a tool developed to identify advancing sedation before it is compounded by continued opioid administration and results in clinically significant respiratory depression or apnea. The POSS indicates the nurse may administer opioids to a patient at sedation level S (*sleep, easy to arouse*) if it has been determined that the patient's respiratory status (rate, depth, regularity, and airway patency) is optimal. Patients assigned a sedation level of 1 or 2 may receive opioid administration; however, beginning at sedation level 3, the recommendation is that the nurse should provide nonopioid therapies to treat pain because the patient is becoming too sedated. Other sedation scales commonly used in the PACU are the RASS (Richmond Agitation–Sedation Scale), Aldrete Scale (see Fig. 16-3), and Glasgow Coma Scale (Hall & Stanley, 2019).

Patient-Controlled Analgesia. The goal is pain prevention rather than sporadic pain control. Patients recover more quickly when adequate pain relief measures are used, and patient-controlled analgesia (PCA) permits patients to administer their own pain medication when needed. Most patients are candidates for PCA. The two requirements for PCA are an understanding of the need to self-dose and the physical ability to self-dose.

The amount of medication delivered by the IV or epidural route and the time span during which the opioid medication is released are controlled by the PCA device. PCA promotes patient participation in care; eliminates delayed administration of analgesic medications; maintains a therapeutic drug level; and enables the patient to move, turn, cough, and take deep breaths with less pain, thus reducing postoperative pulmonary complications (Rothrock, 2019).

Multimodal Analgesia. The use of more than one method of analgesia, referred to as multimodal analgesia, is a growing trend to manage postoperative pain. Some of these methods are started in the preoperative area; however, the effects are seen in the postoperative area. The most common analgesics used for postoperative pain are a mixture of opioid and nonopioid analgesics (i.e., acetaminophen and NSAIDs) and local anesthetics. A multimodal approach may combine agents in any of the analgesic groups to provide effective pain relief and minimize adverse effects (Odom-Forren, 2018). A balanced, multimodal approach to pain management within the larger framework of an Enhanced Recovery After Surgery (ERAS) pathway has become standard at many institutions for perioperative care, to control postsurgical pain, reduce opioid-related adverse events, hasten postsurgical recovery, and shorten length of hospital stay (Montgomery & McNamara, 2016). ERAS is an evidence-based, multimodal care model resulting in substantial improvements in clinical outcomes and cost savings (Ljungqvist, Scott, & Fearon, 2017).

Epidural Infusions and Intrapleural Anesthesia. Epidural analgesia involves a continuous infusion of local anesthetics through a catheter and is the most widely used neuraxial technique for acute postoperative pain (Wolfe, 2018). A local opioid or a combination anesthetic (opioid plus local anesthetic agent) is used in the epidural infusion. Epidural infusions are used with caution in chest procedures because the analgesic may ascend along the spinal cord and affect respiration. Intrapleural anesthesia involves the administration of a local anesthetic by a catheter between the parietal and visceral pleura. It provides sensory anesthesia without affecting motor function to the intercostal muscles. This anesthesia allows more effective coughing and deep breathing in conditions such as cholecystectomy, renal surgery, and rib fractures, in which pain in the thoracic region would interfere with these exercises.

Postoperative nurses may also care for patients who received a preoperative local anesthetic block. The intended effects of pain relief may last for hours or up to days, depending on the method used. Nurses should include the location of the block, when it was administered, current pain level, and insertion site assessment when providing report to the inpatient nursing unit. Patient discharge instructions include information about when

to expect the return of sensation, mobility precautions with decreased sensation, and care of the dressing at the insertion site.

Other Pain Relief Measures. For pain that is difficult to control, a subcutaneous pain management system may be used. In this system, a nylon catheter is inserted at the site of the affected area. The catheter is attached to a pump that delivers a continuous amount of local anesthetic at a specific amount determined and prescribed by the primary provider (see Fig. 16-4).

Nonpharmacologic pain management approaches may be used as components of multimodal pain management plans of care. Effective methods include music therapy, guided imagery, Reiki, and therapeutic massage (Poulson, Coto, & Cooney, 2019). Changing the patient's position, using distraction, applying cool washcloths to the face, and providing back massage may be useful in relieving general discomfort temporarily, promoting relaxation, and rendering medication more effective when it is given.

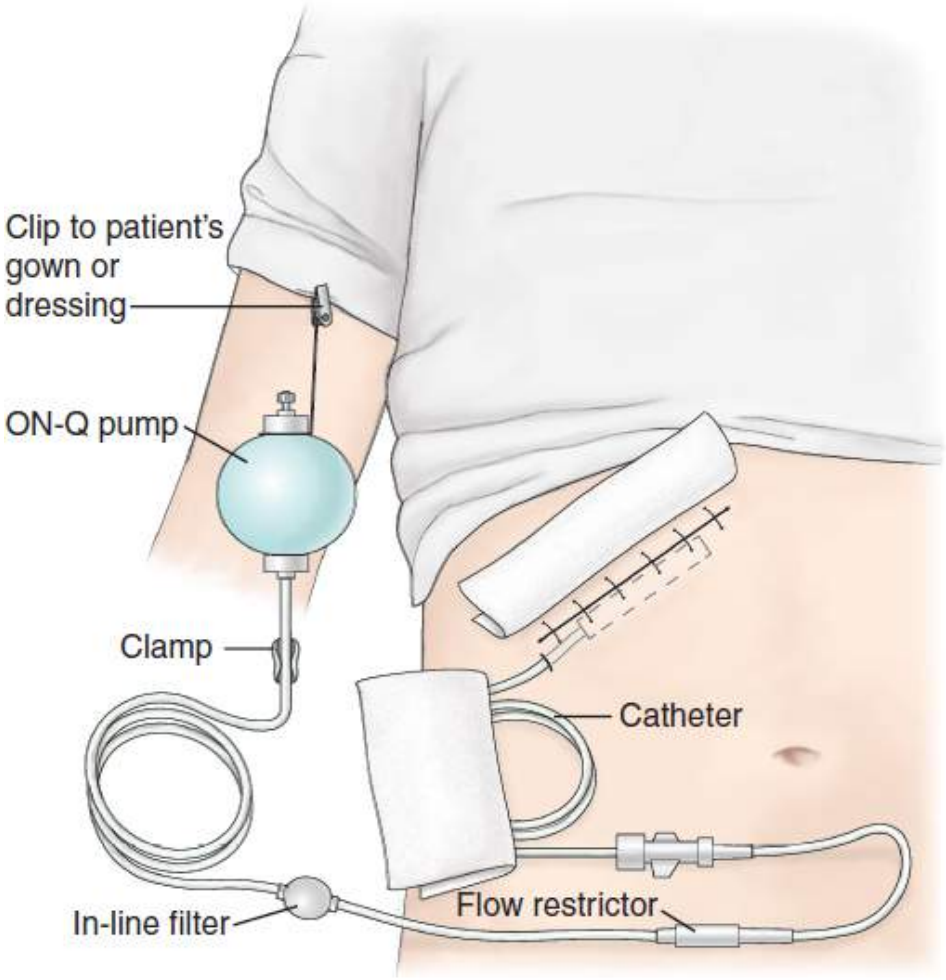

Figure 16-4 • Subcutaneous pain management system consists of a pump, filter, and catheter that delivers a specific amount of prescribed local anesthetic at the rate determined by the physician. Redrawn with permission from Kimberly-Clark Corporation, Neenah, WI.

PROMOTING CARDIAC OUTPUT

If signs and symptoms of shock or hemorrhage occur, treatment and nursing care are implemented as described in the discussion of care in the PACU and in Chapter 11.

Although most patients do not hemorrhage or go into shock, changes in circulating volume, the stress of surgery, and the effects of medications and preoperative preparations all affect cardiovascular function. Volume status assessment in the PACU can be difficult because vasoconstriction from surgical stress and hypothermia can compensate for hypovolemia (Odom-Forren, 2018). Close monitoring is indicated to detect and correct conditions such as fluid volume deficit, altered tissue perfusion, and decreased cardiac output, all of which can increase the patient's discomfort, place him or her at risk of complications, and prolong the hospital stay. Consequently, fluid replacement must be carefully managed, and intake and

output records must be accurate. IV fluid replacement may be prescribed for up to 24 hours after surgery or until the patient is stable and tolerating oral fluids.

Nursing management includes assessing the patency of the IV lines and ensuring that the correct fluids are given at the prescribed rate. Intake and output, including emesis and output from wound drainage systems, are recorded separately and totaled to determine fluid balance. If the patient has an indwelling urinary catheter, hourly outputs are monitored and should not be less than 0.5 mL/kg/h or 25 mL/h; oliguria is reported immediately (Odom-Forren, 2018). Electrolyte levels and hemoglobin and hematocrit levels are monitored. Decreased hemoglobin and hematocrit levels can indicate blood loss or dilution of circulating volume by IV fluids. If dilution is contributing to the decreased levels, the hemoglobin and hematocrit will rise as the stress response abates and fluids are mobilized and excreted.

Venous stasis from dehydration, immobility, and pressure on leg veins during surgery put the patient at risk for VTE. Leg exercises and frequent position changes are initiated early in the postoperative period to stimulate circulation. Patients should avoid positions that compromise venous return, such as raising the bed's knee gatch, placing a pillow under the knees, sitting for long periods, and dangling the legs with pressure at the back of the knees. Venous return is promoted by antiembolism stockings and early ambulation.

Encouraging Activity

Early ambulation has a significant effect on recovery and the prevention of complications (e.g., atelectasis, hypostatic pneumonia, gastrointestinal [GI] discomfort, circulatory problems) (Rothrock, 2019). Postoperative activity orders are checked before the patient is assisted to get out of bed, in many instances, on the evening following surgery. Sitting up at the edge of the bed for a few minutes may be all that the patient who has undergone a major surgical procedure can tolerate at first.

Ambulation reduces postoperative abdominal distention by increasing GI tract and abdominal wall tone and stimulating peristalsis. Early ambulation prevents stasis of blood, and thromboembolic events occur less frequently. Pain is often decreased when early ambulation is possible, and the hospital stay is shorter and less costly.

Despite the advantages of early ambulation, patients may be reluctant to get out of bed on the evening of surgery. Reminding them of the importance of early mobility in preventing complications may help patients overcome their fears. When a patient gets out of bed for the first time, orthostatic hypotension, also called *postural hypotension,* is a concern. Orthostatic hypotension is an abnormal drop in blood pressure that occurs as the patient changes from a supine to a standing position. It is common after surgery because of changes in circulating blood volume and bed rest. Signs and

symptoms include a decrease of 20 mm Hg in systolic blood pressure or 10 mm Hg in diastolic blood pressure, weakness, dizziness, and fainting (Weber & Kelley, 2018). Patients may report a sense of dizziness or fainting, along with a marked drop in blood pressure. Older adults are at increased risk for orthostatic hypotension secondary to age-related changes in vascular tone. To detect orthostatic hypotension, the nurse assesses the patient's blood pressure first in the supine position, after the patient sits up, again after the patient stands, and 2 to 3 minutes later. Gradual position change gives the circulatory system time to adjust. If the patient becomes dizzy, they are returned to the supine position, and ambulation is delayed for several hours.

To assist the postoperative patient in getting out of bed for the first time after surgery, the nurse:

- Helps the patient move gradually from the lying position to the sitting position by raising the head of the bed and encourages the patient to splint the incision when applicable.
- Positions the patient completely upright (sitting) and turned so that both legs are hanging over the edge of the bed.
- Helps the patient stand beside the bed.

After becoming accustomed to the upright position, the patient may start to walk. The nurse should be at the patient's side to give physical support and encouragement. Care must be taken not to tire the patient; the extent of the first few periods of ambulation varies with the type of surgical procedure and the patient's physical condition and age.

Whether or not the patient can ambulate early in the postoperative period, bed exercises are encouraged to improve circulation. Bed exercises consist of the following:

- Arm exercises (full range of motion, with specific attention to abduction and external rotation of the shoulder)
- Hand and finger exercises
- Foot exercises to prevent VTE, footdrop, and toe deformities and to aid in maintaining good circulation
- Leg flexion and leg-lifting exercises to prepare the patient for ambulation
- Abdominal and gluteal contraction exercises

Hampered by pain, dressings, IV lines, or drains, many patients cannot engage in activity without assistance. Helping the patient increase the activity level on the first postoperative day is important to prevent complications related to prolonged inactivity. One way to increase the patient's activity is to have the patient perform as much routine hygiene care as possible. Setting up the patient to bathe with a bedside wash basin or, if possible, assisting the patient to the bathroom to sit in a chair at the

sink not only gets the patient moving but helps restore a sense of self-control and prepares the patient for discharge.

For a safe discharge to home, patients need to be able to ambulate a functional distance (e.g., length of the house or apartment), get in and out of bed unassisted, and be independent with toileting. Patients can be asked to perform as much as they can and then to call for assistance. The patient and the nurse can collaborate on a schedule for progressive activity that includes ambulating in the room and hallway and sitting out of bed in a chair. Assessing the patient's vital signs before, during, and after a scheduled activity helps the nurse and patient determine the rate of progression. By providing physical support, the nurse maintains the patient's safety; by communicating a positive attitude about the patient's ability to perform the activity, the nurse promotes the patient's confidence. The nurse encourages the patient to continue to perform bed exercises, wear pneumatic compression or prescribed antiembolism stockings when in bed, and rest as needed. If the patient has had orthopedic surgery of the lower extremities or will require a mobility aid (i.e., walker, crutches) at home, a physical therapist may be involved the first time the patient gets out of bed to educate him or her to ambulate safely or to use the mobility aid correctly.

Caring for Wounds

Wound Healing. Wounds heal by different mechanisms, depending on the condition of the wound.

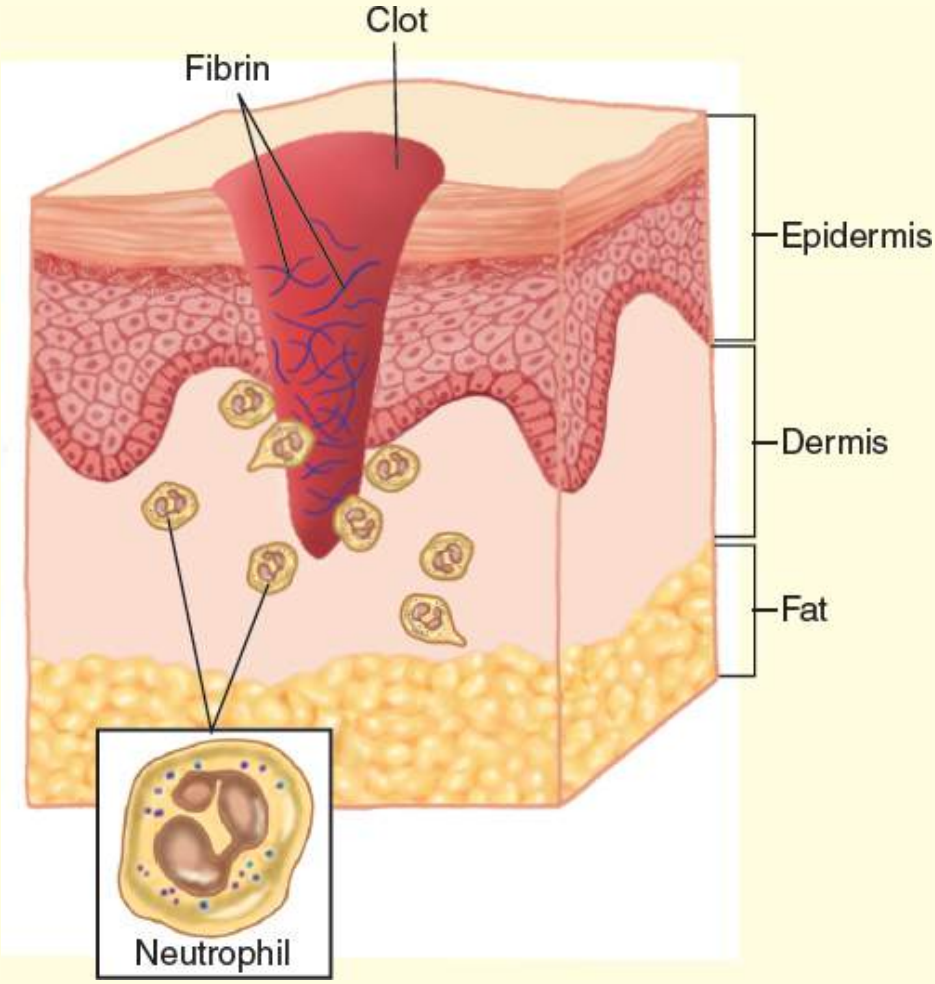
The healing of skin wounds follows three general phases, the inflammatory phase, the proliferative phase, and then wound contraction and remodeling phase. Each of these phases is mediated through cytokines and growth factors (Norris, 2019). See **Chart 16-5** for explanations and illustrations of these three phases.

Surgical wound healing occurs in two ways, by **first-intention or second-intention wound healing** (Norris, 2019). A sutured surgical incision is an example of first-intention healing. A larger wound, such as a burn heals by secondary intention.

Chart 16-5

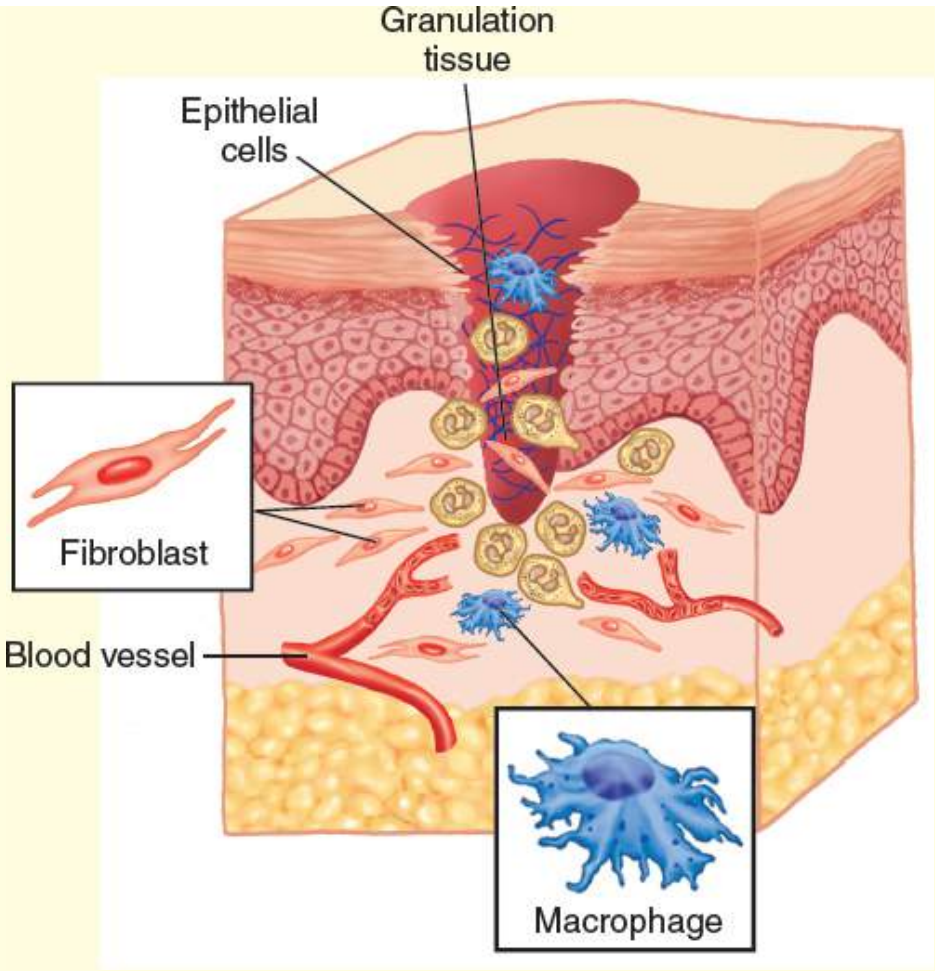
Three Phases of Wound Healing

Inflammatory Phase



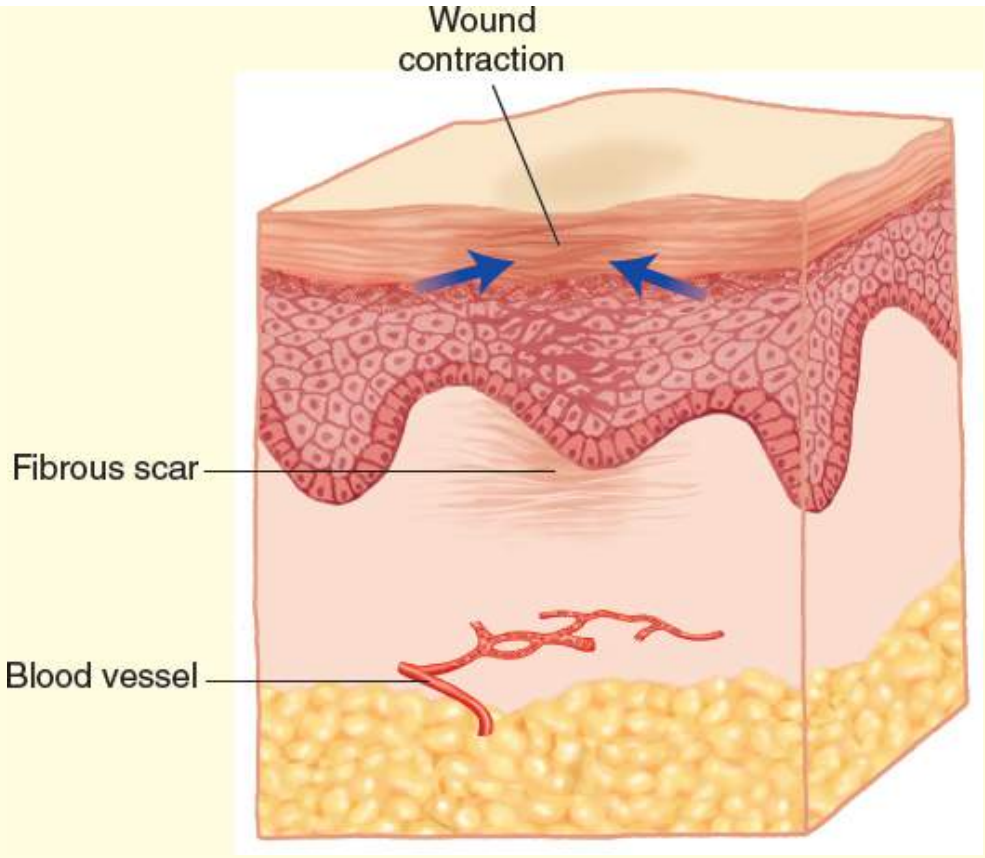
The inflammatory phase begins at the time of injury with the formation of a blood clot and the migration of phagocytic white blood cells into the wound site. The first cells to arrive, the neutrophils, ingest and remove bacteria and cellular debris. After 24 hours, the neutrophils are joined by macrophages, which continue to ingest cellular debris and play an essential role in the production of growth factors for the proliferative phase.

Proliferative Phase



The primary processes during this phase focus on the building of new tissue to fill the wound space. The key cell during this phase is the *fibroblast*, a connective tissue cell that synthesizes and secretes the collagen, proteoglycans, and glycoproteins needed for wound healing. Fibroblasts also produce a family of growth factors that induce angiogenesis (growth of new blood vessels) and endothelial cell proliferation and migration. The final component of the proliferative phase is epithelialization, during which epithelial cells at the wound edges proliferate to form a new surface layer that is similar to that which was destroyed by the injury.

Wound Contraction and Remodeling Phase



This phase begins approximately 3 weeks after injury with the development of the fibrous scar and can continue for 6 months or longer, depending on the extent of the wound. During this phase, there is a decrease in vascularity and continued remodeling of scar tissue by simultaneous synthesis of collagen by fibroblasts and lysis by collagenase enzymes. As a result of these two processes, the architecture of the scar is capable of increasing its tensile strength, and the scar shrinks so it is less visible.

Reprinted with permission from Norris, T. L. (2018). *Porth's pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer.

With shorter hospital stays, much of the healing takes place at home, and both the hospital and the transitional or home health nurse needs to be well versed in the principles of wound healing.

Ongoing assessment of the surgical site involves inspection for approximation of wound edges, integrity of sutures or staples, redness, discoloration, warmth, swelling, unusual tenderness, or drainage. The area around the wound should also be inspected for a reaction to tape or trauma from tight bandages. Risk factors for altered wound healing include poor nutrition, smoking, diabetes, and poor hygiene (Nasser, Kosty, Shah, et al., 2018; Norris, 2019). Specific nursing assessments and interventions that

address these factors and help promote wound healing are presented in Table 16-3.

TABLE 16-3 Factors Affecting Wound Healing

Factors	Rationale	Nursing Interventions
Age of patient	The older the patient, the less resilient the tissues.	Handle all tissues gently.
Bathing protocol	Use of chlorhexidine gluconate shower and preoperative wipes as a means for antimicrobial skin antisepsis.	Educate patient regarding use and importance. Confirm use with patient in preoperative area.
Hemorrhage	Accumulation of blood creates dead spaces as well as dead cells that must be removed. The area becomes a growth medium for organisms.	Monitor vital signs. Observe incision site for evidence of bleeding and infection.
Hypovolemia	Insufficient blood volume leads to vasoconstriction and reduced oxygen and nutrients available for wound healing.	Monitor for volume deficit (circulatory impairment). Correct by fluid replacement as prescribed.
Temperature Management	Hypothermia causes poor tissue oxygenation and thus poor perfusion needed for wound healing.	Assess the patient's temperature pre-, intra-, and postoperatively. Implement warm blanket or forced air warming measures.
Local Factors		
Edema	Reduces blood supply by exerting increased interstitial pressure on vessels.	Elevate part; apply cool compresses.
Inadequate dressing technique:		
Too small	Permits bacterial invasion and contamination.	Follow guidelines for proper dressing technique.
Too tight	Reduces blood supply carrying nutrients and oxygen.	
Nutritional deficits	Protein–calorie depletion may occur.	Correct deficits; this may require parenteral nutritional therapy.
	Insulin secretion may be inhibited, causing blood glucose to rise.	Monitor blood glucose levels.
		Administer vitamin supplements as prescribed.
Foreign bodies	Foreign bodies retard healing.	Keep wounds free of dressing threads, ensure sterility of implanted items.
Oxygen deficit	Insufficient oxygen may be due to	Encourage deep

(tissue oxygenation insufficient)	inadequate lung and cardiovascular function as well as localized vasoconstriction.	breathing, turning, and controlled coughing.
Drainage accumulation	Accumulated secretions hamper healing process.	Monitor closed drainage systems for proper functioning. Institute measures to remove accumulated secretions.
Medications		
Corticosteroids	May mask presence of infection by impairing normal inflammatory response.	Be aware of action and effect of medications patient is receiving.
Anticoagulants	May cause hemorrhage.	
Broad-spectrum and specific antibiotics	Effective if given immediately before surgery for specific pathology or bacterial contamination. Ineffective if given after wound is closed due to intravascular coagulation at the periphery of the surgical site.	
Patient overactivity	Prevents approximation of wound edges. Resting favors healing.	Use measures to keep wound edges approximated: taping, bandaging, splints. Encourage rest.
Systemic Disorders		
Hemorrhagic shock Acidosis Hypoxia Kidney injury Hepatic disease Sepsis	These depress cell functions that directly affect wound healing.	Be familiar with the nature of the specific disorder. Administer prescribed treatment. Cultures may be indicated to determine appropriate antibiotic.
Immunosuppressed state	Patient is more vulnerable to bacterial and viral invasion; defense mechanisms are impaired.	Provide maximum protection to prevent infection. Restrict visitors with colds; institute mandatory hand hygiene by all staff.
Wound Stressors		
Vomiting Valsalva maneuver Heavy coughing Straining	Produce tension on wounds, particularly of the torso.	Encourage frequent turning and ambulation, and administer antiemetic

	medications as prescribed. Assist patient in splinting incision.

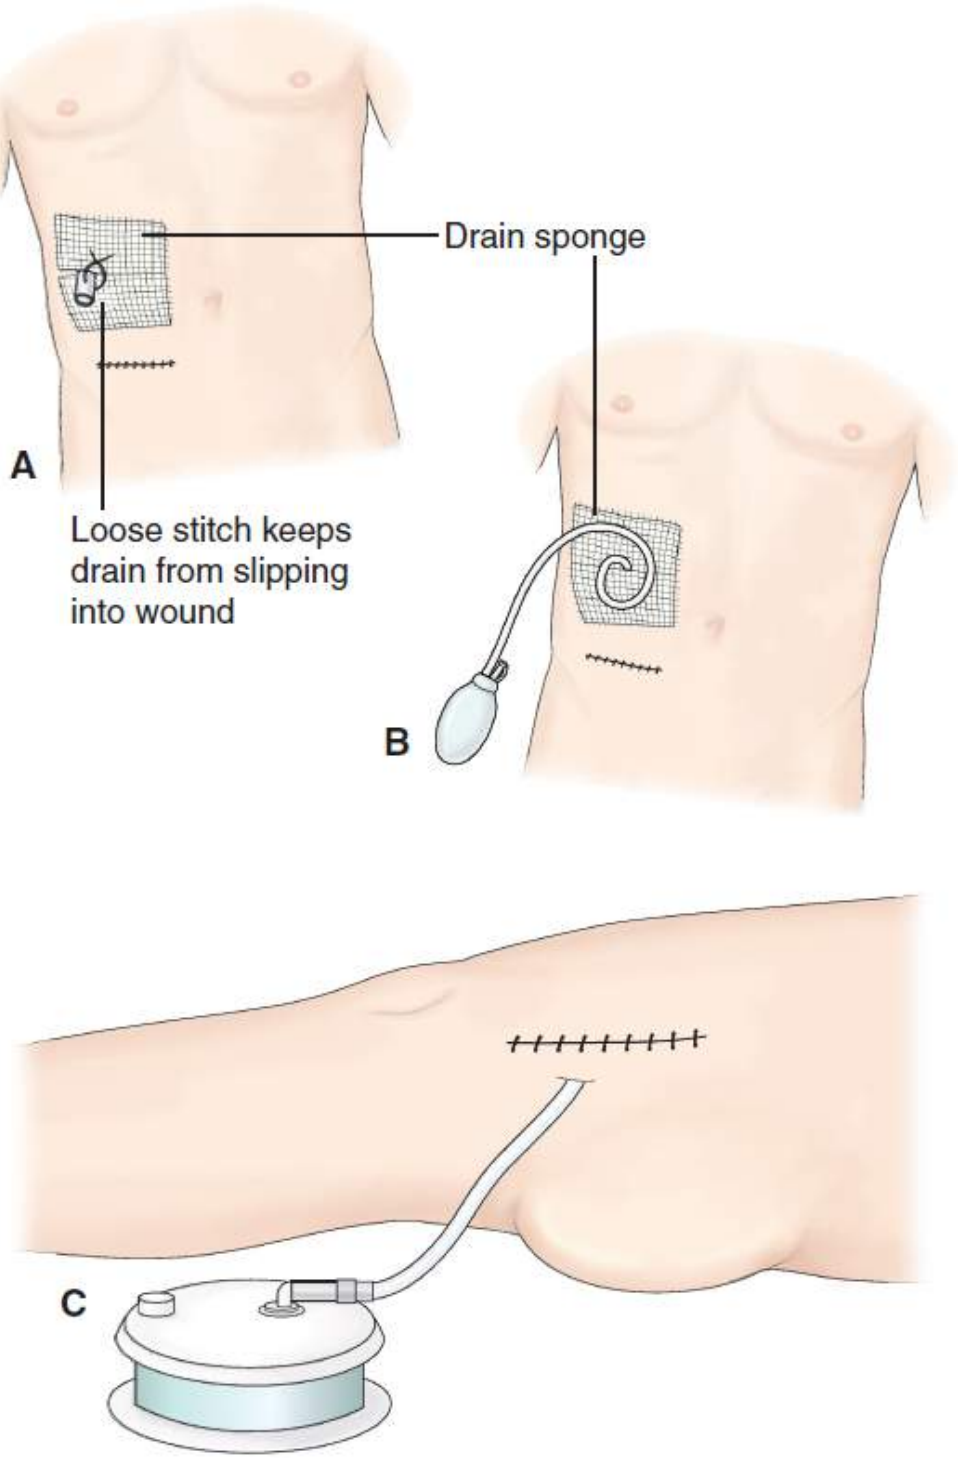

Figure 16-5 • Types of surgical drains: **A.** Penrose. **B.** Jackson–Pratt. **C.** Hemovac.

Caring for Surgical Drains. Nursing interventions to promote wound healing also include management of surgical drains. Drains are tubes that exit the peri-incisional area, either into a portable wound suction device (closed) or into the dressings (open). The principle involved is to allow the escape of fluids that could otherwise serve as a culture medium for bacteria. In portable wound suction, the use of gentle, constant suction enhances drainage of these fluids and collapses the skin flaps against the underlying tissue, thus removing "dead space." Types of wound drains include the Penrose, Jackson-Pratt, and Hemovac drains (see Fig. 16-5). Output (drainage) from wound systems is recorded.

Wound vacuum-assisted closure (VAC) devices are used on open wounds allowed to heal on their own. The wound VAC is a foam dressing that uses negative pressure suction at the wound surface. The vacuum removes debris while promoting granulation tissue growth and blood flow. Wound VACs are placed intraoperatively and the foam dressing is changed periodically as the wound shrinks in size (see Fig. 16-6). The amount, pressure, and color of drainage should be assessed and recorded. Patients should be assessed for pain as nerve endings may grow into the sponge as tissue regrows.

The amount of bloody drainage on the surgical dressing is assessed frequently. Spots of drainage on the dressings are outlined with a pen, and the date and time of the outline are recorded on the dressing so that increased drainage can be easily seen. A certain amount of bloody drainage in a wound drainage system or on the dressing is expected, but excessive amounts should be reported to the surgeon. Increasing amounts of fresh blood on the dressing should be reported immediately. Some wounds are irrigated heavily before closure in the OR, and open drains exiting the wound may be embedded in the dressings. These wounds may drain large amounts of blood-tinged fluid that saturate the dressing. The dressing can be reinforced with sterile gauze bandages; the time at which they were reinforced should be documented. If drainage continues, the surgeon should be notified so that the dressing can be changed. Multiple similar drains are numbered or otherwise labeled (e.g., left lower quadrant, left upper quadrant) so that output measurements can be reliably and consistently recorded.

Changing the Dressing

The surgical dressing is placed in the operating suite by a member of the surgical team. Dressing changes (if needed) in the immediate postoperative period are performed by the nurse. A dressing is applied to a wound for one or more of the following reasons: (1) to provide a proper environment for wound healing; (2) to absorb drainage; (3) to splint or immobilize the wound; (4) to protect the wound and new epithelial tissue from mechanical injury; (5) to protect the wound from bacterial contamination and from soiling by feces, vomitus, and urine; (6) to promote hemostasis, as in a pressure dressing; and (7) to provide mental and physical comfort for the patient.

The patient is told that the dressing is to be changed and that changing the dressing is a simple procedure associated with little discomfort. The dressing change is performed at a suitable time (e.g., not at mealtimes or when visitors are present). Privacy is provided, and the patient is not unduly exposed. Assurance is given that the incision will shrink as it heals and that the redness will fade.

The nurse performs hand hygiene before and after the dressing change and wears disposable gloves (sterile or clean as needed) for the dressing change itself. Most dressing changes following surgery are sterile. In accordance with standard precautions, dressings are never touched by ungloved hands because of the danger of transmitting pathogenic organisms. The tape or adhesive portion of the dressing is removed by pulling it parallel with the skin surface and in the direction of hair growth rather than at right angles. Alcohol wipes or nonirritating solvents aid in removing adhesive painlessly and quickly. The soiled dressing is removed and deposited in a container designated for disposal of biomedical waste.

Gloves are changed, and a new dressing is applied. If the patient is sensitive to adhesive tape, the dressing may be held in place with hypoallergenic tape. Many tapes are porous to prevent skin maceration. Some wounds become edematous after having been dressed, causing considerable tension on the tape. If the tape is not flexible, the stretching bandage will also cause a shear injury to the skin. This can result in denuded areas or large blisters and should be avoided. An elastic adhesive bandage (Elastoplast, 3M Microfoam) may be used to hold dressings in place over mobile areas, such as the neck or the extremities, or where pressure is required.

While changing the dressing, the nurse has an opportunity to educate the patient on how to care for the incision and change the dressings at home. The nurse observes for indicators of the patient's readiness to learn, such as looking at the incision, expressing interest, or assisting in the dressing change. Information on self-care activities and possible signs of infection is summarized in **Chart 16-6.**

Maintaining Normal Body Temperature

The patient is still at risk for malignant hyperthermia and hypothermia in the postoperative period. Efforts are made to identify malignant hyperthermia and to treat it early and promptly (Rothrock, 2019).

Patients who have received anesthesia are susceptible to chills and drafts. Interventions to avoid hypothermia, temperatures below 36°C (98.6°F), begin in the preoperative area (see Chapter 14) and continue throughout the intraoperative period (see Chapter 15). Low body temperature is reported to the primary provider. The room is maintained at a comfortable temperature, and blankets are provided to prevent chilling. Treatment includes oxygen administration, adequate hydration, and proper nutrition including glycemic control. The patient is also monitored for cardiac arrhythmias. The risk of hypothermia is greater in older adults and in patients who were in the cool OR environment for a prolonged period.

Managing Gastrointestinal Function and Resuming Nutrition

Discomfort of the GI tract (nausea, vomiting, and hiccups) and resumption of oral intake are issues for the patient and affect their outcome following surgery. (See the earlier discussion of PONV in the PACU.)

If the risk of vomiting is high due to the nature of surgery, a nasogastric tube is inserted preoperatively and remains in place throughout the surgery and the immediate postoperative period. A nasogastric tube also may be inserted before surgery if postoperative distention is anticipated. In addition, a nasogastric tube may be inserted if a patient who has food in the stomach requires emergency surgery.

Hiccups, produced by intermittent spasms of the diaphragm secondary to irritation of the phrenic nerve, can occur after surgery. The irritation may be direct, such as from stimulation of the nerve by a distended stomach, subdiaphragmatic abscess, or abdominal distention; indirect, such as from toxemia or uremia that stimulates the nerve; or reflexive, such as from irritation from a drainage tube or obstruction of the intestines. These occurrences usually are mild, transitory attacks that cease spontaneously. If hiccups persist, they may produce considerable distress and serious effects, such as vomiting, exhaustion, and wound dehiscence. Chlorpromazine (a phenothiazine) is the only drug approved to treat intractable hiccups (Aroke & Hicks, 2019).

Chart 16-6 **PATIENT EDUCATION**

Wound Care Instructions

Until Sutures Are Removed

1. Keep the wound dry and clean.
   - If there is no dressing, ask your nurse or physician if you can bathe or shower.
   - If a dressing or splint is in place, do not remove it unless it is wet or soiled.
   - If wet or soiled, change dressing yourself if you have been taught to do so; otherwise, call your nurse or physician for guidance.
   - If you have been taught, instruction might be as follows:
   - Cleanse area *gently* with sterile normal saline once or twice daily.
   - Cover with a sterile Telfa pad™ or gauze square large enough to cover wound.
   - Apply hypoallergenic tape (Dermicel™ or paper). Adhesive is not recommended because it is difficult to remove without possible injury to the incisional site.
2. Immediately report any of these signs of infection:
   - Redness, marked swelling exceeding 0.5 inch (2.5 cm) from incision site; tenderness; or increased warmth around wound
   - Red streaks in skin near wound
   - Pus or discharge, foul odor
   - Chills or temperature higher than 37.7°C (100°F)
3. If soreness or pain causes discomfort, apply a dry cool pack (containing ice or cold water) or take prescribed acetaminophen tablets every 4 to 6 hours. Avoid using aspirin without direction or instruction because bleeding can occur with its use.
4. Swelling after surgery is common. To help reduce swelling, elevate the affected part to the level of the heart.
   - Hand or arm:
   - Sleep—elevate arm on pillow at side
   - Sitting—place arm on pillow on adjacent table
   - Standing—rest affected hand on opposite shoulder; support elbow with unaffected hand
   - Leg or foot:
   - Sitting—place a pillow on a facing chair; provide support underneath the knee
   - Lying—place a pillow under affected leg

After Sutures Are Removed

Although the wound appears to be healed when sutures are removed, it is still tender and will continue to heal and strengthen for several weeks.

- Follow recommendations of physician or nurse regarding extent of activity.
- Keep suture line clean; do not rub vigorously; pat dry. Wound edges may look red and may be slightly raised. This is normal.
- If the site continues to be red, thick, and painful to pressure after 8 weeks, consult the health care provider. (This may be due to excessive collagen formation and should be checked.)

Quality and Safety Nursing Alert

Any condition that is persistent or considered intractable, such as hiccups, should be reported to the primary provider so that appropriate measures can be implemented.

Once PONV has subsided and the patient is fully awake and alert, the sooner they can tolerate a usual diet, the more quickly normal GI function will resume. Taking food by mouth stimulates digestive juices and promotes gastric function and intestinal peristalsis. The return to normal dietary intake should proceed at a pace set by the patient. The nature of the surgery and the type of anesthesia directly affect the rate at which normal gastric activity resumes. Enhanced recovery programs encourage early nutrition as a way to maintain fluid balance, prevent postoperative ileus, and decrease overall length of stay (Persico et al., 2019).

Clear liquids are typically the first substances desired and tolerated by the patient after surgery. Water, juice, and tea may be given in increasing amounts. Cool fluids are tolerated more easily than those that are ice cold or hot. Soft foods (gelatin, custard, milk, and creamed soups) are added gradually after clear fluids have been tolerated. As soon as the patient tolerates soft foods well, solid food may be given.

Assessment and management of GI function are important after surgery because the GI tract is subject to uncomfortable or potentially life-threatening complications. Any postoperative patient may suffer from distention. Postoperative distention of the abdomen results from the accumulation of gas in the intestinal tract. Manipulation of the abdominal

organs during surgery may produce a loss of normal peristalsis for 24 to 48 hours, depending on the type and extent of surgery. Even though nothing is given by mouth, swallowed air and GI tract secretions enter the stomach and intestines; if not propelled by peristalsis, they collect in the intestines, producing distention and causing the patient to complain of fullness or pain in the abdomen. Most often, the gas collects in the colon. Abdominal distention is further increased by immobility, anesthetic agents, and the use of opioid medications.

After major abdominal surgery, distention may be avoided by having the patient turn frequently, exercise, and ambulate as early as possible. This also alleviates distention produced by swallowing air, which is common in anxious patients. A nasogastric tube inserted before surgery may remain in place until full peristaltic activity (indicated by the passage of flatus) has resumed. The nurse detects bowel sounds by listening to the abdomen with a stethoscope. Bowel sounds are documented so that diet progression can occur.

Paralytic ileus and intestinal obstruction are potential postoperative complications that occur more frequently in patients undergoing intestinal or abdominal surgery (see Chapter 41).

Promoting Bowel Function

Constipation can occur after surgery as a minor or a serious complication. Decreased mobility, decreased oral intake, and opioid analgesic medications can contribute to difficulty having a bowel movement. In addition, irritation and trauma to the bowel during surgery may inhibit intestinal movement for several days. The combined effect of early ambulation, improved dietary intake, and a stool softener (if prescribed) promotes bowel elimination. Multimodal analgesia regimens in surgical patients minimize opioid-related adverse effects such as nausea, vomiting, and reduced gastric motility (Wolfe, 2018). The nurse should assess the abdomen for distention and the presence and frequency of bowel sounds. If the patient does not have a bowel movement by the second or third postoperative day, the primary provider should be notified and a laxative or other test or intervention may be needed.

Managing Voiding

The type of procedure, length of case, and patient position may have warranted a catheter being placed in the patient's urinary tract in the OR. In the postoperative period, any urine that was collected using a catheter (indwelling or straight) during the operative procedure should be noted. This information will assist the nurse to anticipate the patient's voiding needs.

Urinary retention after surgery can occur for various reasons. Anesthetics, anticholinergic agents, and opioids interfere with the

perception of bladder fullness and the urge to void and inhibit the ability to initiate voiding and completely empty the bladder. Abdominal, pelvic, and hip surgery may increase the likelihood of retention secondary to pain. In addition, some patients find it difficult to use the bedpan or urinal in the recumbent position.

Bladder distention and the urge to void should be assessed at the time of the patient's arrival at the unit and frequently thereafter. The patient is expected to void within 8 hours after surgery (this includes time spent in the PACU). If the patient has an urge to void and cannot, or if the bladder is distended and no urge is felt or the patient cannot void, catheterization is not delayed solely on the basis of the 8-hour time frame. All methods to encourage the patient to void should be tried (e.g., letting water run, applying heat to the perineum). The bedpan should be warm; a cold bedpan causes discomfort and automatic tightening of muscles (including the urethral sphincter). If the patient cannot void on a bedpan, it may be possible to use a commode or a toilet (if there is one in the PACU). Male patients are often permitted to sit up or stand beside the bed to use the urinal; however, safeguards should be taken to prevent the patient from falling or fainting due to loss of coordination from medications or orthostatic hypotension. If the patient has not voided within the specified time frame, a portable bladder ultrasound is performed to check for urinary retention (see Chapter 47, Fig. 47-8). The patient is catheterized, and the catheter is removed after the bladder has emptied. Straight intermittent catheterization is preferred over indwelling catheterization because the risk of infection is increased with an indwelling catheter.

Even if the patient voids, the bladder may not empty. The nurse notes the amount of urine voided and palpates the suprapubic area for distention or tenderness. Postvoid residual urine may be assessed by using either straight catheterization or a portable bladder ultrasound scanner and is considered diagnostic of urinary retention. Bladder scanning is an effective way to detect urinary retention in patients who have had general and regional anesthesia. Research suggests that frequent bladder scanning decreases incontinence as retention is detected early and treated before an incontinent episode (Wishart, 2019).

Maintaining a Safe Environment

During the immediate postoperative period, the patient recovering from anesthesia should have two side rails up, and the bed should be in the low position. The nurse assesses the patient's level of consciousness and orientation and determines whether the patient can resume wearing assistive devices as needed (e.g., eyeglasses, hearing aid). Impaired vision, inability to hear postoperative instructions, or inability to communicate verbally places the patient at risk for injury. All objects the patient may need should be within reach, especially the call light. Any immediate

postoperative prescribed therapies concerning special positioning, equipment, or interventions should be implemented as soon as possible. The patient is instructed to ask for assistance with any activity. Although restraints are occasionally necessary for a patient who is disoriented, they should be avoided if at all possible (see Chapter 1 for further discussion on use of restraints). Agency policy on the use of restraints must be consulted and followed.

Any surgical procedure has the potential for injury due to disrupted neurovascular integrity resulting from prolonged awkward positioning in the OR, manipulation of tissues, inadvertent severing of nerves or blood vessels, or tight bandages. Any orthopedic or neurologic surgery or surgery involving the extremities carries a risk of peripheral nerve damage. Vascular surgeries, such as replacement of sections of diseased peripheral arteries or insertion of an arteriovenous graft, put the patient at risk for thrombus formation at the surgical site and subsequent ischemia of tissues distal to the thrombus. Assessment includes having the patient move the hand or foot distal to the surgical site through a full range of motion, assessing all surfaces for intact sensation, and assessing peripheral pulses (Rothrock, 2019).

Providing Emotional Support to the Patient and Family

Although patients and families are undoubtedly relieved that surgery is over, stress and anxiety levels may remain high in the immediate postoperative period. Many factors contribute to this stress and anxiety, including pain, being in an unfamiliar environment, inability to control one's circumstances or care for oneself, fear of the long-term effects of surgery, fear of complications, fatigue, spiritual distress, altered role responsibilities, ineffective coping, and altered body image, and all are potential reactions to the surgical experience. The nurse helps the patient and family work through their stress and anxieties by providing reassurance and information and by spending time listening to and addressing their concerns. The nurse describes hospital routines and what to expect in the time until discharge and explains the purpose of nursing assessments and interventions. Informing patients when they will be able to drink fluids or eat, when they will be getting out of bed, and when tubes and drains will be removed helps them gain a sense of control and participation in recovery and engages them in the plan of care. Acknowledging family members' concerns and accepting and encouraging their participation in the patient's care assist them in feeling that they are helping their loved one. The nurse can modify the environment to enhance rest and relaxation by providing privacy, reducing noise, adjusting lighting, providing enough seating for family members, and encouraging a supportive atmosphere.

TABLE 16-4 Select Postoperative Complications

Body System/Type	Complications
Respiratory	Atelectasis, pneumonia, pulmonary embolism, aspiration
Cardiovascular	Shock, thrombophlebitis, DVT, pulmonary embolism
Neurologic	Delirium, stroke
Skin/Wound	Breakdown, infection, dehiscence, evisceration, delayed healing, hemorrhage, hematoma
Gastrointestinal	Constipation, paralytic ileus, bowel obstruction
Urinary	Acute urine retention, urinary tract infection
Functional	Weakness, fatigue, functional decline

DVT, deep vein thrombosis.

Managing Potential Complications

The postoperative patient is at risk for complications as outlined next and summarized in Table 16-4.

Venous Thromboembolism. Serious potential VTE complications of surgery include DVT and PE (Rothrock, 2019).

Prevention of DVT and PE development includes pharmacologic prophylaxis (e.g., subcutaneous heparin) (Odom-Forren, 2018). External pneumatic compression and antiembolism stockings can be used alone or in combination with low-dose heparin. The stress response that is initiated by surgery inhibits the thrombolytic (fibrinolytic) system, resulting in blood hypercoagulability. Dehydration, low cardiac output, blood pooling in the extremities, and bed rest add to the risk of thrombosis formation. Although all postoperative patients are at some risk, factors such as a history of thrombosis, malignancy, trauma, obesity, indwelling venous catheters, and hormone use (e.g., estrogen) increase the risk. The first symptom of DVT may be a pain or cramp in the calf, although many patients are asymptomatic. Other signs and symptoms include tachypnea, chest pain, hemoptysis, shortness of breath, and a sense of impending doom (Odom-Forren, 2018).

The benefits of early ambulation and leg exercises in preventing DVT cannot be overemphasized, and these activities are recommended for all patients, regardless of their risk. It is important to avoid the use of blanket rolls, pillow rolls, or any form of elevation that can constrict vessels under the knees. Even prolonged "dangling" (having the patient sit on the edge of the bed with legs hanging over the side) can be dangerous and is not recommended in susceptible patients because pressure under the knees can impede circulation. Adequate hydration is also encouraged; the patient can be offered juices and water throughout the day to avoid dehydration. (Refer to Chapter 26 for discussion of DVT and PE.)

Hematoma. At times, concealed bleeding occurs beneath the skin at the surgical site. This hemorrhage usually stops spontaneously but results in clot (hematoma) formation within the wound. If the clot is small, it will be absorbed and need not be treated. If the clot is large, the wound usually bulges somewhat, and healing will be delayed unless the clot is removed. Evacuation of the clot requires surgery where several sutures are removed by the surgeon, the clot is evacuated, and the wound is packed lightly with gauze. Healing occurs usually by granulation, or a secondary closure may be performed.

Infection (Wound Sepsis). The creation of a surgical wound disrupts the integrity of the skin, bypassing the body's primary defense and protection against infection. Exposure of deep body tissues to pathogens in the environment places the patient at risk for infection of the surgical site, and a potentially life-threatening complication such as infection can increase the length of hospital stay, costs of care, and risk of further complications.

Joint Commission–approved hospitals measure surgical site infections (SSIs) for the first 30 or 90 days following surgical procedures based on national standards. Reduction of SSIs remains an important National Patient Safety Goal (see Chapter 14, Chart 14-7) (Joint Commission, 2019).

Multiple factors, including the type of wound, place the patient at potential risk for infection. Surgical wounds are classified according to the degree of contamination. Table 16-5 defines the classification of surgical wounds and SSI rates per category. Patient-related factors include age, nutritional status, diabetes, smoking, obesity, remote infections, endogenous mucosal microorganisms, altered immune response, length of preoperative stay, and severity of illness (Rothrock, 2019). Factors related to the surgical procedure are proper ventilation in the surgical space, aseptic technique of personnel, sterile instrument use, and overall room cleanliness (Armellino, 2017). The focus of infection prevention has transitioned from controlling infections to preventing their occurrence. Prevention efforts include skin antisepsis, preoperative bathing, hair removal, antimicrobial prophylaxis, and patient temperature management (Padgette & Wood, 2018). (Preoperative and intraoperative risks and interventions are discussed in Chapters 14 and 15.) Postoperative care of the wound centers on assessing the wound, preventing contamination and infection before wound edges have sealed, and enhancing healing.

Signs and symptoms of wound infection include increased pulse rate and temperature; an elevated white blood cell count; wound swelling, warmth, tenderness, or discharge; and increased incisional pain. Local signs may be absent if the infection is deep. *Staphylococcus aureus* accounts for many postoperative wound infections. Other infections may result from *Escherichia coli, Proteus vulgaris, Aerobacter aerogenes, Pseudomonas aeruginosa,* and other organisms. Although they are rare, beta-hemolytic

streptococcal or clostridial infections can be rapid and deadly and need strict infection control practices to prevent the spread of infection to others. Intensive medical and nursing care is essential if the patient is to survive (Ackley & Ladwig, 2017).

When a wound infection is diagnosed in a surgical incision, the surgeon may remove one or more sutures or staples and, using aseptic precautions, separate the wound edges with a pair of blunt scissors or a hemostat. Once the incision is opened, a drain may be inserted. If the infection is deep, an incision and drainage procedure may be necessary. Antimicrobial therapy and a wound care regimen are also initiated.

Wound Dehiscence and Evisceration. Wound **dehiscence** (disruption of surgical incision or wound) and **evisceration** (protrusion of wound contents) are serious surgical complications (see Fig. 16-7). Dehiscence and evisceration are especially serious when they involve abdominal incisions or wounds. These complications result from sutures giving way, from infection, or, more frequently, from marked distention or strenuous cough. They may also occur because of increasing age, anemia, poor nutritional status, obesity, malignancy, diabetes, the use of steroids, and other factors in patients undergoing abdominal surgery.

TABLE 16-5 Wound Classification and Associated Surgical Site Infection Risk

Surgical Category	Determinants of Category	Expected Risk of Postsurgical Infection (%)
Clean	Nontraumatic site Uninfected site No inflammation No break in aseptic technique No entry into respiratory, alimentary, genitourinary, or oropharyngeal tracts	1–3
Clean contaminated	Entry into respiratory, alimentary, genitourinary, or oropharyngeal tracts without unusual contamination Appendectomy Minor break in aseptic technique Mechanical drainage	3–7
Contaminated	Open, newly experienced traumatic wounds Gross spillage from gastrointestinal tract Major break in aseptic technique Entry into genitourinary or biliary tract when urine or bile is infected	7–16
Dirty	Traumatic wound with delayed repair, devitalized tissue, foreign bodies, or fecal contamination Acute inflammation and purulent drainage encountered during procedure	16–29

Adapted from Edmiston, C. E., Jr., & Spencer, M. (2014). Patient care interventions to help reduce the risk of surgical site infections. *AORN Journal*, *100*(6), 590–602.

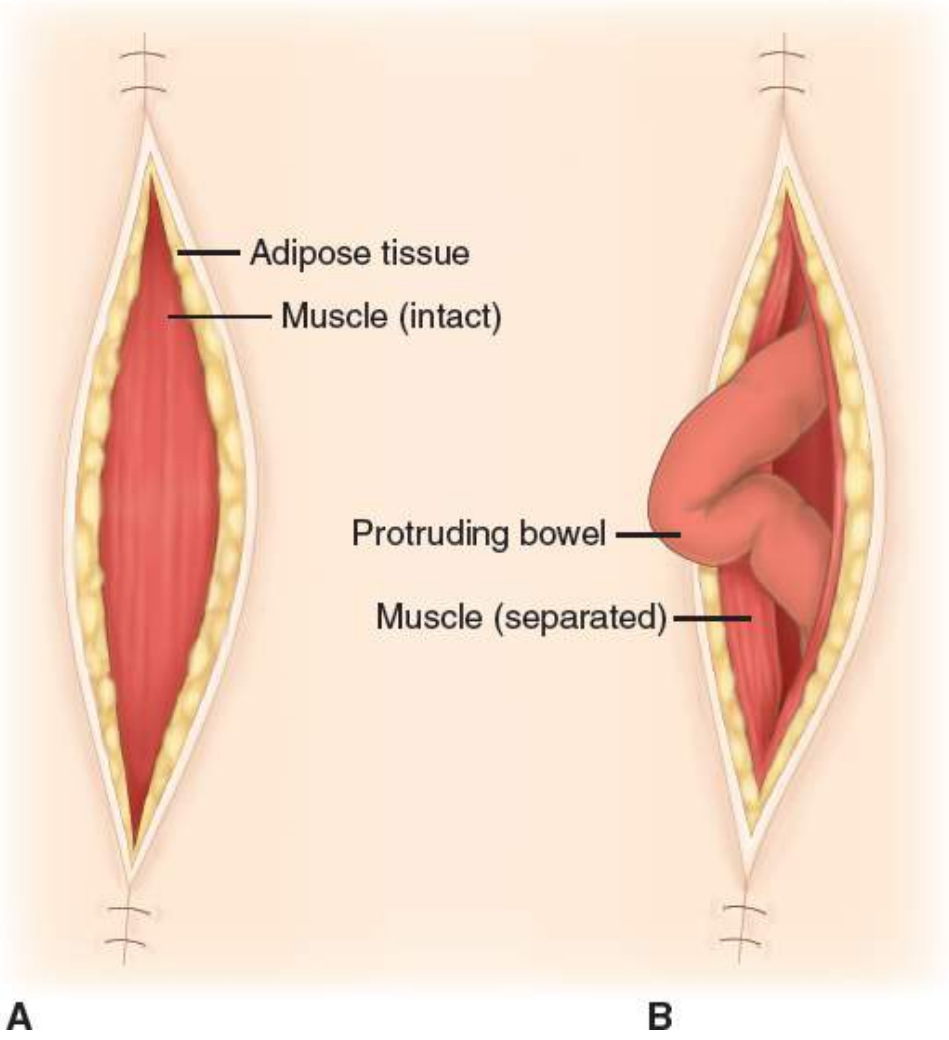

Figure 16-7 • **A.** Wound dehiscence. **B.** Wound evisceration.

When the wound edges separate slowly, the intestines may protrude gradually or not at all, and the earliest sign may be a gush of bloody (serosanguineous) peritoneal fluid from the wound. When a wound ruptures suddenly, coils of intestine may push out of the abdomen. The patient may report that "something gave way." The evisceration causes pain and may be associated with vomiting.

Quality and Safety Nursing Alert

If disruption of a wound occurs, the patient is placed in the low Fowler position and instructed to lie as still as possible. These actions minimize protrusion of body tissues. The protruding coils of intestine are covered with sterile dressings moistened with sterile saline solution, and the surgeon is notified at once.

An abdominal binder can provide support and guard against dehiscence and may be used along with the primary dressing, especially in patients with weak or pendulous abdominal walls or when rupture of a wound has occurred.

Gerontologic Considerations. Older patients recover more slowly, have longer hospital stays, and are at greater risk for development of postoperative complications. Cardiovascular, respiratory, renal, hepatic, thermoregulatory, sensory, and cognition problems unique to the older adult can cause complications throughout the recovery phase (Odom-Forren, 2018). Expert nursing care can help the older adult avoid these complications or minimize their effects (Rothrock, 2019).

Potential causes of postoperative delirium are multifactorial (see Chart 16-7). Skilled and frequent assessment of mental status and of all physiologic factors helps the nurse plan care because delirium may be the initial or only indicator of infection, fluid and electrolyte imbalance, or deterioration of respiratory or hemodynamic status in the older adult patient. Factors that determine whether a patient is at risk for delirium include age, history of alcohol abuse, preoperative cognitive function, physical function, serum chemistries, and type of surgery.

Chart 16-7

Potential Causes of Postoperative Delirium

- Acid–base disturbances
- Acute myocardial infarction
- Age >80 years
- Alcohol withdrawal
- Blood loss
- Cerebral hypoxia
- Decreased cardiac output
- Dehydration
- Emergent surgery
- Fecal impaction
- Fluid and electrolyte imbalance
- Heart failure
- High stress or anxiety levels
- History of dementia like symptoms
- Hypercarbia
- Hypothermia or hyperthermia
- Hypoxia
- Infection (urinary tract, wound, respiratory)
- Medications (anticholinergics, benzodiazepines, central nervous system depressants)
- Polypharmacy
- Presence of multiple diseases
- Sensory impairments
- Unfamiliar surroundings and sensory deprivation
- Unrelieved pain
- Urinary retention

Recognizing postoperative delirium and identifying and treating its underlying cause are the goals of care. Postoperative delirium is sometimes mistaken for preexisting dementia or is attributed to age. In addition to monitoring and managing identifiable causes, the nurse implements supportive interventions. Keeping the patient in a well-lit room and in close proximity to staff can reduce sensory deprivation. At the same time, distracting and unfamiliar noises should be minimized. Because pain can contribute to postoperative delirium, adequate pain control without oversedation is essential (Rothrock, 2019).

The patient is reoriented as often as necessary, and staff should introduce themselves each time they come in contact with the patient. Engaging the patient in conversation and care activities and placing a clock and calendar nearby may improve cognitive function. Physical activity should not be

neglected while the patient is confused because physical deterioration can worsen delirium and place the patient at increased risk for other complications. Restraints should be avoided because they can worsen confusion. A staff member is asked to stay with the patient instead. Medications may be given during episodes of acute confusion but should be discontinued as soon as possible to avoid side effects.

Other problems confronting the older postoperative patient, such as pneumonia, altered bowel function, DVT, weakness, and functional decline, often can be prevented by early and progressive ambulation. Prolonged sitting positions are avoided as they promote venous stasis in the lower extremities. A physical therapy referral may be indicated to promote safe, regular exercise for the older adult.

Urinary incontinence can be prevented by providing easy access to the call bell and the commode and by prompting voiding. Early ambulation and familiarity with the room help the patient become self-sufficient sooner.

Optimal nutrition can help promote wound healing and anesthesia recovery. The nurse and patient can consult with the dietitian to plan appealing, high-protein meals that provide sufficient fiber, calories, and vitamins. Nutritional supplements, such as Ensure™ or Sustacal™, may be recommended. Multivitamins, iron, and vitamin C supplements may be prescribed to aid in tissue healing, formation of new red blood cells, and overall nutritional status.

In addition to monitoring and managing physiologic recovery of the older adult, the nurse identifies and addresses psychosocial needs. The older adult may require much encouragement and support to resume activities, and the pace may be slow. Sensory deficits may require frequent repetition of instructions, and decreased physiologic reserve may necessitate frequent rest periods. The older adult may require extensive discharge planning to coordinate both professional and family care providers, and the nurse, social worker, or case management resource may institute the plan for continuing and transitional care.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Patient education is critical during postoperative care and includes what can be expected at every stage of the surgical process, including after discharge. It is important for nurses to assess patients preoperatively, especially outpatients, to determine their ability to manage at home and begin educating them about managing any postoperative wound care, drains, or other daily care needs (Lahr & Elliot, 2018). Although needs are specific to individual patients and the procedures they have undergone, general patient education needs prior to discharge have been identified (see Chart 16-3).

Continuing and Transitional Care. Community-based and transitional care services are frequently necessary after surgery. Older patients, patients who live alone, patients without family support, and patients with preexisting chronic illness or disabilities are often in greatest need. Planning for discharge involves arranging for necessary services early in the acute care hospitalization for wound care, drain management, catheter care, infusion therapy, and physical or occupational therapy. The home, community-based, or transitional care nurse coordinates these activities and services.

During home visits, the nurse assesses the patient for postoperative complications by assessment of the surgical incision, respiratory and cardiovascular status, adequacy of pain management, fluid and nutritional status, and the patient's progress in returning to preoperative status. The nurse evaluates the patient's ability to administer prescribed medications, manage dressing changes, drainage systems and other devices. The nurse may change dressings or catheters if needed. The nurse identifies any additional services that are needed and assists the patient and family to arrange for them. Previous education is reinforced, and the patient is reminded to keep follow-up appointments. The patient and family are educated about signs and symptoms to be reported to the surgeon. In addition, the nurse provides information about how to obtain needed supplies and suggests resources or support groups.

Evaluation

Expected patient outcomes may include the following:

1. Maintains optimal respiratory function
    a. Performs deep-breathing exercises
    b. Displays clear breath sounds
    c. Uses incentive spirometer as prescribed
    d. Splints incisional site when coughing to reduce pain
2. Indicates that pain is decreased in intensity
3. Increases activity as prescribed
    a. Alternates periods of rest and activity
    b. Progressively increases ambulation
    c. Resumes normal activities within the prescribed time frame
    d. Performs activities related to self-care
4. Wound heals without complication
5. Maintains body temperature within normal limits
6. Resumes oral intake
    a. Reports absence of nausea and vomiting
    b. Eats at least 75% of usual diet

c. Is free of abdominal distress and gas pains
d. Exhibits normal bowel sounds

7. Reports resumption of usual bowel elimination pattern
8. Resumes usual voiding pattern
9. Is free of injury
10. Exhibits decreased anxiety
11. Acquires knowledge and skills necessary to manage regimen after discharge
12. Experiences no complications

CRITICAL THINKING EXERCISES

1 ipc A 38-year-old woman is admitted to the PACU following open abdominal surgery for excision of a benign tumor and lysis of adhesions. The patient has been a smoker for many years and begins coughing as soon as she is transferred from the OR stretcher to the bed in PACU. How will you, as the nurse receiving this patient, facilitate an interprofessional discussion to improve her care and increase her chance of a good surgical outcome? What information is essential to obtain from the OR team during handoff report?

2 pq A 60-year-old man with obesity and a history of diabetes is admitted to the PACU following a right shoulder repair. He received multimodal analgesia, including a peripheral nerve block, and is scheduled to be discharged home. Identify the essential information you would need reported from the OR team. What are your immediate priorities in delivering care to this patient? He is transferred to Phase II PACU. What are your priorities for discharge instructions and education for this patient?

3 ebp An 80-year-old man has had a right total knee replacement. The anesthesia given was a spinal anesthetic. What signs and symptoms might he exhibit as he awakens from the surgery? As the PACU nurse, what complications should you observe for as he recovers? Describe an evidence-based nursing care plan for the patient during his hospital stay.

UNIT 4 Gas Exchange and Respiratory Function

Case Study

PROVIDING EVIDENCE-BASED CARE FOR A PATIENT WITH COVID-19

The medical unit where you work has just been designated to exclusively admit patients with coronavirus 2019 (COVID-19). A 35-year-old male admitted to the unit has a history of asthma and

hypertension that are both normally well controlled with medication. His temperature is 39°C (101.4°F), he has a cough and tests positive for COVID-19. The nurse manager asks you to develop an evidence-based plan of care that can be individualized for this patient and used as a template for other patients admitted to your unit with COVID-19.

QSEN Competency Focus: Evidence-Based Practice (EBP)

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Evidence-Based Practice Definition: Integrate best current evidence with clinical expertise and patient/family preferences and values for delivery of optimal health care.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Differentiate clinical opinion from research and evidence summaries	Identify the pathophysiologic basis for why patients with asthma and hypertension are at higher risk for COVID-19. What is the strength of the evidence for an evidence-based plan of care for this patient?
Skills	
Locate evidence reports related to clinical practice topics and guidelines	What strategies would you use to search for and then identify appropriate evidence for developing an evidence-based plan of care for this patient? What resources might you mobilize for this patient so he can become educated on the best practices to prevent the spread of COVID-19 while he is in the hospital and upon discharge?
Attitudes	
Value the concept of EBP as integral to determining best clinical practice	Reflect on your attitudes toward using EBP for patients with COVID-19. Do you tend to think that infection is inevitable in patients with risk factors?

17 Assessment of Respiratory Function

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the structures and functions of the upper and lower respiratory tracts and concepts of ventilation, diffusion, perfusion, and ventilation–perfusion imbalances.
2. Explain and demonstrate proper techniques utilized to perform a comprehensive respiratory assessment.
3. Discriminate between normal and abnormal assessment findings of the respiratory system identified by inspection, palpation, percussion, and auscultation.
4. Recognize and evaluate the major symptoms of respiratory dysfunction by applying concepts from the patient's health history and physical assessment findings.
5. Identify the diagnostic tests used to evaluate respiratory function and related nursing implications.

NURSING CONCEPTS

Assessment
Oxygenation
Perfusion

GLOSSARY

apnea: temporary cessation of breathing

bronchophony: abnormal increase in clarity of transmitted voice sounds heard when auscultating the lungs

bronchoscopy: direct examination of the larynx, trachea, and bronchi using an endoscope

cilia: short, fine hairs that provide a constant whipping motion that serves to propel mucus and foreign substances away from the lung toward the larynx

compliance: measure of the force required to expand or inflate the lungs

crackles: nonmusical, discontinuous popping sounds during inspiration caused by delayed reopening of the airways heard on chest auscultation

dyspnea: subjective experience that describes an uncomfortable or painful breathing sensation when either at rest or while walking or climbing stairs; also commonly referred to as shortness of breath

egophony: abnormal change in tone of voice that is heard when auscultating the lungs

fremitus: vibrations of speech felt as tremors of the chest wall during palpation

hemoptysis: expectoration of blood from the respiratory tract

hypoxemia: decrease in arterial oxygen tension in the blood

hypoxia: decrease in oxygen supply to the tissues and cells

obstructive sleep apnea: temporary absence of breathing during sleep secondary to transient upper airway obstruction

orthopnea: shortness of breath when lying flat; relieved by sitting or standing

oxygen saturation: percentage of hemoglobin that is bound to oxygen

physiologic dead space: portion of the tracheobronchial tree that does not participate in gas exchange

pulmonary diffusion: exchange of gas molecules (oxygen and carbon dioxide) from areas of high concentration to areas of low concentration

pulmonary perfusion: blood flow through the pulmonary vasculature

respiration: gas exchange between atmospheric air and the blood and between the blood and cells of the body

rhonchi: deep, low-pitched snoring sound associated with partial airway obstruction, heard on chest auscultation

stridor: continuous, high-pitched, musical sound heard on inspiration, best heard over the neck; may be heard without use of a stethoscope, secondary to upper airway obstruction

tachypnea: abnormally rapid respirations

tidal volume: volume of air inspired and expired with each breath during normal breathing

ventilation: movement of air in and out of the airways

wheezes: continuous musical sounds associated with airway narrowing or partial obstruction

whispered pectoriloquy: whispered sounds heard loudly and clearly upon thoracic auscultation

Disorders of the respiratory system are common and are encountered by nurses in every setting, from the community to the intensive care unit. Expert assessment skills must be developed and used to provide the best care for patients with acute and chronic respiratory problems. Alterations in respiratory status have been identified as important predictors of clinical deterioration in hospitalized patients (Institute for Healthcare Improvement [IHI], 2019). To differentiate between normal and abnormal assessment findings and recognize subtle changes that may negatively impact patient outcomes, nurses require an understanding of respiratory function and the significance of abnormal diagnostic test results.

Anatomic and Physiologic Overview

The respiratory system is composed of the upper and lower respiratory tracts. Together, the two tracts are responsible for **ventilation** (movement of air in and out of the airways). The upper respiratory tract, known as the upper airway, warms and filters inspired air so that the lower respiratory tract (the lungs) can accomplish gas exchange or diffusion. Gas exchange involves delivering oxygen to the tissues through the bloodstream and expelling waste gases, such as carbon dioxide, during expiration. The respiratory system depends on the cardiovascular system for perfusion, or blood flow through the pulmonary system (Norris, 2019).

Anatomy of the Respiratory System

Upper Respiratory Tract

Upper airway structures consist of the nose; paranasal sinuses; pharynx, tonsils, and adenoids; larynx; and trachea.

Nose

The nose serves as a passageway for air to pass to and from the lungs. It filters impurities and humidifies and warms the air as it is inhaled. The nose is

composed of an external and an internal portion. The external portion protrudes from the face and is supported by the nasal bones and cartilage. The anterior nares (nostrils) are the external openings of the nasal cavities.

The internal portion of the nose is a hollow cavity separated into the right and left nasal cavities by a narrow vertical divider, the septum. Each nasal cavity is divided into three passageways by the projection of the turbinates from the lateral walls. The turbinate bones are also called *conchae* (the name suggested by their shell-like appearance). Because of their curves, these bones increase the mucous membrane surface of the nasal passages and slightly obstruct the air flowing through them (Fig. 17-1).

Air entering the nostrils is deflected upward to the roof of the nose, and it follows a circuitous route before it reaches the nasopharynx. It comes into contact with a large surface of moist, warm, highly vascular, ciliated mucous membrane (called *nasal mucosa*) that traps practically all of the dust and organisms in the inhaled air. The air is moistened, warmed to body temperature, and brought into contact with sensitive nerves. Some of these nerves detect odors; others provoke sneezing to expel irritating dust. Mucus, secreted continuously by goblet cells, covers the surface of the nasal mucosa and is moved back to the nasopharynx by the action of the **cilia** (short, fine hairs).

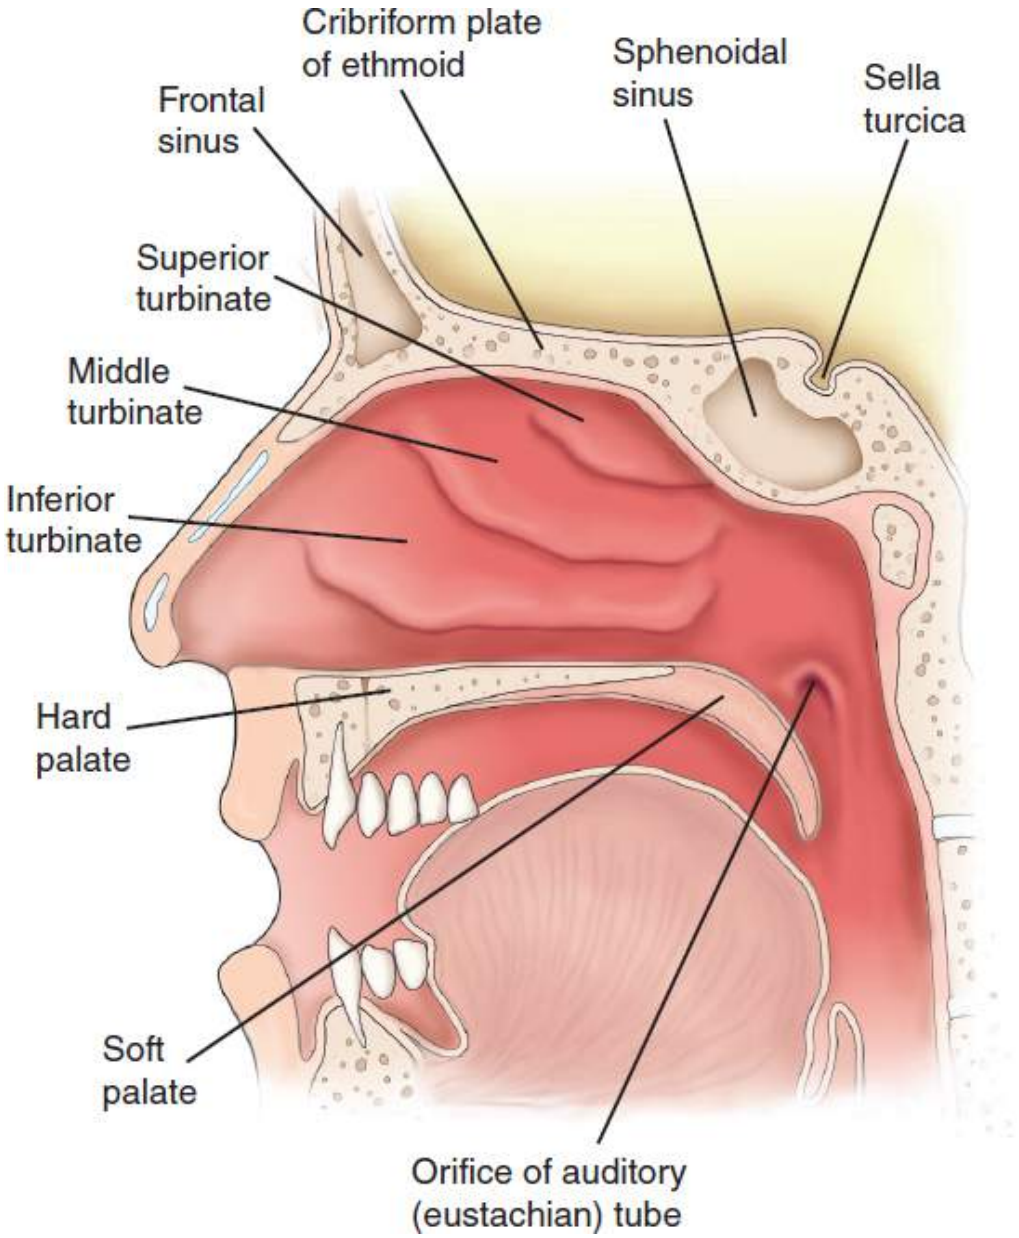

Figure 17-1 • Cross-section of nasal cavity.

Paranasal Sinuses

The paranasal sinuses include four pairs of bony cavities that are lined with nasal mucosa and ciliated pseudostratified columnar epithelium. These airspaces are connected by a series of ducts that drain into the nasal cavity. The sinuses are named by their location: frontal, ethmoid, sphenoid, and maxillary (Fig. 17-2). A prominent function of the sinuses is to serve as a resonating chamber in speech. The sinuses are a common site of infection.

Pharynx, Tonsils, and Adenoids

The pharynx, or throat, is a tubelike structure that connects the nasal and oral cavities to the larynx. It is divided into three regions: nasal, oral, and laryngeal.

The nasopharynx is located posterior to the nose and above the soft palate. The oropharynx houses the faucial, or palatine, tonsils. The laryngopharynx extends from the hyoid bone to the cricoid cartilage. The epiglottis forms the entrance to the larynx.

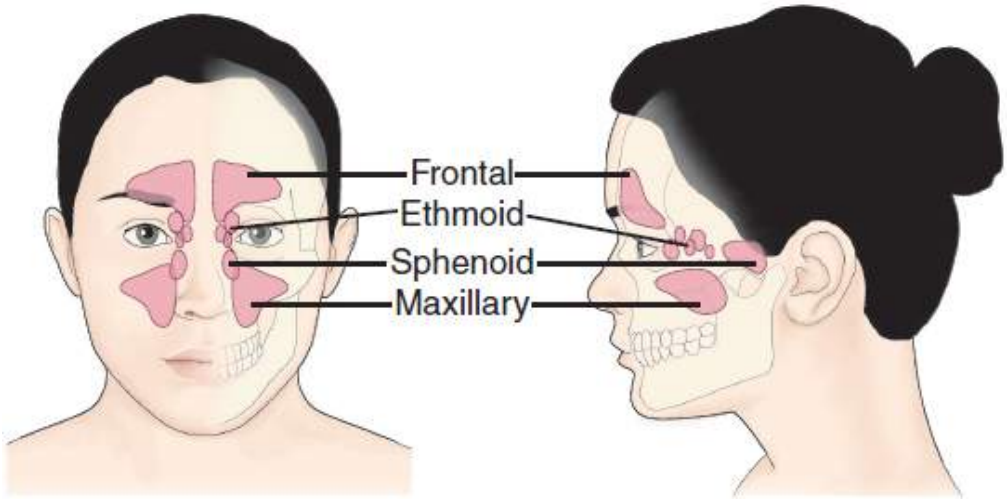

Figure 17-2 • The paranasal sinuses.

The adenoids, or pharyngeal tonsils, are located in the roof of the nasopharynx. The tonsils, the adenoids, and other lymphoid tissue encircle the throat. These structures are important links in the chain of lymph nodes guarding the body from invasion by organisms entering the nose and the throat. The pharynx functions as a passageway for the respiratory and digestive tracts.

Larynx

The larynx, or voice box, is a cartilaginous epithelium-lined organ that connects the pharynx and the trachea and consists of the following:

- *Epiglottis:* a valve flap of cartilage that covers the opening to the larynx during swallowing
- *Glottis:* the opening between the vocal cords in the larynx
- *Thyroid cartilage:* the largest of the cartilage structures; part of it forms the Adam's apple
- *Cricoid cartilage:* the only complete cartilaginous ring in the larynx (located below the thyroid cartilage)
- *Arytenoid cartilages:* used in vocal cord movement with the thyroid cartilage
- *Vocal cords:* ligaments controlled by muscular movements that produce sounds; located in the lumen of the larynx

Although the major function of the larynx is vocalization, it also protects the lower airway from foreign substances and facilitates coughing; it is, therefore, sometimes referred to as the "watchdog of the lungs" (Norris, 2019).

Trachea

The trachea, or windpipe, is composed of smooth muscle with C-shaped rings of cartilage at regular intervals. The cartilaginous rings are incomplete on the posterior surface and give firmness to the wall of the trachea, preventing it from collapsing. The trachea serves as the passage between the larynx and the right and left main stem bronchi, which enter the lungs through an opening called the *hilus*.

Lower Respiratory Tract

The lower respiratory tract consists of the lungs, which contain the bronchial and alveolar structures needed for gas exchange.

Lungs

The lungs are paired elastic structures enclosed in the thoracic cage, which is an airtight chamber with distensible walls (Fig. 17-3). Each lung is divided into lobes. The right lung has upper, middle, and lower lobes, whereas the left lung consists of upper and lower lobes (Fig. 17-4). Each lobe is further subdivided into two to five segments separated by fissures, which are extensions of the pleura.

Pleura

The lungs and wall of the thoracic cavity are lined with a serous membrane called the *pleura.* The visceral pleura covers the lungs; the parietal pleura lines the thoracic cavity, lateral wall of the mediastinum, diaphragm, and inner aspects of the ribs. The visceral and parietal pleura and the small amount of pleural fluid between these two membranes serve to lubricate the thorax and the lungs and permit smooth motion of the lungs within the thoracic cavity during inspiration and expiration.

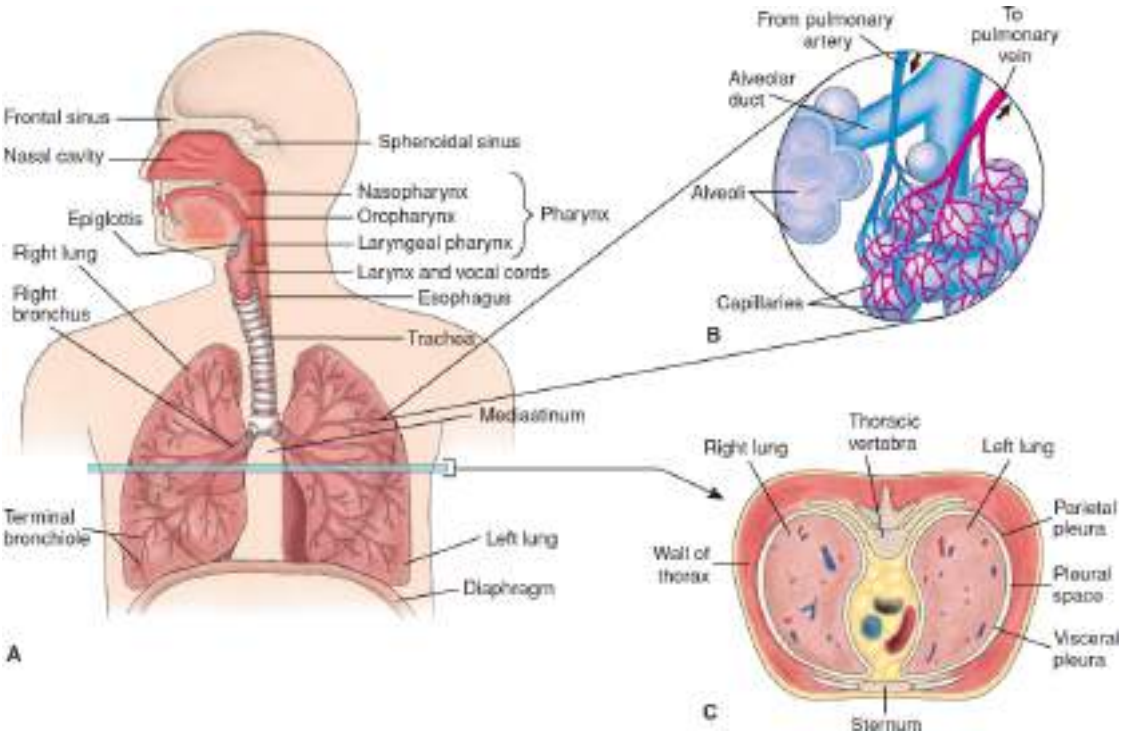

Figure 17-3 • The respiratory system. **A.** Upper respiratory structures and the structures of the thorax. **B.** Alveoli. **C.** A horizontal cross-section of the lungs.

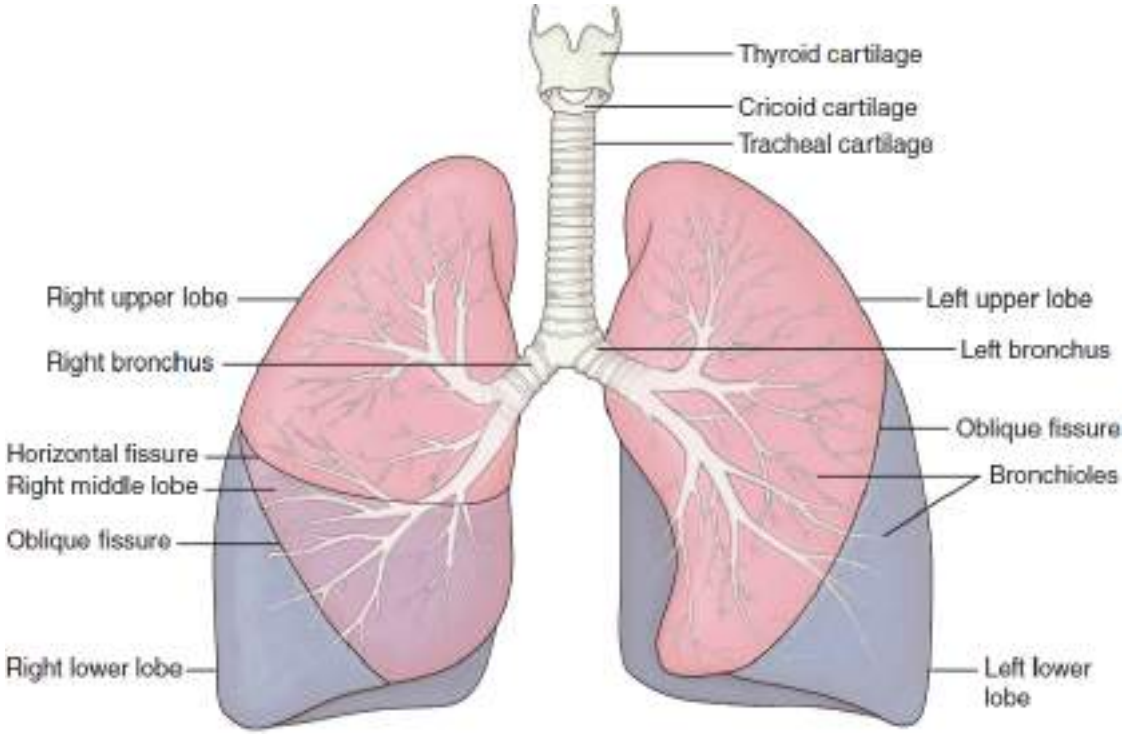

Figure 17-4 • Anterior view of the lungs. The lungs consist of five lobes. The right lung has three lobes (upper, middle, lower); the left has two (upper and lower). The lobes are further subdivided by fissures. The bronchial tree, another lung structure, inflates with air to fill the lobes.

Mediastinum

The mediastinum is in the middle of the thorax, between the pleural sacs that contain the two lungs. It extends from the sternum to the vertebral column and contains all of the thoracic tissue outside the lungs (heart, thymus, the aorta and vena cava, and esophagus).

Bronchi and Bronchioles

There are several divisions of the bronchi within each lobe of the lung. First are the lobar bronchi (three in the right lung and two in the left lung). Lobar bronchi divide into segmental bronchi (10 on the right and 8 on the left); these structures facilitate effective postural drainage in the patient. Segmental bronchi then divide into subsegmental bronchi. These bronchi are surrounded by connective tissue that contains arteries, lymphatics, and nerves.

The subsegmental bronchi then branch into bronchioles, which have no cartilage in their walls. Their patency depends entirely on the elastic recoil of the surrounding smooth muscle and on the alveolar pressure. The bronchioles contain submucosal glands, which produce mucus that covers the inside lining of the airways. The bronchi and bronchioles are also lined with cells that have surfaces covered with cilia. These cilia create a constant whipping motion that propels mucus and foreign substances away from the lungs toward the larynx.

The bronchioles branch into terminal bronchioles, which do not have mucous glands or cilia. Terminal bronchioles become respiratory bronchioles, which are considered to be the transitional passageways between the conducting airways and the gas exchange airways. Up to this point, the conducting airways contain about 150 mL of air in the tracheobronchial tree that does not participate in gas exchange, known as **physiologic dead space.** The respiratory bronchioles then lead into alveolar ducts and sacs and then alveoli (see Fig. 17-3). Oxygen and carbon dioxide exchange takes place in the alveoli.

Alveoli

The lung is made up of about 300 million alveoli, constituting a total surface area between 50 and 100 m^2 (Norris, 2019). There are three types of alveolar cells. Type I and type II cells make up the alveolar epithelium. Type I cells account for 95% of the alveolar surface area and serve as a barrier between the air and the alveolar surface; type II cells account for only 5% of this area but are responsible for producing type I cells and surfactant. Surfactant reduces surface tension, thereby improving overall lung function. Alveolar macrophages, the third type of alveolar cells, are phagocytic cells that ingest foreign matter and, as a result, provide an important defense mechanism.

Function of the Respiratory System

The cells of the body derive the energy they need from the oxidation of carbohydrates, fats, and proteins. This process requires oxygen. Vital tissues, like the brain and the heart, cannot survive long without a continuous supply of oxygen. As a result of oxidation, carbon dioxide is produced and must be removed from the cells to prevent the buildup of acid waste products. The respiratory system performs this function by facilitating life-sustaining processes such as oxygen transport, respiration, ventilation, and gas exchange.

Oxygen Transport

Oxygen is supplied to, and carbon dioxide is removed from, cells by way of the circulating blood through the thin walls of the capillaries. Oxygen diffuses from the capillary through the capillary wall to the interstitial fluid. At this point, it diffuses through the membrane of tissue cells, where it is used by mitochondria for cellular respiration. The movement of carbon dioxide occurs by diffusion in the opposite direction—from cell to blood.

Respiration

After these tissue capillary exchanges, blood enters the systemic venous circulation and travels to the pulmonary circulation. The oxygen concentration

in blood within the capillaries of the lungs is lower than that in the lungs' alveoli. Because of this concentration gradient, oxygen diffuses from the alveoli to the blood. Carbon dioxide, which has a higher concentration in the blood than in the alveoli, diffuses from the blood into the alveoli. Movement of air in and out of the airways continually replenishes the oxygen and removes the carbon dioxide from the airways and the lungs. This whole process of gas exchange between the atmospheric air and the blood and between the blood and cells of the body is called **respiration.**

Ventilation

Ventilation requires movement of the walls of the thoracic cage and of its floor, the diaphragm. The effect of these movements is alternately to increase and decrease the capacity of the chest. When the capacity of the chest is increased, air enters through the trachea (inspiration) and moves into the bronchi, bronchioles, and alveoli, and inflates the lungs. When the chest wall and the diaphragm return to their previous positions (expiration), the lungs recoil and force the air out through the bronchi and the trachea. Inspiration occurs during the first third of the respiratory cycle; expiration occurs during the latter two thirds. The inspiratory phase of respiration normally requires energy; the expiratory phase is normally passive, requiring very little energy. Physical factors that govern airflow in and out of the lungs are collectively referred to as the mechanics of ventilation and include air pressure variances, resistance to airflow, and lung compliance.

Air Pressure Variances

Air flows from a region of higher pressure to a region of lower pressure. During inspiration, movements of the diaphragm and intercostal muscles enlarge the thoracic cavity and thereby lower the pressure inside the thorax to a level below that of atmospheric pressure. As a result, air is drawn through the trachea and the bronchi into the alveoli. During expiration, the diaphragm relaxes and the lungs recoil, resulting in a decrease in the size of the thoracic cavity. The alveolar pressure then exceeds atmospheric pressure, and air flows from the lungs into the atmosphere.

Airway Resistance

Resistance is determined by the radius, or size of the airway through which the air is flowing, as well as by lung volumes and airflow velocity. Any process that changes the bronchial diameter or width affects airway resistance and alters the rate of airflow for a given pressure gradient during respiration (Chart 17-1). With increased resistance, greater-than-normal respiratory effort is required to achieve normal levels of ventilation.

Compliance

Compliance is the elasticity and expandability of the lungs and thoracic structures. Compliance allows the lung volume to increase when the difference in pressure between the atmosphere and the thoracic cavity (pressure gradient) causes air to flow in. Factors that determine lung compliance are the surface tension of the alveoli, the connective tissue and water content of the lungs, and the compliance of the thoracic cavity.

Chart 17-1

Causes of Increased Airway Resistance

Common phenomena that may alter bronchial diameter, which affects airway resistance, include the following:

- Contraction of bronchial smooth muscle—as in asthma
- Thickening of bronchial mucosa—as in chronic bronchitis
- Obstruction of the airway—by mucus, a tumor, or a foreign body
- Loss of lung elasticity—as in emphysema, which is characterized by connective tissue encircling the airways, thereby keeping them open during both inspiration and expiration

Compliance is determined by examining the volume–pressure relationship in the lungs and the thorax. Compliance is normal (1 L/cm H_2O) if the lungs and the thorax easily stretch and distend when pressure is applied. Increased compliance occurs if the lungs have lost their elastic recoil and become overdistended (e.g., in emphysema). Decreased compliance occurs if the lungs and the thorax are "stiff." Conditions associated with decreased compliance include severe obesity, pneumothorax, hemothorax, pleural effusion, pulmonary edema, atelectasis, pulmonary fibrosis, and acute respiratory distress syndrome (ARDS). Lungs with decreased compliance require greater-than-normal energy expenditure by the patient to achieve normal levels of ventilation.

Lung Volumes and Capacities

Lung function, which reflects the mechanics of ventilation, is viewed in terms of lung volumes and lung capacities. Lung volumes are categorized as tidal volume, inspiratory reserve volume, expiratory reserve volume, and residual volume. Lung capacity is evaluated in terms of vital capacity, inspiratory capacity, functional residual capacity, and total lung capacity. These terms are explained in Table 17-1.

Pulmonary Diffusion and Perfusion

Pulmonary diffusion is the process by which oxygen and carbon dioxide are exchanged from areas of high concentration to areas of low concentration at the air–blood interface. The alveolar–capillary membrane is ideal for diffusion because of its thinness and large surface area. In the normal healthy adult, oxygen and carbon dioxide travel across the alveolar–capillary membrane without difficulty as a result of differences in gas concentrations in the alveoli and capillaries.

Pulmonary perfusion is the actual blood flow through the pulmonary vasculature. The blood is pumped into the lungs by the right ventricle through the pulmonary artery. The pulmonary artery divides into the right and left branches to supply both lungs. Normally, about 2% of the blood pumped by the right ventricle does not perfuse the alveolar capillaries. This shunted blood drains into the left side of the heart without participating in alveolar gas exchange. Bronchial arteries extending from the thoracic aorta also support perfusion but do not participate in gas exchange, further diluting oxygenated blood exiting through the pulmonary vein (Norris, 2019).

TABLE 17-1 Lung Volumes and Lung Capacities

Term	Symbol	Description	Normal Value*	Significance
Lung Volumes				
Tidal volume	VT or TV	The volume of air inhaled and exhaled with each breath	500 mL or 5–10 mL/kg	The tidal volume may not vary, even with severe disease.
Inspiratory reserve volume	IRV	The maximum volume of air that can be inhaled after a normal inhalation	3000 mL	
Expiratory reserve volume	ERV	The maximum volume of air that can be exhaled forcibly after a normal exhalation	1100 mL	Expiratory reserve volume is decreased with restrictive conditions, such as obesity, ascites, pregnancy.
Residual volume	RV	The volume of air remaining in the lungs after a maximum exhalation	1200 mL	Residual volume may be increased with obstructive disease.
Lung Capacities				
Vital capacity	VC	The maximum volume of air exhaled from the point of maximum inspiration: VC = TV + IRV + ERV	4600 mL	A decrease in vital capacity may be found in neuromuscular disease, generalized fatigue, atelectasis, pulmonary edema, COPD, and obesity.
Inspiratory capacity	IC	The maximum volume of air inhaled after normal expiration: IC = TV + IRV	3500 mL	A decrease in inspiratory capacity may indicate restrictive disease. It may also be decreased in obesity.
Functional residual capacity	FRC	The volume of air remaining in the lungs after a normal expiration: FRC = ERV + RV	2300 mL	Functional residual capacity may be increased with COPD and decreased in ARDS and obesity.
Total lung capacity	TLC	The volume of air in the lungs after a maximum inspiration: TLC = TV + IRV + ERV + RV	5800 mL	Total lung capacity may be decreased with restrictive disease such as atelectasis and pneumonia and increased in COPD.

*Values for healthy men; women are 20–25% less.
ARDS, acute respiratory distress syndrome; COPD, chronic obstructive pulmonary disease.
Adapted from West, J. B., & Luks, A. M. (2016). West's respiratory physiology: The essentials (10th ed.). Philadelphia, PA: Wolters Kluwer Health Lippincott Williams & Wilkins.

The pulmonary circulation is considered a low-pressure system because the systolic blood pressure in the pulmonary artery is 20 to 30 mm Hg and the diastolic pressure is 5 to 15 mm Hg. Because of these low pressures, the pulmonary vasculature normally can vary its capacity to accommodate the blood flow it receives. However, when a person is in an upright position, the pulmonary artery pressure is not great enough to supply blood to the apex of the lung against the force of gravity. Thus, when a person is upright, the lung may be considered to be divided into three sections: an upper part with poor blood supply, a lower part with maximal blood supply, and a section between

the two with an intermediate supply of blood. When a person who is lying down turns to one side, more blood passes to the dependent lung.

Perfusion is also influenced by alveolar pressure. The pulmonary capillaries are sandwiched between adjacent alveoli. If the alveolar pressure is sufficiently high, the capillaries are squeezed. Depending on the pressure, some capillaries completely collapse, whereas others narrow.

Pulmonary artery pressure, gravity, and alveolar pressure determine the patterns of perfusion. In lung disease, these factors vary, and the perfusion of the lung may become abnormal.

Ventilation and Perfusion Balance and Imbalance

Adequate gas exchange depends on an adequate ventilation–perfusion (V./Q.) ratio. In different areas of the lung, the V./Q. ratio varies. Airway blockages, local changes in compliance, and gravity may alter ventilation. Alterations in perfusion may occur with a change in the pulmonary artery pressure, alveolar pressure, or gravity.

V./Q. imbalance occurs as a result of inadequate ventilation, inadequate perfusion, or both. There are four possible V./Q. states in the lung:normal V./Q. ratio, low V./Q. ratio (shunt), high V./Q. ratio (dead space), and absence of ventilation and perfusion (silent unit) (Chart 17-2). V./Q. imbalance causes shunting of blood, resulting in **hypoxia** (low level of cellular oxygen). Shunting appears to be the main cause of hypoxia after thoracic or abdominal surgery and most types of respiratory failure. Severe hypoxia results when the amount of shunting exceeds 20%. Supplemental oxygen may eliminate hypoxia, depending on the type of V./Q. imbalance.

Gas Exchange

Partial Pressure of Gases

The air we breathe is a gaseous mixture consisting mainly of nitrogen (78%), oxygen (21%), argon (1%), and trace amounts of other gases including carbon dioxide, methane, and helium, among other gases. The atmospheric pressure at sea level is about 760 mm Hg. Partial pressure is the pressure exerted by each type of gas in a mixture of gases. The partial pressure of a gas is proportional to the concentration of that gas in the mixture. The total pressure exerted by the gaseous mixture, whether in the atmosphere or in the lungs, is equal to the sum of the partial pressures. The partial pressure of nitrogen is approximately 596 mm Hg, oxygen is 152 mm Hg, and argon is 7.6 mm Hg. Chart 17-3 identifies and defines terms and abbreviations related to partial pressure of gases. However, the partial pressure of gases will be affected when the air is inhaled and humidified by the pulmonary tract. It is possible to calculate the partial pressure of gases, specifically oxygen, within the alveoli.

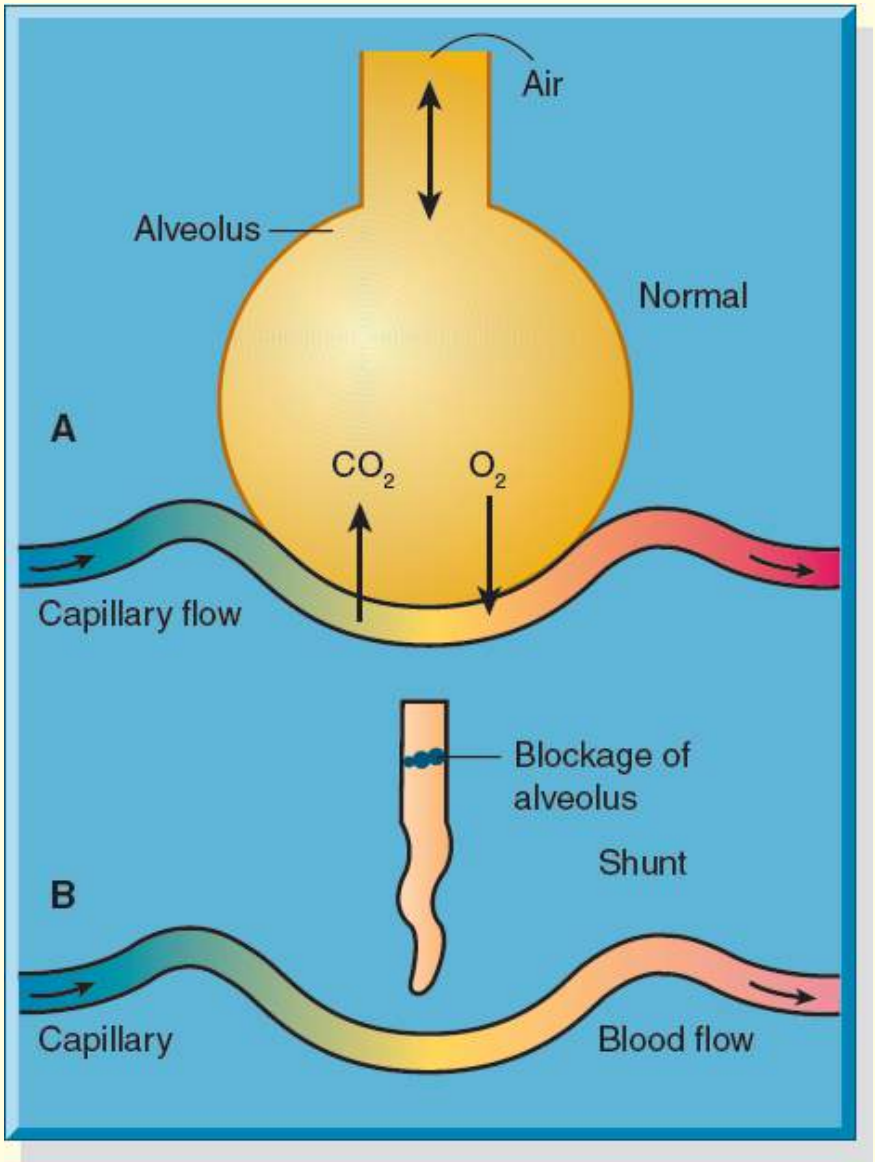
Chart 17-2

Normal Ratio (A)

In the healthy lung, a given amount of blood passes an alveolus and is matched with an equal amount of gas **(A).** The ratio is 1:1 (ventilation matches perfusion).

Low Ventilation–Perfusion Ratio: Shunts (B)

Low ventilation–perfusion states may be called *shunt-producing disorders.* When perfusion exceeds ventilation, a shunt exists **(B).** Blood bypasses the alveoli without gas exchange occurring. This is seen with obstruction of the distal airways, such as with pneumonia, atelectasis, tumor, or a mucus plug.

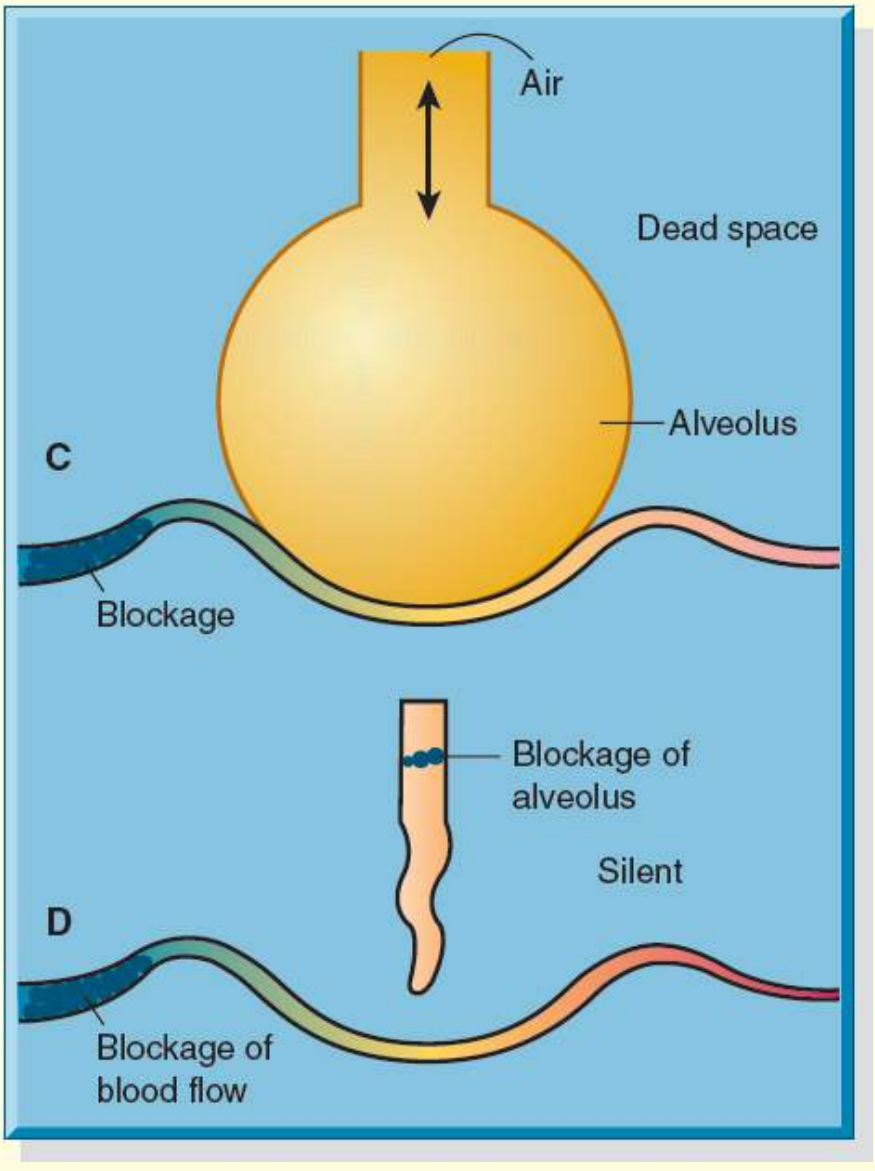


High Ventilation–Perfusion Ratio: Dead Space (C)

When ventilation exceeds perfusion, dead space results **(C).** The alveoli do not have an adequate blood supply for gas exchange to occur. This is characteristic of a variety of disorders, including pulmonary emboli, pulmonary infarction, and cardiogenic shock.

Silent Unit (D)

In the absence of both ventilation and perfusion or with limited ventilation and perfusion, a condition known as a silent unit occurs **(D).** This is seen with pneumothorax and severe acute respiratory distress syndrome.



Once the air enters the trachea, it becomes fully saturated with water vapor, which displaces some of the other gases. Water vapor exerts a pressure of 45 mm Hg when it fully saturates a mixture of gases at the body temperature of 37°C (98.6°F). Nitrogen and oxygen are responsible for almost all of the

remaining 715 mm Hg pressure. Once this mixture enters the alveoli, it is further diluted by carbon dioxide. In the alveoli, the water vapor continues to exert a pressure of 45 mm Hg. Under typical baseline conditions (i.e., without supplemental oxygen and at sea level), the partial pressure of alveolar oxygen (PAO_2) is approximately 100 mm Hg. This pressure ensures diffusion of oxygen across the alveolar–capillary membranes, and then eventually into the arterial blood and to red blood cells for transport to meet systemic oxygenation needs (Sharma, Hashmi, & Rawat, 2019).

Chart 17-3

Partial Pressure Abbreviations

P = Pressure
PO_2 = Partial pressure of oxygen
PCO_2 = Partial pressure of carbon dioxide
PAO_2 = Partial pressure of alveolar oxygen
$PACO_2$ = Partial pressure of alveolar carbon dioxide
PaO_2 = Partial pressure of arterial oxygen
$PaCO_2$ = Partial pressure of arterial carbon dioxide
$Pv\text{-}O_2$ = Partial pressure of venous oxygen
$Pv\text{-}CO_2$ = Partial pressure of venous carbon dioxide
P_{50} = Partial pressure of oxygen when the hemoglobin is 50% saturated

When a gas is exposed to a liquid, the gas dissolves in the liquid until equilibrium is reached. The dissolved gas also exerts a partial pressure. At equilibrium, the partial pressure of the gas in the liquid is the same as the partial pressure of the gas in the gaseous mixture. Oxygenation of venous blood in the lung illustrates this point. In the lung, venous blood and alveolar oxygen are separated by a very thin alveolar membrane. Oxygen diffuses across this membrane to dissolve in the blood until the partial pressure of oxygen in the blood is the same as that in the alveoli. However, because carbon dioxide is a by-product of oxidation in the cells, venous blood contains carbon dioxide at a higher partial pressure than that in the alveolar gas. In the lung, carbon dioxide diffuses out of venous blood into the alveolar gas. At equilibrium, the partial pressure of carbon dioxide in the blood and in alveolar gas is the same. The changes in partial pressure are shown in Figure 17-5.

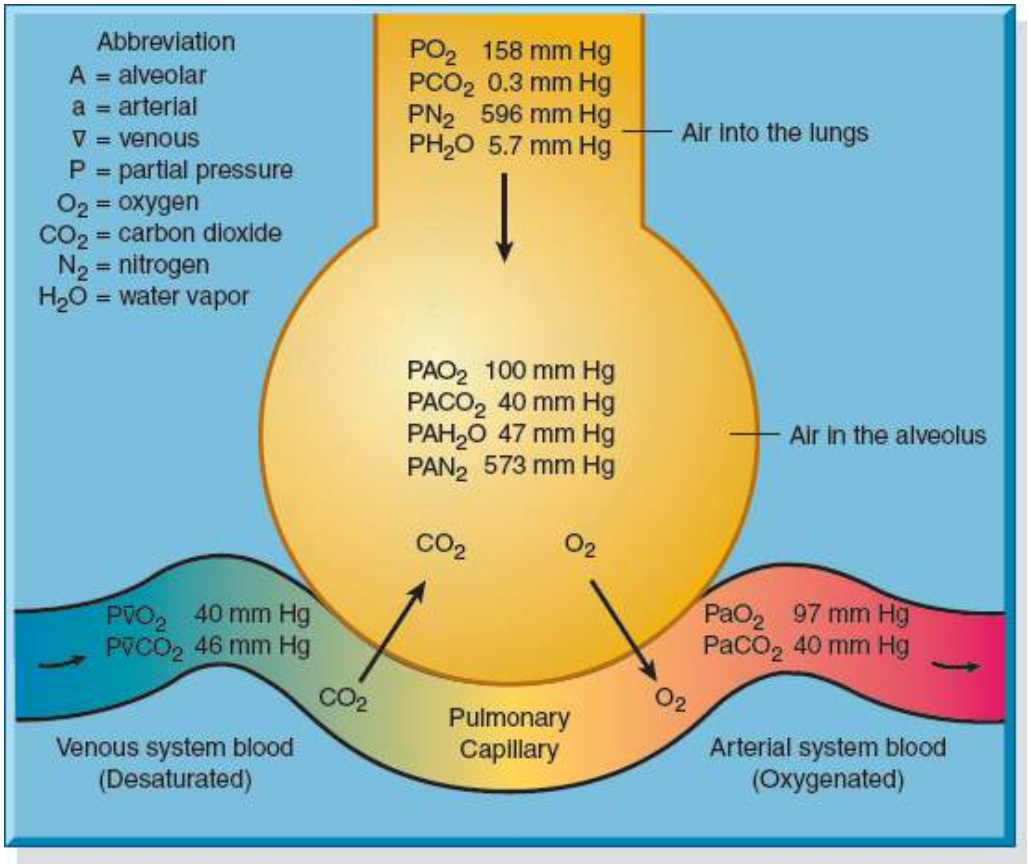


Figure 17-5 • Changes occur in the partial pressure of gases during respiration. These values vary as a result of the exchange of oxygen and carbon dioxide and the changes that occur in their partial pressures as venous blood flows through the lungs.

Effects of Pressure on Oxygen Transport

Oxygen and carbon dioxide are transported simultaneously, either dissolved in blood or combined with hemoglobin in red blood cells. Each 100 mL of normal arterial blood carries 0.3 mL of oxygen physically dissolved in the plasma and 20 mL of oxygen in combination with hemoglobin. Large amounts of oxygen can be transported in the blood because oxygen combines easily with hemoglobin to form oxyhemoglobin:

$$O_2 + Hgb \leftrightarrow HgbO_2$$

The volume of oxygen physically dissolved in the plasma is measured by the partial pressure of oxygen in the arteries (PaO_2). The higher the PaO_2, the greater the amount of oxygen dissolved. For example, at a PaO_2 of 10 mm Hg, 0.03 mL of oxygen is dissolved in 100 mL of plasma. At PaO_2 of 20 mm Hg, twice this amount is dissolved in plasma, and at PaO_2 of 100 mm Hg, 10 times this amount is dissolved. Therefore, the amount of dissolved oxygen is directly

proportional to the partial pressure, regardless of how high the oxygen pressure becomes.

The amount of oxygen that combines with hemoglobin depends on both the amount of hemoglobin in the blood and on PaO_2, although only up to a PaO_2 of about 150 mm Hg. This is measured as **oxygen saturation** (SaO_2), the percentage of the O_2 that could be carried if all the hemoglobin held the maximum possible amount of O_2. When the PaO_2 is 150 mm Hg, hemoglobin is 100% saturated and does not combine with any additional oxygen. When hemoglobin is 100% saturated, 1 g of hemoglobin combines with 1.34 mL of oxygen. Therefore, in a person with 14 g/dL of hemoglobin, each 100 mL of blood contains about 19 mL of oxygen associated with hemoglobin. If the PaO_2 is less than 150 mm Hg, the percentage of hemoglobin saturated with oxygen decreases. For example, at a PaO_2 of 100 mm Hg (normal value), saturation is 97%; at a PaO_2 of 40 mm Hg, saturation is 70%.

Oxyhemoglobin Dissociation Curve

The oxyhemoglobin dissociation curve (Chart 17-4) shows the relationship between the partial pressure of oxygen (PaO_2) and the percentage of saturation of oxygen (SaO_2). The percentage of saturation can be affected by carbon dioxide, hydrogen ion concentration, temperature, and 2,3-diphosphoglycerate. An increase in these factors shifts the curve to the right, thus less oxygen is picked up in the lungs, but more oxygen is released to the tissues, if PaO_2 is unchanged. A decrease in these factors causes the curve to shift to the left, making the bond between oxygen and hemoglobin stronger. If the PaO_2 is still unchanged, more oxygen is picked up in the lungs, but less oxygen is given up to the tissues. The unusual shape of the oxyhemoglobin dissociation curve is a distinct advantage to the patient for two reasons:

1. If the PaO_2 decreases from 100 to 80 mm Hg as a result of lung disease or heart disease, the hemoglobin of the arterial blood remains almost maximally saturated (94%), and the tissues do not suffer from hypoxia.

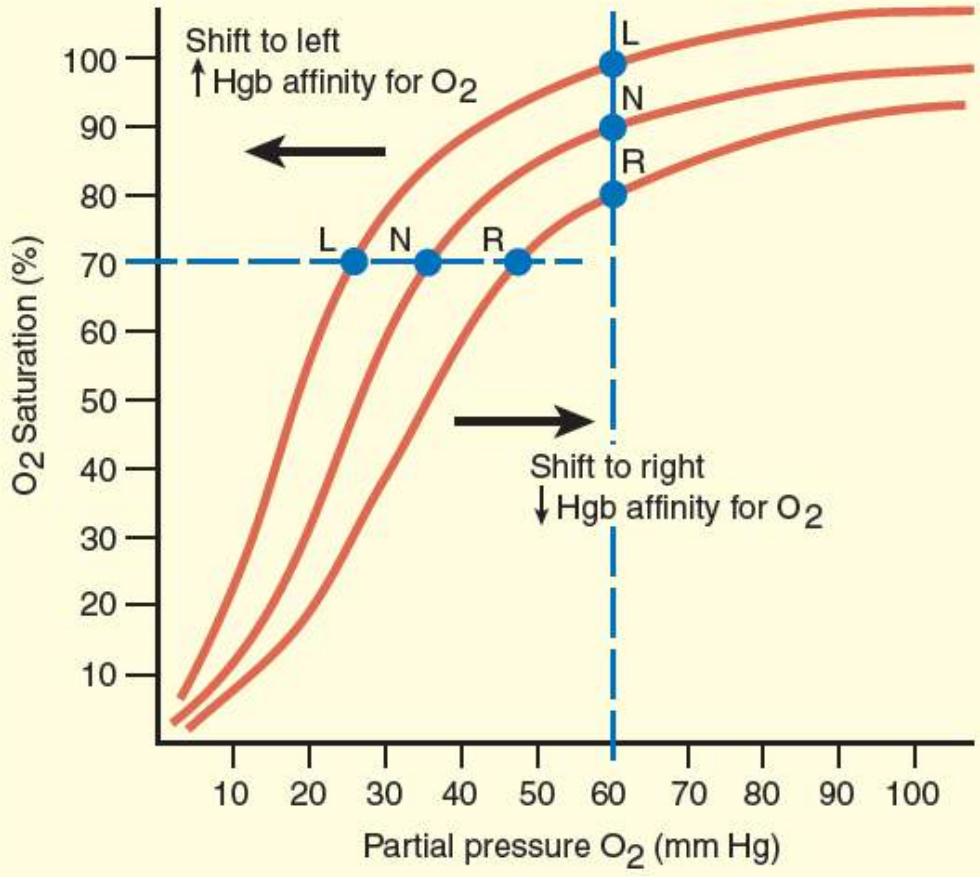
Chart 17-4

Oxyhemoglobin Dissociation Curve

The oxyhemoglobin dissociation curve is marked to show three oxygen levels:

1. Normal levels—PaO_2 >70 mm Hg
2. Relatively safe levels—PaO_2 45–70 mm Hg
3. Dangerous levels—PaO_2 <40 mm Hg

The normal (middle) curve (N) shows that 75% saturation occurs at a PaO_2 of 40 mm Hg. If the curve shifts to the right (R), the same saturation (75%) occurs at the higher PaO_2 of 57 mm Hg. If the curve shifts to the left (L), 75% saturation occurs at a PaO_2 of 25 mm Hg.



2. When the arterial blood passes into tissue capillaries and is exposed to the tissue tension of oxygen (about 40 mm Hg), hemoglobin gives up large quantities of oxygen for use by the tissues.

With a normal value for PaO_2 (80 to 100 mm Hg) and SaO_2 (95% to 98%), there is a 15% margin of excess oxygen available to the tissues. With a normal hemoglobin level of 15 mg/dL and a PaO_2 level of 40 mm Hg (SaO_2 75%), there is adequate oxygen available for the tissues but no reserve for physiologic stresses that increase tissue oxygen demand. If a serious incident

occurs (e.g., bronchospasm, aspiration, hypotension, or cardiac arrhythmias) that reduces the intake of oxygen from the lungs, tissue hypoxia results.

An important consideration in the transport of oxygen is cardiac output, which determines the amount of oxygen delivered to the body and affects lung and tissue perfusion. If the cardiac output is normal (5 L/min), the amount of oxygen delivered to the body per minute is normal. Under normal conditions, only 250 mL of oxygen is used per minute, which is approximately 25% of available oxygen. The rest of the oxygen returns to the right side of the heart, and the PaO_2 of venous blood drops from 80 to 100 mm Hg to about 40 mm Hg. If cardiac output falls, however, the amount of oxygen delivered to the tissues also falls and may be inadequate to meet the body's needs.

Carbon Dioxide Transport

At the same time that oxygen diffuses from the blood into the tissues, carbon dioxide diffuses from tissue cells to blood and is transported to the lungs for excretion. The amount of carbon dioxide in transit is one of the major determinants of the acid–base balance of the body. Normally, only 6% of the venous carbon dioxide is removed in the lungs and enough remains in the arterial blood to exert a pressure of 40 mm Hg. Most of the carbon dioxide (90%) is carried by red blood cells; the small portion (5%) that remains dissolved in the plasma (partial pressure of carbon dioxide [PCO_2]) is the critical factor that determines carbon dioxide movement in or out of the blood.

Although the many processes involved in respiratory gas transport seem to occur in intermittent stages, the changes are rapid, simultaneous, and continuous.

Neurologic Control of Ventilation

Resting respiration is the result of cyclic excitation of the respiratory muscles by the phrenic nerve. The rhythm of breathing is controlled by respiratory centers in the brain. The inspiratory and expiratory centers in the medulla oblongata and pons control the rate and depth of ventilation to meet the body's metabolic demands.

The apneustic center in the lower pons stimulates the inspiratory medullary center to promote deep, prolonged inspirations. The pneumotaxic center in the upper pons is thought to control the pattern of respirations.

Several groups of receptor sites assist in the brain's control of respiratory function. The central chemoreceptors, located in the medulla, respond to chemical changes in the cerebrospinal fluid, which result from chemical changes in the blood. These receptors respond to an increase or decrease in the pH and convey a message to the lungs to change the depth and then the rate of ventilation to correct the imbalance. The peripheral chemoreceptors are located

in the aortic arch and the carotid arteries and respond first to changes in PaO_2, then to partial pressure of carbon dioxide ($PaCO_2$) and pH.

Mechanoreceptors in the lung include stretch, irritant, and juxtacapillary receptors, and respond to changes in resistance by altering breathing patterns to support optimal lung function. For example, the Hering–Breuer reflex is activated by stretch receptors in the alveoli. When the lungs are distended, inspiration is inhibited; as a result, the lungs do not become overdistended.

Proprioceptors in the muscles and chest wall respond to body movements, causing an increase in ventilation. Thus, range-of-motion exercises in a patient who is immobile stimulate breathing. Finally, baroreceptors, also located in the aortic and carotid bodies, respond to an increase or decrease in arterial blood pressure and cause reflex hypoventilation or hyperventilation.

Gerontologic Considerations

A gradual decline in respiratory function begins in early to middle adulthood and affects the structure and function of the respiratory system. The vital capacity of the lungs and the strength of the respiratory muscles peak between 20 and 25 years of age and decrease thereafter. With aging (40 years and older), changes occur in the alveoli that reduce the surface area available for the exchange of oxygen and carbon dioxide. At approximately 50 years of age, the alveoli begin to lose elasticity. A decrease in vital capacity occurs with the loss of chest wall mobility, which restricts the tidal flow of air. The amount of respiratory dead space increases with age. These changes result in a decreased diffusion capacity for oxygen with increasing age, producing lower oxygen levels in the arterial circulation. Older adults have a decreased ability to rapidly move air in and out of the lungs.

Gerontologic changes in the respiratory system are summarized in Table 17-2. Despite these changes, in the absence of chronic pulmonary disease, older adults are able to carry out activities of daily living, but they may have decreased tolerance for, and require additional rest after, prolonged or vigorous activity.

Assessment

Health History

The health history initially focuses on the patient's presenting problem and associated symptoms. In conducting the history, the nurse should explore the onset, location, duration, character, aggravating and alleviating factors, radiation (if relevant), and timing of the presenting problem and associated

signs and symptoms. The nurse should also explore how these factors impact the patient's activities of daily living, usual work and family activities, and quality of life.

Common Symptoms

The major signs and symptoms of respiratory disease are dyspnea, cough, sputum production, chest pain, wheezing, and hemoptysis. During the health history, the nurse should also consider nonpulmonary diseases when evaluating symptoms, as these symptoms may occur with a variety of other illnesses.

TABLE 17-2 Age-Related Changes in the Respiratory System

	Structural Changes	Functional Changes	History and Physical Findings
Defense Mechanisms (Respiratory and Nonrespiratory)	↓ Number of cilia and ↓ mucus ↓ Cough and gag reflex Loss of surface area of the capillary membrane Lack of a uniform or consistent ventilation and/or blood flow	↓ Protection against foreign particles ↓ Protection against aspiration ↓ Antibody response to antigens ↓ Response to hypoxia and hypercapnia (chemoreceptors)	↓ Cough reflex and mucus ↑ Infection rate History of respiratory infections, chronic obstructive pulmonary disease (COPD), pneumonia. Risk factors: smoking, environmental exposure, exposure to tuberculosis (TB)
Lung	↓ Size of airway ↑ Diameter of alveolar ducts ↑ Collagen of alveolar walls ↑ Thickness of alveolar membranes ↓ Elasticity of alveolar sacs	↑ Airway resistance ↑ Pulmonary compliance ↓ Expiratory flow rate ↓ Oxygen diffusion capacity ↑ Dead space Premature closure of airways ↑ Air trapping ↓ Expiratory flow rates Ventilation–perfusion mismatch ↓ Exercise capacity ↑ Anteroposterior (AP) diameter	Unchanged total lung capacity (TLC) ↑ Residual volume (RV) ↓ Inspiratory reserve volume (IRV) ↓ Expiratory reserve volume (ERV) ↓ Forced vital capacity (FVC) and vital capacity (VC) ↑ Functional residual capacity (FRC) ↓ PaO_2 ↑ CO_2
Chest Wall and Muscles	Calcification of intercostal cartilages Arthritis of costovertebral joints ↓ Continuity of diaphragm Osteoporotic changes ↓ Muscle mass Muscle atrophy	↑ Rigidity and stiffness of thoracic cage ↓ Respiratory muscle strength ↑ Work of breathing ↓ Capacity for exercise ↓ Peripheral chemosensitivity ↑ Risk for inspiratory muscle fatigue	Kyphosis, barrel chest Skeletal changes ↑ AP diameter Shortness of breath ↑ Abdominal and diaphragmatic breathing ↓ Maximum expiratory flow rates

↓, decreased; ↑, increased.
Adapted from Ramly, E., Kaafarani, H. M. A., & Velmahos, G. C. (2015). The effect of aging on pulmonary function: Implications for monitoring and support of the surgical and trauma patient. *Surgical Clinics of North America*, *95*(1), 53–69.

Dyspnea

The official American Thoracic Society Statement (2012) defines **dyspnea** as a subjective feeling of discomfort while breathing; its causes may include multiple physiologic, psychological, environmental, or social factors (Parshall, Schwartzstein, Adams, et al., 2012). In general, acute diseases of the lungs produce a more severe grade of dyspnea than do chronic diseases. Sudden dyspnea in a healthy person may indicate pneumothorax (air in the pleural cavity), acute respiratory obstruction, allergic reaction, or myocardial infarction. In patients who are immobilized, sudden dyspnea may denote pulmonary embolism (PE). Dyspnea and **tachypnea** (abnormally rapid respirations) accompanied by progressive **hypoxemia** (low blood oxygen level) in a person who has recently experienced lung trauma, shock, cardiopulmonary bypass, or multiple blood transfusions may signal ARDS. **Orthopnea** (shortness of breath when lying flat, relieved by sitting or standing) may be found in patients with heart disease and occasionally in patients with chronic obstructive pulmonary disease (COPD); dyspnea with an expiratory wheeze occurs with COPD. Dyspnea associated with noisy breathing may result from a narrowing of the airway or localized obstruction of a major bronchus by a tumor or foreign body. The high-pitched sound heard (usually on inspiration) when someone is breathing through a partially blocked upper airway is called **stridor.** To help determine the cause of dyspnea, the nurse should ask the following questions:

- Is the shortness of breath related to other symptoms? Is a cough present?
- Was the onset of shortness of breath sudden or gradual?
- At what time of day or night does the shortness of breath occur?
- Is the shortness of breath worse when lying flat?
- How much exertion triggers shortness of breath? Does it occur with exercise? Climbing stairs? At rest?
- How severe is the shortness of breath? On a scale of 0 to 10, if 0 is not at all breathless and 10 is very breathless, how hard is it to breathe?

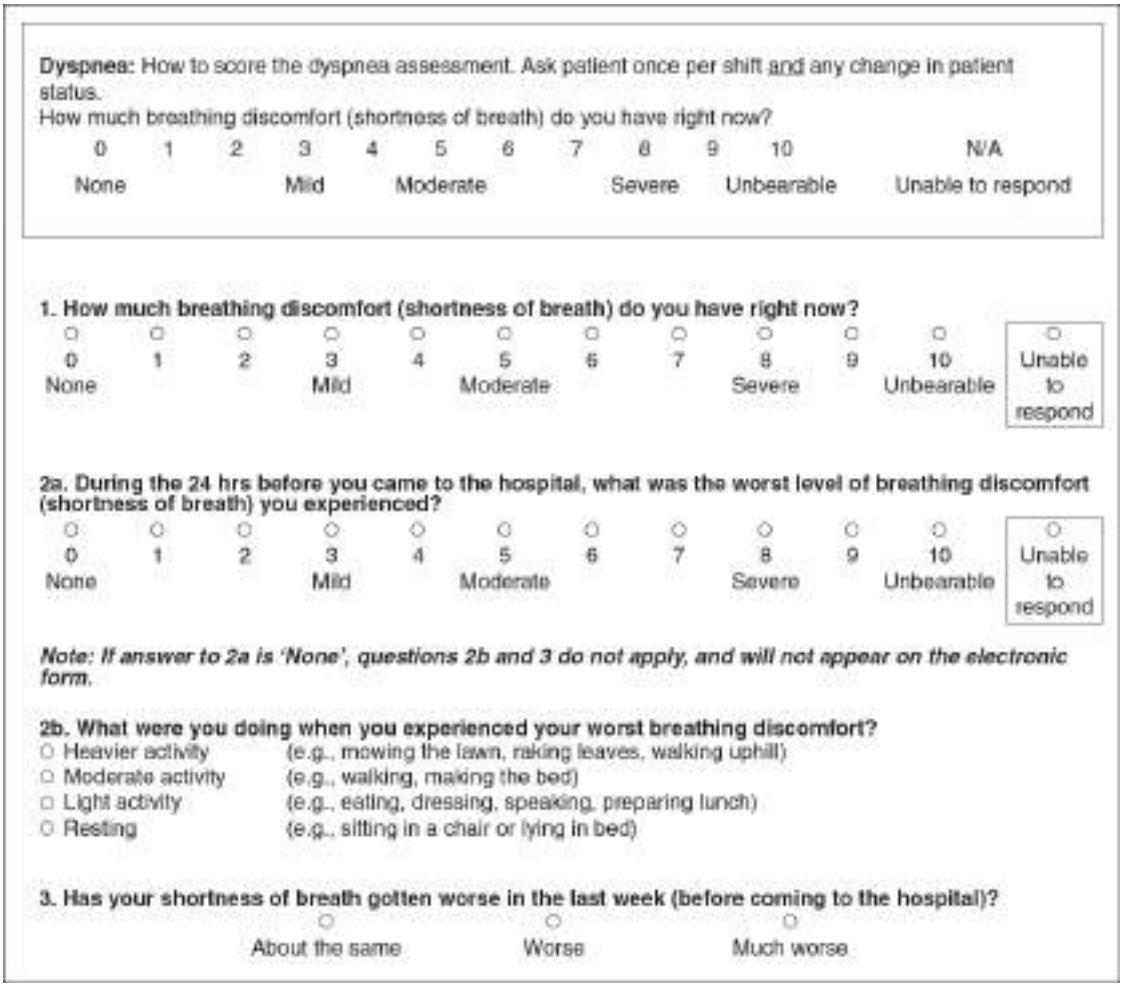
Because patients use a variety of terms to describe breathlessness, the nurse must explore what these terms mean to each patient. The use of a standardized tool to assess dyspnea, as part of the routine nursing assessment, can be beneficial (Fig. 17-6). It is especially important to assess the patient's rating of the intensity or distress of breathlessness, what breathing feels like, and its impact on the patient's general health, function, and quality of life (Baker,

DeSanto-Madeya, & Banzett, 2017). See the Nursing Research Profile in Chart 17-5.

Cough

Cough is a reflex that protects the lungs from the accumulation of secretions or the inhalation of foreign bodies. Its presence or absence can be a diagnostic clue because some disorders cause coughing and others suppress it. The cough reflex may be impaired by weakness or paralysis of the respiratory muscles, prolonged inactivity, the presence of a nasogastric tube, or depressed function of the brain's medullary centers (e.g., anesthesia, brain disorders).

Cough results from irritation or inflammation of the mucous membranes anywhere in the respiratory tract and is associated with multiple pulmonary disorders. Mucus, pus, blood, or an airborne irritant, such as smoke or a gas, may stimulate the cough reflex. Common causes of cough include asthma, gastrointestinal reflux disease, infection, and side effects of medications, such as angiotensin-converting enzyme (ACE) inhibitors (Norris, 2019).



Dyspnea: How to score the dyspnea assessment. Ask patient once per shift and any change in patient status.
How much breathing discomfort (shortness of breath) do you have right now?

0	1	2	3	4	5	6	7	8	9	10	N/A
None			Mild		Moderate			Severe		Unbearable	Unable to respond

1. How much breathing discomfort (shortness of breath) do you have right now?

0	1	2	3	4	5	6	7	8	9	10	Unable to respond
None			Mild		Moderate			Severe		Unbearable	

2a. During the 24 hrs before you came to the hospital, what was the worst level of breathing discomfort (shortness of breath) you experienced?

0	1	2	3	4	5	6	7	8	9	10	Unable to respond
None			Mild		Moderate			Severe		Unbearable	

Note: If answer to 2a is 'None', questions 2b and 3 do not apply, and will not appear on the electronic form.

2b. What were you doing when you experienced your worst breathing discomfort?

- Heavier activity (e.g., mowing the lawn, raking leaves, walking uphill)
- Moderate activity (e.g., walking, making the bed)
- Light activity (e.g., eating, dressing, speaking, preparing lunch)
- Resting (e.g., sitting in a chair or lying in bed)

3. Has your shortness of breath gotten worse in the last week (before coming to the hospital)?

About the same | Worse | Much worse

Figure 17-6 • Dyspnea scale and patient's report of current and recent dyspnea. Reprinted from Baker, K. M., DeSanto-Madeya, S., & Banzett, R. B. (2017). Routine dyspnea assessment and documentation: Nurses experience yields wide acceptance. *BMC Nursing, 16*(3), 1–11. This article is distributed under the terms of the Creative Commons Attribution 4.0 International License (www.creativecommons.org/licenses/by/4.0), which permits unrestricted use, distribution, and reproduction in any medium.

To help determine the cause of the cough, the nurse inquires about the onset and time of coughing. Coughing at night may indicate the onset of left-sided heart failure or bronchial asthma. A cough in the morning with sputum production may indicate bronchitis. A cough that worsens when the patient is supine suggests postnasal drip (rhinosinusitis). Coughing after food intake may indicate aspiration of material into the tracheobronchial tree or reflux. A cough of recent onset is usually from an acute infection.

The nurse assesses the character of the cough and associated symptoms. A dry, irritative cough is characteristic of an upper respiratory tract infection of viral origin, or it may be a side effect of ACE inhibitor therapy. An irritative, high-pitched cough can be caused by laryngotracheitis. A brassy cough is the

result of a tracheal lesion, and a severe or changing cough may indicate bronchogenic carcinoma. Pleuritic chest pain that accompanies coughing may indicate pleural or chest wall (musculoskeletal) involvement. Violent coughing causes bronchial spasm, obstruction, and further irritation of the bronchi and may result in syncope (fainting).

Concept Mastery Alert

A nurse interviewing a patient who says he has a dry, irritating cough that is not "bringing anything up" should ask whether he is taking ACE inhibitors.

A persistent cough may affect a patient's quality of life and may produce embarrassment, exhaustion, inability to sleep, and pain. Therefore, the nurse should explore how a chronic cough impacts all aspects of the patient's life.

Chart 17-5 **NURSING RESEARCH PROFILE**

Dyspnea Assessment

Baker, K. M., DeSanto-Madeya, S., & Banzett, R. B. (2017). Routine dyspnea assessment and documentation: Nurses' experience yields wide acceptance. *BMC Nursing, 16*(3), 1–11.

Purpose

The study aims to explore nurses' approaches to dyspnea assessment, their perception of patient response, and their perception of the utility and burden of dyspnea measurement.

Design

This was a qualitative, descriptive study utilizing a three-part assessment of practice: a series of focus group interviews, a time-motion observation, and a randomized, anonymous online survey. A convenience sample of 63 nurses from six medical-surgical units participated in 12 half-hour focus group sessions. The focus group included questions about the process nurses used for assessment of dyspnea, views on the importance of dyspnea assessment and awareness, patients' abilities to rate and use a dyspnea scale, impact of routine assessment on workflow, and suggestions for improvement. Focus group sessions were conducted during regular work shifts and were recorded. Forty registered nurses representing 14 medical-surgical inpatient units were randomly selected for participation in the time-motion study. For this observation, a clinical nurse specialist recorded the time nurses spent assessing and documenting pain and dyspnea during routine morning nursing assessment of patients. The online survey addressed issues raised during the focus group sessions. Seventy registered nurses, from 14 inpatient medical-surgical units, were randomly selected to complete the anonymous, online survey.

Findings

Nursing assessment of dyspnea and pain took less than 1 min. Overwhelmingly, most of the nurses surveyed (94%) reported understanding the importance of assessing dyspnea. They described assessment of dyspnea as "easy" or "very easy" to complete and that the utilization of an assessment tool enhanced awareness of dyspnea, improved workflow, and standardized documentation.

Nursing Implications

Findings from this study support the use of a standardized tool to assess dyspnea as part of routine nursing assessment of patients.

Sputum Production

Sputum production is the reaction of the lungs to any constantly recurring irritant and often results from persistent coughing. It may also be associated

with a nasal discharge. The nature of the sputum is often indicative of its cause. A profuse amount of purulent sputum (thick and yellow, green, or rust colored) or a change in color of the sputum is a common sign of a bacterial infection. Thin, mucoid sputum frequently results from viral bronchitis. A gradual increase of sputum over time may occur with chronic bronchitis or bronchiectasis. Pink-tinged mucoid sputum suggests a lung tumor. Profuse, frothy, pink material, often welling up into the throat, may indicate pulmonary edema. Foul-smelling sputum and bad breath point to the presence of a lung abscess, bronchiectasis, or an infection caused by fusospirochetal or other anaerobic organisms.

Chest Pain

Chest pain or discomfort may be associated with pulmonary, cardiac, gastrointestinal, or musculoskeletal disease or anxiety. Chest pain associated with pulmonary conditions may be sharp, stabbing, and intermittent, or it may be dull, aching, and persistent. The pain usually is felt on the side where the pathologic process is located, although it may be referred elsewhere—for example, to the neck, back, or abdomen.

Chest pain may occur with pneumonia, pulmonary infarction, or pleurisy, or as a late symptom of bronchogenic carcinoma. In carcinoma, the pain may be dull and persistent because the cancer has invaded the chest wall, mediastinum, or spine.

Lung disease does not always cause thoracic pain because the lungs and the visceral pleura lack sensory nerves and are insensitive to pain stimuli. However, the parietal pleura have a rich supply of sensory nerves that are stimulated by inflammation and stretching of the membrane. Pleuritic pain from irritation of the parietal pleura is sharp and seems to "catch" on inspiration; patients often describe it as being "like the stabbing of a knife." Patients are more comfortable when they lay on the affected side because this position splints the chest wall, limits expansion and contraction of the lung, and reduces the friction between the injured or diseased pleurae on that side. Pain associated with cough may be reduced manually by splinting the rib cage.

The nurse assesses the onset, quality, intensity, and radiation of pain and identifies and explores precipitating factors and their relationship to the patient's position. In addition, the nurse must assess the relationship of pain to the inspiratory and expiratory phases of respiration (see Chapter 9 for further discussion on assessment of pain).

Wheezing

Wheezing is a high-pitched, musical sound which is continuous, meaning it is heard on either expiration (asthma) or inspiration (bronchitis). It is often the major finding in a patient with bronchoconstriction or airway narrowing (see later discussion under Thoracic Auscultation).

Hemoptysis

Hemoptysis is the expectoration of blood from the respiratory tract. It can present as small to moderate blood-stained sputum to a large hemorrhage and always warrants further investigation. The onset of hemoptysis is usually sudden, and it may be intermittent or continuous. The most common causes are:

- Pulmonary infection
- Carcinoma of the lung
- Abnormalities of the heart or blood vessels
- Pulmonary artery or vein abnormalities
- PE or infarction

The nurse must determine the source of the bleeding, as the term *hemoptysis* is reserved for blood coming from the respiratory tract. Potential sources of bleeding include the gums, nasopharynx, lungs, or stomach. The nurse may be the only witness to the episode, and when evaluating the bleeding episode, the following points should be considered:

- Bloody sputum from the nose or the nasopharynx is usually preceded by considerable sniffing, with blood possibly appearing in the nose.
- Blood from the lung is usually bright red, frothy, and mixed with sputum. Initial symptoms include a tickling sensation in the throat, a salty taste, a burning or bubbling sensation in the chest, and perhaps chest pain, in which case, the patient tends to splint the bleeding side. This blood has an alkaline pH (greater than 7).
- Blood from the stomach is vomited rather than expectorated, may be mixed with food, and is usually much darker and often referred to as "coffee ground emesis." This blood has an acid pH (less than 7).

Past Health, Social, and Family History

In addition to the presenting problem and associated symptoms, the history should also focus on the patient's health, personal, and social history, and the family health history. Specific questions are asked about childhood illnesses, immunizations (including the most recent influenza and pneumonia vaccinations), medical conditions, injuries, hospitalizations, surgeries, allergies, and current medications (including over-the-counter medications and herbal remedies). Personal and social history addresses issues such as diet, exercise, sleep, recreational habits, and religion. Psychosocial factors that may affect the patient are also explored (Chart 17-6).

The nurse assesses for risk factors and genetic factors that may contribute to the patient's lung condition (Charts 17-7 and 17-8). Many lung disorders are related to or exacerbated by tobacco smoke; therefore, smoking history (including exposure to secondhand smoke) is also obtained. Smoking history is

usually expressed in pack-years, which is the number of packs of cigarettes smoked per day times the number of years the patient has smoked. It is important to find out whether the patient is still smoking or when the patient quit smoking. The nurse should also ask patients whether they use electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars, or any other smokeless tobacco products. In 2016, the U.S. Food and Drug Administration (FDA) finalized a rule that extended its regulatory authority to all tobacco products, including e-cigarettes, cigars, hookah, and pipe tobacco. The new rule mandates health warnings on products, bans free samples, and restricts youth (those under the age of 18) access to newly regulated tobacco products. The FDA has not found ENDS to be safe or effective in helping smokers curb the habit, as previously marketed by some manufacturers. The FDA has approved five forms of nicotine replacement therapy including nicotine gum, nicotine skin patches, nicotine lozenges, nicotine oral inhaled products, and nicotine nasal spray (American Lung Association, 2020). The American Lung Association views ENDS as a public health threat and calls for additional research regarding the risks and long-term effects to better understand potential risks (American Lung Association, 2019). In January 2018, The National Academies of Sciences, Engineering, and Medicine released a report on the public health consequences of e-cigarettes. The report presented 47 conclusions from a review of 800 studies and concluded that using e-cigarettes causes health risks. E-cigarettes contain and emit a number of potentially toxic substances such as propylene glycol, acetaldehyde, acrolein, and formaldehyde, among others. Acrolein, also used as a weed killer, is known to cause acute lung injury, COPD, asthma, and lung cancer. Additionally, e-cigarette use is associated with an increased risk for cough, wheeze, and asthma exacerbations in adolescents (The National Academies of Sciences, Engineering, and Medicine, 2018). Differences in socioeconomic factors, rooted in race and ethnicity, may predispose certain groups to greater burdens related to lung disease and should also be considered (Chart 17-9).

Chart 17-6 **ASSESSMENT**

Assessing Psychosocial Factors Related to Respiratory Function and Disease

- What strategies does the patient use to cope with the signs, symptoms, and challenges associated with pulmonary disease?
- What effect has the pulmonary disease had on the patient's quality of life, goals, role within the family, and occupation?
- What changes has the pulmonary disease had on the patient's family and relationships with family members?
- Does the patient exhibit depression, anxiety, anger, hostility, dependency, withdrawal, isolation, avoidance, nonadherence, acceptance, or denial?
- What support systems does the patient use to cope with the illness?
- Are resources (relatives, friends, or community groups) available? Do the patient and the family use them effectively?

Chart 17-7 RISK FACTORS

Respiratory Disease

- Atypical immune responses in disease (e.g., asthma)
- Exposure to indoor pollutants (e.g., tobacco smoke, radon gas)
- Exposure to outdoor pollutants (e.g., smog, vehicle exhaust emissions, pollen)
- Genetic makeup
- Infection (e.g., influenza, pneumonia)
- Obesity
- Personal or family history of lung disease
- Smoking (e.g., cigarettes, e-cigarettes)

Adapted from American Lung Association. (2019). Protecting your lungs: Tips to keep your lungs healthy. Retrieved on 12/22/2019 at: www.lung.org/lung-health-and-diseases/protecting-your-lungs

If the patient is experiencing severe dyspnea, the nurse may need to modify the questions asked and the timing of the health history to avoid increasing the patient's breathlessness and anxiety. Once the history is complete, the nurse conducts a comprehensive assessment. Data obtained from both the history and the assessment guide the development of a nursing care plan and patient education.

Chart 17-8 GENETICS IN NURSING PRACTICE

Respiratory Disorders

Various conditions that affect gas exchange and respiratory function are influenced by genetic factors. Some are known to have a direct inherited pathway while others have a strong familial association, but the exact inheritance pattern is not entirely clear. The following are examples of respiratory disorders with a known or associated familial component:

- Asthma
- Cystic fibrosis
- Chronic obstructive pulmonary disease
- Alpha$_1$-antitrypsin deficiency
- Primary ciliary dyskinesia
- Pulmonary fibrosis
- Pulmonary hypertension
- Tuberous sclerosis

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Genetic Respiratory Disorders

- Assess family history for three generations for family members with histories of respiratory impairment.
- Assess family history for individuals with early-onset chronic pulmonary disease and family history of hepatic disease in infants (clinical symptoms of alpha$_1$-antitrypsin deficiency).
- Inquire about family history of cystic fibrosis, an autosomal recessive inherited respiratory disorder.

Patient Assessment Specific to Genetic Respiratory Disorders

- Assess for symptoms such as changes in respiratory status and triggers that precede changes in respiratory function
- Frequency of respiratory tract infections or sinus infections
- Determine exposure to environmental risks (e.g., radon, asbestos) or occupational exposures (e.g., coal miner, sandblaster, painter)
- Determine presence of secondary risk factors (e.g., smoking or exposure or secondhand smoke)
- Assess for:
  - Clubbing of fingers
  - Skin color in general or the presence of white patches on the skin
  - Presence of angiofibromas or ungual fibromas (seen with primary ciliary dyskinesia)
- Assess for presence and frequency of:
  - Wheezing or coughing

- Mucous production (frequency, amount, and characteristics of the mucous)
- Mucosal edema

- Assess for multisystem effects (gastrointestinal disorders, pancreatic insufficiency, liver or kidney disorders)

Physical Assessment of the Respiratory System

General Appearance

The patient's general appearance may give clues to respiratory status. In particular, the nurse inspects for clubbing of the fingers and notes skin color.

Clubbing of the Fingers

Clubbing of the fingers is a change in the normal nail bed. It appears as sponginess of the nail bed and loss of the nail bed angle (Fig. 17-7). It is a sign of lung disease that is found in patients with chronic hypoxic conditions, chronic lung infections, or malignancies of the lung. Clubbing can also be seen in congenital heart disease and other chronic infections or inflammatory conditions, such as endocarditis or inflammatory bowel disease (Hogan-Quigley, Palm, & Bickley, 2017).

Cyanosis

Cyanosis, a bluish coloring of the skin, is a very late indicator of hypoxia. The presence or absence of cyanosis is determined by the amount of unoxygenated hemoglobin in the blood. Cyanosis appears when there is at least 5 g/dL of unoxygenated hemoglobin. A patient with a hemoglobin level of 15 g/dL does not demonstrate cyanosis until 5 g/dL of that hemoglobin becomes unoxygenated, reducing the effective circulating hemoglobin to two thirds of the normal level.

Chart 17-9

Disparities in Pulmonary Health Related to Socioeconomics, Race, and Ethnicity: A Snapshot

- Individuals living in rural areas are more likely to use tobacco and be exposed to secondhand smoke at work and at home, to start smoking at a younger age, and to use more than 15 cigarettes daily, yet have less access to smoking cessation programs.
- Individuals with lower income and lower levels of education are more likely to use tobacco products.
- Adults living below the poverty level are more likely to experience severe asthma exacerbations, hospitalizations, and death.
- More Hispanics live and work in areas with greater levels of pollution, have higher prevalence rates of asthma than Caucasians, and yet are less likely to be diagnosed with asthma than all other racial and ethnic groups. Hispanics are less likely than non-Hispanic Whites to receive health insurance as a benefit from an employer.
- African American men are 37% more likely to get lung cancer than Caucasian men even though smoking rates between these two groups are comparable.
- American Indians/Alaska Natives and African Americans are at a higher risk of complications resulting from influenza and pneumonia.
- Death rates for African Americans are 55 percent higher for asthma than among Caucasians.
- Older African Americans and older Hispanics are less likely than older Caucasians to receive influenza vaccines (28% and 24% less, respectively) and pneumonia vaccines (37% and 46%, respectively).

Adapted from American Lung Association. Disparities in lung health series. Retrieved on 6/23/2019 at: www.lung.org/our-initiatives/research/lung-health-disparities

Figure 17-7 • Clubbed finger. In clubbing, the distal phalanx of each finger is rounded and bulbous. The nail plate is more convex, and the angle between the plate and the proximal nail fold increases to 180 degrees or more. The proximal nail fold, when palpated, feels spongy or floating. Among the many causes are chronic hypoxia and lung cancer.

A patient with anemia rarely manifests cyanosis, and a patient with polycythemia may appear cyanotic even if adequately oxygenated. Therefore, cyanosis is *not* a reliable sign of hypoxia.

Assessment of cyanosis is affected by room lighting, the patient's skin color, and the distance of the blood vessels from the surface of the skin. In the presence of a pulmonary condition, central cyanosis is assessed by observing the color of the tongue and lips. This indicates a decrease in oxygen tension in the blood. Peripheral cyanosis results from decreased blood flow to the body's periphery (fingers, toes, or earlobes), as in vasoconstriction from exposure to cold, and does not necessarily indicate a central systemic problem.

Upper Respiratory Structures

For a routine examination of the upper airway, only a simple light source, such as a penlight, is necessary. A more thorough examination requires the use of a nasal speculum.

Nose and Sinuses

The nurse inspects the external nose for lesions, asymmetry, or inflammation and then asks the patient to tilt the head backward. Gently pushing the tip of

the nose upward, the nurse examines the internal structures of the nose, inspecting the mucosa for color, swelling, exudate, or bleeding. The nasal mucosa is normally redder than the oral mucosa. It may appear swollen and hyperemic if the patient has a common cold; however, in allergic rhinitis, the mucosa appears pale and swollen.

Next, the nurse inspects the septum for deviation, perforation, or bleeding. Most people have a slight degree of septal deviation; such deviation usually causes no symptoms. However, actual displacement of the cartilage into either the right or left side of the nose may produce nasal obstruction.

While the head is still tilted back, the nurse inspects the inferior and middle turbinates. In chronic rhinitis, nasal polyps may develop between the inferior and middle turbinates; they are distinguished by their gray appearance. Unlike the turbinates, they are gelatinous and freely movable.

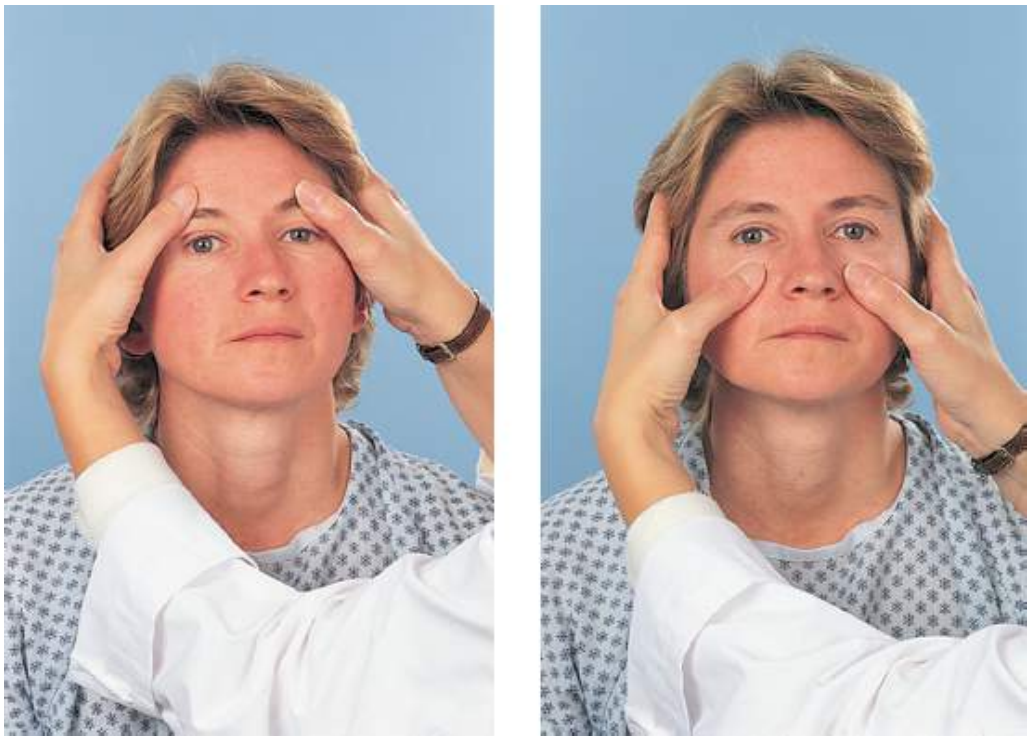

Figure 17-8 • Technique for palpating the frontal sinuses at left and the maxillary sinuses at right.

Next, the nurse may palpate the frontal and maxillary sinuses for tenderness (Fig. 17-8). Using the thumbs, the nurse applies gentle pressure in an upward fashion at the supraorbital ridges (frontal sinuses) and in the cheek area adjacent to the nose (maxillary sinuses). Tenderness in either area suggests inflammation. The frontal and maxillary sinuses can be inspected by transillumination (passing a strong light through a bony area, such as the sinuses, to inspect the cavity; see Fig. 17-9). If the light fails to penetrate, the cavity likely contains fluid or pus.

Mouth and Pharynx

After the nasal inspection, the nurse assesses the mouth and the pharynx, instructing the patient to open the mouth wide and take a deep breath. Usually, this flattens the posterior tongue and briefly allows a full view of the anterior and posterior pillars, tonsils, uvula, and posterior pharynx (see Chapter 39, Fig. 39-2). The nurse inspects these structures for color, symmetry, and evidence of exudate, ulceration, or enlargement. If a tongue blade is needed to depress the tongue to visualize the pharynx, it is pressed firmly beyond the midpoint of the tongue to avoid a gagging response.

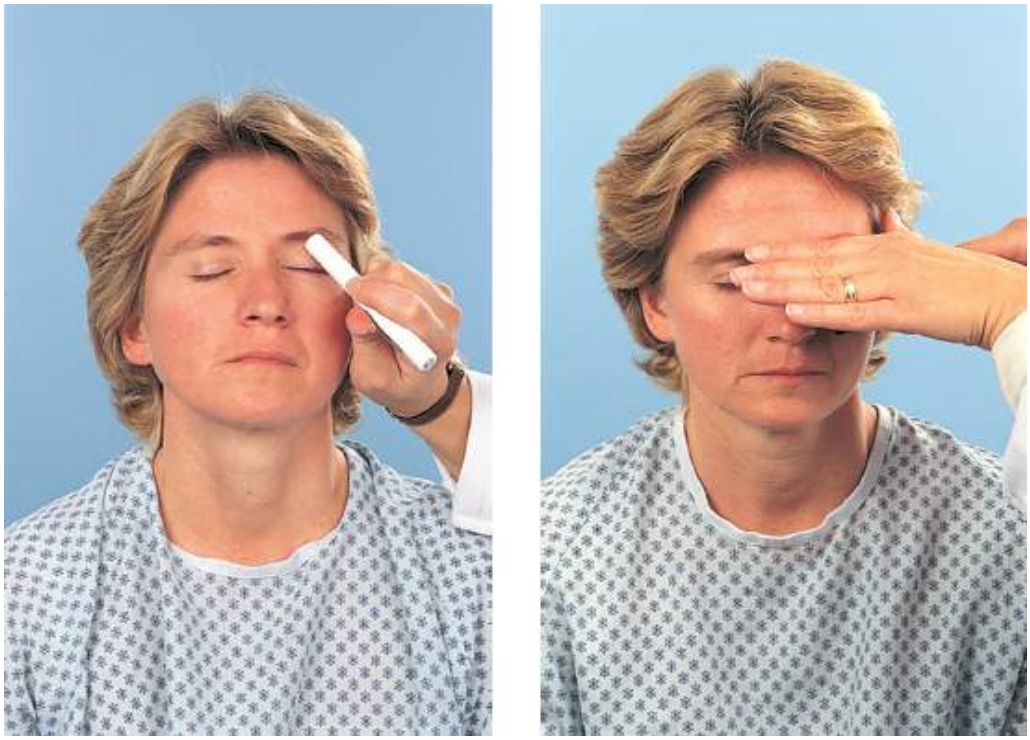

Figure 17-9 • At left, the nurse positions the light source for transillumination of the frontal sinus. At right, the nurse shields the patient's brow and shines the light. In normal conditions (a darkened room), the light should shine through the tissues and appear as a reddish glow (above the nurse's hand) over the sinus.

Trachea

Next, the position and mobility of the trachea are noted by direct palpation. This is performed by placing the thumb and the index finger of one hand on either side of the trachea just above the sternal notch. The trachea is highly sensitive and palpating too firmly may trigger a coughing or gagging response. The trachea is normally in the midline as it enters the thoracic inlet behind the sternum; however, it may be deviated by masses in the neck or the

mediastinum. Pulmonary disorders such as a pneumothorax or pleural effusion may also displace the trachea.

Lower Respiratory Structures and Breathing

Assessment of the lower respiratory structures includes inspection, palpation, percussion, and auscultation of the thorax. The patient should be positioned as necessary prior to the assessment.

Positioning

To assess the posterior thorax and the lungs, the patient should be in a sitting position with arms crossed in front of the chest and hands placed on the opposite shoulders (Hogan-Quigley et al., 2017). This position separates the scapulae widely and exposes more lung area for assessment. If the patient is unable to sit, with the patient supine, the nurse should roll the patient from side to side to complete the posterior examination. To assess the anterior thorax and lungs, the patient should be either supine or sitting. The supine position allows easier displacement of the patient's breast tissue, improving the nurse's ability to perform the chest examination.

Thoracic Inspection

Inspection of the thorax provides information about the respiratory system, the musculoskeletal structure, and the patient's nutritional status. The nurse observes the skin over the thorax for color and turgor and for evidence of loss of subcutaneous tissue. It is important to note asymmetry, if present. In documenting or reporting the findings, anatomic landmarks are used as points of reference (Chart 17-10).

Chest Configuration

Normally, the ratio of the anteroposterior diameter to the lateral diameter is 1:2. However, there are four main deformities of the chest associated with respiratory disease that alter this relationship: barrel chest, funnel chest (pectus excavatum), pigeon chest (pectus carinatum), and kyphoscoliosis.

Barrel Chest. Barrel chest occurs as a result of overinflation of the lungs, which increases the anteroposterior diameter of the thorax. It occurs with aging and is a hallmark sign of emphysema and COPD. In a patient with emphysema, the ribs are more widely spaced and the intercostal spaces tend to bulge on expiration. The appearance of the patient with advanced emphysema is thus quite characteristic, allowing the nurse to detect its presence easily, even from a distance.

Funnel Chest (Pectus Excavatum). Funnel chest occurs when there is a depression in the lower portion of the sternum. This may compress the heart

and great vessels, resulting in murmurs. Funnel chest may occur with rickets or Marfan syndrome.

Pigeon Chest (Pectus Carinatum). A pigeon chest occurs as a result of the anterior displacement of the sternum, which also increases the anteroposterior diameter. This may occur with rickets, Marfan syndrome, or severe kyphoscoliosis.

Kyphoscoliosis. Kyphoscoliosis is characterized by elevation of the scapula and a corresponding S-shaped spine. This deformity limits lung expansion within the thorax. It may occur with osteoporosis and other skeletal disorders that affect the thorax.

Breathing Patterns and Respiratory Rates

Observation of the rate, depth, and symmetry during respiration is a simple but important aspect of assessment. The normal adult who is at rest comfortably takes 12 to 20 breaths/min (Hogan-Quigley et al., 2017). Except for the occasional sigh, respirations are quiet with a regular rate, depth, and rhythm. The normal pattern associated with breathing is known as eupnea. Certain pathologic conditions may alter the rate and rhythm and are characteristic of certain disease states. For example, wheezing is commonly seen in the patient with asthma. Changes found during the act of breathing may be the first clinical sign that the patient's condition is deteriorating (IHI, 2019). The rate and depth of various patterns of respiration are presented in Table 17-3.

Concept Mastery Alert

There are subtle differences between Cheyne–Stokes and Biot's respiration patterns. Between regularly cycled periods of apnea, Cheyne–Stokes respirations demonstrate a regular pattern with the rate and depth of breathing increasing and then decreasing. In Biot's respiration, irregularly cycled periods of apnea are interspersed with cycles of normal rate and depth.

Temporary pauses of breathing, or **apnea,** may be noted. When episodes of apnea occur repeatedly during sleep, secondary to transient upper airway blockage, the condition is called **obstructive sleep apnea.** In thin people, it is quite normal to note a slight retraction of the intercostal spaces during quiet breathing. Bulging of the intercostal spaces during expiration implies obstruction of expiratory airflow, as in emphysema. Marked retraction on inspiration, particularly if asymmetric, implies blockage of a branch of the respiratory tree. Asymmetric bulging of the intercostal spaces, on either side of the thorax, is created by an increase in pressure within the hemithorax. This may be a result of air trapped under pressure within the pleural cavity, where it is not normally present (pneumothorax), or the pressure of fluid within the pleural space (pleural effusion).

Use of Accessory Muscles

In addition to breathing patterns and respiratory rates, the nurse should observe for the use of accessory muscles, such as the sternocleidomastoid, scalene, and trapezius muscles during inspiration, and the abdominal and internal intercostal muscles during expiration. These muscles provide additional support to assist the breathing effort during times of exertion as seen in exercise or certain disease states (Hogan-Quigley et al., 2017).

Chart 17-10

Locating Thoracic Landmarks

With respect to the thorax, location is defined both horizontally and vertically. With respect to the lungs, location is defined by lobe.

Horizontal Reference Points

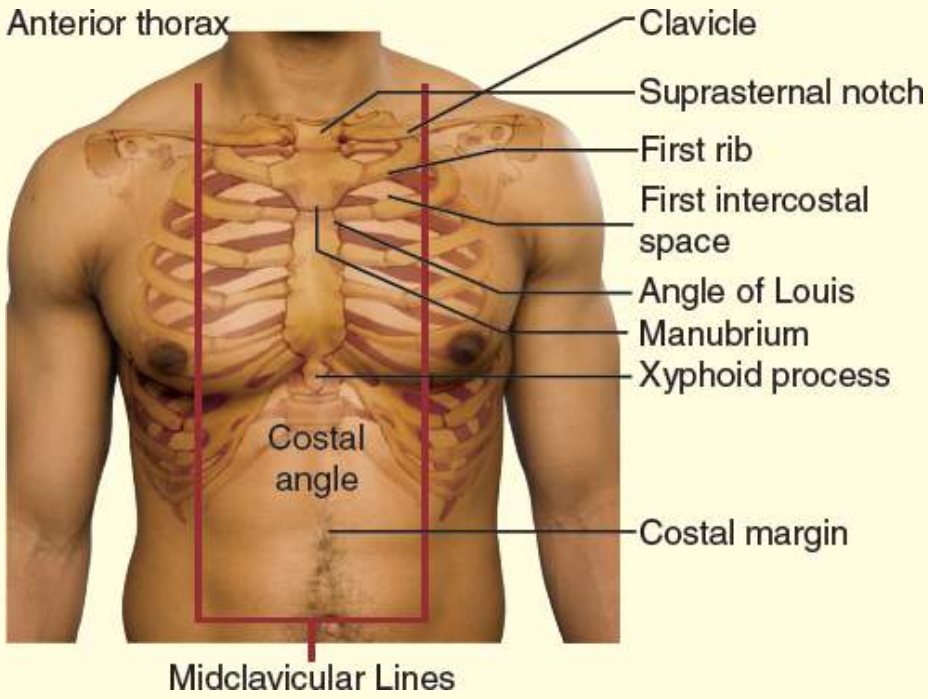
Horizontally, thoracic locations are identified according to their proximity to the rib or the intercostal space under the examiner's fingers. On the anterior surface, identification of a specific rib is facilitated by first locating the angle of Louis. This is where the manubrium joins the body of the sternum in the midline. The second rib joins the sternum at this prominent landmark.

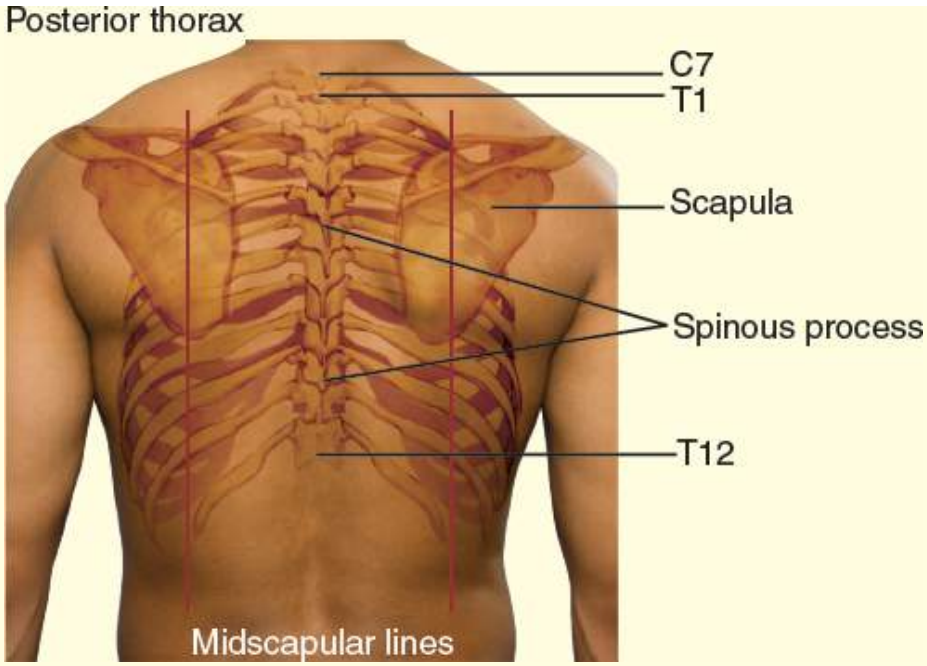
Other ribs may be identified by counting down from the second rib. The intercostal spaces are referred to in terms of the rib immediately above the intercostal space; for example, the fifth intercostal space is directly below the fifth rib.

Locating ribs on the posterior surface of the thorax is more difficult. The first step is to identify the spinous process. This is accomplished by finding the seventh cervical vertebra (*vertebra prominens*), which is the most prominent spinous process. When the neck is slightly flexed, the seventh cervical spinous process stands out. Other vertebrae are then identified by counting downward.

Vertical Reference Points

Several imaginary lines are used as vertical referents or landmarks to identify the location of thoracic findings. The *midsternal line* passes through the center of the sternum. The *midclavicular line* is an imaginary line that descends from the middle of the clavicle. The *point of maximal impulse* of the heart normally lies along this line on the left thorax.





When the arm is abducted from the body at 90 degrees, imaginary vertical lines may be drawn from the anterior axillary fold, from the middle of the axilla, and from the posterior axillary fold. These lines are called, respectively, the *anterior axillary line,* the *midaxillary line,* and the *posterior axillary line.* A line drawn vertically through the superior and inferior poles of the scapula is called the *scapular line,* and a line drawn down the center of the vertebral column is called the *vertebral line.* Using these landmarks, for example, the examiner communicates findings by referring to an area of dullness extending from the vertebral to the scapular line between the 7th and 10th ribs on the right.

Lobes of the Lungs

The lobes of the lung may be mapped on the surface of the chest wall in the following manner. The line between the upper and lower lobes on the left begins at the fourth thoracic spinous process posteriorly, proceeds around to cross the fifth rib in the midaxillary line, and meets the sixth rib at the sternum. This line on the right divides the right middle lobe from the right lower lobe. The line dividing the right upper lobe from the middle lobe is an incomplete one that begins at the fifth rib in the midaxillary line, where it intersects the line between the upper and lower lobes and traverses horizontally to the sternum. Thus, the upper lobes are dominant on the anterior surface of the thorax, and the lower lobes are dominant on the posterior surface. There is no presentation of the right middle lobe on the posterior surface of the chest.

TABLE 17-3 Rates and Depths of Respiration

Type	Description
Eupnea 	Normal, breathing at 12–20 breaths/min
Bradypnea 	Slower than normal rate (<10 breaths/min), with normal depth and regular rhythm Associated with increased intracranial pressure, brain injury, and drug overdose
Tachypnea 	Rapid, shallow breathing >24 breaths/min Associated with pneumonia, pulmonary edema, metabolic acidosis, septicemia, severe pain, or rib fracture
Hypoventilation 	Shallow, irregular breathing
Hyperpnea	Increased depth of respirations, see also hyperventilation
Hyperventilation 	Increased rate and depth of breathing that results in decreased $PaCO_2$ level Inspiration and expiration nearly equal in duration Associated with exertion, anxiety, and metabolic acidosis Called *Kussmaul's respiration* if associated with diabetic ketoacidosis or untreated kidney failure
Apnea	Period of cessation of breathing; time duration varies; apnea may occur briefly during other

	breathing disorders, such as with sleep apnea; life-threatening if sustained
Cheyne–Stokes 	Regular cycle where the rate and depth of breathing increase, then decrease until apnea (usually about 20 s) occurs Duration of apnea may vary and progressively lengthen; therefore, it is timed and reported. Associated with heart failure and damage to the respiratory center (drug induced, tumor, trauma)
Biot's respiration 	Periods of normal breathing (3–4 breaths), followed by a varying period of apnea (usually 10–60 s) Also called *ataxic breathing;* associated with complete irregularity Associated with respiratory depression resulting from drug overdose and brain injury, normally at the level of the medulla
Obstructive 	Prolonged expiratory phase of respiration Associated with airway narrowing and seen in asthma, chronic obstructive pulmonary disease, and bronchitis

Adapted from Hogan-Quigley, B., Palm, M. L., & Bickley, L. (2017). *Bates' nursing guide to physical examination and history taking* (2nd ed.). Philadelphia, PA: Wolters Kluwer Health Lippincott Williams & Wilkins.

Thoracic Palpation

The nurse palpates the thorax for tenderness, masses, lesions, respiratory excursion, and vocal fremitus. If the patient has reported an area of pain or if

lesions are apparent, the nurse performs direct palpation with the fingertips (for skin lesions and subcutaneous masses) or with the ball of the hand (for deeper masses or generalized flank or rib discomfort).

Respiratory Excursion

Respiratory excursion is an estimation of thoracic expansion and may disclose significant information about thoracic movement during breathing. The nurse assesses the patient for range and symmetry of excursion. For anterior assessment, the nurse places the thumbs along the costal margin of the chest wall and instructs the patient to inhale deeply. The nurse observes movement of the thumbs during inspiration and expiration. This movement is normally symmetric (Hogan-Quigley et al., 2017).

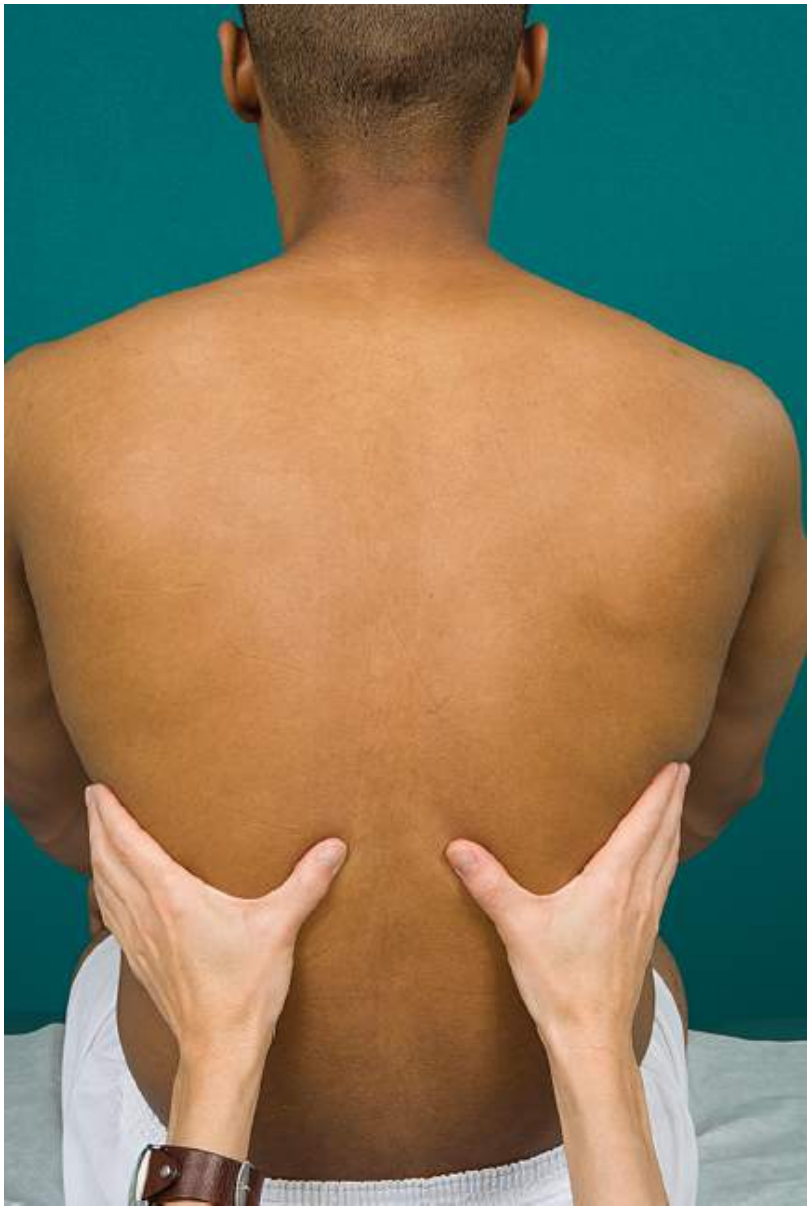

Figure 17-10 • Method for assessing posterior respiratory excursion. Place both hands posteriorly at the level of T9 or T10. Slide hands medially to pinch a small amount of skin between your thumbs. Observe for symmetry as the patient exhales fully following a deep inspiration.

Posterior assessment is performed by placing the thumbs adjacent to the spinal column at the level of the 10th rib (Fig. 17-10). The hands lightly grasp the lateral rib cage. Sliding the thumbs medially about 2.5 cm (1 inch) raises a small skin fold between the thumbs. The patient is instructed to take a full inspiration and to exhale fully. The nurse observes for normal flattening of the skin fold and feels the symmetric movement of the thorax.

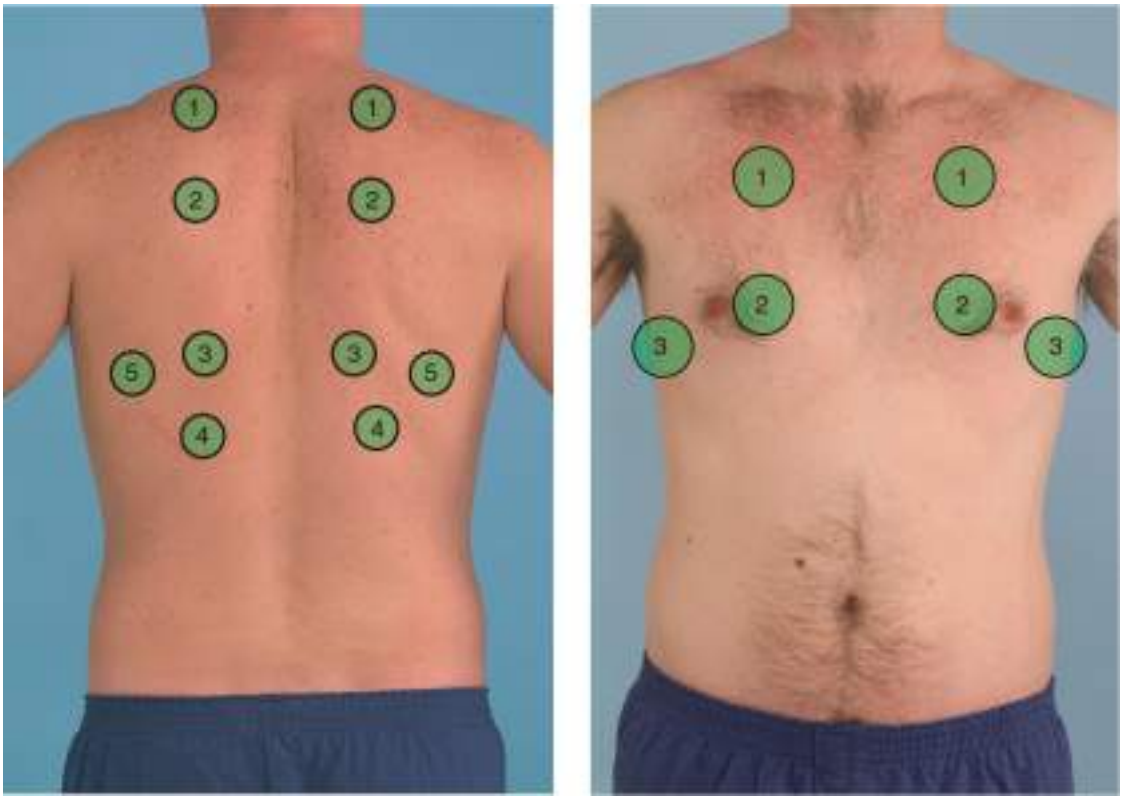

Figure 17-11 • Palpation sequence for tactile fremitus: posterior thorax (**left**) and anterior thorax (**right**).

Decreased chest excursion may be caused by chronic fibrotic disease. Asymmetric excursion may be due to splinting secondary to pleurisy, fractured ribs, trauma, or unilateral bronchial obstruction.

Tactile Fremitus

Tactile **fremitus** describes vibrations of the chest wall that result from speech detected on palpation. Normally, sounds generated by the larynx travel distally along the bronchial tree to set the chest wall in resonant motion. This is most pronounced with consonant sounds.

Normal fremitus varies on the basis of numerous factors. It is influenced by the thickness of the chest wall, especially muscle, and the subcutaneous tissue associated with obesity. It is also influenced by pitch; lower-pitched sounds travel better through the normal lung and produce greater vibration of the chest wall. Therefore, fremitus is more pronounced in men than in women because of the deeper male voice. Normally, fremitus is most pronounced where the large bronchi are closest to the chest wall, is more prominent on the right side, and is decreased or absent over the anterior chest wall which overlies the heart and great vessels (Hogan-Quigley et al., 2017).

The patient is asked to repeat "ninety-nine" or "one, one, one" as the nurse's hands move down the patient's thorax (Hogan-Quigley et al., 2017). The vibrations are detected with the palmar surfaces of the hands, or the ulnar

aspect of the extended hands, on the thorax. The hand or hands are moved in sequence down the thorax. Corresponding areas of the thorax are compared (Fig. 17-11). Bony areas are not assessed.

TABLE 17-4 Characteristics of Percussion Sounds

Sound	Relative Intensity	Relative Pitch	Relative Duration	Location Example	Examples
Flatness	Soft	High	Short	Thigh	Large pleural effusion
Dullness	Medium	Medium	Medium	Liver	Lobar pneumonia
Resonance	Loud	Low	Long	Normal lung	Simple chronic bronchitis
Hyperresonance	Very loud	Lower	Longer	None normally	Emphysema, pneumothorax
Tympany	Loud	High*	Medium	Gastric air bubble or puffed-out cheek	Large pneumothorax

*Distinguished mainly by its musical timbre.
Adapted from Hogan-Quigley, B., Palm, M. L., & Buckley, L. (2017). Bates' nursing guide to physical examination and history taking (2nd ed.). Philadelphia, PA: Wolters Kluwer Health Lippincott Williams & Wilkins.

Air does not conduct sound well; however, a solid substance such as tissue does, provided that it has elasticity and is not compressed. Therefore, an increase in solid tissue per unit volume of lung enhances fremitus, and an increase in air per unit volume of lung impedes sound. Patients with emphysema exhibit almost no tactile fremitus. A patient with consolidation of a lobe of the lung from pneumonia has increased tactile fremitus over that lobe.

Thoracic Percussion

Percussion produces audible and tactile vibration and allows the nurse to determine whether underlying tissues are filled with air, fluid, or solid material. Healthy lung tissue is resonant. Dullness over the lung occurs when air-filled lung tissue is replaced by fluid or solid tissue. Table 17-4 reviews percussion sounds and their characteristics. Percussion is also used to estimate the size and location of certain structures within the thorax (e.g., diaphragm, heart, liver).

Percussion usually begins with the posterior thorax. The nurse percusses across each shoulder top, locating the 5-cm width of resonance overlying the lung apices (Fig. 17-12). Then the nurse proceeds down the posterior thorax, percussing symmetric areas at intervals of 5 to 6 cm (2 to 2.5 inches). To perform percussion, the middle finger of the nondominant hand is firmly placed against the area of the chest wall to be percussed. The distal interphalangeal joint of this finger is struck with the tip of the middle finger of the dominant hand. This finger is partially flexed, and percussion occurs in a smooth, dartlike fashion. Bony structures (scapulae or ribs) are not percussed.

To perform percussion over the anterior chest, the nurse begins in the supraclavicular area and proceeds downward, from one intercostal space to the next. Dullness noted to the left of the sternum between the third and fifth intercostal spaces is a normal finding, because that is the location of the heart.

Similarly, there is a normal span of liver dullness below the lung at the right costal margin (Hogan-Quigley et al., 2017).

Diaphragmatic Excursion

The normal resonance of the lung stops at the diaphragm. The position of the diaphragm is different during inspiration and expiration.

To assess the position and motion of the diaphragm, the nurse instructs the patient to take a deep breath and hold it while the maximal descent of the diaphragm is percussed. The point at which the percussion note at the midscapular line changes from resonance to dullness is marked with a pen. The patient is then instructed to exhale fully and hold it while the nurse again percusses downward to the dullness of the diaphragm. This point is also marked. The distance between the two markings indicates the range of motion of the diaphragm.

Maximal excursion of the diaphragm may be as much as 8 to 10 cm (3 to 4 inches) in healthy, tall young men, but for most people, it is usually 5 to 7 cm (2 to 2.75 inches). Normally, the diaphragm is about 2 cm (0.75 inch) higher on the right because of the location of the liver. Decreased diaphragmatic excursion may occur with pleural effusion. Atelectasis, diaphragmatic paralysis, or pregnancy may account for a diaphragm that is positioned high in the thorax (Hogan-Quigley et al., 2017).

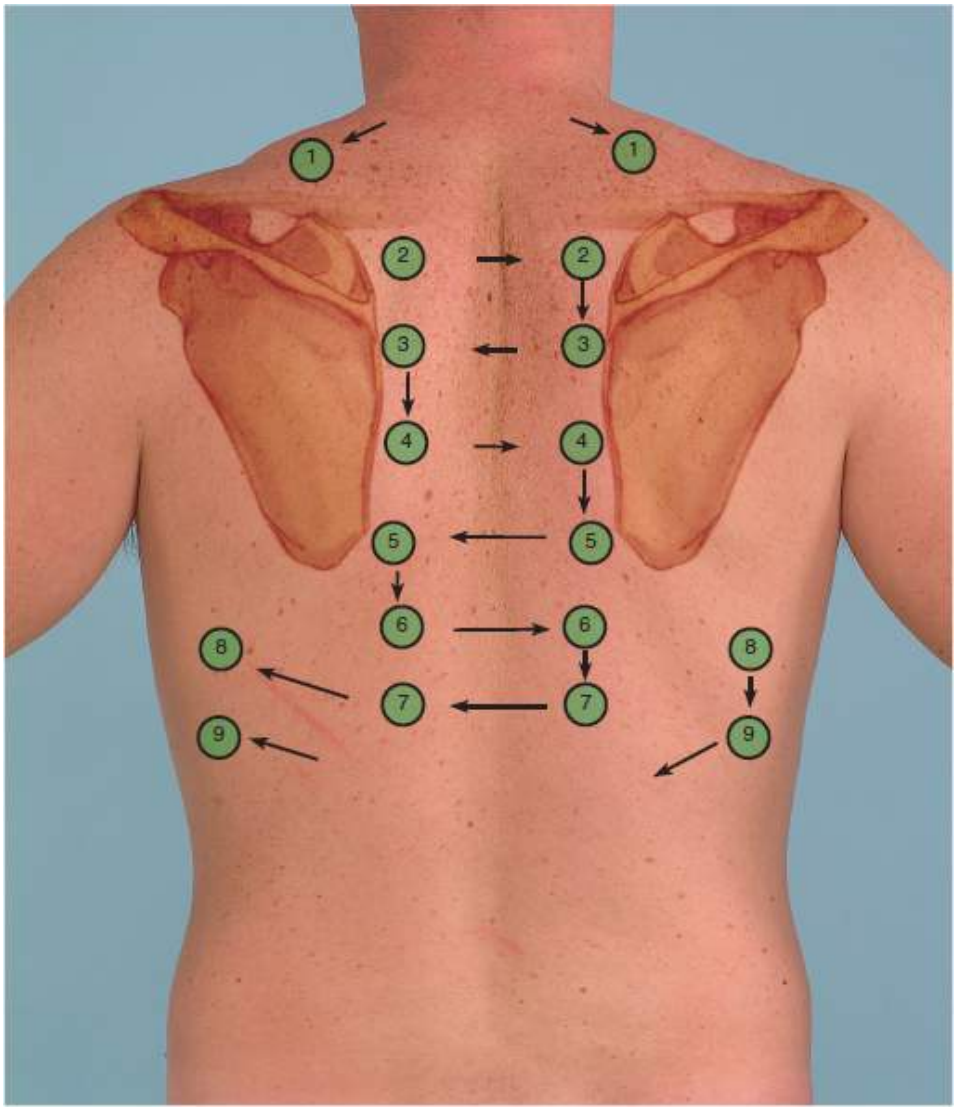

Figure 17-12 • Percussion of the posterior thorax. With the patient in a sitting position, symmetric areas of the lungs are percussed at 5-cm intervals. This progression starts at the apex of each lung and concludes with percussion of each lateral chest wall.

Thoracic Auscultation

Assessment concludes with auscultation of the anterior, posterior, and lateral thorax. Auscultation helps the nurse assess the flow of air through the bronchial tree and evaluate the presence of fluid or solid obstruction in the lung. The nurse auscultates for normal breath sounds, adventitious sounds, and voice sounds.

The nurse places the diaphragm of the stethoscope firmly against the bare skin of the chest wall as the patient breathes slowly and deeply through the mouth. Corresponding areas of the chest are auscultated in a systematic fashion from the apices to the bases and along midaxillary lines. The sequence of auscultation is similar to that used for percussion. The nurse may need to

listen to two full inspirations and expirations at each anatomic location for valid interpretation of the sound heard. Repeated deep breaths may result in symptoms of hyperventilation (e.g., lightheadedness); this is avoided by having the patient rest and breathe normally periodically during the examination.

Breath Sounds

Normal breath sounds are distinguished by their location over a specific area of the lung and are identified as vesicular, bronchovesicular, and bronchial (tubular) breath sounds (Table 17-5).

The location, quality, and intensity of breath sounds are determined during auscultation. When airflow is decreased by bronchial obstruction (atelectasis) or when fluid (pleural effusion) or tissue (obesity) separates the air passages from the stethoscope, breath sounds are diminished or absent. For example, the breath sounds of the patient with emphysema are faint or often completely inaudible. When they are heard, the expiratory phase is prolonged. In the patient with obesity, breath sounds may be inaudible. Bronchial and bronchovesicular sounds that are audible anywhere except over the main bronchus in the lungs signify pathology, usually indicating consolidation in the lung (e.g., pneumonia, heart failure). This finding requires further evaluation.

Adventitious Sounds

An abnormal condition that affects the bronchial tree and alveoli may produce adventitious (additional) sounds. Some adventitious sounds are divided into two categories: **crackles,** or nonmusical, discontinuous sounds; and **wheezes,** or continuous musical sounds (Table 17-6). **Rhonchi,** a type of wheezing, are lower-pitched continuous sounds heard over the lungs in partial airway obstruction. Depending on their location and severity, wheezes and rhonchi may be heard with or without a stethoscope. The duration of the sound is the important distinction to make in identifying the sound as discontinuous or continuous. Friction rubs may be either discontinuous or continuous. Stridor is a continuous, high-pitched musical sound which is heard over the neck. This sound is caused by an interruption of airflow and indicates a narrowing of the upper respiratory tract. Stridor warrants emergent attention.

Voice Sounds

The sound heard through the stethoscope as the patient speaks is known as vocal resonance. The nurse should assess voice sounds when abnormal breath sounds are auscultated. The vibrations produced in the larynx are transmitted to the chest wall as they pass through the bronchi and alveolar tissue. Voice sounds are evaluated by having the patient repeat “ninety-nine” or “eee” while the nurse listens with the stethoscope in corresponding areas of the chest from the apices to the bases. With normal physiology, the sounds are faint and indistinct. Pathology that increases lung density, such as pneumonia and

pulmonary edema, alters this normal physiologic response and may result in the following sounds:

- **Bronchophony** describes vocal resonance that is more intense and clearer than normal.
- **Egophony** describes voice sounds that are distorted. It is best appreciated by having the patient repeat the letter E. The distortion produced by consolidation transforms the sound into a clearly heard A rather than E.

TABLE 17-5 Breath Sounds

	Duration of Sounds	Intensity of Expiratory Sound	Pitch of Expiratory Sound	Locations Where Heard Normally
Vesicular*	Inspiratory sounds last longer than expiratory ones.	Soft	Relatively low	Entire lung field except over the upper sternum and between the scapulae
Bronchovesicular	Inspiratory and expiratory sounds are about equal.	Intermediate	Intermediate	Often in the first and second interspaces anteriorly and between the scapulae (over the main bronchus)
Bronchial	Expiratory sounds last longer than inspiratory ones.	Loud	Relatively high	Over the manubrium, if heard at all
Tracheal	Inspiratory and expiratory sounds are about equal.	Very loud	Relatively high	Over the trachea in the neck

*The thickness of the bars indicates intensity of breath sounds. The steeper their incline, the higher the pitch of the sounds.
Adapted from Hogan-Quigley, B., Palm, M. L., & Buckley, L. (2017). *Bates' nursing guide to physical examination and history taking* (2nd ed.). Philadelphia, PA: Wolters Kluwer Health Lippincott Williams & Wilkins.

TABLE 17-6 Abnormal (Adventitious) Breath Sounds

Breath Sound	Description	Etiology
Crackles		
Crackles in general	Nonmusical, discontinuous popping sounds that occur during inspiration (while usually heard on inspiration, they may also be heard on expiration); may or may not be cleared by coughing	Secondary to fluid in the airways or alveoli or to delayed opening of collapsed alveoli during inspiration Associated with heart failure and pulmonary fibrosis
Coarse crackles	Discontinuous popping sounds heard in early inspiration and throughout expiration; harsh, moist sound originating in the large bronchi; can be heard over any lung region; do not vary with body position	Associated with obstructive pulmonary disease
Fine crackles	Soft, high-pitched, discontinuous popping sounds heard in mid to late inspiration; sounds like hair rubbing together; originates in the alveoli, especially in dependent areas; may vary with body position	Associated with interstitial pneumonia, restrictive pulmonary disease (e.g., fibrosis); fine crackles in early inspiration are associated with bronchitis or pneumonia
Wheezes		
Wheezes in general	Continuous, musical, high-pitched, shrill sound usually heard on expiration but may be heard on inspiration depending on the cause	Associated with bronchial wall oscillation and narrowed airway diameter or partially obstructed airway Associated with chronic bronchitis or bronchiectasis
Rhonchi	Deep, lower-pitched rumbling sounds, snoring quality, heard primarily during expiration; may clear with coughing	Associated with secretions or tumor; variant of a wheeze; caused by air moving through narrowed tracheobronchial passages
Friction Rubs		
Pleural friction rub	Discontinuous, low-pitched, rubbing or grating sound, like two pieces of leather being rubbed together (sound imitated by rubbing thumb and finger together near the ear) Heard during inspiration and expiration May subside when patient holds breath; coughing will not clear sound Best heard in axillae and bases of lungs	Secondary to inflammation and loss of lubricating pleural fluid between the visceral and parietal pleurae
Other Breath Sounds		
Stridor	Continuous, high-pitched, musical sound, heard over the neck	Narrowing of the upper respiratory tract; immediate

intervention is warranted

Adapted from Hogan-Quigley, B., Palm, M. L., & Bickley, L. (2017). *Bates' nursing guide to physical examination and history taking* (2nd ed.). Philadelphia, PA: Wolters Kluwer Health Lippincott Williams & Wilkins.

- **Whispered pectoriloquy** describes the ability to clearly and distinctly hear whispered sounds that should not normally be heard.

Whenever an abnormality is detected on examination, it should be evident using more than one assessment method. A change in tactile fremitus is more subtle and can be missed, but bronchophony can be noted loudly and clearly.

Interpreting Findings

The physical findings for the most common respiratory diseases are summarized in Table 17-7.

Assessment of Respiratory Function in the Patient Who Is Acutely or Critically Ill

Assessment of respiratory status is essential for the well-being of the patient who is acutely or critically ill. Often, such a patient is intubated and receiving mechanical ventilation. The nurse analyzes findings from the health history and assessment while considering laboratory and diagnostic test results. After checking the ventilator settings to make sure that they are set as prescribed and that alarms are always in the "on" position, the nurse must assess for patient–ventilator synchrony and for agitation, restlessness, and other signs of respiratory distress (nasal flaring, excessive use of intercostals and accessory muscles, uncoordinated movement of the chest and abdomen, and a report by the patient of shortness of breath). The nurse must note changes in the patient's vital signs and evidence of hemodynamic instability and report them to the primary provider, because they may indicate that the mechanical ventilation is ineffective or that the patient's status has deteriorated. It is important for the nurse to position the patient to promote adequate oxygenation and ventilation and to prevent potential complications. For example, the patient may need to be positioned with the head of bed elevated to prevent aspiration, especially if the patient is receiving enteral feedings. Alternatively, in patients with ARDS who are experiencing refractory hypoxemia, prone positioning is recommended (see Chapter 19). In addition, the patient's mental status should be assessed and compared to previous status. Lethargy and somnolence may be signs of increasing carbon dioxide levels and should not be considered insignificant, even if the patient is receiving sedation or analgesic agents.

Chest auscultation, percussion, and palpation are essential and routine parts of the evaluation of the patient who is critically ill, with or without mechanical

ventilation. A recumbent patient must be turned to assess all lung fields. Dependent areas must be assessed for normal breath sounds and adventitious sounds. Failure to examine the dependent areas of the lungs can result in missing the findings associated with disorders such as atelectasis or pleural effusion.

TABLE 17-7 Assessment Findings in Common Respiratory Disorders

This table lists the typical changes seen in respiratory disorders. The changes described vary with the extent and severity of the disorder. Use the table for the direction of typical changes, not for absolute distinctions.

Condition	Percussion Note	Trachea	Breath Sounds	Adventitious Sounds	Tactile Fremitus and Transmitted Voice Sounds
Normal The tracheobronchial tree and alveoli are open; pleurae are thin and close together; mobility of the chest wall is unimpaired.	Resonant	Midline	Vesicular, except perhaps bronchovesicular and bronchial sounds over the large bronchi and trachea, respectively	None, except perhaps a few transient inspiratory crackles at the bases of the lungs	Normal
Chronic Bronchitis The bronchi are chronically inflamed and a productive cough is present. Airway obstruction may develop.	Resonant	Midline	Vesicular (normal)	Noisy or scattered coarse crackles in early inspiration and perhaps expiration; or wheezes or rhonchi	Normal
Left-Sided Heart Failure (Early) Increased pressure in the pulmonary veins causes congestion and interstitial edema (around the alveoli); bronchial mucosa may become edematous.	Resonant	Midline	Vesicular	Late inspiratory crackles in the dependent portions of the lungs; possibly wheezes	Normal
Lobar Pneumonia Alveoli fill with fluid or blood cells, as in pneumonia, pulmonary edema, or pulmonary hemorrhage.	Dull over the airless area	Midline	Bronchial over the involved area	Late inspiratory crackles over the involved area	Increased over the involved area, with bronchophony, egophony, and whispered pectoriloquy
Partial Lobar Obstruction Atelectasis: When a plug in a main stem bronchus (as from mucus or a foreign object) obstructs bronchial airflow, affected alveoli collapse and become airless.	Dull over the airless area	May be shifted toward involved side	Usually absent when bronchial plug persists. Exceptions include right upper lobe atelectasis, where adjacent tracheal sounds may be transmitted.	None	Usually absent when the bronchial plug persists. In exceptions (e.g., right upper lobe atelectasis) may be increased
Pleural Effusion Fluid accumulates in the pleural space and separates air-filled lung from the chest wall, blocking the transmission breath sounds.	Dull to flat over the fluid	Shifted toward the unaffected side in a large effusion	Decreased to absent, but bronchial breath sounds may be heard near top of large effusion	None, except a possible pleural rub	Decreased to absent, but may be increased toward the top of a large effusion
Pneumothorax When air leaks into the pleural space, usually unilaterally, the lung recoils away from the chest wall. Pleural air blocks transmission of sound.	Hyperresonant or tympanitic over the pleural air	Shifted toward the unaffected side if tension pneumothorax	Decreased to absent over the pleural air	None, except a possible pleural rub	Decreased to absent over the pleural air
Chronic Obstructive Pulmonary Disease (COPD) Slowly progressive disorder in which the distal airspaces enlarge and lungs become hyperinflated. Chronic inflammation may precede or follow the development of COPD.	Diffusely hyperresonant	Midline	Decreased to absent with delayed expiration	None, or the crackles, wheezes, and rhonchi of associated chronic bronchitis	Decreased
Asthma Widespread usually reversible airflow obstruction with bronchial hyperresponsiveness and underlying inflammation. During attacks, as air flow decreases lungs hyperinflate.	Resonant to diffusely hyperresonant	Midline	Often obscured by wheezes	Wheezes, possibly crackles	Decreased

Tests of the patient's respiratory status are easily performed at the bedside by measuring the respiratory rate, end-tidal carbon dioxide ($ETCO_2$), tidal volume, minute ventilation, vital capacity, inspiratory force, and compliance. These tests are particularly important for patients who are at risk for pulmonary complications, including those who have undergone chest or abdominal surgery, have had prolonged anesthesia, or have preexisting pulmonary disease, and those who are older or have obesity. These tests are also used routinely for patients who are mechanically ventilated. Although some of these tests are performed by respiratory therapists, it is useful for nurses to understand the significance of these test results.

The patient whose chest expansion is limited by external restrictions such as obesity or abdominal distention, or who cannot breathe deeply because of postoperative pain, sedation, or drug overdose will inhale and exhale a low volume of air (referred to as low tidal volumes). Prolonged hypoventilation at low tidal volumes can produce alveolar collapse (atelectasis). Consequently, when the forced residual capacity decreases, compliance is reduced, and the patient must breathe faster to maintain the same degree of tissue oxygenation. These events can be exaggerated in patients who have preexisting pulmonary diseases; in older adult patients whose airways are less compliant because the small airways may collapse during expiration; or in patients with obesity or who have relatively low tidal volumes even when healthy. (More details of the assessment of the patient with various lung disorders are described in subsequent chapters in this unit.)

Quality and Safety Nursing Alert

The nurse should not rely only on visual inspection of the rate and depth of a patient's respiratory excursions to determine the adequacy of ventilation. Respiratory excursions may appear normal or exaggerated due to an increased work of breathing, but the patient may actually be moving only enough air to ventilate the dead space. If there is any question regarding adequacy of ventilation, the nurse should use auscultation or pulse oximetry (or both) for additional assessment of respiratory status.

Tidal Volume

The volume of each breath is referred to as the **tidal volume** (see Table 17-1 to review lung capacities and volumes). A spirometer is an instrument that can be used at the bedside to measure volumes. If the patient is breathing through an endotracheal (ET) tube or tracheostomy, the spirometer is directly attached to it and the exhaled volume is obtained from the reading on the gauge. In other

patients, the spirometer is attached to a facemask or a mouthpiece positioned so that it is airtight, and the exhaled volume is measured.

The tidal volume may vary from breath to breath. To ensure that the measurement is reliable, it is important to measure the volumes of several breaths and to note the range of tidal volumes, together with the average tidal volume.

Minute Ventilation

Because respiratory rates and tidal volumes vary widely from breath to breath, these data alone are unreliable indicators of adequate ventilation. However, the tidal volume multiplied by the respiratory rate provides what is called *minute ventilation* or *minute volume,* the volume of air exchanged per minute. This value is useful in detecting respiratory failure. In practice, the minute volume is not calculated but is measured directly using a spirometer. In a patient receiving mechanical ventilation, minute volume is often monitored by the ventilator and can be viewed on the monitoring screen.

Minute ventilation may be decreased by a variety of conditions that result in hypoventilation. When the minute ventilation falls, alveolar ventilation in the lungs also decreases and the $PaCO_2$ increases.

Vital Capacity

Vital capacity is measured by having the patient take in a maximal breath and exhale fully through a spirometer. The normal value depends on the patient's age, gender, body build, and weight.

Quality and Safety Nursing Alert

Most patients can generate a vital capacity twice the volume they normally breathe in and out (tidal volume). If the vital capacity is less than 10 mL/kg, the patient will be unable to sustain spontaneous ventilation and will require respiratory assistance.

When the vital capacity is exhaled at a maximal flow rate, the forced vital capacity (FVC) is measured. Most patients can exhale at least 80% of their vital capacity in 1 second (forced expiratory volume in 1 second, or FEV_1) and almost all of it in 3 seconds (FEV_3). A reduction in FEV_1 suggests abnormal pulmonary airflow. If the patient's FEV_1 and FVC are proportionately reduced, maximal lung expansion is restricted in some way. If the reduction in FEV_1 greatly exceeds the reduction in FVC (FEV_1/FVC less than 85%), the patient may have some degree of airway obstruction.

Inspiratory Force

Inspiratory force evaluates the effort the patient is making during inspiration. It does not require patient cooperation and, therefore, is a useful measurement in the patient who is unconscious. The equipment needed for this measurement includes a manometer that measures negative pressure and adapters that are connected to an anesthesia mask or a cuffed ET tube. The manometer is attached, and the airway is completely occluded for 10 to 20 seconds while the inspiratory efforts of the patient are registered on the manometer. The normal inspiratory pressure is about 100 cm H_2O. If the negative pressure registered after 15 seconds of occluding the airway is less than about 25 cm H_2O, mechanical ventilation is usually required because the patient lacks sufficient muscle strength for deep breathing or effective coughing.

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in patients with respiratory conditions. The nurse should educate the patient on the purpose of the studies, what to expect, and any possible side effects related to these examinations prior to testing. The nurse should note trends in results because they provide information about disease progression as well as the patient's response to therapy.

Pulmonary Function Tests

Pulmonary function tests (PFTs) are routinely used in patients with chronic respiratory disorders to aid diagnosis. They are performed to assess respiratory function and to determine the extent of dysfunction, response to therapy, and as screening tests in potentially hazardous industries, such as coal mining and those that involve exposure to asbestos and other noxious irritants. PFTs are also used prior to surgery to screen patients who are scheduled for thoracic and upper abdominal surgical procedures, patients who are obese, and symptomatic patients with a history suggesting high risk. Such tests include measurements of lung volumes, ventilatory function, and the mechanics of breathing, diffusion, and gas exchange.

PFTs generally are performed by a respiratory therapist using a spirometer that has a volume-collecting device attached to a recorder that demonstrates volume and time simultaneously. Several tests are carried out because no single measurement provides a complete picture of pulmonary function. The most frequently used PFTs are described in Table 17-8. Technology is available that allows for more complex assessment of pulmonary function. Methods include exercise tidal flow–volume loops, negative expiratory pressure, nitric oxide, forced oscillation, and diffusing capacity for helium or

carbon monoxide. These assessment methods allow for detailed evaluation of expiratory flow limitations and airway inflammation (Pagana, Pagana, & Pagana, 2017).

PFT results are interpreted on the basis of the degree of deviation from normal, taking into consideration the patient's height, weight, age, gender, and ethnicity. Because there is a wide range of normal values, PFTs may not detect early localized changes. The patient with respiratory symptoms usually undergoes a complete diagnostic evaluation, even if the results of PFTs are "normal." Patients with respiratory disorders may be taught how to measure their peak flow rate (which reflects maximal expiratory flow) at home using a spirometer. This allows them to monitor the progress of therapy, to alter medications and other interventions as needed on the basis of caregiver guidelines, and to notify the primary provider if there is inadequate response to their own interventions. (Instructions for home care education are described in Chapter 20, which discusses asthma.)

TABLE 17-8 Pulmonary Function Tests

Term Used	Symbol	Description	Remarks
Forced vital capacity	FVC	Vital capacity performed with a maximally forced expiratory effort	Forced vital capacity is often reduced in chronic obstructive pulmonary disease because of air trapping
Forced expiratory volume (qualified by subscript indicating the time interval in seconds)	FEV_t (usually FEV_1)	Volume of air exhaled in the specified time during the performance of forced vital capacity; FEV_1 is volume exhaled in 1 s	A valuable clue to the severity of the expiratory airway obstruction
Ratio of timed forced expiratory volume to forced vital capacity	FEV_t/FVC%, usually FEV_1/FVC%	FEV_t expressed as a percentage of the forced vital capacity	Another way of expressing the presence or absence of airway obstruction
Forced expiratory flow	$FEF_{200–1200}$	Mean forced expiratory flow between 200 and 1200 mL of the FVC	An indicator of large airway obstruction
Forced midexpiratory flow	$FEF_{25–75\%}$	Mean forced expiratory flow during the middle half of the FVC	Slowed in small airway obstruction
Forced end-expiratory flow	$FEF_{75–85\%}$	Mean forced expiratory flow during the terminal portion of the FVC	Slowed in obstruction of smallest airways
Maximal voluntary ventilation	MVV	Volume of air expired in a specified period (12 s) during repetitive maximal effort	An important factor in exercise tolerance

Arterial Blood Gas Studies

Arterial blood gas (ABG) studies aid in assessing the ability of the lungs to provide adequate oxygen and remove carbon dioxide, which reflects ventilation, and the ability of the kidneys to reabsorb or excrete bicarbonate ions to maintain normal body pH, which reflects metabolic states. ABG levels are obtained through an arterial puncture at the radial, brachial, or femoral artery or through an indwelling arterial catheter. Pain (related to nerve injury or noxious stimulation), infection, hematoma, and hemorrhage are potential

complications that may be associated with obtaining ABGs (Pagana et al., 2017) (see Chapter 10 for discussion of ABG analysis).

Venous Blood Gas Studies

Venous blood gas (VBG) studies provide additional data on oxygen delivery and consumption. VBG levels reflect the balance between the amount of oxygen used by tissues and organs and the amount of oxygen returning to the right side of the heart in the blood. VBG levels can be obtained by drawing blood from the venous circulation; this test is performed to provide an estimation of this balance when the ability to draw ABGs is not feasible. Mixed venous oxygen saturation ($S\overline{v}O_2$) levels, the most accurate indicator of this balance, can be obtained only from blood samples drawn from a pulmonary artery catheter. However, central venous oxygen saturation ($Sc\overline{v}O_2$) levels, which are measured using blood drawn from a central venous catheter placed in the superior vena cava, closely approximate $S\overline{v}O_2$ levels and are, therefore, useful as an alternative measure in patients without pulmonary artery catheters (Morton, Reck, & Headly, 2018).

Pulse Oximetry

Pulse oximetry, or SpO_2, is a noninvasive method of continuously monitoring the oxygen saturation of hemoglobin (SaO_2). Although pulse oximetry does not replace blood gas analysis, it is an effective tool to monitor for changes in SaO_2 and can easily be used in the home and various health care settings.

A probe or sensor is attached to the fingertip (Fig. 17-13), forehead, earlobe, or bridge of the nose. The sensor detects changes in oxygen saturation levels by monitoring light signals generated by the oximeter and reflected by blood pulsing through the tissue at the probe. Normal SpO_2 values are more than 95%. Values less than 90% indicate that the tissues are not receiving enough oxygen, in which case further evaluation is needed. Advantages of pulse oximetry include the ability to obtain rapid results and continuous data using a noninvasive technique. Limitations of pulse oximetry include its inability to detect significant hyperoxemia (excess levels of oxygen), and to measure PaO_2 and ventilation. In order to ensure accurate readings, the nurse should verify correct placement of the probe and decrease or eliminate excess motion (e.g., from patient shivering or movement of the extremity). Readings are unreliable in settings of hypothermia, hemodynamic instability, or low perfusion states (e.g., shock, vasoconstriction, or decreased perfusion of the limb), and when a patient has dark skin or is wearing nail polish. In these situations, analysis of ABGs should be conducted, and when hyperoxemia is suspected, analysis of PaO_2 or $PaCO_2$ is required (Mechem, 2019).

Figure 17-13 • Measuring blood oxygenation with pulse oximetry reduces the need for invasive procedures, such as drawing blood for analysis of oxygen levels. **A.** Self-contained digital fingertip pulse oximeter, which incorporates the sensor and the display into one

unit. **B.** Tabletop model with sensor attached. Memory permits tracking heart rate and oxygen saturation over time.

End-Tidal Carbon Dioxide

End-tidal carbon dioxide ($ETCO_2$) monitoring is a noninvasive method of monitoring partial pressure of carbon dioxide (CO_2) at end exhalation. $ETCO_2$ monitoring is considered to be a reliable tool for detecting and monitoring life-threatening conditions because it provides immediate information about ventilation, perfusion, and metabolism by determining the concentration of CO_2. Changes in $ETCO_2$ and the concentration of CO_2 at the end of each breath can help to diagnose or indicate the severity of a disease or the outcome of a treatment. It is now part of the standard of care for all patients receiving general anesthesia, procedural sedation and/or analgesia, and is frequently part of routine monitoring in the prehospital and acute care settings (Krauss, Falk, & Ladde, 2018).

The application of $ETCO_2$ monitoring can indicate early respiratory depression and impaired airway function sooner than other devices, helping nurses to detect potential complications earlier (Aminiahidashti, Shafiee, Kiasari, et al., 2018). Data are reported as a number (capnometry) or as a number and a waveform (capnography). Capnography uses infrared technology to obtain results and monitors four phases of the respiratory cycle to depict the CO_2 concentrations of each phase.

A capnometry device, such as the colorimetric $ETCO_2$ detector, is a portable device which contains litmus paper that changes color when exposed to CO_2. An improper ET intubation, for instance with esophageal intubation, will not result in CO_2 exchange and thus the color of the litmus paper will not change (Krauss et al., 2018). $ETCO_2$ monitoring is the most reliable indicator that an ET tube is placed in the trachea during intubation (Krauss et al., 2018). Some additional indications for $ETCO_2$ monitoring include continuous monitoring of ET tube placement during patient transport, confirming return of spontaneous circulation with cardiopulmonary resuscitation, determining a prognosis in patients with trauma, and as an early indicator of respiratory compromise (Aminiahidashti et al., 2018; Krauss et al., 2018; Smallwood & Walsh, 2017). The clinician should use caution when interpreting results in patients who are mechanically ventilated with a bag or mask ventilation device, or who have received sodium bicarbonate, or who have ingested carbonated beverages or antacids, as any of these can result in false-positive results (Aminiahidashti et al., 2018).

Cultures

Throat, nasal, and nasopharyngeal cultures can identify pathogens responsible for respiratory infections, such as pharyngitis. Throat cultures are performed in adults with severe or ongoing sore throats accompanied by fever and lymph node enlargement and are most useful in detecting streptococcal infection. Rapid strep tests are now available that can provide results within 15 minutes, often replacing the need for throat cultures. Other sources of infection, such as *Staphylococcus aureus* or *Influenza,* are detected via nasal or nasopharyngeal cultures. Ideally, all cultures should be obtained prior to the initiation of antibiotic therapy. Results usually take between 48 and 72 hours, with preliminary reports available usually within 24 hours. Cultures may be repeated to assess a patient's response to therapy (Pagana et al., 2017).

Sputum Studies

Sputum is obtained for analysis to identify pathogenic organisms and to determine whether malignant cells are present. Periodic sputum examinations may be necessary for patients receiving antibiotics, corticosteroids, and immunosuppressive medications for prolonged periods because these agents are associated with opportunistic infections.

Sputum samples ideally are obtained early in the morning before the patient has had anything to eat or drink. The patient is instructed to clear the nose and the throat and rinse the mouth to decrease contamination of the sputum and not to simply spit saliva into the container. Rather, after taking a few deep breaths, the patient coughs deeply and expectorates sputum from the lungs into a sterile container.

If the patient cannot expel an adequate sputum sample following the above techniques, coughing can be induced by administering an aerosolized hypertonic solution via a nebulizer. Other methods of collecting sputum specimens include endotracheal or transtracheal aspiration or bronchoscopic removal. The nurse should label the specimen and send it to the laboratory as soon as possible to avoid contamination.

Imaging Studies

Imaging studies, including x-rays, computed tomography (CT), magnetic resonance imaging (MRI), and radioisotope or nuclear scanning may be part of any diagnostic workup, ranging from a determination of the extent of infection in sinusitis to tumor growth in cancer.

Chest X-Ray

Normal pulmonary tissue is radiolucent because it consists mostly of air and gases; therefore, densities produced by fluid, tumors, foreign bodies, and other pathologic conditions can be detected by x-ray examination. In the absence of

symptoms, a chest x-ray may reveal an extensive pathologic process in the lungs. The routine chest x-ray consists of two views: the posteroanterior projection and the lateral projection. Chest x-rays are usually obtained after full inspiration because the lungs are best visualized when they are well aerated. In addition, the diaphragm is at its lowest level and the largest expanse of lung is visible. Patients, therefore, need to be able to take a deep breath and hold it without discomfort. Chest x-rays are contraindicated in pregnant women.

Nursing Interventions

The nurse should notify the patient that chest x-rays do not require fasting, nor typically cause pain. However, in order to best visualize the lungs, the patient must be able to take a deep breath and hold it without discomfort, while the technician takes the images. The patient will be positioned in a standing, sitting, or recumbent position, in order to obtain the appropriate view of the chest (posterior–anterior, lateral, oblique, or decubitus position). The patient will be asked to wear a gown, remove metal objects from the chest, such as necklaces, and may be given a lead shield to minimize radiation exposure to the thyroid gland, ovaries, or testicles (Pagana et al., 2017).

Computed Tomography

A CT of the chest is an imaging method in which the lungs, mediastinum, and vascular structures within the chest are scanned in successive layers by a narrow-beam x-ray. The images produced provide a cross-sectional view of the chest. Whereas a chest x-ray shows major contrasts between body densities such as bone, soft tissue, and air, a CT scan can distinguish fine tissue density. A CT scan may be used to define pulmonary nodules and small tumors adjacent to pleural surfaces that are not visible on routine chest x-rays and to demonstrate mediastinal abnormalities and hilar adenopathy, which are difficult to visualize with other techniques. Contrast agents are useful when evaluating the mediastinum and its contents, particularly its vasculature. CT with contrast agent is not suitable for patients with compromised kidney function, or those with an allergy to iodine dye or shellfish, or who are pregnant, claustrophobic, or have severe obesity. Patients taking metformin should withhold the dose the day of the test in order to prevent lactic acidosis from developing (Pagana et al., 2017; Thompson & Kabrhel, 2018).

Advancements in CT scanning technology, referred to as multidetection, spiral, or helical CT, enable the chest to be scanned quickly while generating an extensive number of images that can generate a three-dimensional analysis (Pagana et al., 2017).

Nursing Interventions

The nurse should inform patients preparing for CT scans that they will be required to remain supine and still for a short period, typically less than 30 minutes, while a body scanner surrounds them and takes multiple images. Patients typically do not experience claustrophobia during CT scanning but can be given antianxiety medications preprocedure if this is a concern. If contrast agent is required, patients will need to stay *nil per os* (NPO) for 4 hours prior to the examination. In this case, the nurse should also assess for allergies to iodine or shellfish (Pagana et al., 2017). Vital signs should be monitored and documented before, during, and after the scan especially if sedation or analgesia is administered.

Pulmonary Angiography

Pulmonary angiography is used to investigate congenital abnormalities of the pulmonary vascular tree, and less frequently PE, when less invasive tests are inconclusive. This study has primarily been replaced by CT scan of the chest. To visualize the pulmonary vessels, a radiopaque agent is injected through a catheter, which has been initially inserted into a vein (e.g., jugular, subclavian, brachial, or femoral vein) and then threaded into the pulmonary artery. Contraindications include allergy to the radiopaque agent, pregnancy, and bleeding abnormalities, whereas potential complications include acute kidney injury, acidosis, cardiac arrhythmias, and bleeding (Pagana et al., 2017).

CT pulmonary angiography (CTPA) combines pulmonary angiography and CT scan imaging. CTPA images the pulmonary arteries and is used primarily if treatment is required for a PE. This procedure typically takes no longer than 30 minutes to complete (Pagana et al., 2017). The patient lies in a supine position on an x-ray table. A catheter is placed in the femoral vein, advanced into the inferior vena cava and into the pulmonary artery. Contrast agent and fluoroscopy are utilized for visualization of the pulmonary vasculature when CTPA is performed. The same contraindications for CT with contrast agent apply to CTPA (Pagana et al., 2017; Thompson & Kabrhel, 2018).

Nursing Interventions

Prior to the angiography, the nurse should verify that informed consent has been obtained; assess for known allergies that may suggest allergies to radiopaque agent (e.g., iodine and shellfish); assess anticoagulation status and renal function; ensure that the patient has not eaten or had anything to drink preprocedurally as prescribed (normally for 4 hours); and administer preprocedure medications that may include antianxiety medications, secretion-reducing agents, and antihistamines (Pagana et al., 2017). The nurse should instruct patients that they may experience a warm flushing sensation or chest pain during the injection of the dye. If an arterial puncture is necessary, the affected extremity will need to be immobilized for a certain amount of time depending on the size of the sheath used and the type of arterial closure device

employed. Introduction of the catheter into the right ventricle may trigger ventricular irritability. Therefore, during and after the procedure, the patient should be monitored for cardiac arrhythmias such as premature ventricular contractions (PVCs). Following the procedure, the nurse should closely monitor vital signs, level of consciousness, oxygen saturation, and the vascular access site for bleeding or hematoma, and perform frequent assessment of neurovascular status. It may be indicated to apply cold compresses to the puncture site to decrease swelling (Pagana et al., 2017).

Magnetic Resonance Imaging

MRI is similar to a CT scan except that magnetic fields and radiofrequency signals are used instead of radiation. MRI is able to better distinguish between normal and abnormal tissues than CT and, therefore, yields a much more detailed diagnostic image. MRI is used to characterize pulmonary nodules; to help stage bronchogenic carcinoma (assessment of chest wall invasion); and to evaluate inflammatory activity in interstitial lung disease, acute PE, and chronic thrombolytic pulmonary hypertension. Contraindications for MRI include severe obesity, claustrophobia, confusion and agitation, and having implanted metal or metal support devices that are considered unsafe (Pagana et al., 2017). Various labels and icons are used to indicate whether a medical device is safe or unsafe for use during MRI. Recent improvements in technology have contributed to the design of certain medical devices, such as infusion pumps and ventilators, deemed safe for the MRI room. The nurse should consult with specially trained MRI personnel to clarify the safety of various devices (Wells & Murphy, 2014). Gadolinium-based contrast agents used during MRI may potentially lead to nephrogenic systemic fibrosis in patients with reduced kidney function. Therefore, additional kidney function testing may be necessary, especially in adults older than 60 years of age (Pagana et al., 2017).

Nursing Interventions

Patients scheduled for MRI should be instructed to remove all metal items such as hearing aids, hair clips, and medication patches with metallic foil components (e.g., nicotine patches). Prior to the MRI, the nurse should assess for the presence of implanted metal devices, such as aneurysm clips or a cardiac implantable electronic device. Patients with any type of cardiac implantable electronic device need to be screened to determine if they can safely undergo MRI (Indik, Gimbel, Abe, et al., 2017).

The nurse should inform patients preparing for MRI that they will need to lie flat and remain still for between 30 and 90 minutes, while the table that they are on moves into a large tubular magnet. Patients should be notified that they will hear a loud humming or thumping noise. Earplugs are typically offered to patients to minimize this noise. Patients will be able to communicate

with the MRI staff via a microphone and earphones. The nurse should clarify with the primary provider or the technologist if the prescribed test requires the use of a contrast agent or if the patient should remain NPO pre-examination. Patients who experience claustrophobia should be offered antianxiety medications preprocedure or be scheduled at a facility that uses an open MRI system (Pagana et al., 2017).

Fluoroscopic Studies

Fluoroscopy, which allows live x-ray images to be generated via a camera to a video screen, is used to assist with invasive procedures, such as a chest needle biopsy or transbronchial biopsy, that are performed to identify lesions. It also may be used to study the movement of the chest wall, mediastinum, heart, and diaphragm; to detect diaphragm paralysis; and to locate lung masses. The specific procedure performed under fluoroscopy will guide those respective nursing interventions (e.g., see nursing interventions described in the Lung Biopsy Procedures section).

Radioisotope Diagnostic Procedures (Lung Scans)

Several types of lung scans—V./Q. scan, gallium scan, and positron emission tomography (PET)—are performed to assess normal lung functioning, pulmonary vascular supply, and gas exchange. Pregnancy is a contraindication for these scans.

A V./Q. lung scan is performed by injecting a radioactive agent into a peripheral vein and then obtaining a scan of the chest to detect radiation. The isotope particles pass through the right side of the heart and are distributed into the lungs in proportion to the regional blood flow, making it possible to trace and measure blood perfusion through the lung. This procedure is used clinically to measure the integrity of the pulmonary vessels relative to blood flow and to evaluate blood flow abnormalities, as seen in PE. The imaging time is 20 to 40 minutes, during which the patient lies under the camera with a mask fitted over the nose and the mouth. This is followed by the ventilation component of the scan. The patient takes a deep breath of a mixture of oxygen and radioactive gas, which diffuses throughout the lungs. A scan is performed to detect ventilation abnormalities in patients who have regional differences in ventilation. It may be helpful in the diagnosis of bronchitis, asthma, inflammatory fibrosis, pneumonia, emphysema, and lung cancer. Ventilation without perfusion is seen with PE.

A gallium scan is a radioisotope lung scan used to detect inflammatory conditions, abscesses, adhesions, and the presence, location, and size of tumors. It is used to stage bronchogenic cancer and to document tumor regression after chemotherapy or radiation. Gallium is injected intravenously,

and scans are obtained at intervals (e.g., 6, 24, and 48 hours) to evaluate gallium uptake by the pulmonary tissues.

PET is a radioisotope study with advanced diagnostic capabilities that is used to evaluate lung nodules for malignancy. PET can detect and display metabolic changes in tissue, distinguish normal tissue from diseased tissue (such as in cancer), differentiate viable from dead or dying tissue, and show regional blood flow. PET is more accurate in detecting malignancies than CT and has equivalent accuracy in detecting malignant nodules when compared with invasive procedures such as thoracoscopy. Images from PET scans are now being superimposed on CT and MRI images to enhance the accuracy of diagnosis (Pagana et al., 2017).

Nursing Interventions

For each of these nuclear scans, the nurse should educate the patient on what to expect. Intravenous access is required. Chest x-ray should be performed prior to a V./Q. scan. Patients should be told that V./Q. and gallium scans require only a small amount of radioisotopes; therefore, radiation safety measures are not indicated. Normally, the patient may eat or drink prior to V./Q. or gallium scans. Multiple factors can hinder the uptake of radioactive agents used for a PET scan. The nurse should instruct the patient to avoid caffeine, alcohol, and tobacco for 24 hours prior to the PET scan and abstain from food and fluids for 4 hours prior to the scan. Accurate results depend on an empty bladder; thus, a Foley catheter may be indicated. The nurse should encourage fluid intake postprocedure to facilitate the elimination of radioisotopes in the urine (Pagana et al., 2017).

Endoscopic Procedures

Endoscopic procedures include bronchoscopy, thoracoscopy, and thoracentesis.

Bronchoscopy

Bronchoscopy is the direct inspection and examination of the larynx, trachea, and bronchi through either a flexible fiberoptic bronchoscope or a rigid bronchoscope (Fig. 17-14). The fiberoptic scope is used more frequently in current practice.

Procedure

The purposes of diagnostic bronchoscopy are (1) to visualize tissues and determine the nature, location, and extent of the pathologic process; (2) to collect secretions for analysis and to obtain a tissue sample for diagnosis; (3) to determine whether a tumor can be resected surgically; and (4) to diagnose sources of hemoptysis.

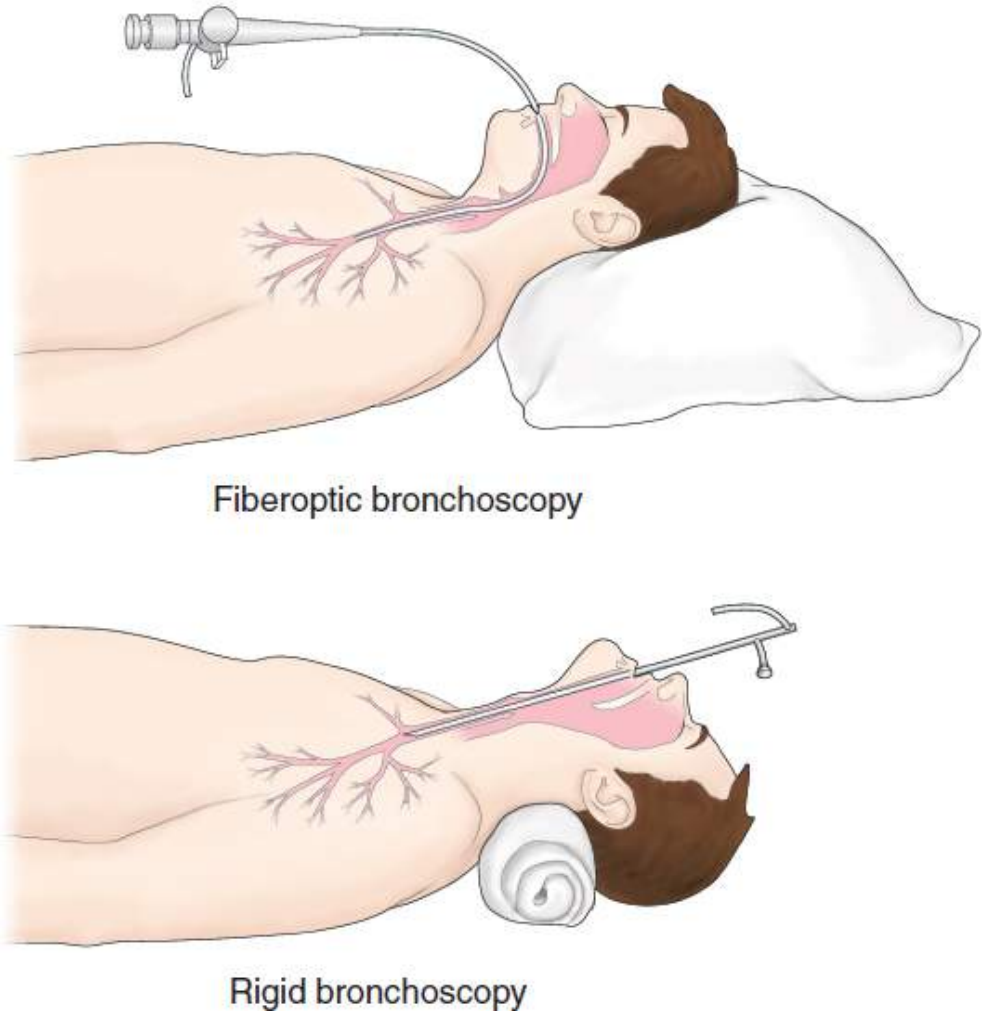

Figure 17-14 • Endoscopic bronchoscopy permits visualization of bronchial structures. The bronchoscope is advanced into bronchial structures orally. Bronchoscopy permits the clinician to not only diagnose but also treat various lung problems.

Therapeutic bronchoscopy is used to (1) remove foreign bodies or secretions from the tracheobronchial tree, (2) control bleeding, (3) treat postoperative atelectasis, (4) destroy and excise lesions, and (5) provide brachytherapy (endobronchial radiation therapy). It has also been used to insert stents to relieve airway obstruction that is caused by tumors or miscellaneous benign conditions or that occurs as a complication of lung transplantation.

The fiberoptic bronchoscope is a thin, flexible bronchoscope that can be directed into the segmental bronchi. Because of its small size, its flexibility, and its excellent optical system, it allows increased visualization of the peripheral airways and is ideal for diagnosing pulmonary lesions. Fiberoptic bronchoscopy allows biopsy of previously inaccessible tumors and can be performed at the bedside. It also can be performed through ET or tracheostomy tubes of patients on ventilators. Cytologic examinations can be performed without surgical intervention.

The rigid bronchoscope is a hollow metal tube with a light at its end. It is used mainly for removing foreign substances, investigating the source of massive hemoptysis, or performing endobronchial surgical procedures. Rigid bronchoscopy is performed in the operating room, not at the bedside.

Possible complications of bronchoscopy include a reaction to the local anesthetic, oversedation, prolonged fever, infection, aspiration, vasovagal response, laryngospasm, bronchospasm, hypoxemia, pneumothorax, and bleeding (Pagana et al., 2017).

Nursing Interventions

Before the procedure, the nurse should verify that informed consent has been obtained. Food and fluids are withheld for 4 to 8 hours before the test to reduce the risk of aspiration when the cough reflex is blocked by anesthesia. The patient must remove dentures and other oral prostheses. The nurse explains the procedure to the patient to reduce fear and decrease anxiety and then administers preoperative medications (usually atropine and a sedative or opioid) as prescribed to inhibit vagal stimulation (thereby guarding against bradycardia, arrhythmias, and hypotension), suppress the cough reflex, sedate the patient, and relieve anxiety.

Quality and Safety Nursing Alert

Sedation given to patients with respiratory insufficiency may precipitate respiratory arrest.

The examination is usually performed under local anesthesia or moderate sedation; however, general anesthesia may be used for rigid bronchoscopy. A topical anesthetic such as lidocaine is normally sprayed on the pharynx or dropped on the epiglottis and vocal cords and into the trachea to suppress the cough reflex and minimize discomfort.

After the procedure, the patient must take nothing by mouth until the cough reflex returns, because the preoperative sedation and local anesthesia impair the protective laryngeal reflex and swallowing. Once the patient demonstrates a cough reflex, the nurse may offer ice chips and eventually fluids. In the older adult patient, the nurse assesses for confusion and lethargy, which may be owing to the large doses of lidocaine given during the procedure. The nurse also monitors the patient's respiratory status and observes for hypoxia, hypotension, tachycardia, arrhythmias, hemoptysis, and dyspnea. Any abnormality is reported promptly. A small amount of blood-tinged sputum and fever may be expected within the first 24 hours (Pagana et al., 2017). The patient is not discharged from the postanesthesia care unit (PACU) until adequate cough reflex and respiratory status are present. The nurse instructs

the patient and caregivers to report any shortness of breath or bleeding immediately.

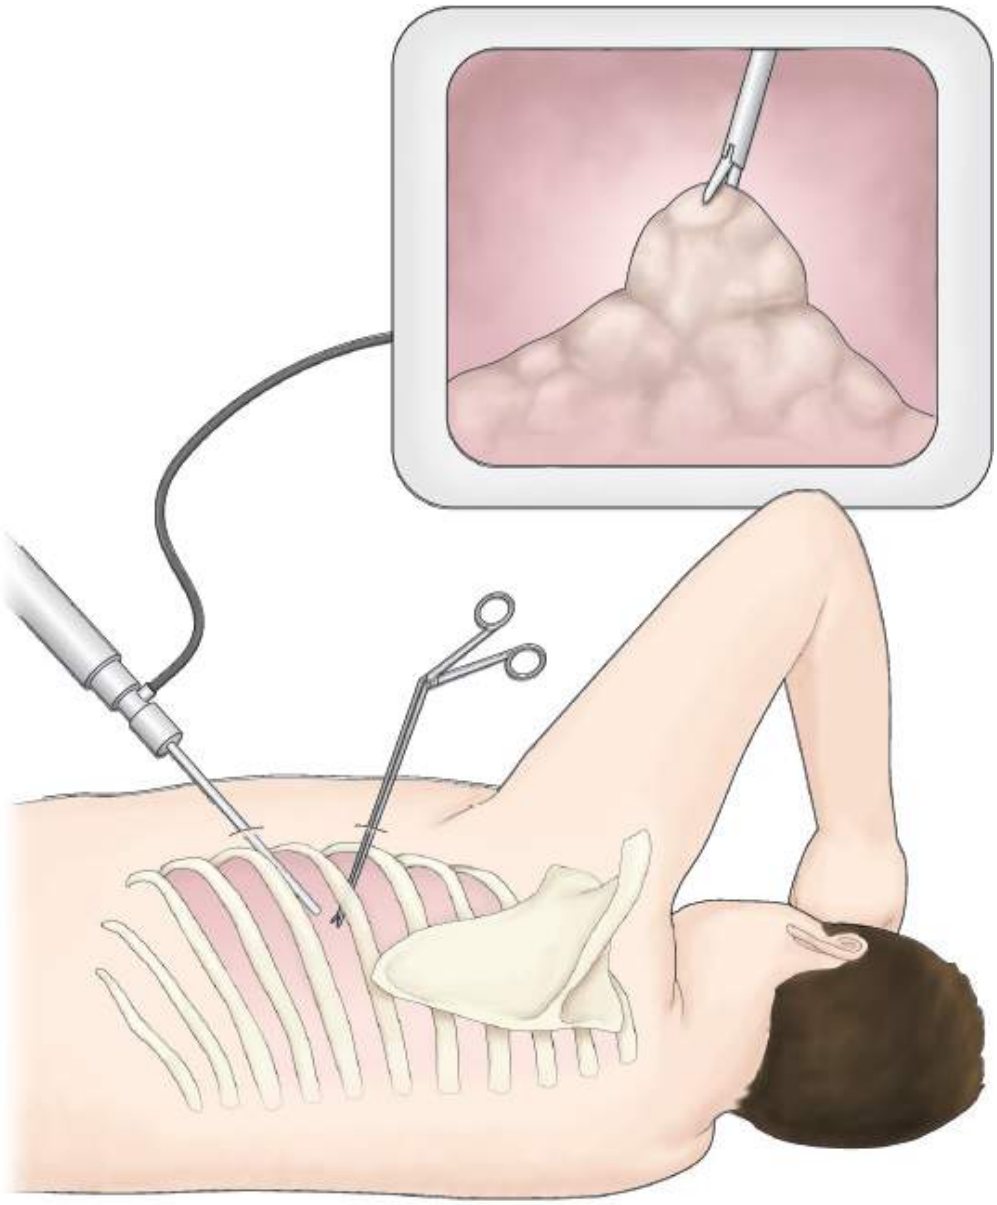

Figure 17-15 • Endoscopic thoracoscopy. Like bronchoscopy, thoracoscopy uses fiberoptic instruments and video cameras for visualizing thoracic structures. Unlike bronchoscopy, thoracoscopy usually requires the surgeon to make a small incision before inserting the endoscope. A combined diagnostic–treatment procedure, thoracoscopy includes excising tissue for biopsy.

Thoracoscopy

Thoracoscopy is a diagnostic procedure in which the pleural cavity is examined with an endoscope and fluid and tissues can be obtained for analysis (Fig. 17-15).

Procedure

This procedure is performed in the operating room, normally under anesthesia. Small incisions are made into the pleural cavity in an intercostal space at the location indicated by clinical and diagnostic findings. The fiberoptic mediastinoscope is inserted into the pleural cavity, any fluid present is aspirated, and the pleural cavity is inspected through the instrument. After the procedure, a chest tube may be inserted to facilitate re-expansion of the lung.

Thoracoscopy is primarily indicated in the diagnostic evaluation and treatment of pleural effusions, pleural disease, and tumor staging. Biopsies of the lesions and resection of tissues can be performed under visualization for diagnosis.

Thoracoscopic procedures have expanded with the availability of video monitoring, which permits improved visualization of the lung. Video-assisted thoracoscopy (VATS) may be used in the diagnosis and treatment of empyema, pleural effusion, pulmonary and pleural masses, and pneumothorax. Although VATS does not replace the need for thoracotomy in the treatment of some lung cancers, its use continues to grow, because it is less invasive than open surgical procedures, and hospitalization and recovery are shorter.

Nursing Interventions

The nurse should follow routine preoperative practices, such as ensuring that informed consent is obtained and that the patient remains NPO prior to the procedure. Postoperatively, the nurse should monitor vital signs, pain level, and respiratory status, and should look for signs of bleeding and infection at the incisional site. Shortness of breath may indicate a pneumothorax and should be reported immediately. If a chest tube was inserted during the procedure, monitoring of the chest drainage system and chest tube insertion site is essential (see Chapter 19).

Thoracentesis

In some respiratory disorders, pleural fluid may accumulate. Thoracentesis (aspiration of fluid and air from the pleural space) is performed for diagnostic or therapeutic reasons. Purposes of the procedure include removal of fluid and, very rarely, air from the pleural cavity; aspiration of pleural fluid for analysis; pleural biopsy; and instillation of medication into the pleural space. Studies of pleural fluid include Gram stain culture and sensitivity, acid-fast staining and culture, differential cell count, cytology, pH, total protein, lactic dehydrogenase, glucose, amylase, triglycerides, and cancer markers such as carcinoembryonic antigen.

For the procedural guidelines for assisting with a thoracentesis, go to thepoint.lww.com/Brunner15e.

Biopsy

Biopsy—the excision of a small amount of tissue—may be performed to permit examination of cells from the upper and lower respiratory structures and adjacent lymph nodes. Local, topical, or moderate sedation, or general anesthesia, may be given, depending on the site and the procedure.

Pleural Biopsy

Pleural biopsy is accomplished by needle biopsy of the pleura, thoracoscopy, or pleuroscopy, a visual exploration through a fiberoptic pleuroscope inserted into the pleural space or through a thoracotomy. Pleural biopsy is performed when there is pleural exudate of undetermined origin or when there is a need to culture or stain the tissue to identify tuberculosis or fungi.

Lung Biopsy Procedures

Lung biopsy is performed to obtain tissue for examination when other diagnostic testing indicates potential interstitial lung disease, such as cancer, infection, or sarcoidosis. Several nonsurgical lung biopsy techniques are used because they yield accurate information with low morbidity: transbronchial brushing or needle aspiration, transbronchial lung biopsy, and percutaneous (through-the-skin) needle biopsy. Possible complications for all methods include pneumothorax, pulmonary hemorrhage, and empyema (Pagana et al., 2017).

Procedure

In transbronchial brushing, a fiberoptic bronchoscope is introduced into the bronchus under fluoroscopy. A small brush attached to the end of a flexible wire is inserted through the bronchoscope. Under direct visualization, the area under suspicion is brushed back and forth, causing cells to slough off and adhere to the brush. The catheter port of the bronchoscope may be used to irrigate the lung tissue with saline solution to secure material for additional studies. The brush is removed from the bronchoscope, and a slide is made for examination under the microscope. The brush may be cut off and sent to the pathology laboratory for analysis. This procedure is especially useful in the immunologically compromised patient.

In transbronchial needle aspiration, a catheter with a needle is inserted into the tissue through the bronchoscope and aspirated, whereas in transbronchial lung biopsy, biting or cutting forceps are introduced by a fiberoptic bronchoscope to excise the tissue.

In percutaneous needle biopsy, a cutting needle or a spinal-type needle is used to obtain a tissue specimen for histologic study under fluoroscopic or CT guidance. Analgesia may be given before the procedure. The skin over the biopsy site is cleansed and anesthetized and a small incision is made. The biopsy needle is inserted through the incision into the pleura with the patient holding their breath in midexpiration. The surgeon guides the needle into the periphery of the lesion and obtains a tissue sample from the mass.

Nursing Interventions

After the procedure, recovery and home care are similar to those for bronchoscopy and thoracoscopy. Nursing care involves monitoring the patient for complications such as shortness of breath, bleeding, or infection. In preparation for discharge, the patient and the family are instructed to report pain, shortness of breath, visible bleeding, redness of the biopsy site, or purulent drainage (pus) to the primary provider immediately. Patients who have undergone biopsy are often anxious because of the need for the biopsy and the potential findings; the nurse must consider this in providing postbiopsy care and patient education.

Lymph Node Biopsy

The scalene lymph nodes, which are enmeshed in the deep cervical pad of fat overlying the scalenus anterior muscle, drain the lungs and mediastinum and may show histologic changes from intrathoracic disease. If these nodes are palpable on physical examination, a scalene node biopsy may be performed. A biopsy of these nodes may be performed to detect spread of pulmonary disease to the lymph nodes and to establish a diagnosis or prognosis in such diseases as Hodgkin lymphoma, sarcoidosis, fungal disease, tuberculosis, and carcinoma.

Procedure

Mediastinoscopy is the endoscopic examination of the mediastinum for exploration and biopsy of mediastinal lymph nodes that drain the lungs; this examination does not require a thoracotomy. Biopsy is usually performed through a suprasternal incision. Mediastinoscopy is carried out to detect mediastinal involvement of pulmonary malignancy and to obtain tissue for diagnostic studies of other conditions (e.g., sarcoidosis).

An anterior mediastinotomy is thought to provide better exposure and diagnostic possibilities than a mediastinoscopy. An incision is made in the area of the second or third costal cartilage. The mediastinum is explored, and

biopsies are performed on any lymph nodes found. Chest tube drainage is required after the procedure. Mediastinotomy is particularly valuable to determine whether a pulmonary lesion is resectable.

Nursing Interventions

Postprocedure care focuses on providing adequate oxygenation, monitoring for bleeding, and providing pain relief. The patient may be discharged a few hours after the chest drainage system is removed. The nurse should instruct the patient and the family about monitoring for changes in respiratory status, taking into consideration the impact of anxiety about the potential findings of the biopsy on their ability to remember those instructions.

CRITICAL THINKING EXERCISES

1 ebp You are caring for an 82-year-old male who was transferred to the medical-surgical unit from the postanesthesia care unit (PACU), status post appendectomy. The patient is currently alert to time, person, and place and his vital signs are as follows: temperature 37.5°C (99.0°F), HR 79 bpm, BP 125/74, RR 16 breaths/min, and SaO_2 96% on oxygen at 2 L/min via nasal cannula. The patient is receiving morphine via patient-controlled analgesia (PCA) for pain management. What changes in his assessment would indicate that he is at risk for developing respiratory depression? What evidence-based scales and diagnostic tests could help you to identify this potential complication?

2 pq A patient with a significant pulmonary history is admitted to the medical unit where you work with complaints of shortness of breath. He reports that he worked in the coal mines for 42 years and smokes cigarettes every day. As part of the history, he tells you, "For the past couple of days, I can't seem to catch my breath." He informs you that he coughs up "yellow stuff" throughout the day and it has been "thicker" than usual. What components of his assessment are most important for you to perform first?

18 Management of Patients with Upper Respiratory Tract Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe nursing management of patients with upper airway disorders and of patients with epistaxis.
2. Compare and contrast the upper respiratory tract infections according to cause, incidence, clinical manifestations, management, and the significance of preventive health care.
3. Use the nursing process as a framework for care of the patient with upper airway infection and the patient undergoing laryngectomy.

NURSING CONCEPTS

Infection
Oxygenation

GLOSSARY

alaryngeal communication: alternative modes of speaking that do not involve the normal larynx; used by patients whose larynx has been surgically removed

aphonia: impaired ability to use one's voice due to disease or injury to the larynx

apnea: cessation of breathing

dysphagia: difficulty swallowing

epistaxis: hemorrhage from the nose due to rupture of tiny, distended vessels in the mucous membrane of any area of the nose

herpes simplex: a cutaneous viral infection with painful vesicles and erosions on the tongue, palate, gingiva, buccal membranes, or lips (*synonym:* cold sore)

laryngectomy: surgical removal of all or part of the larynx and surrounding structures

laryngitis: inflammation of the larynx; may be caused by voice abuse, exposure to irritants, or infectious organisms

nuchal rigidity: stiffness of the neck or inability to bend the neck

pharyngitis: inflammation of the throat

rhinitis: inflammation of the mucous membranes of the nose

rhinitis medicamentosa: rebound nasal congestion commonly associated with overuse of over-the-counter nasal decongestants

rhinorrhea: drainage of a large amount of fluid from the nose

rhinosinusitis: inflammation of the nares and paranasal sinuses, including frontal, ethmoid, maxillary, and sphenoid sinuses; replaces the term *sinusitis*

tonsillitis: inflammation of the tonsils

xerostomia: dryness of the mouth

Upper respiratory tract disorders are those that involve the nose, paranasal sinuses, pharynx, larynx, trachea, or bronchi. Many of these conditions are relatively minor, and their effects are limited to mild and temporary discomfort and inconvenience for the patient. However, others are acute, severe, and life-threatening and may require permanent alterations in breathing and speaking. Therefore, the nurse must have expert assessment skills, an understanding of the wide variety of disorders that may affect the upper airway, and an awareness of the impact of these alterations on patients. Patient education is an important aspect of nursing care because many of these disorders are treated outside the hospital or at home by patients themselves. When caring for patients with acute, life-threatening disorders, the nurse needs highly developed assessment and clinical management skills, along with a focus on rehabilitation needs.

UPPER AIRWAY INFECTIONS

Upper airway infections (otherwise known as upper respiratory infections [URIs]) are the most common cause of illness and affect most people on occasion. Some infections are acute, with symptoms that last several days; others are chronic, with symptoms that may last for weeks or months or recur. A URI is often defined as an infection of the mucous membranes of the nose, sinuses, pharynx, upper trachea, or larynx (Pokorski, 2015).

The common cold is the most frequently occurring example of a URI. URIs occur when microorganisms such as viruses and bacteria are inhaled. There are many causative organisms, and people are susceptible throughout life. Viruses, the most common cause of URIs, affect the upper respiratory passages and lead to subsequent mucous membrane inflammation. URIs are the most common reason for seeking health care and for absences from school and work (Pokorski, 2015).

URIs affect the nasal cavity; ethmoidal air cells; and frontal, maxillary, and sphenoid sinuses; as well as the pharynx, larynx, and upper portion of the trachea. On average, adults typically develop two to four URIs per year because of the wide variety of respiratory viruses that circulate in the community (Weinberger, Cockrill, & Mandel, 2019). Although patients are rarely hospitalized for the treatment of URIs, nurses working in community settings or long-term care facilities may encounter patients who have these infections. It is important for nurses to recognize the signs and symptoms of URIs and provide appropriate care. Nurses in these settings also can influence patient outcomes through patient education. Special considerations with regard to URIs in older adults are summarized in Chart 18-1.

Rhinitis

Rhinitis is a group of disorders characterized by inflammation and irritation of the mucous membranes of the nose. These conditions can have a significant impact on quality of life and contribute to sinus, ear, and sleep problems and learning disorders. Rhinitis often coexists with other respiratory disorders, such as asthma. It affects between 10% and 30% of the population worldwide annually. Viral rhinitis, especially the common cold, affects approximately one billion individuals yearly (Meneghetti, 2018).

Rhinitis may be acute or chronic, and allergic or nonallergic. Allergic rhinitis is further classified as seasonal or perennial rhinitis and is commonly associated with exposure to airborne particles such as dust, dander, or plant pollens in people who are allergic to these substances. Seasonal rhinitis occurs during pollen seasons, and perennial rhinitis occurs throughout the year. See

Chapter 33 for detailed descriptions of allergic disorders, including allergic rhinitis.

Pathophysiology

Rhinitis may be caused by a variety of factors, including changes in temperature or humidity; odors; infection; age; systemic disease; use of over-the-counter (OTC) and prescribed nasal decongestants; and the presence of a foreign body. Allergic rhinitis may occur with exposure to allergens such as foods (e.g., peanuts, walnuts, Brazil nuts, wheat, shellfish, soy, cow's milk, eggs), medications (e.g., penicillin, sulfa medications, aspirin), and particles in the indoor and outdoor environment (Chart 18-2). The most common cause of nonallergic rhinitis is the common cold (Peters, 2015).

Chart 18-1

Upper Respiratory Tract Disorders in Older Adults

- Upper respiratory infections in older adults may have more serious consequences if patients have concurrent medical problems that compromise their respiratory or immune status.
- Influenza causes exacerbations of chronic obstructive pulmonary disease and reduced pulmonary function.
- Antihistamines and decongestants used to treat upper respiratory disorders must be used cautiously in older adults because of their side effects and potential interactions with other medications.
- The prevalence of nonallergic rhinosinusitis is greater among older adults than among adults of other age groups. Rhinosinusitis is the sixth most common chronic disease among older adults. With anticipated future growth in the older adult population, the need for endoscopic sinus surgery will increase. Older patients with nonallergic rhinosinusitis present with symptoms similar to those of younger adults and experience a similar degree of improvement and quality of life after endoscopic sinus surgery.
- The structure of the nose changes with aging; it lengthens and the tip droops from loss of cartilage. This can cause restriction in airflow and predispose older adult patients to geriatric rhinitis, characterized by increased thin, watery sinus drainage. These structural changes may also adversely affect the sense of smell.
- Laryngitis in older adults is common and may be secondary to gastroesophageal reflux disease (GERD). Older adults are more likely to have impaired esophageal peristalsis and a weaker esophageal sphincter. Treatment measures include sleeping with the head of the bed elevated and the use of medications such as histamine-2 receptor blockers (e.g., famotidine) or proton pump inhibitors (e.g., omeprazole).
- Age-related loss of muscle mass and thinning of the mucous membranes can cause structural changes in the larynx that may change characteristics of the voice. In general, the pitch of voice becomes higher in older adult men and lower in older adult women. The voice also “thins” (decreased projection) and may sound tremulous. These changes should be discriminated from signs that could indicate pathologic conditions.

Adapted from Eliopoulos, C. (2018). *Gerontological nursing* (9th ed.). Philadelphia, PA: Wolters Kluwer; Lehmann, A. E., Scangas, G. A., Sethi, R. K., et al. (2018). Impact of age on sinus surgery outcomes. *The Laryngoscope, 128*, 2681–2687; Valdes, C. J., & Tewfik, M. A. (2018). Rhinosinusitis and allergies in elderly patients. *Clinics in Geriatric Medicine, 34*(2), 217–231.

Drug-induced rhinitis may occur with antihypertensive agents, such as angiotensin-converting enzyme (ACE) inhibitors and beta-blockers; "statins," such as atorvastatin and simvastatin; antidepressants and antipsychotics such as risperidone; aspirin; and some antianxiety medications (Comerford & Durkin, 2020). Figure 18-1 shows the pathologic processes involved in rhinitis and rhinosinusitis. Other causes of rhinovirus are identified in Table 18-1.

Chart 18-2

Examples of Common Indoor and Outdoor Allergens

Common Indoor Allergens

- Dust mite feces
- Dog dander
- Cat dander
- Cockroach droppings
- Molds

Common Outdoor Allergens

- Trees (e.g., oak, elm, western red cedar, ash, birch, sycamore, maple, walnut, cypress)
- Weeds (e.g., ragweed, tumbleweed, sagebrush, pigweed, cockle weed, Russian thistle)
- Grasses (e.g., timothy, orchard, sweet vernal, bermuda, sour dock, redtop, bluegrass)
- Molds (*Alternaria, Cladosporium, Aspergillus*)

Adapted from Patel, B. (2017). Aeroallergens. Retrieved on 5/27/2019 at: www.emedicine.medscape.com/article/137911-overview

Clinical Manifestations

The signs and symptoms of rhinitis include **rhinorrhea** (excessive nasal drainage, runny nose); nasal congestion; nasal discharge (purulent with bacterial rhinitis); sneezing; and pruritus of the nose, roof of the mouth, throat, eyes, and ears. Headache may occur, particularly if rhinosinusitis is also present (see later discussion of rhinosinusitis). Nonallergic rhinitis can occur throughout the year.

TABLE 18-1 Causes of Rhinosinusitis

Category	Causes
Vasomotor	Idiopathic
	Abuse of nasal decongestants (rhinitis medicamentosa)
	Psychological stimulation (anger, sexual arousal)
	Irritants (smoke, air pollution, exhaust fumes, cocaine)
Mechanical	Tumor
	Deviated septum
	Crusting
	Hypertrophied turbinates
	Foreign body
	Cerebrospinal fluid leak
Chronic inflammatory	Polyps (in cystic fibrosis)
	Sarcoidosis
	Wegener granulomatosis
	Midline granuloma
Infectious	Acute viral infection
	Acute or chronic rhinosinusitis
	Rare nasal infections (syphilis, tuberculosis)
Hormonal	Pregnancy
	Use of oral contraceptives
	Hypothyroidism

Adapted from Peters, A. (2015). Rhinosinusitis: Synopsis. Retrieved on 6/2/2019 at: www.worldallergy.org/professional/allergic_diseases_center/rhinosinusitis/sinusitissynopsis.php

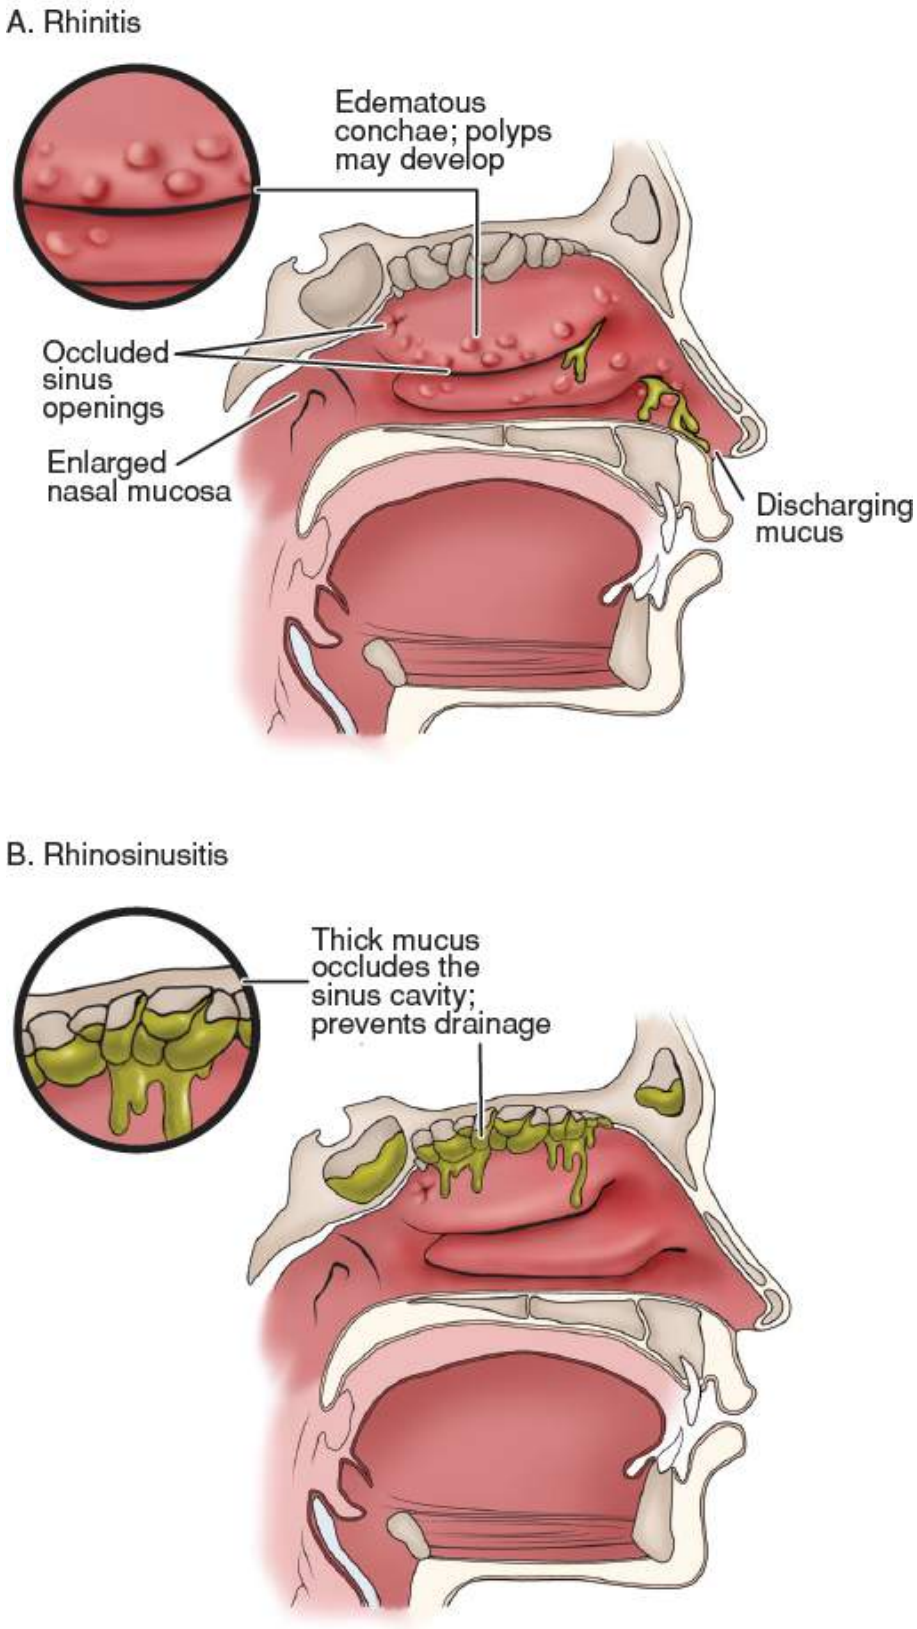

Figure 18-1 • Pathophysiologic processes in rhinitis and rhinosinusitis. Although pathophysiologic processes are similar in

rhinitis and rhinosinusitis, they affect different structures. **A.** In rhinitis, the mucous membranes lining the nasal passages become inflamed, congested, and edematous. The swollen nasal conchae block the sinus openings, and mucus is discharged from the nostrils. **B.** Rhinosinusitis is also marked by inflammation and congestion, with thickened mucous secretions filling the sinus cavities and occluding the openings.

Medical Management

The management of rhinitis depends on the cause, which may be identified through the history and physical examination. The nurse asks the patient about recent symptoms as well as possible exposure to allergens in the home, environment, or workplace. If viral rhinitis is the cause, medications may be prescribed to relieve the symptoms. In allergic rhinitis, allergy tests may be performed to identify possible allergens. Depending on the severity of the allergy, desensitizing immunizations and corticosteroids may be required (see Chapter 33 for more details). If symptoms suggest a bacterial infection, an antimicrobial agent is used. Patients with nasal septal deformities or nasal polyps may be referred to an ear, nose, and throat specialist.

Pharmacologic Therapy

Medication therapy for allergic and nonallergic rhinitis focuses on symptom relief. Antihistamines and nasal sprays may be useful. Antihistamines remain the most common treatment and are given for sneezing, pruritus, and rhinorrhea. (Examples of commonly prescribed antihistamines are discussed in more detail in Chapter 33.) Brompheniramine/pseudoephedrine is an example of combination antihistamine/decongestant medications. Cromolyn, a mast cell stabilizer that inhibits the release of histamine and other chemicals, is also used in the treatment of rhinitis. Oral decongestant agents may be used for nasal obstruction. The use of saline nasal spray can act as a mild decongestant and can liquefy mucus to prevent crusting. Two inhalations of intranasal ipratropium can be given in each nostril two to three times per day for symptomatic relief of rhinorrhea. In addition, intranasal corticosteroids may be used for severe congestion, and ophthalmic agents (cromolyn ophthalmic solution 4%) may be used to relieve irritation, itching, and redness of the eyes. Appropriate allergy treatments may include leukotriene modifiers (e.g., montelukast, zafirlukast, zileuton), and immunoglobulin E modifiers (e.g., omalizumab), which are also components of asthma treatment guidelines (discussed further in Chapter 20). The choice of medications depends on the symptoms, adverse reactions, adherence factors, risk of drug interactions, and cost to the patient (Hauk, 2018).

Nursing Management

Educating Patients About Self-Care

The nurse instructs the patient with allergic rhinitis to avoid or reduce exposure to allergens and irritants, such as dusts, molds, animals, fumes, odors, powders, sprays, and tobacco smoke. Patient education is essential when assisting the patient in the use of all medications. To prevent possible drug interactions, the patient is cautioned to read drug labels before taking any OTC medication.

The nurse instructs the patient about the importance of controlling the environment at home and at work. Saline nasal sprays or aerosols may be helpful in soothing mucous membranes, softening crusted secretions, and removing irritants. The nurse instructs the patient in correct administration of nasal medications. To achieve maximal relief, the patient is instructed to blow the nose before applying any medication into the nasal cavity. In addition, the patient is taught to keep the head upright; spray quickly and firmly into each nostril away from the nasal septum; and wait at least 1 minute before administering the second spray. The container should be cleaned after each use and should never be shared with other people to avoid cross-contamination.

In the case of infectious rhinitis, the nurse reviews hand hygiene technique with the patient as a measure to prevent transmission of organisms. This is especially important for those in contact with vulnerable populations such as the very young, older adults, or people who are immunosuppressed (e.g., patients with human immune deficiency virus [HIV] infection, those taking immunosuppressive medications). In older adults and other high-risk populations, the nurse reviews the importance of receiving an influenza vaccination each year to achieve immunity before the beginning of the flu season.

Viral Rhinitis (Common Cold)

Viral rhinitis is the most frequent viral infection in the general population (Meneghetti, 2018). The term *common cold* often is used when referring to a URI that is self-limited and caused by a virus. The term *cold* refers to an infectious, acute inflammation of the mucous membranes of the nasal cavity characterized by nasal congestion, rhinorrhea, sneezing, sore throat, and general malaise. More broadly, the term refers to an acute URI, whereas terms such as *rhinitis, pharyngitis,* and *laryngitis* distinguish the sites of the symptoms. The term is also used when the causative virus is influenza (the flu). Colds are highly contagious because virus is shed for about 2 days before the symptoms appear and during the first part of the symptomatic phase.

Colds caused by rhinoviruses tend to occur in the early fall and spring. Other viruses tend to cause winter colds (Centers for Disease Control and Prevention [CDC], 2019). Seasonal changes in relative humidity may affect the prevalence of colds. The most common cold-causing viruses survive better when humidity is low, in the colder months of the year.

Colds are caused by as many as 200 different viruses. Rhinoviruses are the most likely causative organisms. Other viruses implicated in the common cold include coronavirus, adenovirus, respiratory syncytial virus, influenza virus, and parainfluenza virus. Each virus may have multiple strains; as a result, people are susceptible to colds throughout life (Buensalido, 2019b). Some virus strains may be particularly virulent, causing more severe manifestations than those implicated with common colds, such as the SARS-CoV-2 virion, which caused the COVID-19 pandemic. Development of a vaccine against the multiple strains of virus is almost impossible. Immunity after recovery is variable and depends on many factors, including a person's natural host resistance and the specific virus that caused the cold. Despite popular belief, cold temperatures and exposure to cold rainy weather do not increase the incidence or severity of the common cold.

Clinical Manifestations

Signs and symptoms of viral rhinitis may include low-grade fever, nasal congestion, rhinorrhea and nasal discharge, halitosis, sneezing, tearing watery eyes, "scratchy" or sore throat, general malaise, chills, and often headache and muscle aches. As the illness progresses, cough usually appears. In some people, the virus exacerbates **herpes simplex,** commonly called a *cold sore* (Chart 18-3).

The symptoms of viral rhinitis may last from 1 to 2 weeks. If severe systemic respiratory symptoms occur, it is no longer considered viral rhinitis but one of the other acute URIs. Allergic conditions can affect the nose, mimicking the symptoms of a cold.

Medical Management

Management consists of symptomatic therapy that includes adequate fluid intake, rest, prevention of chilling, and the use of expectorants as needed. Warm salt-water gargles soothe the sore throat, and nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin or ibuprofen, relieve aches and pains. Antihistamines are used to relieve sneezing, rhinorrhea, and nasal congestion. Petroleum jelly can soothe irritated, chapped, and raw skin around the nares (Buensalido, 2019b).

Guaifenesin, an expectorant, is available without a prescription and is used to promote removal of secretions. Antimicrobial agents (antibiotics) should not

be used, because they do not affect the virus or reduce the incidence of bacterial complications. In addition, their inappropriate use has been implicated in the development of organisms resistant to therapy.

Chart 18-3

Colds and Cold Sores (Herpes Simplex Virus)

Overview

Herpes labialis is an infection that is caused by herpes simplex virus type 1 (HSV-1). Herpes labialis is extremely contagious and can be spread through contaminated razors, towels, and dishes. It is activated by overexposure to sunlight or wind, colds, influenza and similar infections, heavy alcohol use, and physical or emotional stress.

Statistics

- Once the patient is infected with this virus, it can lie latent in the cells. The incubation period is between 2 and 12 d.
- Between 50% and 80% of Americans are infected by age 30 y, because HSV-1 is typically transmitted during childhood through nonsexual contact.
- Estimates suggest that 80% of people infected are asymptomatic.

Clinical Manifestations

- Herpes labialis is characterized by an eruption of small, painful blisters on the skin of the lips, mouth, gums, tongue, or the skin around the mouth. The blisters are commonly referred to as cold sores or fever blisters.
- Early symptoms of herpes labialis include burning, itching, and increased sensitivity or tingling sensation. These symptoms may occur several days before the appearance of lesions.
- Lesions appear as macules or papules, progressing to small blisters (vesicles) filled with clear, yellowish fluid. They are raised, red, and painful and can break and ooze. The lesions typically extend through the epidermis and penetrate into the underlying dermis, consistent with a partial-thickness wound.
- Eventually, yellow crusts slough over the lesions to reveal pink, healing skin.
- Typically, the virus is no longer detectable in the lesion or wound 5 d after the vesicle has developed.

Medical and Nursing Management

- Antiviral medications (e.g., acyclovir, valacyclovir) may be prescribed to minimize the symptoms and the duration or length of flare-up.
- Acetaminophen may be given for analgesia.
- Topical anesthetics such as lidocaine can help in the control of discomfort.
- Occlusive dressings have been shown to speed the healing process. Occlusive ointments with antiviral properties (e.g., docosanol) might be considered for lip and mucosal lesions.

Patient Education

- Patients should understand that the virus can be transmitted by people who are asymptomatic.
- Patients should seek treatment with antiviral medications and ointments when they are first experiencing symptoms (e.g., tingling, burning, or itching sensations) as early treatment with these drugs can result in a speedier recovery.
- Although herpes simplex virus type 2 (HSV-2) typically causes painful vesicular and ulcerative lesions in the genital and anal areas, HSV-1 may also cause genital herpes. Oral–genital contact can spread oral herpes to the genitals (and vice versa). People with active herpetic lesions should avoid oral sex.

Photo reprinted with permission from Ayoade, F. (2018). Herpes simplex. Retrieved on 5/27/2019 at: www.emedicine.medscape.com/article/218580-overview

Topical nasal decongestants (e.g., phenylephrine nasal and oxymetazoline nasal) should be used with caution. Topical therapy delivers medication directly to the nasal mucosa, and its overuse can produce **rhinitis medicamentosa**, or rebound rhinitis. Most patients treat the common cold with OTC medications that produce moderate clinical benefits, such as relief of symptoms.

In addition, alternative medicines (e.g., echinacea, zinc lozenges, and zinc nasal spray) are frequently used to treat the common cold; however, evidence regarding their effectiveness in shortening the symptomatic phase is limited (Mousa, 2017). The inhalation of steam or heated, humidified air has been a mainstay of home remedies to treat the common cold; however, the value of this therapy has not been demonstrated.

Nursing Management

Educating Patients About Self-Care

Most viruses can be transmitted in several ways: direct contact with infected secretions, inhalation of large particles from others' coughing or sneezing, or inhalation of small particles (aerosol) that may be suspended in the air for up to an hour. Implementation of appropriate hand hygiene measures (see Chapter 66, Chart 66-1 for further information) remains the most effective measure to prevent transmission of organisms. The nurse educates the patient about how to break the chain of infection with appropriate hand hygiene and the use of tissues to avoid the spread of the virus with coughing and sneezing, and to cough or sneeze into the upper arm if tissues are not readily available. The nurse instructs the patient about methods to treat symptoms of the common cold and provides both verbal and written information to assist in the prevention and management of URIs.

Rhinosinusitis

Rhinosinusitis, formerly called *sinusitis,* is an inflammation of the paranasal sinuses and nasal cavity. The American Academy of Otolaryngology–Head and Neck Surgery Foundation (2018; Rosenfeld, Andes, Bhattacharyya, et al., 2015) recommends the use of the term *rhinosinusitis* because sinusitis is almost always accompanied by inflammation of the nasal mucosa. Rhinosinusitis affects about 35 million people in the United States each year and accounts for 16 million office visits (Brook, 2018a).

Uncomplicated rhinosinusitis occurs without extension of inflammation outside of the paranasal sinuses and nasal cavity. Rhinosinusitis is classified by duration of symptoms as acute (less than 4 weeks), subacute (4 to 12 weeks), and chronic (more than 12 weeks). Rhinosinusitis can be caused by a bacterial or viral infection.

Acute Rhinosinusitis

Acute rhinosinusitis is classified as acute bacterial rhinosinusitis (ABRS) or acute viral rhinosinusitis (AVRS). Recurrent acute rhinosinusitis is characterized by four or more acute episodes of ABRS per year (Patel & Hwang, 2019) and is discussed with chronic rhinosinusitis (CRS).

Pathophysiology

Acute rhinosinusitis usually follows a viral URI or cold, such as an unresolved viral or bacterial infection, or an exacerbation of allergic rhinitis. Normally, the sinus openings into the nasal passages are clear and infections resolve

promptly. However, if their drainage is obstructed by a deviated septum or by hypertrophied turbinates, spurs, or nasal polyps or tumors, sinus infection may persist as a secondary infection or progress to an acute suppurative process (causing purulent discharge).

Nasal congestion, caused by inflammation, edema, and transudation of fluid secondary to URI, leads to obstruction of the sinus cavities (see Fig. 18-1). This provides an excellent medium for bacterial growth. Other conditions and activities that can block the normal flow of sinus secretions include abnormal structures of the nose, enlarged adenoids, diving and swimming, tooth infection, trauma to the nose, tumors, and the pressure of foreign objects. Some people are more prone to rhinosinusitis because exposure to environmental hazards such as paint, sawdust, and chemicals may result in chronic inflammation of the nasal passages.

Bacterial organisms account for more than 60% of the cases of acute rhinosinusitis. Typical pathogens include *Streptococcus pneumoniae, Haemophilus influenzae,* and less commonly *Staphylococcus aureus,* and *Moraxella catarrhalis* (Brook, 2018b). Biofilms, which consist of organized, heterogeneous communities of bacteria, have been found to be 10 to 1000 times more resistant to antibiotic treatment and more likely to contribute to host resistance when compared with other bacteria. They serve as bacterial reservoirs that can cause systemic illness when released into the circulation. Although antibiotics kill bacteria in the biofilm margin, cells deep in the biofilm are not affected, allowing for regrowth once antibiotic therapy has been discontinued. Pathogens in the upper respiratory tract that form biofilms include those species listed earlier as well as *Pseudomonas aeruginosa.*

Other organisms that are occasionally isolated include *Chlamydia pneumoniae, Streptococcus pyogenes,* viruses, and fungi (*Aspergillus fumigatus*). Fungal infections occur most often in patients who are immunosuppressed (Brook, 2018b). The most common organisms found with health care-associated (nosocomial) infections include *P. aeruginosa, Escherichia coli, Proteus mirabilis, Klebsiella pneumoniae,* and *Enterobacter* species, accounting for 60% of those cases (Brook, 2018b).

Clinical Manifestations

Symptoms of ABRS include purulent nasal drainage (anterior, posterior, or both) accompanied by nasal obstruction or a combination of facial pain, pressure, or a sense of fullness (referred to collectively as facial pain–pressure–fullness), or both (Rosenfeld et al., 2015; Sedaghat, 2017). The facial pain–pressure–fullness may involve the anterior face or the periorbital region. The patient may also report cloudy or colored nasal discharge congestion, blockage, or stuffiness as well as a localized or diffuse headache. Patients with ABRS may present with a high fever (i.e., 39°C [102°F] or higher). In

addition, the occurrence of symptoms for 10 days or more after the initial onset of upper respiratory symptoms indicates ABRS (Brook, 2018a).

The symptoms of AVRS are similar to those of ABRS, except the patient does not present with a high fever, nor with the same intensity of symptoms (e.g., there tends to be an absence of facial pain–pressure–fullness), nor with symptoms that persist for as long a period of time. Symptoms of AVRS occur for fewer than 10 days after the onset of upper respiratory symptoms and do not worsen (Papadakis, McPhee, & Rabow, 2018).

Assessment and Diagnostic Findings

A careful history and physical examination are performed. The head and neck, particularly the nose, ears, teeth, sinuses, pharynx, and chest, are examined. There may be tenderness to palpation over the infected sinus area. The sinuses are percussed using the index finger, tapping lightly to determine whether the patient experiences pain. Although less frequently performed, transillumination of the affected area may reveal a decrease in the transmission of light with rhinosinusitis (see Chapter 17). Diagnostic imaging (x-ray, computed tomography [CT], magnetic resonance imaging [MRI]) is not recommended and generally not needed for the diagnosis of acute rhinosinusitis if the patient meets clinical diagnostic criteria (Aring & Chan, 2016; Rosenfeld et al., 2015). When a complication or alternative diagnosis is suspected, diagnostic imaging may be indicated to help identify inflammatory changes, bone destruction, and anatomic variations that can guide sinus surgery (if indicated).

To confirm the diagnosis of maxillary and frontal rhinosinusitis and identify the pathogen, sinus aspirates may be obtained. Flexible endoscopic culture techniques and swabbing of the sinuses have been used for this purpose (Papadakis et al., 2018).

Complications

If untreated, acute rhinosinusitis may lead to severe complications. Local complications include osteomyelitis and mucocele (cyst of the paranasal sinuses). Osteomyelitis requires prolonged antibiotic therapy and at times removal of necrotic bone. Intracranial complications, although rare, include cavernous sinus thrombosis, meningitis, brain abscess, ischemic brain infarction, and severe orbital cellulitis (Papadakis et al., 2018). Mucoceles may require surgical treatment to establish intranasal drainage or complete excision with ablation of the sinus cavity. Brain abscesses occur by direct spread and can be life-threatening. Frontal epidural abscesses are usually quiescent but can be detected by CT scan.

Medical Management

Treatment of acute rhinosinusitis depends on the cause; a 14-day course of antibiotics is prescribed for bacterial cases (Tewfik, 2018). The goals of treatment for acute rhinosinusitis are to shrink the nasal mucosa, relieve pain, and treat infection. Because of the inappropriate use of antibiotics for nonbacterial illness, including AVRS, and the resulting resistance that has occurred, oral antibiotics are only prescribed when there is sufficient empiric evidence that the patient has ABRS (e.g., high fever or symptoms that persist for at least 10 days or worsening symptoms following a viral respiratory illness).

Antibiotics should be given as soon as the diagnosis of ABRS is established. Amoxicillin or amoxicillin–clavulanic acid are the antibiotics of choice. For patients who are allergic to penicillin, doxycycline or respiratory quinolones such as levofloxacin or moxifloxacin can be prescribed (CDC, 2017). Other antibiotics prescribed previously to treat ABRS, including cephalosporins (e.g., cephalexin, cefuroxime, cefaclor, and cefixime), macrolides (e.g., clarithromycin and azithromycin), and trimethoprim–sulfamethoxazole are no longer recommended because they are not effective in treating antibiotic-resistant organisms that are now more commonly implicated in ABRS (Tewfik, 2018). Intranasal saline lavage is an effective adjunct therapy to antibiotics in that it may relieve symptoms, reduce inflammation, and help clear the passages of stagnant mucus. Neither decongestants nor antihistamines are recommended adjunctive medications for treating ABRS (Tewfik, 2018).

Treatment of AVRS typically involves nasal saline lavage and decongestants (guaifenesin/pseudoephedrine). Decongestants or nasal saline sprays can increase patency of the ostiomeatal unit and improve drainage of the sinuses. Topical decongestants should not be used for longer than 3 or 4 days. Oral decongestants must be used cautiously in patients with hypertension. OTC antihistamines, such as diphenhydramine and cetirizine, and prescription antihistamines, such as fexofenadine, are used if an allergic component is suspected.

Intranasal corticosteroids have been shown to produce complete or marked improvement in acute symptoms of either bacterial or viral rhinosinusitis; however, they are only recommended for use in patients with a previous history of allergic rhinitis (Rosenfeld et al., 2015). Examples of intranasal corticosteroids, side effects, and contraindications are presented in Table 18-2.

Nursing Management

Educating Patients About Self-Care

Patient education is an important aspect of nursing care for the patient with acute rhinosinusitis. The nurse instructs the patient about symptoms of complications that require immediate follow-up. Referral to the primary provider is indicated if periorbital edema and severe pain on palpation occur. The nurse instructs the patient about methods to promote drainage of the sinuses, including humidification of the air in the home and the use of warm compresses to relieve pressure. The patient is advised to avoid swimming, diving, and air travel during the acute infection. Patients using tobacco are instructed to immediately stop smoking or using any form of tobacco. Many patients use nasal sprays incorrectly, which can lead to several side effects that include nasal irritation, nasal burning, bad taste, and drainage in the throat or even **epistaxis** (hemorrhage from the nose). Therefore, if an intranasal corticosteroid is prescribed, it is important to instruct the patient about the correct use of prescribed nasal sprays through demonstration, explanation, and return demonstration to evaluate the patient's understanding of the correct method of administration. The nurse also educates the patient about the side effects of prescribed and OTC nasal sprays and about rhinitis medicamentosa (rebound congestion). Once the decongestant is discontinued, the nasal passages close and congestion results. Appropriate medications to use for pain relief include acetaminophen and NSAIDs such as ibuprofen, naproxen sodium, and aspirin for adults older than 20 years as long as there are no contraindications to use.

TABLE 18-2 Select Nasal Corticosteroids and Common Side Effects

Nasal Corticosteroids	Side Effects	Contraindications (for All Nasal Corticosteroids)
Beclomethasone	Nasal irritation, headache, nausea, lightheadedness, epistaxis, rhinorrhea, watering eyes, sneezing, dry nose and throat	Avoid in patients with recurrent epistaxis, glaucoma, and cataracts. Patients who have been exposed to measles/varicella or who have adrenal insufficiency should avoid these medications.
Budesonide	Epistaxis, pharyngitis, cough, nasal irritation, bronchospasm	
Mometasone	Headache, viral infection, pharyngitis, epistaxis, cough, dysmenorrhea, musculoskeletal pain, arthralgia	
Triamcinolone	Pharyngitis, epistaxis, cough, headache	

Adapted from Comerford, K. C., & Durkin, M. T. (Eds.). (2020). *Nursing2020 drug handbook*. Philadelphia, PA: Wolters Kluwer; Peters, A. (2015). Rhinosinusitis: Synopsis. Retrieved on 5/8/2019 at: www.worldallergy.org/professional/allergic_diseases_center/rhinosinusitis/sinusitissynopsis.php

The nurse tells patients with recurrent rhinosinusitis to begin decongestants, such as pseudoephedrine, at the first sign of rhinosinusitis. This promotes drainage and decreases the risk of bacterial infection. Patients should also check with their primary provider or pharmacist before using OTC medications because many cold medications can worsen symptoms or other health problems, specifically hypertension.

The nurse stresses the importance of following the recommended antibiotic regimen because a consistent blood level of the medication is critical to treat the infection. The nurse educates the patient about the early signs of a sinus infection and recommends preventive measures such as following healthy practices and avoiding contact with people with URIs.

The nurse explains to the patient that fever, severe headache, and **nuchal rigidity** (stiffness of the neck or inability to bend the neck) are signs of the potential complication of meningitis. Patients with chronic symptoms of rhinosinusitis who do not have marked improvement in 4 weeks with continuous medical treatment may be candidates for functional endoscopic sinus surgery (FESS, see later discussion) (Tajudeen & Kennedy, 2017).

Quality and Safety Nursing Alert

Patients with nasotracheal and nasogastric tubes in place are at the risk for development of sinus infections (Brook, 2018a; Brook, 2018b). Thus, accurate assessment of patients with these tubes is critical. Removal of the nasotracheal or nasogastric tube as soon as the patient's condition permits allows the sinuses to drain, possibly avoiding septic complications.

Chronic Rhinosinusitis and Recurrent Acute Rhinosinusitis

The prevalence of CRS is about 146 per 1000 population in the United States and occurs most commonly in young and middle-aged adults (Brook, 2018b). It is diagnosed when the patient has experienced 12 weeks or longer of two or more of the following symptoms: mucopurulent drainage, nasal obstruction, facial pain–pressure–fullness, or hyposmia (decreased sense of smell). It is estimated that in about 40% of patients, CRS is accompanied by nasal polyps (Rosenfeld et al., 2015). Recurrent acute rhinosinusitis is diagnosed when four or more episodes of ABRS occur per year with no signs or symptoms of rhinosinusitis between the episodes. The use of antibiotics in patients with recurrent acute rhinosinusitis is higher than in patients with CRS. Both CRS and recurrent acute rhinosinusitis affect quality of life as well as physical and social function (Hamilos, 2018).

Pathophysiology

Mechanical obstruction in the ostia of the frontal, maxillary, and anterior ethmoid sinuses (known collectively as the ostiomeatal complex) is the usual cause of CRS and recurrent acute rhinosinusitis. Obstruction prevents adequate drainage of the nasal passages, resulting in accumulation of secretions and an ideal medium for bacterial growth. Persistent blockage in an adult may occur because of infection, allergy, or structural abnormalities. Other associated conditions and factors may include cystic fibrosis, ciliary dyskinesia, neoplastic disorders, gastroesophageal reflux disease, tobacco use, and environmental pollution (Brook, 2018a).

Both aerobic and anaerobic bacteria have been implicated in CRS and recurrent rhinosinusitis. Common aerobic bacteria include alpha-hemolytic streptococci, microaerophilic streptococci, and *S. aureus*. Common anaerobic bacteria include gram-negative bacilli, *Peptostreptococcus,* and *Fusobacterium*.

In addition, immunodeficiency should be considered in patients with CRS or acute recurrent rhinosinusitis. Acute fulminant/invasive rhinosinusitis is a

life-threatening illness and is commonly attributed to *Aspergillus* in immunocompromised patients. Chronic fungal sinusitis also poses a risk. Chronic invasive fungal sinusitis occurs in immunocompromised patients along with fungus ball/mycetoma and allergic fungal sinusitis—the more common forms of chronic fungal sinusitis—which are considered noninvasive conditions in immunocompromised patients. The fungus ball is characterized by the presence of a noninvasive accumulation of a dense conglomeration of fungal hyphae in one sinus cavity, usually the maxillary sinus. The fungus generally remains contained in the fungus ball, which consists of mucopurulent cheesy or claylike materials within the sinus, but can become invasive when immunosuppression occurs, leading to encephalopathy (Ramadan, 2018). Symptoms include nasal stuffiness, nasal discharge, and facial pain. Vision loss, headache, and cranial nerve palsies have been identified in patients with a sphenoid sinus fungal ball (Ramadan, 2018).

Clinical Manifestations

Clinical manifestations of CRS include impaired mucociliary clearance and ventilation, cough (because the thick discharge constantly drips backward into the nasopharynx), chronic hoarseness, chronic headaches in the periorbital area, periorbital edema, and facial pain. As a result of chronic nasal congestion, the patient is usually required to breathe through the mouth. Snoring, sore throat, and, in some situations, adenoidal hypertrophy may also occur. Symptoms are generally most pronounced on awakening in the morning. Fatigue and nasal congestion are also common. Many patients experience a decrease in smell and taste and a sense of fullness in the ears.

Assessment and Diagnostic Findings

The health assessment focuses on onset and duration of symptoms. It addresses the quantity and quality of nasal discharge and cough, the presence of pain, factors that relieve or aggravate the pain, and allergies. It is essential to obtain any history of comorbid conditions, including asthma and history of tobacco use and smoking or use of electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars. A history of fever, fatigue, previous episodes and treatments and previous response to therapies is also obtained.

In the physical assessment, the external nose is evaluated for any evidence of anatomic abnormality. A crooked-appearing external nose may imply septal deviation internally. The nasal mucous membranes are assessed for erythema, pallor, atrophy, edema, crusting, discharge, polyps, erosions, and septal perforations or deviations. Appropriate lighting improves visualization of the nasal cavity and should be used in every examination. Pain on examination of

the teeth, with tapping with a tongue blade, suggests tooth infection (Bickley & Szilagyi, 2017).

Assessment of the posterior oropharynx may reveal purulent or mucoid discharge, which is indicative of an infection caused by CRS. The patient's eyes are examined for conjunctival erythema, tearing, photophobia, and edema of the lids. Additional assessment techniques include transillumination of the sinuses and palpation of the sinuses. The frontal and maxillary sinuses are palpated, and the patient is asked whether this produces tenderness. The pharynx is inspected for erythema and discharge and palpated for cervical node adenopathy (Hamilos, 2018).

Imaging studies such as x-ray, sinoscopy, ultrasound, CT scanning, and MRI may be used in the diagnosis of CRS. X-ray is an inexpensive and readily available tool to assess disorders of the paranasal sinuses. A CT scan of the paranasal sinuses can identify mucosal abnormalities, sinus ostial obstruction, anatomic variants, sinonasal polyposis, and neoplastic disease. In addition, nasal endoscopy allows for visualization of the posterior nasal cavity, nasopharynx, and sinus drainage pathways and can identify posterior septal deviation and polyps. Osseous destruction, extrasinus extension of the disease process, and local invasion suggest malignancy (Rosenfeld et al., 2015).

Complications

Complications of CRS, although uncommon, include severe orbital cellulitis, subperiosteal abscess, cavernous sinus thrombosis, meningitis, encephalitis, and ischemic infarction. CRS can lead to intracranial infection either by direct spread through bone or via venous channels, resulting in epidural abscess, subdural empyema, meningitis, and brain abscess. Clinical sequelae can include personality changes with frontal lobe abscesses, headache, symptoms of elevated intracranial pressure to include alterations of consciousness, visual changes, focal neurologic deficits, seizures, and, ultimately, coma and death.

Frontal rhinosinusitis can lead to osteomyelitis of the frontal bones. Patients typically present with headache, fever, and a characteristic doughy edema over the involved bone. Ethmoid rhinosinusitis may result in orbital cellulitis, which usually begins with edema of the eyelids and rapidly progresses to ptosis (droopy eyelid), proptosis (bulging eye), chemosis (edema of the bulbar conjunctiva), and diminished extraocular movements. Patients are usually febrile and acutely ill and require immediate attention, because pressure on the optic nerve can lead to loss of vision and spread of infection can lead to intracranial infection (Brook, 2018a). Cavernous sinus thrombophlebitis can result from extension of infection along venous channels from the orbit, ethmoid or frontal sinuses, or nose. Symptoms may include altered consciousness, lid edema, and proptosis, as well as third, fourth, and sixth cranial nerve palsies.

Medical Management

Medical management of CRS and recurrent acute rhinosinusitis is similar to that of acute rhinosinusitis. General measures include encouraging adequate hydration and recommending the use of OTC nasal saline sprays, antispasmodic agents such as acetaminophen or NSAIDs, and decongestants such as oxymetazoline and pseudoephedrine (Brook, 2018b; Tewfik, 2018). Patients are instructed to sleep with the head of the bed elevated and to avoid exposure to cigarette smoke and fumes. Patients are cautioned to avoid caffeine and alcohol, which can cause dehydration.

Prescribed antibiotics may include amoxicillin–clavulanic acid, erythromycin–sulfisoxazole, second- or third-generation cephalosporins such as cefuroxime or cefixime, or newer fluoroquinolones such as moxifloxacin (Brook, 2018b). The course of antibiotic treatment for CRS and recurrent ABRS is typically as long as 2 to 4 weeks to effectively eradicate the offending organism, and may be indicated for up to 12 months in some cases (Brook, 2018b). Corticosteroid nasal sprays such as fluticasone or beclomethasone may be indicated in patients with concomitant allergic rhinitis or nasal polyps. Patients with allergic rhinitis may also benefit from the addition of a mast cell stabilizer such as cromolyn. For patients with concomitant asthma, leukotriene inhibitors such as montelukast and zafirlukast may be used (Brook, 2018b).

Surgical Management

If standard medical therapy fails and symptoms persist, FESS may be indicated to correct structural deformities that obstruct the ostia (openings) of the sinuses. FESS is a minimally invasive surgical procedure that is associated with reduced postoperative discomfort and improvement in the patient's quality of life. In particular, FESS is associated with either complete or moderate relief of symptoms in more than 85% to 91% of patients (Patel, 2016). Some of the specific procedures performed include excising and cauterizing nasal polyps, correcting a deviated septum, incising and draining the sinuses, aerating the sinuses, and removing tumors. Computer-assisted or computer-guided surgery is used to increase the precision of the surgical procedure and to minimize complications. Antimicrobial agents are typically prescribed after surgery (Patel, 2016).

Surgical intervention is first-line treatment in acute invasive fungal rhinosinusitis to excise the fungus ball and necrotic tissue and drain the sinuses. Patients require aggressive surgical débridement and drainage as well as systemic antifungal medications (Ramadan, 2018).

Nursing Management

Patients usually perform care measures for rhinosinusitis at home; therefore, nursing management consists of good patient education.

Educating Patients About Self-Care

Many people with sinus infections tend to blow their nose frequently and with force to clear their nasal passages. Doing so often increases the symptoms; therefore, the patient is instructed to blow the nose gently and to use tissue to remove the nasal drainage. Increasing fluid intake, applying local heat (hot wet packs), and elevating the head of the bed promote drainage of the sinuses. The nurse also instructs the patient about the importance of following the prescribed medication regimen. Instructions on the early signs of a sinus infection are provided, and preventive measures are reviewed. The nurse instructs the patient about signs and symptoms that require follow-up and provides these instructions verbally and in writing. Instructions in alternative formats (e.g., large font, patient's language) may be needed to increase the patient's understanding and adherence to the treatment plan. The nurse encourages the patient to follow up with their primary provider if symptoms persist (American Academy of Otolaryngology–Head and Neck Surgery Foundation, 2018).

Quality and Safety Nursing Alert

URIs, specifically CRS and recurrent acute rhinosinusitis, may be linked to primary or secondary immune deficiency or treatment with immunosuppressive therapy (e.g., for cancer or organ transplantation). Typical symptoms may be blunted or absent due to immunosuppression. Immunocompromised patients are at the increased risk for acute or chronic fungal infections; these infections can progress rapidly and become life-threatening (Brook, 2018a; Brook, 2018b). Thus, assessment, early reporting of symptoms to the patient's primary provider, and immediate initiation of treatment are essential.

Pharyngitis

Acute Pharyngitis

Acute **pharyngitis** is a sudden painful inflammation of the pharynx, the back portion of the throat that includes the posterior third of the tongue, soft palate, and tonsils. It is commonly referred to as a sore throat. In the United States,

approximately 12 million health care visits are due to acute pharyngitis each year (Chow & Doron, 2018). Because of environmental exposure to viral agents and poorly ventilated rooms, the incidence of viral pharyngitis peaks during winter and early spring in regions that have warm summers and cold winters. Viral pharyngitis spreads easily in the droplets of coughs and sneezes, as well as from unclean hands that have been exposed to the contaminated fluids.

Pathophysiology

Viral infection causes most cases of acute pharyngitis. Responsible viruses include the adenovirus, influenza virus, Epstein–Barr virus, and herpes simplex virus. Bacterial infection accounts for the remainder of cases. Five percent to 15% of adults with pharyngitis have group A beta-hemolytic streptococcus (GABHS), which is commonly referred to as group A streptococcus (GAS) or streptococcal pharyngitis. Streptococcal pharyngitis warrants the use of antibiotic treatment. When GAS causes acute pharyngitis, the condition is known as strep throat. The body responds by triggering an inflammatory response in the pharynx. This results in pain, fever, vasodilation, edema, and tissue damage, manifested by redness and swelling in the tonsillar pillars, uvula, and soft palate. A creamy exudate may be present in the tonsillar pillars (Fig. 18-2). Other organisms implicated in acute pharyngitis include groups B and G streptococci, *Neisseria gonorrhoeae, Mycoplasma pneumoniae, C. pneumoniae, Arcanobacterium haemolyticum,* and HIV (Chow & Doron, 2018).

Uncomplicated viral infections usually subside promptly, within 3 to 10 days after onset. However, pharyngitis caused by bacteria, such as GAS, is a more severe illness. If left untreated, the complications can be severe and life-threatening. Complications include rhinosinusitis, otitis media, peritonsillar abscess, mastoiditis, and cervical adenitis. In rare cases, the infection may lead to sepsis, pneumonia, meningitis, rheumatic fever, and glomerulonephritis (Buensalido, 2019a).

Clinical Manifestations

The signs and symptoms of acute pharyngitis include a fiery-red pharyngeal membrane and tonsils, lymphoid follicles that are swollen and flecked with white-purple exudate, enlarged and tender cervical lymph nodes, and no cough. Fever (higher than 38.3°C [101°F]) and malaise also may be present. Occasionally, patients with GAS pharyngitis exhibit vomiting, anorexia, and a scarlatina-form rash with urticaria known as scarlet fever.

People who have streptococcal pharyngitis suddenly develop a painful sore throat 1 to 5 days after being exposed to the streptococcus bacteria. They

usually report malaise, fever (with or without chills), headache, myalgia, painful cervical adenopathy, and nausea. The tonsils appear swollen and erythematous, and they may or may not have an exudate. The roof of the mouth is often erythematous and may demonstrate petechiae. Bad breath is common.

Assessment and Diagnostic Findings

Accurate diagnosis of pharyngitis is essential to determine the cause (viral or bacterial) and to initiate treatment early. Rapid antigen detection testing (RADT) uses swabs that collect specimens from the posterior pharynx and tonsil. RADT is reported to be 90% to 95% sensitive, thus facilitating earlier treatment and earlier symptom improvement and reductions in pathogen transmission. Negative results should be confirmed by a throat culture (Acerra, 2018). In most communities, preliminary culture reports are available in 24 hours. Once a definitive diagnosis of GAS is made, administration of appropriate antibiotics hastens symptom resolution and reduces the transmission of the illness.

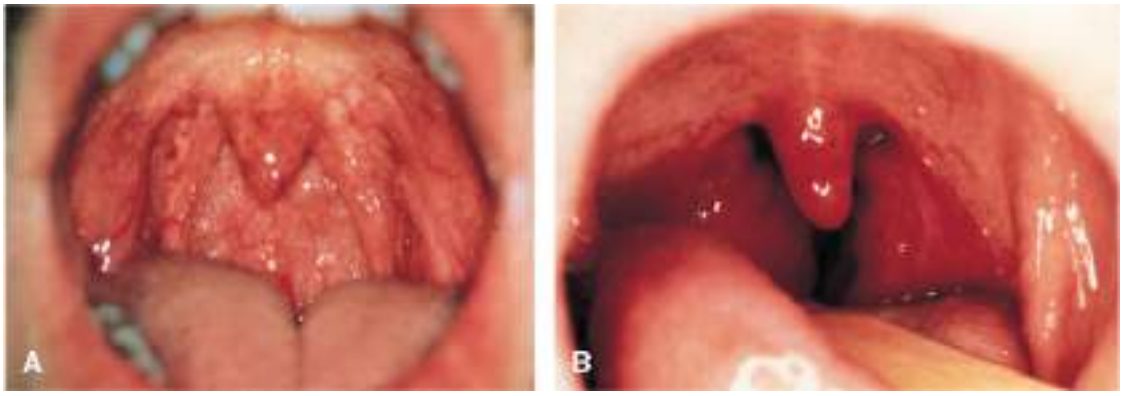

Figure 18-2 • Pharyngitis—inflammation without exudate. **A.** Redness and vascularity of the pillars and uvula are mild to moderate. **B.** Redness is diffuse and intense. Each patient would probably complain of a sore throat. Reprinted with permission from the Wellcome Trust, National Medical Slide Bank, London, UK.

Medical Management

Viral pharyngitis is treated with supportive measures because antibiotics have no effect on the causal organism. Bacterial pharyngitis is treated with a variety of antimicrobial agents (Uyeki, Bernstein, Bradley, et al., 2018).

Pharmacologic Therapy

If the cause of pharyngitis is bacterial, penicillin is usually the treatment of choice. Penicillin V potassium given orally for 10 days is the regimen of choice. Penicillin injections are recommended only if there is a concern that the patient will not adhere to therapy (Papadakis et al., 2018).

For patients who are allergic to penicillin or have organisms that are resistant to erythromycin (one fifth of GAS and most *S. aureus* organisms are resistant to penicillin and erythromycin), cephalosporins and macrolides (clarithromycin and azithromycin) may be used. Once-daily azithromycin may be given for only 3 days due to its long half-life (Acerra, 2018). A 5- or 10-day course of cephalosporin may be prescribed. Five-day administration of cefpodoxime and cefuroxime has also been successful in producing bacteriologic cures.

Severe sore throats can also be relieved by analgesic medications. For example, aspirin or acetaminophen can be taken at 4- to 6-hour intervals; if required, acetaminophen with codeine can be taken three or four times daily. In severe cases, gargles with benzocaine may relieve symptoms.

Nutritional Therapy

A liquid or soft diet is provided during the acute stage of the disease, depending on the patient's appetite and the degree of discomfort that occurs with swallowing. Cool beverages, warm liquids, and flavored frozen desserts such as ice pops are often soothing. Occasionally, the throat is so sore that liquids cannot be taken in adequate amounts by mouth. In severe situations, intravenous (IV) fluids may be needed. Otherwise, the patient is encouraged to drink as much fluid as possible (at least 2 to 3 L/day).

Nursing Management

Nursing care for patients with viral pharyngitis focuses on symptomatic management. For patients who demonstrate signs of strep throat and have a history of rheumatic fever, who have scarlet fever, or who have symptoms suggesting peritonsillar abscess, nursing care focuses on prompt initiation and correct administration of prescribed antibiotic therapy. The nurse instructs the patient about signs and symptoms that warrant prompt contact with the primary provider. These include dyspnea, drooling, inability to swallow, and inability to fully open the mouth.

The nurse instructs the patient to stay in bed during the febrile stage of illness and to rest frequently once up and about. Used tissues should be disposed of properly to prevent the spread of infection. The nurse (or the patient or family member, if the patient is not hospitalized) should examine the skin once or twice daily for possible rash, because acute pharyngitis may precede some other communicable diseases (e.g., rubella).

Depending on the severity of the pharyngitis and the degree of pain, warm saline gargles or throat irrigations are used. The benefits of this treatment depend on the degree of heat that is applied. The nurse educates the patient about these procedures and about the recommended temperature of the solution, which should be high enough to be effective and as warm as the patient can tolerate, usually 40.6° to 43.3°C (105° to 110°F). Irrigating the throat may reduce spasm in the pharyngeal muscles and relieve soreness of the throat.

An ice collar also can relieve severe sore throats. Mouth care may promote the patient's comfort and prevent the development of fissures (cracking) of the lips and oral inflammation when bacterial infection is present. The nurse instructs the patient to resume activity gradually and to delay returning to work or school until after 24 hours of antibiotic therapy. A full course of antibiotic therapy is indicated in patients with strep infection because of the potential complications such as nephritis and rheumatic fever, which may have their onset 2 or 3 weeks after the pharyngitis has subsided. The nurse instructs the patient and family about the importance of taking the full course of antibiotic therapy and informs them about the symptoms to watch for that may indicate complications.

In addition, the nurse instructs the patient about preventive measures that include not sharing eating utensils, glasses, napkins, food, or towels; cleaning telephones after use; using a tissue to cough or sneeze; disposing of used tissues appropriately; coughing or sneezing into the upper arm if tissues are not readily available; and avoiding exposure to tobacco and secondhand smoke. The nurse also instructs the patient with pharyngitis, especially streptococcal pharyngitis, to replace their toothbrush with a new one.

Chronic Pharyngitis

Chronic pharyngitis is a persistent inflammation of the pharynx. It is common in adults who work in dusty surroundings, use their voice to excess, suffer from chronic cough, or habitually use alcohol and tobacco.

There are three types of chronic pharyngitis:

- Hypertrophic—characterized by general thickening and congestion of the pharyngeal mucous membrane
- Atrophic—probably a late stage of the first type (the membrane is thin, whitish, glistening, and at times wrinkled)
- Chronic granular—characterized by numerous swollen lymph follicles on the pharyngeal wall

Clinical Manifestations

Patients with chronic pharyngitis complain of a constant sense of irritation or fullness in the throat, mucus that collects in the throat and can be expelled by coughing, and difficulty swallowing. This is often associated with intermittent postnasal drip that causes minor irritation and inflammation of the pharynx. A sore throat that is worse with swallowing in the absence of pharyngitis suggests the possibility of thyroiditis, and patients with this symptom are referred for the evaluation of possible thyroiditis.

Medical Management

Treatment of chronic pharyngitis is based on relieving symptoms; avoiding exposure to irritants; and correcting any upper respiratory, pulmonary, gastrointestinal, or cardiac condition that might be responsible for a chronic cough.

Nasal congestion may be relieved by short-term use of nasal sprays or medications containing ephedrine sulfate or phenylephrine. For a patient with a history of allergy, one of the antihistamine decongestant medications, such as pseudoephedrine or brompheniramine/pseudoephedrine, is prescribed orally every 4 to 6 hours. Aspirin (for patients older than 20 years) or acetaminophen is recommended for its analgesic properties.

For adults with chronic pharyngitis, tonsillectomy may be offered as an option, although its effectiveness in reaping long-term improvement in symptoms has not been established (Burton, Glasziou, Chong, et al., 2014). For further information, see the Tonsillitis and Adenoiditis section.

Nursing Management

Educating Patients About Self-Care

The nurse recommends avoidance of alcohol, tobacco, ENDS use, secondhand smoke, and exposure to cold or to environmental or occupational pollutants. The patient may minimize exposure to pollutants by wearing a disposable facemask, preferably an N95 mask, which can filter out 95% of small particles, including dusts and molds (National Institute for Occupational Safety and Health, 2018). The nurse encourages the patient to drink plenty of fluids. Gargling with warm saline solution may relieve throat discomfort. Lozenges keep the throat moistened (Stead, 2017).

Tonsillitis and Adenoiditis

The tonsils are composed of lymphatic tissue and are situated on each side of the oropharynx. The faucial or palatine tonsils and lingual tonsils are located behind the pillars of fauces and tongue, respectively. They frequently serve as the site of infection (**tonsillitis**). Acute tonsillitis can be confused with pharyngitis. Chronic tonsillitis is less common and may be mistaken for other disorders such as allergy, asthma, and rhinosinusitis.

The adenoids or pharyngeal tonsils consist of lymphatic tissue near the center of the posterior wall of the nasopharynx. Infection of the adenoids frequently accompanies acute tonsillitis. Frequently occurring bacterial pathogens include GABHS, the most common organism. The most common viral pathogen is Epstein–Barr virus, although cytomegalovirus may also cause tonsillitis and adenoiditis. Often thought of as a childhood disorder, tonsillitis can occur in adults.

Clinical Manifestations

The symptoms of tonsillitis include sore throat, fever, snoring, and difficulty swallowing. Enlarged adenoids may cause mouth breathing, earache, draining ears, frequent head colds, bronchitis, foul-smelling breath, voice impairment, and noisy respiration. Unusually enlarged adenoids fill the space behind the posterior nares, making it difficult for the air to travel from the nose to the throat and resulting in nasal obstruction. Infection can extend to the middle ears by way of the auditory (eustachian) tubes and may result in acute otitis media, which can lead to spontaneous rupture of the tympanic membranes (eardrums) and further extension of the infection into the mastoid cells, causing acute mastoiditis. The infection also may reside in the middle ear as a chronic, low-grade, smoldering process that eventually may cause permanent deafness.

Assessment and Diagnostic Findings

The diagnosis of acute tonsillitis is primarily clinical, with attention given to whether the illness is viral or bacterial in nature. As in acute pharyngitis, RADT is quick and convenient; however, it is less sensitive than the throat swab culture.

A thorough physical examination is performed and a careful history is obtained to rule out related or systemic conditions. The tonsillar site is cultured to determine the presence of bacterial infection. When cytomegalovirus infection is present, the differential diagnosis should include HIV, hepatitis A, and rubella. In adenoiditis, if recurrent episodes of suppurative otitis media result in hearing loss, comprehensive audiometric assessment is warranted (see Chapter 59).

Medical Management

Tonsillitis is treated with supportive measures that include increased fluid intake, antispasmodic agents, salt-water gargles, and rest. Bacterial infections are treated with penicillin (first-line therapy) or cephalosporins. Viral tonsillitis is not effectively treated with antibiotic therapy.

Tonsillectomy (with or without adenoidectomy) continues to be a commonly performed surgical procedure and remains the treatment of choice for patients with chronic tonsillitis (Shah, 2018). Adults who have undergone a tonsillectomy to treat recurrent streptococcal infections experience a decrease in the number of episodes of streptococcal or other throat infections or days with throat pain (Busaba & Doron, 2018).

Tonsillectomy is indicated if the patient has had repeated episodes of tonsillitis despite antibiotic therapy; hypertrophy of the tonsils and adenoids that could cause obstruction and obstructive sleep apnea (OSA); repeated attacks of purulent otitis media; and suspected hearing loss due to serous otitis media that has occurred in association with enlarged tonsils and adenoids. Indications for adenoidectomy include chronic nasal airway obstruction, chronic rhinorrhea, obstruction of the auditory tube with related ear infections, and abnormal speech. Surgery is also indicated if the patient has developed a peritonsillar abscess that occludes the pharynx, making swallowing difficult and endangering the patency of the airway (particularly during sleep). The presence of persistent tonsillar asymmetry should prompt an excisional biopsy to rule out lymphoma (Papadakis et al., 2018). Antibiotic therapy may be initiated for patients undergoing tonsillectomy or adenoidectomy. Therapy may include oral penicillin or a cephalosporin (e.g., cefdinir or moxifloxacin).

Nursing Management

Providing Postoperative Care

Continuous nursing observation is required in the immediate postoperative and recovery periods because of the risk of hemorrhage, which may also compromise the patient's airway (Drake & Carr, 2017). In the immediate postoperative period, the most comfortable position is prone, with the patient's head turned to the side to allow drainage from the mouth and pharynx. The nurse must not remove the oral airway until the patient's gag and swallowing reflexes have returned. The nurse applies an ice collar to the neck, and a basin and tissues are provided for the expectoration of blood and mucus.

Symptoms of postoperative complications include fever, throat pain, ear pain, and bleeding. Pain can be effectively controlled with analgesic medications. Postoperative bleeding may be seen as bright red blood if the patient expectorates it before swallowing it. If the patient swallows the blood, it becomes brown because of the action of the acidic gastric juice. If the patient

vomits large amounts of dark blood or bright-red blood at frequent intervals, or if the pulse rate and temperature rise and the patient is restless, the nurse notifies the surgeon immediately. The nurse should have the following items ready for the examination of the surgical site for bleeding: a light, a mirror, gauze, curved hemostats, and a waste basin.

Occasionally, suture or ligation of a bleeding vessel is required. In such cases, the patient is taken to the operating room and given general anesthesia. After ligation, continuous nursing observation and postoperative care are required, as in the initial postoperative period. If there is no bleeding, water and ice chips may be given to the patient as soon as desired. The patient is instructed to refrain from too much talking and coughing, because these activities can produce throat pain (see Chapter 16 for further discussion of postoperative nursing care).

Educating Patients About Self-Care

Tonsillectomy and adenoidectomy are usually performed as outpatient surgery, and the patient is sent home from the recovery room once awake, oriented, and able to drink liquids and void. The patient and family must understand the signs and symptoms of hemorrhage. Bleeding may occur up to 8 days after surgery. The nurse instructs the patient about the use of liquid acetaminophen with or without codeine for pain control and explains that the pain will subside during the first 3 to 5 days. The nurse informs the patient about the need to take the full course of any prescribed antibiotic for the first postoperative week (Drake & Carr, 2017).

Alkaline mouthwashes and warm saline solutions are useful in coping with the thick mucus and halitosis that may be present after surgery. The nurse should explain to the patient that a sore throat, stiff neck, minor ear pain, and vomiting may occur in the first 24 hours. The patient should eat an adequate diet with soft foods, which are more easily swallowed than hard foods. The patient should avoid spicy, hot, acidic, or rough foods. Milk and milk products (ice cream and yogurt) may be restricted because they make removal of mucus more difficult for some patients. The nurse instructs the patient about the need to maintain good hydration. The patient is advised to avoid vigorous toothbrushing or gargling because these activities can cause bleeding. The nurse encourages the use of a cool-mist vaporizer or humidifier in the home postoperatively. The patient should avoid smoking and heavy lifting or exertion for 10 days.

Peritonsillar Abscess

Peritonsillar abscess (also called *quinsy*) is the most common major suppurative complication of sore throat accounting for roughly 30% of soft tissue head and neck abscesses. It most commonly afflicts adults between the ages of 20 and 40 years, with the incidence roughly the same between men and women (Flores, 2018). This collection of purulent exudate between the tonsillar capsule and the surrounding tissues, including the soft palate, may develop after an acute tonsillar infection that progresses to a local cellulitis and abscess. Several bacteria are typically implicated in the pathogenesis of these abscesses, including *S. pyogenes, S. aureus, Neisseria* species, and *Corynebacterium* species (Flores, 2018; Shah, 2018). In more severe cases, the infection can spread over the palate and to the neck and chest. Edema can cause airway obstruction, which can be life-threatening and is a medical emergency. Peritonsillar abscess can be life-threatening with mediastinitis, intracranial abscess, and empyemas resulting from spread of infection. Early detection and aggressive management are essential (Flores, 2018).

Clinical Manifestations

The patient with a peritonsillar abscess is acutely ill with a severe sore throat, fever, trismus (inability to open the mouth), and drooling. Inflammation of the medial pterygoid muscle that lies lateral to the tonsil results in spasm, severe pain, and difficulty in opening the mouth fully. The pain may be so intense that the patient has difficulty swallowing saliva. The patient's breath often smells rancid. Other symptoms include a raspy voice, odynophagia (a severe sensation of burning, squeezing pain while swallowing), **dysphagia** (difficulty swallowing), and otalgia (pain in the ear). Odynophagia is caused by the inflammation of the superior constrictor muscle of the pharynx that forms the lateral wall of the tonsil. This causes pain on lateral movement of the head. The patient may also have tender and enlarged cervical lymph nodes. Examination of the oropharynx reveals erythema of the anterior pillar and soft palate as well as a purulent tonsil on the side of the peritonsillar abscess. The tonsil is pushed inferomedially, and the uvula is shifted contralaterally (Flores, 2018).

Assessment and Diagnostic Findings

Emergency department (ED) physicians frequently are the providers who diagnose patients with peritonsillar abscesses. When this occurs in the ED setting, the ED physician decides whether aspiration—an invasive procedure—should be carried out based on the patient's clinical picture. Intraoral ultrasound and transcutaneous cervical ultrasound are used in the diagnosis of peritonsillar cellulitis and abscesses (Gosselin, 2018).

Medical Management

Antimicrobial agents and corticosteroid therapy are used for the treatment of peritonsillar abscess. Antibiotics (usually penicillin) are extremely effective in controlling the infection, and if they are prescribed early in the course of the disease, the abscess may resolve without needing to be incised. However, if the abscess does not resolve, treatment choices include needle aspiration, incision and drainage under local or general anesthesia, and drainage of the abscess with simultaneous tonsillectomy. Following needle aspiration (discussed later) intramuscular administration of clindamycin can be used in the outpatient setting, thus reducing both antibiotic and hospital costs. The use of topical anesthetic agents and throat irrigations may be prescribed to promote comfort along with administration of prescribed analgesic agents (Flores, 2018).

Patients with complications require hospitalization for IV antibiotics, imaging studies, observation, and proper airway management. Rarely, the patient with a peritonsillar abscess presents with acute airway obstruction and requires immediate airway management. Procedures may include intubation, cricothyroidotomy, or tracheotomy (Flores, 2018).

Surgical Management

Needle aspiration may be preferred over a more extensive procedure due to its high efficacy, low cost, and patient tolerance. The mucous membrane over the swelling is first sprayed with a topical anesthetic and then injected with a local anesthetic. Single or repeated needle aspirations are performed to decompress the abscess. Alternatively, the abscess may be incised and drained (Flores, 2018). These procedures are performed best with the patient in the sitting position to make it easier to expectorate the pus and blood that accumulate in the pharynx. The patient experiences almost immediate relief. Incision and drainage is also an effective option but is more painful than needle aspiration.

Tonsillectomy is considered for patients who are poor candidates for needle aspiration or incision and drainage (Flores, 2018).

Nursing Management

If the patient requires intubation, cricothyroidotomy, or tracheotomy to treat airway obstruction, the nurse assists with the procedure and provides support to the patient before, during, and after the procedure. The nurse also assists with the needle aspiration when indicated.

The nurse encourages the patient to use prescribed topical anesthetic agents and assists with throat irrigations or the frequent use of mouthwashes or gargles, using saline or alkaline solutions at a temperature of 40.6° to 43.3°C (105° to 110°F). Gentle gargling after the procedure with a cool normal saline gargle may relieve discomfort. The patient must be upright and clearly

expectorate forward. The nurse instructs the patient to gargle *gently* at intervals of 1 or 2 hours for 24 to 36 hours. Liquids that are cool or at room temperature are usually well tolerated. Adequate fluids must be provided to treat dehydration and prevent its recurrence.

The nurse also observes the patient for complications and instructs the patient about signs and symptoms of complications that require prompt attention by the patient's primary provider. At discharge, the nurse provides verbal and written instructions regarding foods to avoid, when to return to work, and the need to refrain from or cease smoking. The need for continuation of good oral hygiene is also reinforced.

Laryngitis

Laryngitis, an inflammation of the larynx, can occur as a result of voice abuse, exposure to dust, chemicals, smoke and other pollutants; or as part of a URI. It also may be caused by isolated infection involving only the vocal cords. Laryngitis can also be associated with gastroesophageal reflux (referred to as reflux laryngitis).

Laryngitis is very often caused by the pathogens that cause the common cold and pharyngitis; the most common cause is a virus, and laryngitis is often associated with allergic rhinitis or pharyngitis. Bacterial invasion may be secondary. The onset of infection may be associated with exposure to sudden temperature changes, dietary deficiencies, malnutrition, or an immunosuppressed state. Viral laryngitis is common in the winter and is easily transmitted to others.

Clinical Manifestations

Signs of acute laryngitis include hoarseness or **aphonia** (loss of voice) and severe cough. Chronic laryngitis is marked by persistent hoarseness. Other signs of acute laryngitis include sudden onset made worse by cold dry wind. The throat feels worse in the morning and improves when the patient is indoors in a warmer climate. At times, the patient presents with a dry cough and a dry, sore throat that worsens in the evening hours. If allergies are present, the uvula will be visibly edematous. Many patients also complain of a "tickle" in the throat that is made worse by cold air or cold liquids.

Medical Management

Management of acute laryngitis includes resting the voice, avoiding irritants (including smoking), resting, and inhaling cool steam or an aerosol. If the laryngitis is part of a more extensive respiratory infection caused by a bacterial

organism or if it is severe, appropriate antibacterial therapy is instituted. The majority of patients recover with conservative treatment; however, laryngitis tends to be more severe in older adult patients and may be complicated by pneumonia.

For chronic laryngitis, the treatment includes resting the voice, eliminating any primary respiratory tract infection, eliminating smoking, and avoiding secondhand smoke. Corticosteroids, such as beclomethasone, may be given. These preparations have few systemic or long-lasting effects and may reduce local inflammatory reactions. Treatment of reflux laryngitis typically involves use of proton pump inhibitors such as omeprazole given once daily.

Nursing Management

The nurse instructs the patient to rest the voice and to maintain a well-humidified environment. If laryngeal secretions are present during acute episodes, expectorant agents are suggested, along with a daily fluid intake of 2 to 3 L to thin secretions. The nurse instructs the patient about the importance of taking prescribed medications, including proton pump inhibitors, and using continuous positive airway therapy at bedtime, if prescribed for OSA. In cases involving infection, the nurse informs the patient that the symptoms of laryngitis often extend a week to 10 days after completion of antibiotic therapy. The nurse instructs the patient about signs and symptoms that require contacting the primary provider. These signs and symptoms include loss of voice with sore throat that makes swallowing saliva difficult, hemoptysis, and noisy respirations. Continued hoarseness after voice rest or laryngitis that persists for longer than 5 days must be reported because of the possibility of malignancy.

NURSING PROCESS

The Patient with Upper Airway Infection

Assessment

A health history may reveal signs and symptoms of headache, sore throat, pain around the eyes and on either side of the nose, difficulty in swallowing, cough, hoarseness, fever, stuffiness, and generalized discomfort and fatigue. Determining when the symptoms began, what precipitated them, what if anything relieves them, and what aggravates them is part of the assessment. The nurse should also determine any history of allergy or the existence of a concomitant illness. Inspection may reveal swelling, lesions, or asymmetry of the nose as well as bleeding or discharge. The nurse inspects the nasal mucosa for abnormal findings such as increased redness, swelling, exudate, and nasal polyps, which may develop in chronic rhinitis. The mucosa of the nasal turbinates may also be swollen (boggy) and pale bluish-gray. The nurse palpates the frontal and maxillary sinuses for tenderness, which suggests inflammation and then inspects the throat by having the patient open the mouth wide and take a deep breath. Redness, asymmetry, or evidence of drainage, ulceration, or enlargement of the tonsils and pharynx is abnormal. Palpation of the neck lymph nodes for enlargement and tenderness is necessary.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, nursing diagnoses may include the following:

- Impaired airway clearance associated with excessive mucus production secondary to retained secretions and inflammation
- Acute pain associated with upper airway irritation secondary to an infection
- Impaired verbal communication associated with physiologic changes and upper airway irritation secondary to infection or swelling
- Hypovolaemia associated with decreased fluid intake and increased fluid loss secondary to diaphoresis associated with a fever
- Lack of knowledge regarding prevention of URIs, treatment regimen, surgical procedure, or postoperative self-care

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications include:

- Sepsis
- Meningitis or brain abscess
- Peritonsillar abscess, otitis media, or rhinosinusitis

Planning and Goals

The major goals for the patient may include maintenance of a patent airway, relief of pain, maintenance of effective means of communication, normal hydration, knowledge of how to prevent upper airway infections, and absence of complications.

Nursing Interventions

Maintaining a Patent Airway

An accumulation of secretions can block the airway in patients with an upper airway infection. As a result, changes in the respiratory pattern occur and the work of breathing increases to compensate for the blockage. The nurse can implement several measures to loosen thick secretions or to keep the secretions moist so that they can be easily expectorated. Increasing fluid intake helps thin the mucus. The use of room vaporizers or steam inhalation also loosens secretions and reduces inflammation of the mucous membranes. To enhance drainage from the sinuses, the nurse instructs the patient about positioning; this depends on the location of the infection or inflammation. For example, drainage for rhinosinusitis or rhinitis is achieved in the upright position. In some conditions, topical or systemic medications, when prescribed, help relieve nasal or throat congestion.

Promoting Comfort

URIs usually produce localized discomfort. In rhinosinusitis, pain may occur in the area of the sinuses, or a general headache may be produced. In pharyngitis, laryngitis, or tonsillitis, a sore throat occurs. The nurse encourages the patient to take antispasmodic agents, such as acetaminophen with codeine, as prescribed, to relieve this discomfort. A pain intensity rating scale (see Chapter 9) may be used to assess effectiveness of pain relief measures. Other helpful measures include topical anesthetic agents for symptomatic relief of herpes simplex blisters (see Chart 18-3) and sore throats, hot packs to relieve the congestion of rhinosinusitis and promote drainage, and warm water gargles or irrigations to relieve the pain of a sore throat. The nurse encourages rest to relieve the generalized discomfort and fever that accompany many upper airway conditions (especially rhinitis, pharyngitis, and laryngitis). For postoperative care after tonsillectomy and adenoidectomy, an ice collar may reduce swelling and decrease bleeding.

Promoting Communication

Upper airway infections may result in hoarseness or loss of speech. The nurse instructs the patient to refrain from speaking as much as possible and, if possible, to communicate in writing instead. Additional strain on the vocal cords may delay full return of the voice. The nurse encourages the patient and family to use alternative forms of communication, such as a

memo pad, bell, or a smartphone or other electronic devices to signal for assistance.

Encouraging Fluid Intake

Upper airway infections lead to fluid loss. Sore throat, malaise, and fever may interfere with a patient's willingness to eat and drink. The nurse provides a list of easily ingested foods to increase caloric intake during the acute phase of illness. These include soups, gelatin, pudding, yogurt, cottage cheese, high-protein drinks, water, ice, and ice pops. The nurse encourages the patient to drink 2 to 3 L of fluid per day during the acute stage of airway infection, unless contraindicated, to thin the secretions and promote drainage. Liquids (hot or cold) may be soothing, depending on the disorder.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Prevention of most upper airway infections is challenging because of the many potential causes. But because most URIs are transmitted by hand-to-hand contact, the nurse educates the patient and family about techniques to minimize the spread of infection to others, including implementing hand hygiene measures. The nurse advises the patient to avoid exposure to people who are at the risk for serious illness if respiratory infection is transmitted (older adults, people who are immunosuppressed, and those with chronic health problems).

The nurse instructs patients and their families about strategies to relieve symptoms of URIs and reinforces the need to complete the treatment regimen, particularly when antibiotics are prescribed.

Continuing and Transitional Care. Referral for home, community-based, or transitional care is rare. However, it may be indicated for people whose health status was compromised before the onset of the respiratory infection and for those who cannot manage self-care without assistance. In such circumstances, the home health nurse assesses the patient's respiratory status and progress in recovery. The nurse may advise older adult patients and those at increased risk from a respiratory infection to consider annual influenza and pneumococcal vaccination. A follow-up appointment with the primary provider may be indicated for patients with compromised health status to ensure that the respiratory infection has resolved.

Monitoring and Managing Potential Complications

Although major complications of URIs are rare, the nurse must be aware of them and assess the patient for them. Because most patients with URIs are managed at home, patients and their families must be instructed to monitor for signs and symptoms and to seek immediate medical care if the patient's condition does not improve or if the patient's physical status appears to be worsening.

Sepsis or meningitis may occur in patients with compromised immune status or in those with an acute bacterial infection. The patient and caregiver are instructed to seek medical care if the patient's condition fails to improve within several days after the onset of symptoms, if unusual symptoms develop, or if the patient's condition deteriorates. They are instructed about signs and symptoms that require further attention: persistent or high fever, increasing shortness of breath, confusion, and increasing weakness and malaise. The patient with sepsis requires expert care to treat the infection, stabilize vital signs, and prevent or treat septic shock (see Chapter 11). Deterioration of the patient's condition necessitates intensive care measures (e.g., hemodynamic monitoring and administration of vasoactive medications, IV fluids, nutritional support, and corticosteroids) to monitor the patient's status and to support the patient's vital signs. High doses of antibiotics may be given to treat the causative organism. The nurse's role is to monitor the patient's vital signs, hemodynamic status, and laboratory values; administer needed treatment; alleviate the patient's physical discomfort; and provide explanations, education, and emotional support to the patient and family.

Peritonsillar abscess may develop after an acute infection of the tonsils. The patient requires treatment to drain the abscess and receives antibiotics for infection and topical anesthetic agents and throat irrigations to relieve pain and sore throat. Follow-up is necessary to ensure that the abscess resolves; tonsillectomy may be required. The nurse assists the patient in administering throat irrigations and instructs the patient and family about the importance of adhering to the prescribed treatment regimen and recommended follow-up appointments.

In some severe situations, peritonsillar abscess may progress to meningitis or brain abscess. The nurse assesses for changes in mental status ranging from subtle personality changes through drowsiness to coma, nuchal rigidity, and focal neurologic signs that signal increasing cerebral edema around the abscess (see Chapter 64). Seizures, typically tonic–clonic, occur in this setting. Intensive care measures are necessary. High doses of antibiotics may be used to treat the causative organism. The nurse's role is similar to caring for the patient with sepsis in an intensive care setting. The nurse monitors the patient's neurologic status and reports changes immediately.

Otitis media and rhinosinusitis may develop with URI. The patient and family are instructed about the signs and symptoms of otitis media and rhinosinusitis and about the importance of follow-up with the primary provider to ensure adequate evaluation and treatment of these conditions.

Evaluation

Expected patient outcomes may include the following:

1. Maintains a patent airway by managing secretions
   a. Reports decreased congestion
   b. Assumes best position to facilitate drainage of secretions
   c. Uses self-care measures appropriately and consistently to manage secretions during the acute phase of illness
2. Reports relief of pain and discomfort using pain intensity scale
   a. Uses comfort measures: antispasmodic agents, hot packs, gargles, rest
   b. Demonstrates adequate oral hygiene
3. Demonstrates ability to communicate needs, wants, level of comfort
4. Maintains adequate fluid and nutrition intake
5. Utilizes strategies to prevent upper airway infections and allergic reactions
   a. Demonstrates hand hygiene technique
   b. Identifies the value of the influenza vaccine
6. Demonstrates an adequate level of knowledge and performs self-care adequately
7. Becomes free of signs and symptoms of infection
   a. Exhibits normal vital signs (temperature, pulse, respiratory rate)
   b. Absence of purulent drainage
   c. Free of pain in ears, sinuses, and throat
   d. Absence of signs of inflammation
8. Absence of complications
   a. No signs of sepsis: fever, hypotension, deterioration of cognitive status
   b. Vital signs and hemodynamic status normal
   c. No evidence of neurologic involvement
   d. No signs of development of peritonsillar abscess
   e. Resolution of URI without development of otitis media or rhinosinusitis
   f. No signs and symptoms of brain abscess

OBSTRUCTION AND TRAUMA OF THE UPPER RESPIRATORY AIRWAY

Obstructive Sleep Apnea

OSA is a disorder characterized by recurrent episodes of upper airway obstruction and a reduction in ventilation. It is defined as **apnea** (cessation of breathing) during sleep usually caused by repetitive upper airway obstruction. The estimated prevalence of OSA is approximately 26% of adults between the ages of 30 and 70 years (Wickramasinghe, 2019). It is believed that between 4% and 9% of women and 9% and 24% of men in the United States have OSA, and that up to 90% are not diagnosed; these increased rates have been linked to the increase in rates of obesity (Wickramasinghe, 2019) (see Chapter 42). OSA interferes with people's ability to obtain adequate rest, thus affecting memory, learning, and decision making.

Risk factors for OSA include obesity, male gender, postmenopausal status in women, and advanced age. The major risk factor is obesity; a larger neck circumference and increased amounts of peripharyngeal fat narrow and compress the upper airway. Because OSA is often found in patients with hypertension, all adult patients with hypertension should be screened for OSA (Showalter & O'Keefe, 2019). Other associated factors include alterations in the upper airway, such as structural changes (e.g., tonsillar hypertrophy, abnormal posterior positioning of one or both jaws, and variations in craniofacial structures) that contribute to the collapsibility of the upper airway (Wickramasinghe, 2019).

Pathophysiology

The pharynx is a collapsible tube that can be compressed by the soft tissues and structures surrounding it. The tone of the muscles of the upper airway is reduced during sleep. Mechanical factors such as reduced diameter of the upper airway or dynamic changes in the upper airway during sleep may result in obstruction. These sleep-related changes may predispose to upper airway collapse when small amounts of negative pressure are generated during inspiration.

Repetitive apneic events result in hypoxia (decreased oxygen saturation) and hypercapnia (increased concentration of carbon dioxide), which triggers a sympathetic response. As a consequence, patients with OSA have a high prevalence of hypertension. In addition, OSA is associated with an increased risk of myocardial infarction and stroke, which may be mitigated with appropriate treatment (Wickramasinghe, 2019).

Clinical Manifestations

OSA is characterized by frequent and loud snoring with breathing cessation for 10 seconds or longer, for at least five episodes per hour, followed by awakening abruptly with a loud snort as the blood oxygen level drops. Patients

with sleep apnea may have anywhere from five apneic episodes per hour to several hundred per night.

Classic signs and symptoms of OSA include the "3 S's"—namely, *s*noring, *s*leepiness, and *s*ignificant-other report of sleep apnea episodes. Common signs and symptoms of OSA are presented in Chart 18-4. Symptoms typically progress with increases in weight and aging (Wickramasinghe, 2019). Patients are typically unaware of nocturnal upper airway obstruction during sleep. They frequently complain of insomnia, including difficulty in going to sleep, nighttime awakenings, and early morning awakenings with an inability to go back to sleep, as well as chronic fatigue and hypersomnolence (daytime sleepiness). When obtaining the health history, the nurse asks the patient about sleeping during normal activities such as eating or talking. Patients with this symptom are considered to have pathologic hypersomnolence (Wickramasinghe, 2019).

Chart 18-4 ASSESSMENT

Assessing for Obstructive Sleep Apnea

Be alert for the following signs and symptoms of obstructive sleep apnea:

- Excessive daytime sleepiness
- Frequent nocturnal awakening
- Insomnia
- Loud snoring
- Morning headaches
- Intellectual deterioration
- Personality changes, irritability
- Impotence
- Systemic hypertension
- Arrhythmias
- Pulmonary hypertension, cor pulmonale
- Polycythemia
- Enuresis

Adapted from Wickramasinghe, H. (2019). Obstructive sleep apnea. Retrieved on 5/27/2019 at: www.emedicine.medscape.com/article/295807-overview

Assessment and Diagnostic Findings

The diagnosis of sleep apnea is based on clinical features plus a polysomnographic finding (i.e., sleep study), which is the definitive test for OSA. The test is an overnight study, performed in a specialized sleep disorders

center, which continuously measures multiple physiologic signals while the patient sleeps. These signals are analyzed as they are related to stages of sleep; measures include those taken by electroencephalogram (EEG), electro-oculogram, and chin electromyogram (EMG). In addition, cardiac rhythms and arrhythmias are monitored with a single-lead electrocardiogram (ECG) and leg movements are recorded by an anterior tibialis EMG. Airflow at the nose and mouth is monitored using both a thermal sensor and a nasal pressure transducer, breathing effort is monitored using inductance plethysmography, and hemoglobin oxygen saturation is monitored by oximetry. The breathing pattern is analyzed for the presence of apneas and hypopneas. Characteristic findings consistent with OSA include apneic episodes occurring in the presence of respiratory muscle effort, clinically significant apneic episodes lasting 10 seconds or longer, and apneic episodes most prevalent during the rapid eye movement (REM) stage of sleep. Sleep disruption from automated patient arousal is usually seen at the termination of an episode of apnea (Wickramasinghe, 2019).

Medical Management

Patients usually seek medical treatment because their sleeping partners express concern or because they experience excessive sleepiness at inappropriate times or settings (e.g., while driving a car). A variety of treatments are used. Weight loss, avoidance of alcohol, positional therapy (using devices that prevent patients from sleeping on their backs), and oral appliances such as mandibular advancement devices (MADs) are the first steps (American Sleep Apnea Association, 2019; Joshi, 2018). When applied correctly, an MAD advances the mandible so that it is slightly anterior to the upper front teeth, preventing airway obstruction by the tongue and soft tissue during sleep. A randomized controlled trial that compared the effectiveness of these devices among patients with OSA with the more conventional therapy, continuous positive airway pressure (CPAP), found no difference in short-term outcomes between MAD and CPAP, including daytime sleepiness and quality of life, suggesting that MAD is as effective a treatment as CPAP in patients with mild-to-moderate OSA (Petri, Christensen, Svanholt, et al., 2019; Viscuso & Arena, 2016). In more severe cases involving hypoxemia and severe hypercapnia, the treatment includes CPAP or bilevel positive airway pressure (BiPAP) therapy with supplemental oxygen via nasal cannula. CPAP is used to prevent airway collapse, whereas BiPAP makes breathing easier and results in a lower average airway pressure (Patil, Ayappa, Caples, et al., 2019; the use of CPAP and BiPAP is discussed in more detail in Chapter 19).

Surgical Management

Surgical procedures also may be performed to correct OSA. Simple tonsillectomy may be effective for patients with larger tonsils when deemed clinically necessary, or when other options have failed or are refused by patients (Morgan, 2017). Uvulopalatopharyngoplasty is the resection of pharyngeal soft tissue and removal of approximately 15 mm of the free edge of the soft palate and uvula. Effective in about 50% of patients, it is more effective in eliminating snoring than apnea. Nasal septoplasty may be performed for gross anatomic nasal septal deformities. Maxillomandibular surgery may be performed to advance the maxilla and mandible forward in order to enlarge the posterior pharyngeal region (Morgan, 2017). Tracheostomy relieves upper airway obstruction but has numerous adverse effects, including speech difficulties and increased risk of infections. These procedures, as well as other maxillofacial surgeries, are reserved for patients with concomitant cardiovascular disease and life-threatening arrhythmias or severe disability who have not responded to conventional therapy (Papadakis et al., 2018).

Pharmacologic Therapy

Some medications are useful in managing symptoms associated with OSA. Modafinil is approved by the U.S. Food and Drug Administration (FDA) for use in patients who have residual daytime sleepiness despite optimal use of CPAP. The most improvement has been seen in patients who have taken modafinil at daily doses of 200 to 400 mg. Armodafinil is also now approved by the FDA for use in these patients. It is more potent than modafinil because it is pure R-modafinil, which is the most psychoactive compound of modafinil (Wickramasinghe, 2019). Protriptyline given at bedtime may increase the respiratory drive and improve upper airway muscle tone. Medroxyprogesterone acetate and acetazolamide might be prescribed for sleep apnea associated with chronic alveolar hypoventilation; however, their benefits have not been well established. The patient must understand that these medications are not a substitute for CPAP, BiPAP, or MAD. Administration of low-flow nasal oxygen at night can help relieve hypoxemia in some patients but has little effect on the frequency or severity of apnea.

Nursing Management

The patient with OSA may not recognize the potential consequences of the disorder. Therefore, the nurse explains the disorder in terms that are understandable to the patient and relates symptoms (daytime sleepiness) to the underlying disorder. The nurse also instructs the patient and family about treatments, including the correct and safe use of CPAP, BiPAP, MAD, and oxygen therapy, if prescribed. The nurse educates the patient about the risk of untreated OSA and the benefits of treatment approaches.

Epistaxis

Epistaxis, a hemorrhage from the nose, is caused by the rupture of tiny, distended vessels in the mucous membrane of any area of the nose. Rarely does epistaxis originate in the densely vascular tissue over the turbinates. Most commonly, the site is the anterior septum, where three major blood vessels enter the nasal cavity: (1) the anterior ethmoidal artery on the forward part of the roof (Kiesselbach plexus), (2) the sphenopalatine artery in the posterosuperior region, and (3) the internal maxillary branches (the plexus of veins located at the back of the lateral wall under the inferior turbinate).

Several risk factors are associated with epistaxis (Chart 18-5).

Medical Management

Management of epistaxis depends on its cause and the location of the bleeding site. A nasal speculum, penlight, or headlight may be used to identify the site of bleeding in the nasal cavity. Most nosebleeds originate from the anterior portion of the nose. Initial treatment may include applying direct pressure. The patient sits upright with the head tilted forward to prevent swallowing and aspiration of blood and is directed to pinch the soft outer portion of the nose against the midline septum for 5 or 10 minutes continuously. Application of nasal decongestants (phenylephrine, one or two sprays) to act as vasoconstrictors may be necessary. If these measures are unsuccessful in stopping the bleeding, the nose must be examined using good illumination and suction to determine the site of bleeding. Visible bleeding sites may be cauterized with silver nitrate or electrocautery (high-frequency electrical current). A supplemental patch of Surgicel or Gelfoam may be used (Papadakis et al., 2018).

Chart 18-5 RISK FACTORS

Epistaxis

- Local infections (vestibulitis, rhinitis, rhinosinusitis)
- Systemic infections (scarlet fever, malaria)
- Drying of nasal mucous membranes
- Nasal inhalation of corticosteroids (e.g., beclomethasone) or illicit drugs (e.g., cocaine)
- Trauma (digital trauma, blunt trauma, fracture, forceful nose blowing)
- Arteriosclerosis
- Hypertension
- Tumor (sinus or nasopharynx)
- Thrombocytopenia
- Use of aspirin
- Liver disease
- Rendu–Osler–Weber syndrome (hereditary hemorrhagic telangiectasia)

Adapted from Nguyen, Q. A. (2018). Epistaxis. Retrieved on 5/27/2019 at: www.emedicine.medscape.com/article/863220-overview

Alternatively, a cotton tampon may be used to try to stop the bleeding. Suction may be used to remove excess blood and clots from the field of inspection. The search for the bleeding site should shift from the anteroinferior quadrant to the anterosuperior, then to the posterosuperior, and finally to the posteroinferior area. The field is kept clear by using suction and by shifting the cotton tampon.

If the origin of the bleeding cannot be identified, the nose may be packed with gauze impregnated with petrolatum jelly or antibiotic ointment; a topical anesthetic spray and decongestant agent may be used before the gauze packing is inserted, or a balloon-inflated catheter may be used (Fig. 18-3). Alternatively, a compressed nasal sponge may be used. Once the sponge becomes saturated with blood or is moistened with a small amount of saline, it will expand and produce tamponade to halt the bleeding. The packing may remain in place for 3 to 4 days if necessary to control bleeding (Nguyen, 2018). Antibiotics may be prescribed because of the risk of iatrogenic rhinosinusitis and sepsis.

Nursing Management

The nurse monitors the patient's vital signs, assists in the control of bleeding, and provides tissues and an emesis basin to allow the patient to expectorate any excess blood. It is common for patients to be anxious in response to a nosebleed. Blood loss on clothing and handkerchiefs can be frightening, and the nasal examination and treatment are uncomfortable. Assuring the patient in

a calm, efficient manner that bleeding can be controlled can help reduce anxiety. The nurse continuously assesses the patient's airway and breathing as well as vital signs. On rare occasions, a patient with significant hemorrhage requires IV infusions of crystalloid solutions (normal saline) as well as cardiac and pulse oximetry monitoring.

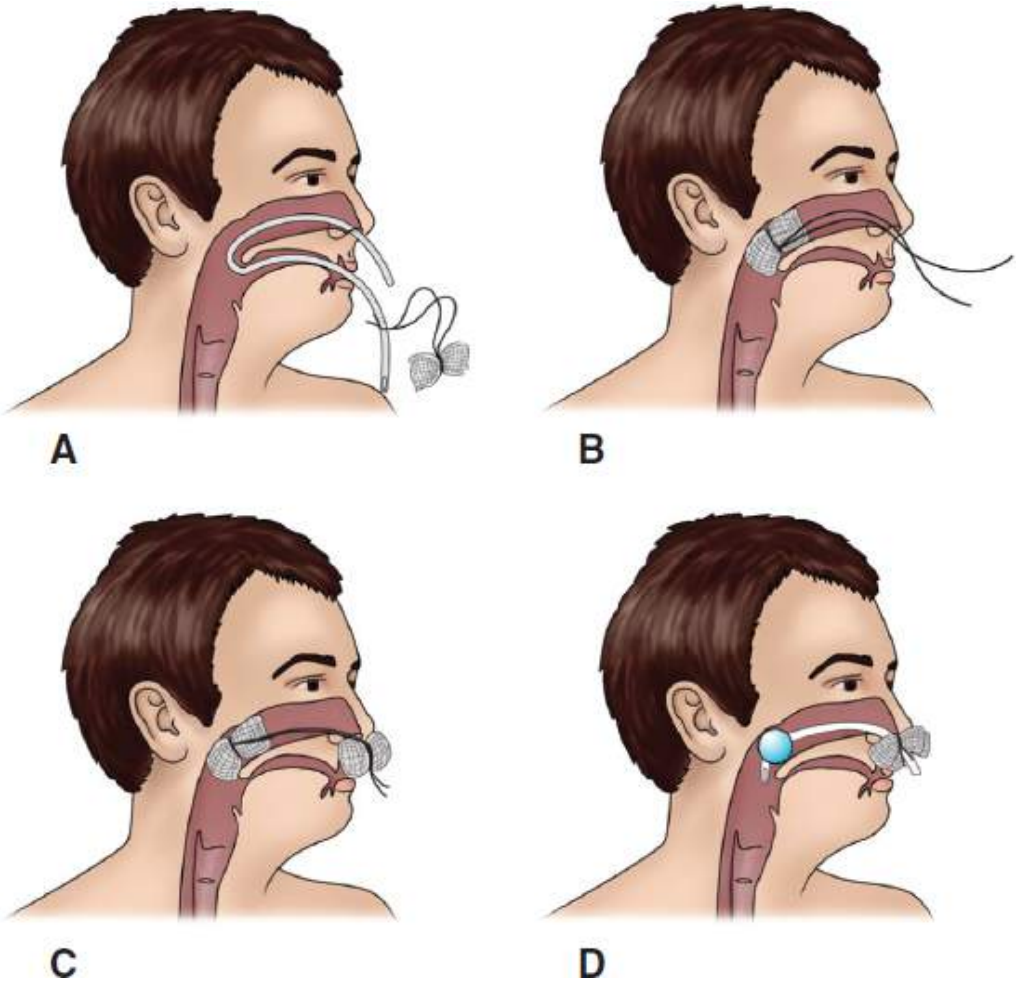

Figure 18-3 • Packing to control bleeding from the posterior nose. **A.** Catheter is inserted and packing is attached. **B.** Packing is drawn into position as the catheter is removed. **C.** Strip is tied over a bolster to hold the packing in place with an anterior pack installed "accordion pleat" style. **D.** Alternative method, using a balloon catheter instead of gauze packing.

Educating Patients About Self-Care

Once the bleeding is controlled, the nurse instructs the patient to avoid vigorous exercise for several days and to avoid hot or spicy foods, tobacco use by smoking, or ENDS use, because this may cause vasodilation and increase the risk of rebleeding. Discharge education includes reviewing ways to prevent

epistaxis: avoiding forceful nose blowing, straining, high altitudes, and nasal trauma (including nose picking). Adequate humidification may prevent drying of the nasal passages. The nurse explains how to apply direct pressure to the nose with the thumb and the index finger for 15 minutes in the case of a recurrent nosebleed. If recurrent bleeding cannot be stopped, the patient is instructed to seek additional medical attention.

Nasal Obstruction

The passage of air through the nostrils is frequently obstructed by a deviation of the nasal septum, hypertrophy of the turbinate bones, or the pressure of nasal polyps. Chronic nasal congestion forces the patient to breathe through the mouth, thus producing dryness of the oral mucosa and associated problems including persistent dry, cracked lips. Patients with chronic nasal congestion often suffer from sleep deprivation due to difficulty maintaining an adequate airway while lying flat and during sleep.

Persistent nasal obstruction also may lead to chronic infection of the nose and result in frequent episodes of nasopharyngitis. Frequently, the infection extends to the nasal sinuses. When rhinosinusitis develops and the drainage from these cavities is obstructed by deformity or swelling within the nose, pain is experienced in the region of the affected sinus.

Medical Management

The treatment of nasal obstruction requires the removal of the obstruction, followed by measures to treat whatever chronic infection exists. In many patients, an underlying allergy also requires treatment. Measures to reduce or alleviate nasal obstruction include nonsurgical as well as surgical techniques. Commonly used medications include nasal corticosteroids (see Table 18-2) as well as oral leukotriene inhibitors, such as montelukast. Treatment with nasal corticosteroids for 1 to 3 months is usually successful for the treatment of small polyps and may even reduce the need for surgical intervention. A short course of oral corticosteroids (6-day course of prednisone) may be beneficial in the treatment of nasal obstruction due to polyps (Papadakis et al., 2018). Additional medications may include antibiotics for the treatment of underlying infection or antihistamines for the management of allergies. Hypertrophied turbinates may be treated by applying an astringent agent to shrink them.

A more aggressive approach in treating nasal obstruction caused by turbinate hypertrophy involves surgical reduction of the hypertrophy. Surgical procedures used to treat obstructive nasal conditions are collectively known as functional rhinoplasty. Technical advances with newer techniques provide a number of options for reconstruction and reshaping of the nose.

Nursing Management

When a surgical procedure is indicated, most often it is performed on an outpatient basis. The nurse explains the procedure to the patient. Postoperatively, the nurse elevates the head of the bed to promote drainage and to alleviate discomfort from edema. Frequent oral hygiene is encouraged to overcome dryness caused by breathing through the mouth. Before discharge from the outpatient or same-day surgical unit, the patient is instructed to avoid blowing the nose with force during the postoperative recovery period. The patient is also instructed about the signs and symptoms of bleeding and infection and when to contact the primary provider. The patient is provided with written postoperative instructions, including emergency phone numbers.

Fractures of the Nose

The location of the nose makes it susceptible to injury. Nasal fracture is the most common facial fracture and the most common fracture in the body (Becker, 2018). Fractures of the nose usually result from a direct assault. Nasal fractures may affect the ascending process of the maxilla and the septum. The torn mucous membrane results in a nosebleed. Complications include hematoma, infection, abscess, and avascular or septic necrosis. However, as a rule, serious consequences usually do not occur.

Clinical Manifestations

The signs and symptoms of a nasal fracture are pain, bleeding from the nose externally and internally into the pharynx, swelling of the soft tissues adjacent to the nose, periorbital ecchymosis, nasal obstruction, and deformity. The patient's nose may have an asymmetric appearance that may not be obvious until the edema subsides.

Assessment and Diagnostic Findings

The nose is examined internally to rule out the possibility that the injury may be complicated by a fracture of the nasal septum and a submucosal septal hematoma. Intranasal examination is performed in all cases to rule out septal hematoma (Papadakis et al., 2018). Because of the swelling and bleeding that occur with a nasal fracture, an accurate diagnosis can be made only after the swelling subsides.

Clear fluid draining from either nostril suggests a fracture of the cribriform plate with leakage of cerebrospinal fluid. Usually, careful inspection or palpation discloses any deviations of the bone or disruptions of the nasal

cartilages. An x-ray may reveal displacement of the fractured bones and may help rule out extension of the fracture into the skull.

Medical Management

A nasal fracture very often produces bleeding from the nasal passage. As a rule, bleeding is controlled with the use of packing. Cold compresses are used to prevent or reduce edema. For the patient who has sustained enough trauma to break the nose or any facial bone, the emergency medical team must consider the possibility of a cervical spine fracture. Therefore, it is essential to ensure a patent airway and to rule out a cervical spine fracture (see Chapter 63). Uncomplicated nasal fractures may be treated initially with antibiotics, analgesic agents, and a decongestant nasal spray.

Treatment of nasal fractures is aimed at restoring nasal function and returning the appearance of the nose to baseline. The patient is referred to a specialist to evaluate the need to realign the bones. Although improved outcomes are obtained when reduction in the fracture is performed during the first 3 hours after the injury, this is often not possible because of the edema. If immediate reduction of the fracture is not possible, it is performed within 3 to 7 days. Timing is important when treating nasal fractures because further delay in treatment may result in problematic bone healing, which ultimately may require surgical intervention that includes rhinoplasty to reshape the external appearance of the nose (Becker, 2018). A septorhinoplasty is performed when the nasal septum needs to be repaired. In patients who develop a septal hematoma, the physician drains the hematoma through a small incision. A septal hematoma that is not drained can lead to permanent deformity of the nose.

Nursing Management

Immediately after the fracture, the nurse applies ice and encourages the patient to keep the head elevated. The nurse instructs the patient to apply ice packs to the nose to decrease swelling. The patient who experiences epistaxis is usually frightened and anxious and needs reassurance. The packing inserted to stop the bleeding may be uncomfortable and unpleasant, and obstruction of the nasal passages by the packing forces the patient to breathe through the mouth. This in turn causes the oral mucous membranes to become dry. Mouth rinses help to moisten the mucous membranes and to reduce the odor and taste of dried blood in the oropharynx and nasopharynx. The use of analgesic agents such as acetaminophen or NSAIDs (e.g., ibuprofen, naproxen) is encouraged. When removing the cotton pledgets, the nurse carefully inspects the mucosa for lacerations or a septal hematoma. The nurse instructs the patient to avoid sports activities for 6 weeks.

Laryngeal Obstruction

Obstruction of the larynx because of edema is a serious condition that may be fatal without swift, decisive intervention. The larynx is a stiff box that will not stretch. It contains a narrow space between the vocal cords (glottis), through which air must pass. Swelling of the laryngeal mucous membranes may close off the opening tightly, leading to life-threatening hypoxia or suffocation. Edema of the glottis occurs rarely in patients with acute laryngitis, occasionally in patients with urticaria, and more frequently in patients with severe inflammation of the throat, as in scarlet fever. It is an occasional cause of death in severe anaphylaxis (angioedema).

TABLE 18-3 Causes of Laryngeal Obstruction

Precipitating Event	Mechanism of Obstruction
History of allergies; exposure to medications, latex, foods (peanuts, tree nuts [e.g., walnuts, pecans]), bee stings	Anaphylaxis
Foreign body	Inhalation/ingestion of meat or other food items, coin, chewing gum, balloon fragments, drug packets (ingested to avoid criminal arrest)
Heavy alcohol consumption; heavy tobacco use	Obstruction from tumor
Family history of airway problems	Suggests angioedema (type I hypersensitivity reaction)
Use of angiotensin-converting enzyme inhibitor	Increased risk of angioedema of the mucous membranes
Recent throat pain or recent fever	Infectious process
History of surgery or previous tracheostomy	Possible subglottic stenosis

Adapted from Reardon, R. F., Mason, P. E., & Clinton, J. E. (2017). Basic airway management and decision-making. In J. D. Roberts (Ed.). *Roberts & Hedges' clinical procedures in emergency medicine* (7th ed.). Philadelphia, PA: Elsevier Saunders.

Hereditary angioedema is also characterized by episodes of life-threatening laryngeal edema. Laryngeal edema in people with hereditary angioedema can occur at any age, although young adults are at greatest risk (Reardon, Mason, & Clinton, 2017). Some causes of laryngeal obstruction appear in Table 18-3.

When foreign bodies are aspirated into the pharynx, the larynx, or the trachea a twofold problem occurs. First, they obstruct the air passages and cause difficulty in breathing, which may lead to asphyxia; later, they may be drawn farther down, entering the bronchi or a bronchial branch and causing symptoms of irritation, such as a croupy cough, expectoration of blood or mucus, or labored breathing.

Clinical Manifestations

The patient's clinical presentation and x-ray findings confirm the diagnosis of laryngeal obstruction. The patient may demonstrate lowered oxygen saturation; however, normal oxygen saturation should not be interpreted as a sign that the obstruction is not significant. The use of accessory muscles to maximize airflow may occur and is often manifested by retractions in the neck or abdomen during inspirations. Patients who demonstrate these symptoms are at an immediate risk of collapse, and respiratory support (i.e., mechanical ventilation or positive-pressure ventilation) is considered.

Assessment and Diagnostic Findings

A thorough history can be very useful in diagnosing and treating the patient with a laryngeal obstruction. However, emergency measures to secure the patient's airway should not be delayed to obtain a history or perform tests. If possible, the nurse obtains a history from the patient or family about heavy alcohol or tobacco consumption, ENDS use, current medications, history of airway problems, recent infections, pain or fever, dental pain or poor dentition, and any previous surgeries, radiation therapy, or trauma.

Medical Management

Medical management is based on the initial evaluation of the patient and the need to ensure a patent airway. If the airway is obstructed by a foreign body and signs of asphyxia are apparent, immediate treatment is necessary using principles from basic and advanced cardiopulmonary resuscitation (CPR). If all efforts are unsuccessful, an immediate tracheotomy is necessary (see Chapter 19 for further discussion). If the obstruction is caused by edema resulting from an allergic reaction, treatment may include immediate administration of subcutaneous epinephrine and a corticosteroid (see Chapter 33). Ice may be applied to the neck in an effort to reduce edema. Continuous pulse oximetry is essential in the patient who has experienced acute upper airway obstruction (Reardon et al., 2017).

Cancer of the Larynx

Cancer of the larynx accounts for approximately half of all head and neck cancers. The American Cancer Society (ACS, 2017) estimates that about 12,410 new cases and 3760 deaths occur annually, with a 5-year relative survival rate that ranges from 32% to 90%, depending on the location of the tumor and its stage at the time of diagnosis (ACS, 2017). Cancer of the larynx

is most common in people older than 65 years and is four times more common in men (ACS, 2017) (Chart 18-6).

Chart 18-6 RISK FACTORS

Laryngeal Cancer

Carcinogens

- Tobacco (smoke, smokeless, e-cigarettes, hookahs, secondhand smoke)
- Heavy alcohol consumption (defined as more than one drink daily)
- Combined effects of alcohol and tobacco
- Asbestos
- Paint fumes
- Wood dust
- Chemicals used in metalworking, petroleum, plastics, and textiles

Other Factors

- Nutritional deficiencies (vitamins)
- Genetic predisposition
- Age (higher incidence after 65 years of age)
- Gender (more common in men)
- Race (more prevalent in African Americans and Whites)
- Weakened immune system

Adapted from American Cancer Society (ACS). (2017). What are the risk factors for laryngeal and hypopharyngeal cancers? Retrieved on 5/27/2019 at: www.cancer.org/Cancer/LaryngealandHypopharyngealCancer/DetailedGuide/laryngeal-and-hypopharyngeal-cancer-risk-factors

Almost all malignant tumors of the larynx arise from the surface epithelium and are classified as squamous cell carcinoma. Approximately 55% of patients with laryngeal cancer present with involved lymph nodes at the time of diagnosis, with bilateral lesions present in 16% of patients (De Vita, Hellman, & Rosenberg, 2018). Recurrence occurs usually within the first 2 to 3 years after diagnosis. The presence of disease after 5 years is often secondary to a new primary malignancy. The incidence of distant metastasis with squamous cell carcinoma of the head and neck (including larynx cancer) is relatively low.

Clinical Manifestations

Hoarseness of more than 2 weeks' duration occurs in the patient with cancer in the glottic area because the tumor impedes the action of the vocal cords during speech. The voice may sound harsh, raspy, and lower in pitch. Affected voice sounds are not always early signs of subglottic or supraglottic cancer, however. The patient may complain of a persistent cough or sore throat and pain and burning in the throat, especially when consuming hot liquids or citrus juices. A lump may be felt in the neck. Later symptoms include dysphagia, dyspnea (difficulty breathing), unilateral nasal obstruction or discharge, persistent hoarseness, persistent ulceration, and foul breath. Cervical lymph adenopathy, unintentional weight loss, a general debilitated state, and pain radiating to the ear may occur with metastasis.

Assessment and Diagnostic Findings

An initial assessment includes a complete history and physical examination of the head and neck. This includes identification of risk factors, family history, and any underlying medical conditions. An indirect laryngoscopy, using a flexible endoscope, is initially performed in the otolaryngologist's office to visually evaluate the pharynx, larynx, and possible tumor. Mobility of the vocal cords is assessed; if normal movement is limited, the growth may affect muscle, other tissue, and even the airway. The lymph nodes of the neck and the thyroid gland are palpated for enlargement.

Diagnostic procedures that may be used include fine-needle aspiration (FNA) biopsy, a barium swallow, endoscopy, CT or MRI scan, and a positron emission tomography (PET) scan (ACS, 2017). FNA biopsy may be done as an initial screening procedure to obtain samples of any enlarged lymph nodes in the neck. A barium swallow may be done if the patient initially presents with a chief complaint of difficulty in swallowing, to outline any structural anomalies of the neck that could pinpoint a tumor. However, if a tumor of the larynx is suspected on an initial examination, a direct laryngoscopic examination is indicated. Laryngoscopy is performed under local or general anesthesia to evaluate all areas of the larynx. In some cases, intraoperative examination obtained by direct microscopic visualization and palpation of the vocal folds may yield a more accurate diagnosis. Samples of the suspicious tissue are obtained for analysis. It is uncommon that human papillomavirus (HPV) is implicated in laryngeal cancers, although it is frequently implicated in oropharyngeal and tonsillar cancers. Whether or not the tumor is positive for HPV does not have an effect on the course of treatment (ACS, 2017).

The classification, including stage of the tumor (i.e., size and histology of the tumor, presence and extent of cervical lymph node involvement) and location of the tumor serve as a basis for treatment. CT scanning and MRI are used to assess regional adenopathy and soft tissues and to stage and determine the extent of a tumor. MRI is also helpful in posttreatment follow-up to detect

a recurrence. PET scanning may also be used to detect recurrence of the laryngeal tumor after treatment.

Medical Management

The goals of treatment of laryngeal cancer include cure; preservation of safe, effective swallowing; preservation of useful voice; and avoidance of permanent tracheostoma (Papadakis et al., 2018). Treatment options include surgery, radiation therapy, and adjuvant chemoradiation therapy. The prognosis depends on the tumor location (i.e., supraglottic, glottis, subglottic), as well as the tumor grade and stage (i.e., using the TNM system; see Chapter 12, Chart 12-3). The treatment plan also depends on whether the cancer is an initial diagnosis or a recurrence. In addition, before treatment begins, a complete dental examination is performed to rule out any oral disease. A consultation with a dental oncologist may be warranted. Any dental problems are resolved, if possible, before surgery and radiotherapy (ACS, 2017).

For patients with early-stage tumors (i.e., stages I and II) and lesions without lymph node involvement, external-beam radiation therapy or conservation surgery (i.e., less invasive surgery, such as vocal cord stripping or cordectomy) may be effective. Other indicated surgical procedures may include transoral endoscopic laser excision or partial **laryngectomy** (i.e., in this instance, removal of part of the larynx) (National Cancer Institute [NCI], 2019). Patients with stage III and IV tumors that are resectable may be advised to have either total laryngectomies with or without postoperative radiation therapy or radiation therapy with concurrent adjuvant chemotherapy (with single-agent cisplatin) and surgical resection aimed at preserving some of the larynx (i.e., organ preservation surgery). Patients with late-stage tumors that extend through cartilage and into soft tissues are generally advised to have total laryngectomies with postoperative radiation therapy (NCI, 2019).

Patients should be educated so that they carefully consider the various side effects and complications associated with the different treatment modalities. The presence of lymph node involvement in the neck can affect the outcome. Supraglottic tumors metastasize early and bilaterally even when there appears to be no lymph node involvement at the time of diagnosis. When the neck lymph nodes are involved, the treatment includes surgery, chemoradiation, or both (Papadakis et al., 2018).

Surgical Management

The overall goals for the patient undergoing surgical treatment include minimizing the effects of surgery on speech, swallowing, and breathing while maximizing the likelihood of a cure of the cancer. Several different curative procedures are available that can offer voice-sparing results while achieving a positive cure rate for the patient who has an early laryngeal carcinoma.

Surgical options include vocal cord stripping, cordectomy, laser surgery, partial laryngectomy, or total laryngectomy (NCI, 2019).

Vocal Cord Stripping

Stripping of the vocal cord is used to treat dysplasia, hyperkeratosis, and leukoplakia and is often curative for these lesions. The procedure involves removal of the mucosa of the edge of the vocal cord, using an operating microscope. Early vocal cord lesions are initially treated with radiation therapy.

Cordectomy

Cordectomy, which is an excision of the vocal cord, is usually performed via transoral laser. This procedure is used for lesions limited to the middle third of the vocal cord. The resulting voice quality is related to the extent of tissue removed.

Laser Surgery

Laser microsurgery is well known to have several advantages for the treatment of early glottic cancers. Treatment and recovery are shorter, with fewer side effects, and treatment may be less costly than for other forms of therapy. Microelectrodes are useful for surgical resection of smaller laryngeal carcinomas. The carbon dioxide (CO_2) laser can be used for the treatment of many laryngeal tumors, with the exception of large vascular tumors. When compared with the results of other treatments for early laryngeal cancer, laser microsurgery is considered to be the method of choice based on patient outcomes (NCI, 2019).

Partial Laryngectomy

A partial laryngectomy (laryngofissure–thyrotomy) is often used for patients in the early stages of cancer in the glottic area when only one vocal cord is involved. The surgery is associated with a very high cure rate. It may also be performed for recurrence when high-dose radiation has failed. A portion of the larynx is removed, along with one vocal cord and the tumor; all other structures remain. The airway remains intact, and the patient is expected to have no difficulty swallowing. The voice quality may change, or the patient may sound hoarse.

Total Laryngectomy

Complete removal of the larynx (total laryngectomy) can provide a cure in most advanced laryngeal cancers, when the tumor extends beyond the vocal cords, or for cancer that recurs or persists after radiation therapy. In a total laryngectomy, the laryngeal structures are removed, including the hyoid bone,

epiglottis, cricoid cartilage, and two or three rings of the trachea. The tongue, pharyngeal walls, and most of the trachea are preserved. A total laryngectomy results in permanent loss of the voice and a change in the airway, requiring a permanent tracheostomy (Fig. 18-4). Occasionally, patients continue to have a laryngectomy tube in the stoma. Laryngectomy tubes are similar in appearance to tracheostomy tubes; however, a laryngectomy tube can be distinguished from a tracheostomy tube because the patient is unable to speak or breathe when the laryngectomy tube is occluded. Patients who have a total laryngectomy require alternatives to normal speech; these may include a prosthetic device, such as a Blom–Singer valve, to speak without aspirating (see later discussion).

Surgery is more difficult when the lesion involves the midline structures or both vocal cords. With or without neck dissection, a total laryngectomy requires a permanent tracheal stoma because the larynx that provides the protective sphincter is no longer present. The tracheal stoma prevents the aspiration of food and fluid into the lower respiratory tract. The patient has no voice but has normal swallowing. A total laryngectomy changes the manner in which airflow is used for breathing and speaking, as depicted in Figure 18-4. The patient has significant loss of the natural voice and the need to breathe through a stoma (an opening) created in the lower neck. Complications that may occur include a salivary leak, wound infection from the development of a pharyngocutaneous fistula, stomal stenosis, and dysphagia secondary to esophageal stricture. In some cases, the patient may be a candidate for a near-total laryngectomy. In this situation, the patient would be a candidate for chemoradiation therapy regimens postoperatively. Voice preservation can be achieved in most cases and tends to be associated with overall improved quality of life (Adil, 2018). Advances in surgical techniques for treating laryngeal cancer may minimize the cosmetic and functional deficits previously seen with total laryngectomy. Some microlaryngeal surgery can be performed endoscopically.

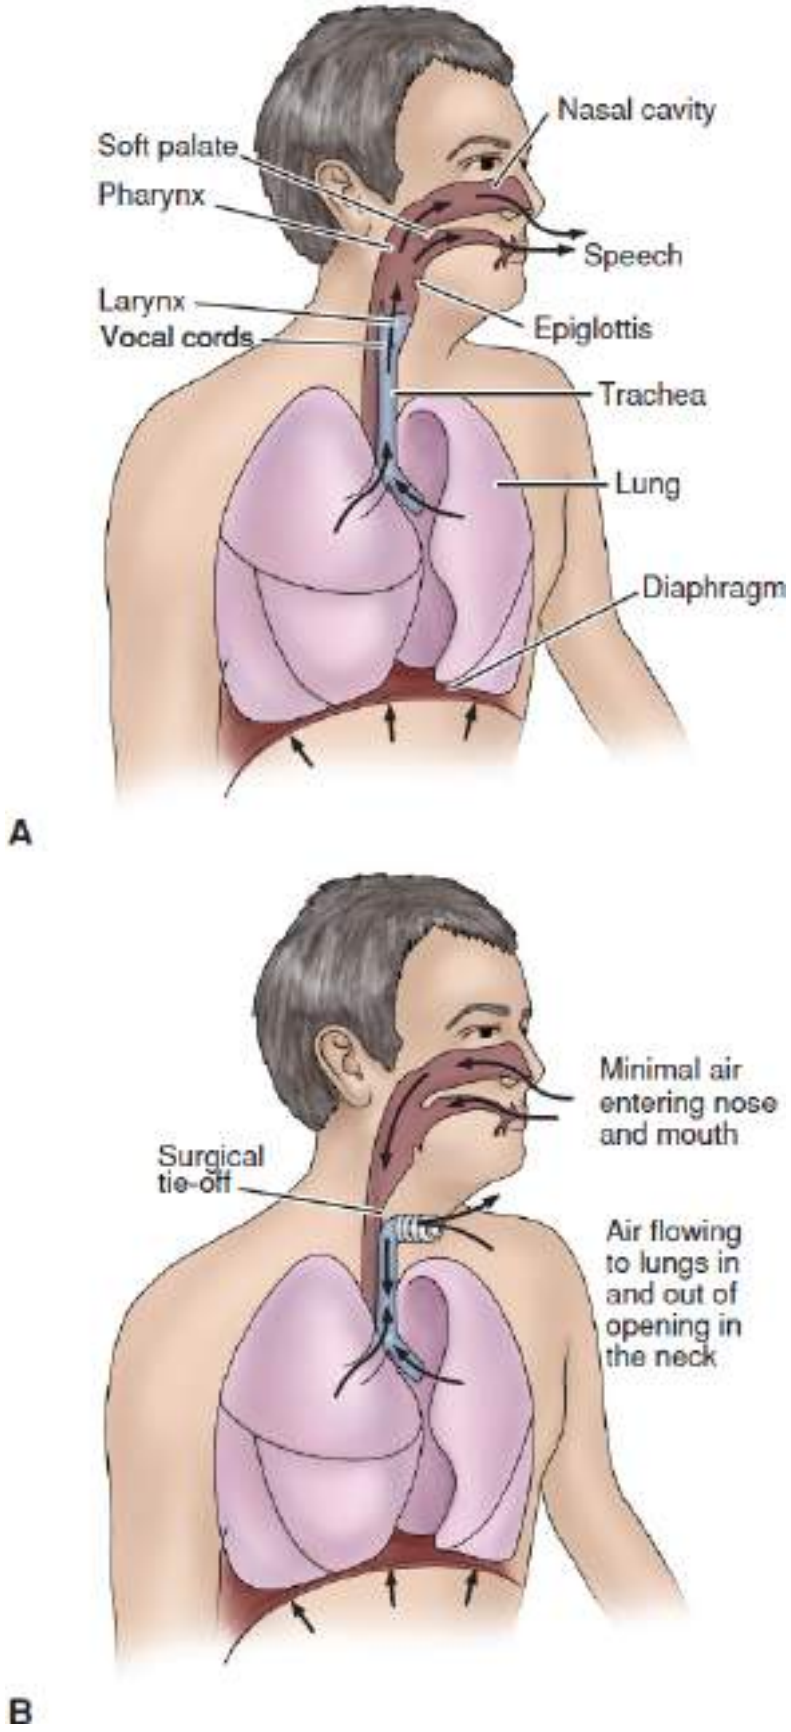

Figure 18-4 • Total laryngectomy produces a change in airflow for breathing and speaking. **A.** Normal airflow. **B.** Airflow after total

laryngectomy.

Radiation Therapy

The goal of radiation therapy is to eradicate the cancer and preserve the function of the larynx. The decision to use radiation therapy is based on several factors, including the staging of the tumor and the patient's overall health status, lifestyle (including occupation), and personal preference. Excellent results have been achieved with radiation therapy in patients with early-stage glottic tumors when only one vocal cord is involved and there is normal mobility of the cord (i.e., with phonation), as well as in small supraglottic lesions. One of the benefits of radiation therapy is that patients retain a near-normal voice. A few may develop chondritis (inflammation of the cartilage) or stenosis; a small number may later require laryngectomy.

Radiation therapy may also be used preoperatively to reduce the tumor size. Radiation therapy is combined with surgery in advanced laryngeal cancer as adjunctive therapy to surgery or chemotherapy and as a palliative measure.

Complications from radiation therapy are a result of external radiation to the head and neck area, which may also include the parotid gland, which is responsible for mucus production. Symptoms may include acute mucositis, ulceration of the mucous membranes, pain, **xerostomia** (dry mouth), loss of taste, dysphasia, fatigue, and skin reactions. Later complications may include laryngeal necrosis, edema, and fibrosis (see Chapter 12).

Speech Therapy

The patient who undergoes a laryngectomy and the patient's family face potentially complex challenges, including significant changes in the ability to communicate. To minimize anxiety and frustration on the part of the patient and family, the loss or alteration of speech is discussed with them. To plan postoperative communication strategies and speech therapy, the speech therapist or pathologist conducts a preoperative evaluation (ACS, 2017). During this time, the nurse discusses with the patient and family the methods of communication that will be available in the immediate postoperative period. These include writing, lip speaking and reading, communication or word boards, or smartphones or other electronic devices. A system of communication is established with the patient, family, nurse, and primary provider and is implemented consistently after surgery.

In addition, a long-term postoperative communication plan for **alaryngeal communication** (modes of speaking not involving the normal larynx) is developed. The three most common techniques of alaryngeal communication are esophageal speech, artificial larynx (electric larynx), and tracheoesophageal puncture. Training in these techniques begins once medical clearance is obtained from the primary provider.

Esophageal Speech

The patient needs the ability to compress air into the esophagus and expel it, setting off a vibration of the pharyngeal esophageal segment for esophageal speech. The technique can be taught once the patient begins oral feedings, approximately 1 week after surgery. First, the patient learns to belch and is reminded to do so an hour after eating. Then, the technique is practiced repeatedly. Later, this conscious belching action is transformed into simple explosions of air from the esophagus for speech purposes. The speech therapist continues to work with the patient to make speech intelligible and as close to normal as possible. Because it takes a long time to become proficient, the success rate is low (ACS, 2017).

Artificial Larynx

If esophageal speech is not successful, or until the patient masters the technique, an electric larynx may be used for communication. This battery-powered apparatus projects sound into the oral cavity. When the mouth forms words (articulation), the sounds from the electric larynx become audible words. The voice that is produced sounds mechanical, and some words may be difficult to understand. The advantage is that the patient is able to communicate with relative ease while working to become proficient at either esophageal or tracheoesophageal puncture speech.

Tracheoesophageal Puncture

The third technique of alaryngeal speech is tracheoesophageal puncture (Fig. 18-5). This technique for voice restoration is simple and has few complications. It is associated with high phonation success, good phonation quality, and steady long-term results. This technique is the most widely used because the speech associated with it most resembles normal speech (the sound produced is a combination of esophageal speech and voice), and it is easily achieved either during the initial surgery to treat the tumor or at a later date (ACS, 2017). A valve is placed in the tracheal stoma to divert air into the esophagus and out the mouth. Once the puncture is surgically created and has healed, a voice prosthesis (Blom–Singer) is fitted over the puncture site. A speech therapist teaches the patient how to produce sounds. Moving the tongue and lips to form the sound into words produces speech as before. To prevent airway obstruction, the prosthesis is removed and cleaned when mucus builds up.

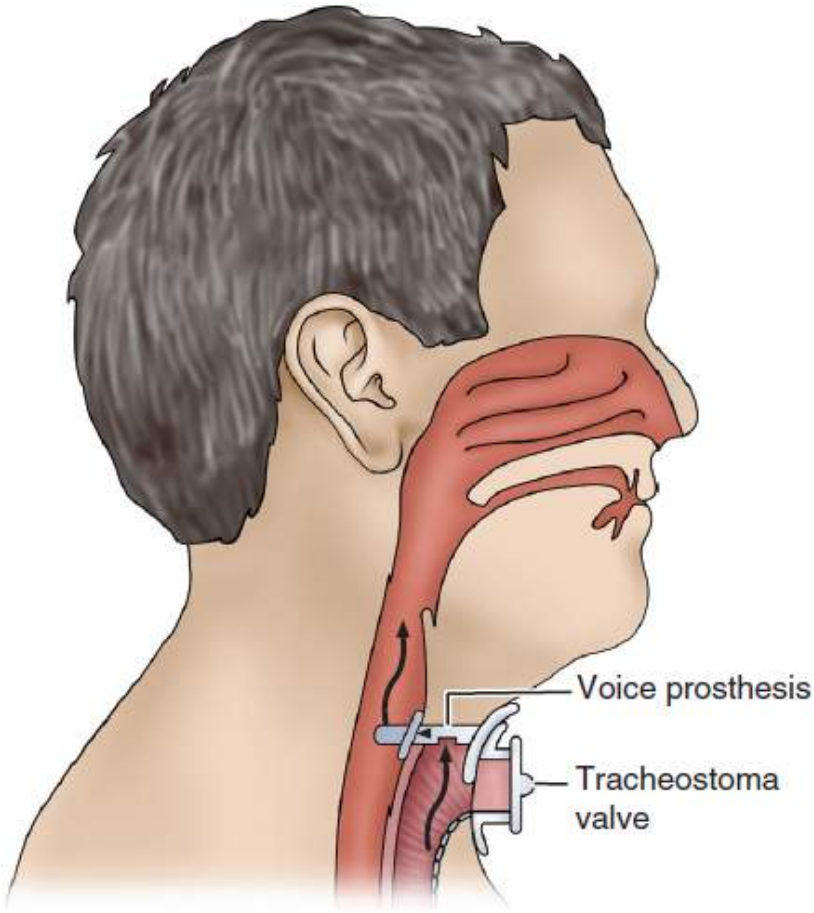

Figure 18-5 • Schematic representation of tracheoesophageal puncture speech. Air travels from the lung through a puncture in the posterior wall of the trachea into the esophagus and out the mouth. A voice prosthesis is fitted over the puncture site.

NURSING PROCESS

The Patient Undergoing Laryngectomy

Assessment

The nurse obtains a health history and assesses the patient's physical, psychosocial, and spiritual domains. The health history focuses on the following symptoms: hoarseness, sore throat, dyspnea, dysphagia, and pain or burning in the throat. The physical assessment includes a thorough head and neck examination with an emphasis on the patient's airway. In addition, the neck and thyroid are palpated for swelling, nodularity, or adenopathy.

The nurse also assesses the patient's general state of nutrition, including height and weight and body mass index and reviews laboratory values that assist in determining the patient's nutritional status (albumin, protein, glucose, and electrolyte levels). If treatment includes surgery, the nurse must know the nature of the surgery to plan appropriate care. If the patient is expected to have no voice as a result of the surgical procedure, a preoperative evaluation by the speech therapist is essential. The patient's ability to hear, see, read, and write is assessed. Visual impairment and functional illiteracy may create additional problems with communication and may require creative approaches to ensure that the patient is able to communicate any needs. Because alcohol abuse is a risk factor for cancer of the larynx, the patient's pattern of alcohol intake must be assessed. Patients who are accustomed to daily consumption of alcohol are at the risk for delirium tremens (alcohol withdrawal syndrome) when alcohol intake is stopped suddenly. It is also not uncommon that patients are active smokers at the time of diagnosis; assessment of readiness for smoking cessation should be done, and nicotine replacements prescribed to avoid nicotine withdrawal, as indicated (NCI, 2019) (see Chapter 23: Promoting Cessation of Tobacco Use).

In addition, the nurse assesses the psychological status of the patient and family. The fear of a diagnosis of cancer is compounded by the possibility of permanent voice loss and, in some cases, some degree of disfigurement. The nurse evaluates the patient's and family's knowledge of the planned surgical procedure and expected postoperative course and assesses their coping methods and support systems. The nurse assesses the patient's spirituality needs based on the patient's individual preferences, beliefs, and culture.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include the following:

- Lack of knowledge about the surgical procedure and postoperative course
- Anxiety associated with the diagnosis of cancer and impending surgery
- Impaired airway clearance associated with excess mucus production secondary to surgical alterations in the airway
- Impaired verbal communication associated with anatomic deficit secondary to removal of the larynx and to edema
- Impaired nutritional intake associated with inability to ingest food secondary to swallowing difficulties
- Disturbed body image and risk for chronic low self-esteem secondary to major neck surgery, change in appearance, and altered structure and function
- Impaired ability to manage regime associated with pain, weakness, fatigue, musculoskeletal impairment related to surgical procedure and postoperative course

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications may include the following:

- Respiratory distress (hypoxia, airway obstruction, tracheal edema)
- Hemorrhage, infection, and wound breakdown
- Aspiration
- Tracheostomal stenosis

Planning and Goals

The major goals for the patient may include attainment of an adequate level of knowledge, reduction in anxiety, maintenance of a patent airway (patient is able to handle own secretions), effective use of alternative means of communication, attainment of optimal levels of nutrition and hydration, improvement in body image and self-esteem, improved self-care management, and absence of complications.

Nursing Interventions

Providing Preoperative Patient Education

The diagnosis of laryngeal cancer often produces misconceptions and fears. Many people assume that loss of speech and disfigurement are inevitable with this condition. Once the primary provider explains the diagnosis and discusses treatment options with the patient and family, the nurse clarifies any misconceptions by identifying the location of the larynx, its function, the nature of the planned surgical procedure, and its effect on speech. Further, the patient's ability to sing, laugh, and whistle will be lost.

Informational materials (written and audiovisual) about the surgery are given to the patient and family for review and reinforcement. If a complete laryngectomy is planned, the patient must understand that the natural voice will be lost, but that special training can provide a means for communicating. The patient needs to know that until training is started, communication will be possible by using the call light, by writing, or by using a communication device. The interdisciplinary team conducts an initial assessment of the patient and family. In addition to the nurse and the primary provider, the team might include an advanced practice nurse (e.g., nurse practitioner), speech therapist, respiratory therapist, social worker, dietitian, and home health nurse. The services of a spiritual advisor are made available to the patient and family, as appropriate.

The nurse also reviews equipment and treatments for postoperative care with the patient and family, educates the patient about important coughing and deep breathing exercises, and helps the patient perform return demonstrations. The nurse clarifies the patient's role in the postoperative and rehabilitation periods. The family's needs must also be addressed because family members are often responsible for complex care of the patient in the home.

Reducing Anxiety

Because surgery of the larynx is performed most often for a malignant tumor, the patient may have many questions: Will the surgeon be able to remove all of the tumor? Is it cancer? Will I die? Will I choke? Will I suffocate? Will I ever speak again? What will I look like? Because of these and other questions, the psychological preparation of the patient is as important as the physical preparation.

Any patient undergoing surgery may have many fears. In laryngeal surgery, these fears may relate to the diagnosis of cancer and the possibility of permanent loss of the voice and disfigurement. The nurse provides the patient and family with opportunities to ask questions, verbalize feelings, and discuss perceptions. The nurse should address any questions and misconceptions the patient and family have. During the preoperative or postoperative period, a visit from someone who has had a laryngectomy may reassure the patient that people are available to assist and that rehabilitation is possible.

In the immediate postoperative period, the nurse attempts to build trust and reduce the patient's anxiety. Active listening provides an environment that promotes open communication and allows the patient to verbalize feelings. Clear instructions and explanations are given to the patient and family in a calm, reassuring manner. The nurse listens attentively, encourages the patient, and identifies and reduces environmental stressors. The nurse seeks to learn from the patient what activities promote feelings of comfort and assists the patient in such activities (e.g., listening to music,

reading). Relaxation techniques such as guided imagery and meditation are often helpful. During episodes of severe anxiety, the nurse remains with the patient and includes them in decision making.

Maintaining a Patent Airway

The nurse helps maintain a patent airway by positioning the patient in the semi-Fowler or Fowler position after recovery from anesthesia. This position decreases surgical edema and promotes lung expansion. Observing the patient for restlessness, labored breathing, apprehension, and increased pulse rate helps identify possible respiratory or circulatory problems. The nurse assesses the patient's lung sounds and reports changes that may indicate impending complications. Medications that depress respiration, particularly opioids, should be used cautiously. However, adequate use of analgesic medications is essential for pain relief because postoperative pain can result in shallow breathing and an ineffective cough (see Chapter 9 for discussion of pain management). The nurse encourages the patient to turn, cough, and take deep breaths. If necessary, suctioning may be performed to remove secretions, but disruption of suture lines must be avoided. The nurse also encourages and assists the patient with early ambulation to prevent atelectasis, pneumonia, and venous thromboemboli formation (e.g., pulmonary embolism and deep vein thrombosis). Pulse oximetry is used to monitor the patient's oxygen saturation level.

If a total laryngectomy was performed, a laryngectomy tube will most likely be in place. In some instances a laryngectomy tube is not used; in others it is used temporarily; and in many it is used permanently. The laryngectomy tube, which is shorter than a tracheostomy tube but has a larger diameter, is the patient's only airway. The care of this tube is similar to that for a tracheostomy tube (see Chapter 19). The nurse changes the inner cannula (if present) every 8 h if it is disposable. Although nondisposable tubes are used infrequently, if one is used, the nurse cleans the inner cannula every 8 h or more often as needed. If a tracheostomy tube without an inner cannula is used, humidification and suctioning of this tube are essential to prevent formation of mucus plugs. If a T-shaped laryngectomy tube is used, both sides of the T-tube should be suctioned to prevent obstruction due to copious secretions. The nurse should also use secure tracheostomy ties to prevent tube dislodgement. The nurse cleans the stoma daily with soap and water or another prescribed solution and a soft cloth or gauze, taking care to prevent water and soap or solution from entering the stoma. If a non–oil-based antibiotic ointment is prescribed, it is applied around the stoma and suture line. If crusting appears around the stoma, the crusts are removed with sterile tweezers and additional ointment is applied.

Wound drains, inserted during surgery, may be in place to assist in removal of fluid and air from the surgical site. Suction also may be used,

but cautiously, to avoid trauma to the surgical site and incision. The nurse observes, measures, and records drainage. When drainage is less than 30 mL/day for 2 consecutive days, the surgeon usually removes the drains.

Frequently, the patient coughs up large amounts of mucus through this opening. Because air passes directly into the trachea without being warmed and moistened by the upper respiratory mucosa, the tracheobronchial tree compensates by secreting excessive amounts of mucus. Therefore, the patient has frequent coughing episodes and may develop a brassy-sounding, mucus-producing cough. The nurse reassures the patient that these problems will diminish in time as the tracheobronchial mucosa adapts to the altered physiology.

After the patient coughs, the tracheostomy opening must be wiped clean and clear of mucus. A simple gauze dressing, washcloth, or even paper towel (because of its size and absorbency) worn below the tracheostomy may serve as a barrier to protect the clothing from the copious mucus that the patient may initially expel.

One of the most important factors in decreasing cough, mucus production, and crusting around the stoma is adequate humidification of the environment. Mechanical humidifiers and aerosol generators (nebulizers) increase the humidity and are important for the patient's comfort. The laryngectomy tube may be removed when the stoma is well healed, within 3 to 6 wk after surgery. The nurse educates the patient about how to clean and change the tube and remove secretions.

Promoting Alternative Communication Methods

Establishing an effective means of communication is usually the ultimate goal in the rehabilitation of the laryngectomy patient. To understand and anticipate the patient's postoperative needs, the nurse works with the patient, speech therapist, and family to encourage the use of alternative communication methods. These means of communication are established preoperatively and must be used consistently by all personnel who come in contact with the patient postoperatively. The patient is now unable to use an intercom system. A call bell or hand bell must be placed within easy reach of the patient. In the immediate postoperative period, a handheld communication device like a Magic Slate, electronic tablet, notebook, or smartphone can be used. If the patient cannot write, a picture–word–phrase board or hand signals can be used. The nurse documents which hand is the patient's dominant hand (e.g., used for writing) so that the opposite arm can be used for IV infusions. (To ensure the patient's privacy, the nurse shreds notes used for communication.)

Writing everything or communicating through gestures can be very time-consuming and frustrating. The patient must be given adequate time to communicate their needs. The patient may become impatient and angry when not understood.

Promoting Adequate Nutrition and Hydration

Postoperatively, the patient may not be permitted to eat or drink for at least 7 d (Suslu, 2016). Alternative sources of nutrition and hydration include IV fluids, enteral feedings through a nasogastric or gastrostomy tube, and parenteral nutrition (see Chapters 39 and 41).

When the patient is ready to start oral feedings, a swallow study (a video fluoroscopy radiology procedure) may be conducted to evaluate the patient's risk of aspiration. Once the patient is cleared for oral feedings, the nurse explains that thick liquids will be used first because they are easy to swallow. Different swallowing maneuvers are attempted with various food consistencies. Once the patient is cleared for food intake, the nurse stays with the patient during initial oral feedings and keeps a suction setup at the bedside for needed suctioning. The nurse instructs the patient to avoid sweet foods, which increase salivation and suppress the appetite. Solid foods are introduced as tolerated. The patient is instructed to rinse the mouth with warm water or mouthwash after oral feedings and to brush the teeth frequently.

Because taste and smell are so closely related, taste sensations are altered for a while after surgery because inhaled air passes directly into the trachea, bypassing the nose and the olfactory end organs. In time, however, the patient usually accommodates to this change and olfactory sensation adapts, often with return of interest in eating. The nurse observes the patient for any difficulty in swallowing, particularly when eating resumes, and reports its occurrence to the primary provider.

The patient's weight and laboratory data are monitored to ensure that nutritional and fluid intake are adequate. In addition, skin turgor and vital signs are assessed for signs of decreased fluid volume.

Promoting Positive Body Image and Self-Esteem

Disfiguring surgery and an altered communication pattern are threats to a patient's body image and self-esteem. The reaction of family members and friends is a major concern for the patient. The nurse encourages the patient to express feelings about the changes brought about by surgery, particularly feelings related to fear, anger, depression, and isolation. Encouraging the use of previous effective coping strategies may be helpful. Referral to a support group, such as the International Association of Laryngectomees (IAL) and WebWhispers, and to resources available through the American Cancer Society may help the patient and family deal with the changes in their lives. Information about these support groups can be found in the Resources section at the end of the chapter.

Promoting Effective Health Management

A positive approach along with promotion of effective health management is important when caring for the patient. The patient should begin

participating in effective health management activities as soon as possible. The nurse assesses the patient's readiness for decision making and encourages the patient to participate actively in performing care. Positive reinforcement is provided when the patient makes an effort in managing health effectively. The nurse needs to be a good listener and a support to the family, especially when explaining the tubes, dressings, and drains that are in place postoperatively.

Monitoring and Managing Potential Complications

The potential complications after laryngectomy include respiratory distress and hypoxia, hemorrhage, infection, wound breakdown, aspiration, and tracheostomal stenosis.

Respiratory Distress and Hypoxia. The nurse monitors the patient for signs and symptoms of respiratory distress and hypoxia, particularly restlessness, irritation, agitation, confusion, tachypnea, the use of accessory muscles, and decreased oxygen saturation on pulse oximetry (SpO_2). Any change in respiratory status requires immediate intervention. Hypoxia may cause restlessness and an initial rise in blood pressure; this is followed by hypotension and somnolence. Cyanosis is a late sign of hypoxia. Obstruction needs to be ruled out immediately by suctioning and by having the patient cough and breathe deeply. Hypoxia and airway obstruction, if not treated immediately, are life-threatening.

Other nursing measures include repositioning of the patient to ensure an open airway and administering oxygen as prescribed. Oxygen is used with caution in patients with chronic obstructive pulmonary disease. The nurse should always be prepared for possible intubation and mechanical ventilation and must be knowledgeable about the hospital's emergency code protocols and skilled in the use of emergency equipment. The nurse must remain with the patient at all times during respiratory distress and initiate a call to the rapid response team as necessary.

Hemorrhage. Bleeding from the drains at the surgical site or with tracheal suctioning may signal the occurrence of hemorrhage. The nurse promptly notifies the surgeon of any active bleeding, which can occur at a variety of sites, including the surgical site, drains, and trachea. Rupture of the carotid artery is especially dangerous. Should this occur, the nurse must apply direct pressure over the artery, summon assistance, and provide emotional support to the patient until the vessel is ligated. The nurse monitors vital signs for changes, particularly increased pulse rate, decreased blood pressure, and rapid deep respirations. Cold, clammy, pale skin may indicate active bleeding. IV fluids and blood components may be given and other measures implemented to prevent or treat hemorrhagic shock. (Management of the patient with shock is discussed in detail in Chapter 11.)

Infection. The nurse monitors the patient for signs of postoperative infection. These include an increase in temperature and pulse, a change in the type of wound drainage, and increased areas of redness or tenderness at the surgical site. Other signs include purulent drainage, odor, and increased wound drainage. The nurse monitors the patient's white blood cell (WBC) count; a rise in WBCs may indicate the body's effort to combat infection. In older adult patients, infection can be present without an increase in the patient's WBC count; therefore, the nurse must monitor the patient for more subtle signs, such as lethargy, weakness, and decreased appetite. WBCs are suppressed in the patient with decreased immune function (e.g., patients receiving chemotherapy or radiation therapy); this predisposes the patient to a severe infection and sepsis. Antimicrobial (antibiotic) medications must be given as scheduled. All suspicious drainage is cultured, and the patient may be placed on the appropriate infection prevention precautions. Strategies are implemented to minimize the exposure of the patient to microorganisms and their spread to others. The nurse reports any significant change in the patient's status to the surgeon.

Wound Breakdown. Wound breakdown caused by infection, poor wound healing, development of a fistula, radiation therapy, or tumor growth can create a life-threatening emergency. The carotid artery, which is close to the stoma, may rupture from erosion if the wound does not heal properly. The nurse observes the stoma area for wound breakdown, hematoma, and bleeding and reports their occurrence to the surgeon. If wound breakdown occurs, the patient must be monitored carefully and identified as at high risk for carotid hemorrhage.

Aspiration. The patient who has undergone a laryngectomy is at the risk for aspiration and aspiration pneumonia due to depressed cough, the sedating effects of anesthetic and analgesic medications, alteration in the airway, impaired swallowing, and the administration of tube feedings. The nurse assesses for the presence of nausea and administers antiemetic medications, as prescribed. The nurse keeps a suction setup available in the hospital and instructs the family to do so at home for use if needed. Patients receiving tube feedings are positioned with the head of the bed at 30 degrees or higher during feedings and for 30 to 45 min after tube feedings. Patients receiving oral feedings are positioned with the head of the bed in an upright position for 30 to 45 min after feedings. For patients with a nasogastric or gastrostomy tube, the placement of the tube and residual gastric volume must be checked before each feeding. High amounts of residual volume (greater than 50% of previous intake) indicate delayed gastric emptying; this can lead to reflux and aspiration (Papadakis et al., 2018). Signs or symptoms of aspiration are reported to the primary provider immediately.

Tracheostomal Stenosis. Tracheostomal stenosis is an abnormal narrowing of the trachea or the tracheostomy stoma. Infection at the stoma site, excessive traction on the tracheostomy tube by the connecting tubing, and persistent high tracheostomy cuff pressure are risk factors for tracheostomal stenosis. The incidence of this condition varies widely, and it is often preventable. The nurse assesses the patient's stoma for signs and symptoms of infection and reports any evidence of this to the primary provider immediately. Tracheostomy care is performed routinely. The nurse assesses the connecting tubing (e.g., ventilation tubing) and secures the tubing to avoid excessive traction on the patient's tracheostomy. The nurse ensures that the tracheostomy cuff is deflated (for a patient with a cuffed tube) except for short periods, such as when the patient is eating or taking medications.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The nurse has an important role in the recovery and rehabilitation of the patient who has had a laryngectomy. To facilitate the patient's ability to manage self-care, discharge instruction begins as soon as the patient is able to participate. Nursing care and patient education in the hospital, outpatient setting, and rehabilitation or long-term care facility must take into consideration the many emotions, physical changes, and lifestyle changes experienced by the patient. In preparing the patient to go home, the nurse assesses the patient's readiness to learn and the level of knowledge about self-care management. The nurse also reassures the patient and family that most self-care management strategies can be mastered. The patient needs to learn a variety of self-care behaviors, including tracheostomy and stoma care, wound care, and oral hygiene. The nurse also instructs the patient about the need for adequate dietary intake, safe hygiene, and recreational activities.

Tracheostomy and Stoma Care. The nurse provides specific instructions to the patient and family about what to expect with a tracheostomy and its management. The nurse instructs the patient and caregiver how to perform suctioning and emergency measures and tracheostomy and stoma care. The nurse stresses the importance of humidification at home and instructs the family to obtain and set up a humidification system before the patient returns home.

For the procedural guidelines for care of the patient with a tracheostomy tube, go to thepoint.lww.com/Brunner15e.

Hygiene and Safety Measures. The nurse instructs the patient and family about safety precautions that are needed because of the changes in structure and function resulting from the surgery. Special precautions are needed in the shower to prevent water from entering the stoma. Wearing a loose-fitting plastic bib over the tracheostomy or simply holding a hand over the opening is effective. Swimming is not recommended because a person with a laryngectomy can drown without submerging their face. Barbers and beauticians need to be alerted so that hair sprays, loose hair, and powder do not get near the stoma, because they can block or irritate the trachea and possibly cause infection. These self-care points are summarized in Chart 18-7.

The nurse educates the patient and caregiver about the signs and symptoms of infection and identifies indications that require contacting the primary provider after discharge. A discussion regarding cleanliness and infection control behaviors is essential. The nurse educates the patient and family to use hand hygiene before and after caring for the tracheostomy, to use tissues to remove mucus, and to dispose of soiled dressings and equipment properly. If the patient's surgery included cervical lymph node dissection, the nurse instructs the patient about how to perform exercises to strengthen the shoulder and neck muscles. A referral to a physical therapist might be helpful.

Recreation and exercise are important for the patient's well-being and quality of life, and all but very strenuous exercise can be enjoyed safely. Avoidance of strenuous exercise and fatigue is important because the patient will have more difficulty speaking when tired, which can be discouraging. Additional safety points to address include the need for the patient to wear or carry medical identification, such as a bracelet or card, to alert medical personnel to the special requirements for resuscitation should this need arise. If resuscitation is needed, direct mouth-to-stoma ventilation should be performed. For home emergency situations, prerecorded emergency messages for police, the fire department, or other rescue services can be kept near the phone or programmed into smartphones or other electronic devices to be used quickly.

Chart 18-7 **HOME CARE CHECKLIST**

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, communication, roles, relationships, and spirituality.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Identify interventions and strategies (e.g., durable medical equipment, oxygen, nebulizer, humidifier) used in adapting to any permanent changes in structure or function.
- Describe ongoing postoperative therapeutic regimen, including stoma care, diet, and activities to perform (e.g., shoulder and neck exercises if a node dissection was performed) and to limit or avoid (e.g., swimming and contact sports).
  - Demonstrate tracheostomy care and tracheal suctioning to clear the airway and handle secretions.
  - Explain the rationale for maintaining adequate humidification with a humidifier or nebulizer.
  - Demonstrate how to clean the skin around the stoma and how to use ointments and tweezers to remove encrustations.
  - State the rationale for wearing a loose-fitting protective cloth at the stoma and covering the stoma when showering or bathing.
  - Discuss the need to avoid sprays, powders, particulates, and cold air from air-conditioning and the environment to prevent irritation of the airway.
  - Demonstrate safe technique in changing the laryngectomy/tracheostomy tube.
  - Identify fluid and caloric needs.
  - Describe mouth care and discuss its importance.
  - Identify the signs and symptoms of wound infection and state what to do about them.
  - Describe safety or emergency measures to implement in case of breathing difficulty or bleeding.
  - State the rationale for wearing or carrying special medical identification and ways to obtain help in an emergency.
  - Demonstrate alternative communication methods.
- Relate how to reach primary provider with questions or to report complications.
- State time and date of follow-up appointments.

- Obtain an annual influenza vaccine, and discuss vaccination against pneumonia with the primary provider.
- State understanding of community resources, support groups, and referrals (if any).
- Identify the need for health promotion (e.g., weight reduction, smoking cessation, and stress management), disease prevention, and screening activities.

Resources

In student resources for Chapter 19 at thepoint.lww.com/Brunner15e, see Procedural Guidelines: Care of the Patient with a Tracheostomy Tube and Procedural Guidelines: Performing Tracheal Suction.

ADL, activities of daily living; IADL, independent activities of daily living.

The nurse instructs and encourages the patient to perform oral care frequently to prevent halitosis and infection. If the patient is receiving radiation therapy, synthetic saliva may be required because of decreased saliva production. Patients receiving radiation therapy frequently report dry mouth, change in taste, lack of appetite, and mouth sores (Cullen, Baumler, Farrington, et al., 2018) (see the Nursing Research Profile in Chart 18-8). The nurse instructs the patient to drink water or sugar-free liquids throughout the day and to use a humidifier at home. Brushing the teeth or dentures and rinsing the mouth several times a day will assist in maintaining proper oral hygiene.

Continuing and Transitional Care. Referral for home, community-based, or transitional care is an important aspect of postoperative care for the patient who has had a laryngectomy and will assist the patient and family in the discharge home. The nurse assesses the patient's general health status and the ability of the patient and family to care for the stoma and tracheostomy. The surgical incisions, nutritional and respiratory status, and adequacy of pain management are also assessed. The nurse assesses for signs and symptoms of complications and the patient's and family's knowledge of signs and symptoms to be reported to the physician. During the home visit, the nurse identifies and addresses other learning needs and concerns of the patient and family, such as adaptation to physical, lifestyle, and functional changes, as well as the patient's progress with learning and using new communication strategies. The nurse assesses the patient's psychological status, reinforces previous instructions, and provides reassurance and support to the patient and family caregivers as needed.

The person who has had a laryngectomy should have regular physical examinations and seek advice concerning any problems related to recovery and rehabilitation. The nurse reminds the patient to participate in health promotion activities and health screening and about the importance of

keeping scheduled appointments with the physician, speech therapist, and other health care providers.

Evaluation

Expected patient outcomes may include the following:

1. Demonstrates an adequate level of knowledge, verbalizing an understanding of the surgical procedure and performing self-care adequately

Chart 18-8 NURSING RESEARCH PROFILE

Mitigating the Effects of Radiation Therapy on the Oral Mucosa of Patients with Head and Neck Cancers

Cullen, L., Baumler, S., Farrington, M., et al. (2018). Oral care for head and neck cancer symptom management. *American Journal of Nursing, 118*(1), 24–34.

Purpose

Patients diagnosed with laryngeal and oropharyngeal cancer (head and neck cancer [HNC]) commonly receive radiation therapy on an outpatient basis. These patients often develop mucositis, which causes symptoms that include pain, difficulty swallowing, dry mouth, change in taste, lack of appetite, and mouth sores. An evidence-based practice intervention at a radiation oncology center in a large academic medical center in the Midwestern United States was designed to reduce the severity of oral mucositis in adults receiving radiation therapy for HNC.

Design

Study participants included adults with HNC who were receiving outpatient radiation therapy with or without concurrent chemotherapy. Twenty participants were recruited to the usual care group. The usual care group received extensive oral care preparation prior to radiation treatment. This included a visit with an oncologic dentist for a professional dental evaluation, fluoride treatments, the provision of oral care supplies, and tooth extraction if needed. Radiation treatment then proceeded as usual for 6 to 8 wk. These participants served as historical controls for the intervention group.

The 85 participants who were then recruited into the intervention group received the same care as those in the usual care group plus targeted education, a comprehensive oral care kit, and information on how to use the kit. The targeted education included a brochure from the U.S. Department of Health and Human Services, *Head and Neck Radiation Treatment and Your Mouth*, and a one-page additional insert, which was developed by the team. Nurses were integral throughout the study process in educating patients about the intervention.

Both clinicians and participants were surveyed at various intervals. Clinicians' (i.e., nurses, physicians, and radiation therapists) knowledge of oral care and correct use of oral care products, perceptions and attitudes about oral care, and behaviors and practices related to the documentation of patients' oral health and education were assessed. Participant feedback was obtained before radiation treatment, during weeks 4 to 5 of treatment, and 1 mo after treatment. The participants' questionnaires included sections that surveyed oral care practices (the frequency of care and products used), perceptions about oral care (feeling well prepared and the usefulness of oral care products), and oral mucositis symptoms.

Findings

The percentage of clinicians with correct responses to knowledge assessment items improved from 71% preimplementation to 80% postimplementation. The clinicians' mean scores on questions capturing their perceptions were higher postimplementation than preimplementation.

Feedback provided by patients during radiation treatment on weeks 4 to 5 demonstrated improvement in oral hygiene behaviors. More patients in the intervention group reported brushing at least daily, using Biotene toothpaste, performing oral rinses at least twice a day, and using lanolin lip balm, compared with those in the usual care group. Patients in the intervention group showed higher adherence with the targeted education and oral care kit intervention which led to a reduction of symptoms at weeks 4 to 5 of radiation treatment, when symptoms are expected to peak. The intervention group reported less severity than the usual care patients regarding the following symptoms: mouth and throat soreness, difficulty swallowing, difficulty eating, and difficulty talking. Furthermore, the intervention group reported less difficulty with xerostomia 1 mo after radiation was completed.

Nursing Implications

Mucositis is a frequent and distressing complication of radiation therapy in the treatment of patients with HNC. Nurses are key members of the treatment team and play many roles in caring for these patients, from assessing patients' symptoms to educating them on ways to reduce these symptoms. Findings from this study show that the distribution of standardized oral care kits and related educational materials can offer an effective way to meet patients' needs and reduce oral mucositis severity in adults treated with radiation therapy for HNC. The success of the project also highlights the key role nurses play in cancer symptom management, before radiation therapy begins, throughout the course of treatment, and in the months afterward.

2. Demonstrates less anxiety
    a. Expresses a sense of hope
    b. Is aware of available community organizations and agencies that provide patient education and support groups
    c. Participates in support group for people with a laryngectomy
3. Maintains a clear airway and handles own secretions; also demonstrates practical, safe, and correct technique for cleaning and changing the tracheostomy or laryngectomy tube
4. Acquires effective communication techniques
    a. Uses assistive devices and strategies for communication (Magic Slate, call bell, picture board, sign language, speech reading, handheld electronic devices, smartphones)
    b. Follows the recommendations of the speech therapist

c. Demonstrates ability to communicate with new communication strategy
d. Reports availability of prerecorded messages to summon emergency assistance by telephone

5. Maintains adequate nutrition and adequate fluid intake
6. Exhibits improved body image, self-esteem, and self-concept
   a. Expresses feelings and concerns
   b. Manages health effectively
   c. Accepts information about support group
7. Adheres to rehabilitation and home care program
   a. Practices recommended speech therapy
   b. Demonstrates proper methods for caring for stoma and laryngectomy or tracheostomy tube (if present)
   c. Verbalizes understanding of symptoms that require medical attention
   d. States safety measures to take in emergencies
   e. Performs oral hygiene as prescribed
8. Absence of complications
   a. Demonstrates a patent airway
   b. No bleeding from surgical site and minimal bleeding from drains; vital signs (blood pressure, temperature, pulse, respiratory rate) are normal
   c. No redness, tenderness, or purulent drainage at surgical site
   d. No wound breakdown
   e. Clear breath sounds; oxygen saturation level within acceptable range; chest x-ray clear
   f. No indications of infection, stenosis, or obstruction of tracheal stoma

CRITICAL THINKING EXERCISES

1 pq A 19-year-old college student presents to the student health center where you work as a staff nurse with complaints of a "stuffed up head," severe headache, green mucous when blowing her nose, and "teeth achiness." She reports a fever of 100.8 for the past 2 days. What further questions do you have regarding her symptoms? What is your priority focus for your physical examination? What diagnostic tests and treatments may you anticipate?

2 ebp You are attending a wedding shower when the bride's grandmother starts bleeding from her nose. You find out from her granddaughter that she has been receiving intravenous pembrolizumab for advanced lung cancer and had her last treatment 5 days ago. What is your priority focus for your nursing assessment? What types of interventions are indicated for epistaxis? What additional concerns do you have for this patient related to her immunotherapy regimen? Would you consider transport to an urgent care center or ED? Why or why not? What is the strength of the evidence that might guide your recommendations for follow-up for this older adult woman?

3 ipc You are working in a family practice clinic and are triaging a 58-year-old male who is complaining of weight loss, difficulty swallowing, sore throat, and hoarseness for the past month. He is worried about having cancer. What risk factors would you screen for in this patient? What type of referral do you expect to be made for this patient? Who else might need to be involved in his care?

19 Management of Patients with Chest and Lower Respiratory Tract Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Identify patients at risk for atelectasis and the nursing interventions related to its prevention and management.
2. Compare the various pulmonary infections with regard to causes, clinical manifestations, nursing management, complications, and prevention.
3. Identify the nursing care of a patient with an endotracheal tube, with mechanical ventilation, or with a tracheostomy.
4. Relate the therapeutic management of acute respiratory distress syndrome to the underlying pathophysiology of the syndrome.
5. Describe preventive measures appropriate for controlling and eliminating occupational lung disease.
6. Discuss the modes of therapy and related nursing management of patients with lung cancer.
7. Use the nursing process as a framework for care of the patient with pneumonia, receiving mechanical ventilation, or with a thoracotomy.
8. Describe the complications of chest trauma and their clinical manifestations and nursing management.
9. Explain the principles of chest drainage and the nursing responsibilities related to the care of the patient with a chest drainage system.

NURSING CONCEPTS

Infection
Oxygenation

GLOSSARY

acute lung injury: an umbrella term for hypoxemic respiratory failure; equivalent to mild acute respiratory distress syndrome (ARDS)

acute respiratory distress syndrome (ARDS): nonspecific pulmonary response to a variety of pulmonary and nonpulmonary insults to the lung; characterized by interstitial infiltrates, alveolar hemorrhage, atelectasis, refractory hypoxemia, and, with the exception of some patients with coronavirus disease 2019 (COVID-19) and ARDS, decreased compliance

airway pressure release ventilation (APRV): mode of mechanical ventilation that allows unrestricted, spontaneous breaths throughout the ventilatory cycle; on inspiration the patient receives a preset level of continuous positive airway pressure, and pressure is periodically released to aid expiration

aspiration: inhalation of either oropharyngeal or gastric contents into the lower airways

atelectasis: collapse or airless condition of the alveoli caused by hypoventilation, obstruction to the airways, or compression

bilevel positive airway pressure (BiPAP): noninvasive spontaneous breath mode of mechanical ventilation that allows for the separate control of inspiratory and expiratory pressures; given via a mask

central cyanosis: bluish discoloration of the skin or mucous membranes due to hemoglobin carrying reduced amounts of oxygen

chest drainage system: the use of a chest tube and closed drainage system to re-expand the lung and to remove excess air, fluid, or blood

consolidation: lung tissue that has become more solid in nature due to collapse of alveoli or infectious process (pneumonia)

continuous mandatory (volume or pressure) ventilation (CMV): also referred to as assist–control (A/C) ventilation; mode of mechanical ventilation in which the patient's breathing pattern may trigger the ventilator to deliver a preset tidal volume or set pressure; in the absence of spontaneous breathing, the machine delivers a controlled breath at a preset minimum rate and tidal volume or set pressure

continuous positive airway pressure (CPAP): positive pressure applied throughout the respiratory cycle to a spontaneously breathing patient to promote alveolar and airway stability and increase functional residual capacity; may be given with endotracheal or tracheostomy tube or by mask

cor pulmonale: "heart of the lungs"; enlargement of the right ventricle from hypertrophy or dilation or as a secondary response to disorders that affect the lungs

empyema: accumulation of purulent material in the pleural space

endotracheal intubation: insertion of a breathing tube (type of artificial airway) through the nose or mouth into the trachea

fraction of inspired oxygen (FiO_2): concentration of oxygen delivered (e.g., 1.0 = 100% oxygen)

hemoptysis: the coughing up of blood from the lower respiratory tract

hemothorax: partial or complete collapse of the lung due to blood accumulating in the pleural space; may occur after surgery or trauma

hypoxemia: decrease in oxygen tension in the arterial blood

hypoxia: decrease in oxygen supply to the tissues and cells

incentive spirometry: method of deep breathing that provides visual feedback to help the patient inhale deeply and slowly and achieve maximum lung inflation

induration: an abnormally hard lesion or reaction, as in a positive tuberculin skin test

intermittent mandatory (volume or pressure) ventilation (IMV): mode of mechanical ventilation that provides a combination of mechanically assisted breaths at a preset volume or pressure and rate and spontaneous breaths

mechanical ventilator: a positive- or negative-pressure breathing device that supports ventilation and oxygenation

orthopnea: shortness of breath when reclining or in the supine position

pleural effusion: abnormal accumulation of fluid in the pleural space

pleural friction rub: localized grating or creaking sound caused by the rubbing together of inflamed parietal and visceral pleurae

pleural space: the area between the parietal and visceral pleurae; a potential space

pneumothorax: partial or complete collapse of the lung due to positive pressure in the pleural space

positive end-expiratory pressure (PEEP): positive pressure maintained at the end of exhalation (instead of a normal zero pressure) to increase functional residual capacity and open collapsed alveoli

pressure support ventilation (PSV): mode of mechanical ventilation in which preset positive pressure is delivered with spontaneous breaths to decrease work of breathing

proportional assist ventilation (PAV): mode of mechanical ventilation that provides partial ventilatory support in proportion to the patient's inspiratory efforts; decreases the work of breathing

purulent: consisting of, containing, or discharging pus

respiratory weaning: process of gradual, systematic withdrawal or removal of ventilator, breathing tube, and oxygen

restrictive lung disease: disease of the lung that causes a decrease in lung volumes

synchronized intermittent mandatory ventilation (SIMV): mode of mechanical ventilation in which the ventilator allows the patient to breathe spontaneously while providing a preset number of breaths to ensure adequate ventilation; ventilated breaths are synchronized with spontaneous breathing

tension pneumothorax: pneumothorax characterized by increasing positive pressure in the pleural space with each breath; this is an emergency situation, and the positive pressure needs to be decompressed or released immediately

thoracentesis: insertion of a needle or catheter into the pleural space to remove fluid that has accumulated and decrease pressure on the lung tissue; may also be used diagnostically to identify potential causes of a pleural effusion

thoracotomy: surgical opening into the chest cavity

tidal volume: volume of air inspired and expired with each breath

tracheostomy tube: indwelling tube inserted directly into the trachea to assist with ventilation

tracheotomy: surgical opening into the trachea

transbronchial: through the bronchial wall, as in a transbronchial lung biopsy

ventilation–perfusion (V./Q.): refers to the ratio between ventilation and perfusion in the lung; matching of ventilation to perfusion optimizes gas exchange

Disorders affecting the chest and lower respiratory tract range from acute to chronic conditions. Many of these disorders are serious and often life-threatening. Patients with chest and lower respiratory tract disorders require care from nurses with astute assessment and clinical management skills as well as knowledge of evidence-based practice. Nurses must also understand the impact of the particular disorder on the patient's quality of life and ability to carry out activities of daily living. Patient and family education is an important nursing intervention in the management of all chest and lower respiratory tract disorders.

INFLAMMATORY AND INFECTIOUS PULMONARY DISORDERS

Inflammatory pulmonary disorders may include relatively common disorders such as atelectasis, as well as uncommon disorders such as aspiration and

sarcoidosis. Infectious pulmonary disorders are responsible for much morbidity and mortality, and include diseases such as pneumonia and tuberculosis, as well as lung abscesses.

Atelectasis

Atelectasis refers to closure or collapse of alveoli and often is described in relation to chest x-ray findings and clinical signs and symptoms. Atelectasis is one of the most commonly encountered abnormalities seen on a chest x-ray (Stark, 2019). Atelectasis may be acute or chronic and may cover a broad range of pathophysiologic changes, from microatelectasis (which is not detectable on chest x-ray) to macroatelectasis with loss of segmental, lobar, or overall lung volume. The most commonly described is acute atelectasis, which occurs most often in the postoperative setting usually following thoracic and upper abdominal procedures or in people who are immobilized and have a shallow, monotonous breathing pattern (Conde & Adams, 2018; Smetana, 2018). Excess secretions or mucus plugs may also cause obstruction of airflow and result in atelectasis in an area of the lung. Atelectasis also is observed in patients with a chronic airway obstruction that impedes or blocks the flow of air to an area of the lung (e.g., obstructive atelectasis in the patient with lung cancer that is invading or compressing the airways). This type of atelectasis is more insidious and slower in onset (Conde & Adams, 2018; Stark, 2019).

Pathophysiology

Atelectasis may be described as either nonobstructive or obstructive. Nonobstructive atelectasis occurs in adults as a result of reduced ventilation. Obstructive atelectasis results from any blockage that impedes the passage of air to and from the alveoli, reducing alveolar ventilation (Stark, 2019). Obstructive atelectasis is the most common type and results from reabsorption of gas (trapped alveolar air is absorbed into the bloodstream); no additional air can enter into the alveoli because of the blockage. As a result, the affected portion of the lung becomes airless and the alveoli collapse. Causes of atelectasis include foreign body, tumor or growth in an airway, altered breathing patterns, retained secretions, pain, alterations in small airway function, prolonged supine positioning, increased abdominal pressure, reduced lung volumes due to musculoskeletal or neurologic disorders, restrictive defects, and specific surgical procedures (e.g., upper abdominal, thoracic, or open heart surgery) (Conde & Adams, 2018).

Patients are at high risk for atelectasis postoperatively because of several factors. A monotonous, low tidal breathing pattern may cause small airway closure and alveolar collapse. This can result from the effects of anesthesia or

analgesic agents, supine positioning, splinting of the chest wall because of pain, or abdominal distention. Secretion retention, airway obstruction, and an impaired cough reflex may also occur, or patients may be reluctant to cough because of pain (Conde & Adams, 2018). Figure 19-1 shows the mechanisms and consequences of acute atelectasis in postoperative patients.

Atelectasis resulting from bronchial obstruction by secretions may also occur in patients with impaired cough mechanisms (e.g., musculoskeletal or neurologic disorders) as well as in those who are debilitated and confined to bed. In addition, atelectasis may develop because of excessive pressure on the lung tissue (i.e., compressive atelectasis), which restricts normal lung expansion on inspiration (Stark, 2019). Such pressure can be produced by a **pleural effusion** (fluid accumulating within the pleural space), a **pneumothorax** (air in the pleural space), or a **hemothorax** (blood in the pleural space). The **pleural space** is the area between the parietal and the visceral pleurae, and is normally a potential rather than an actual space. Pressure may also be produced by a pericardial effusion (pericardium distended with fluid), tumor growth within the thorax, or an elevated diaphragm.

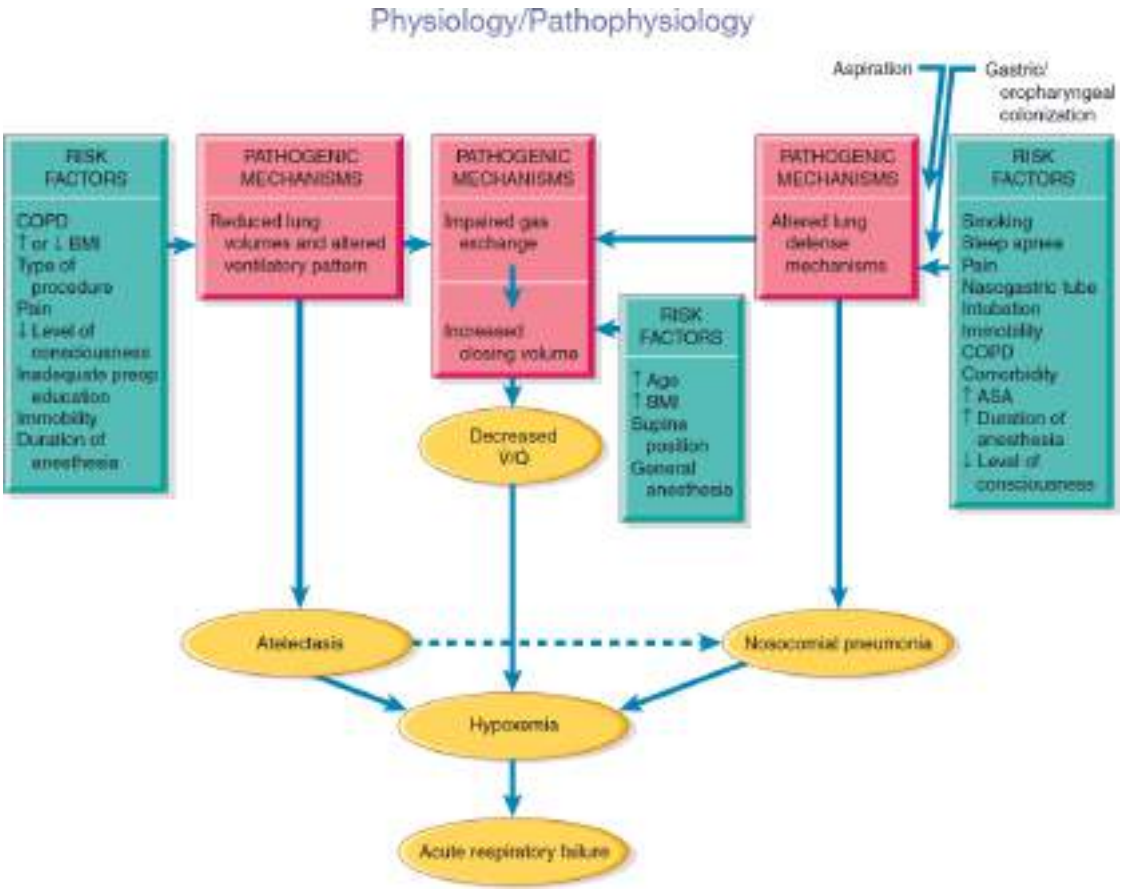

Figure 19-1 • Relationship of risk factors, pathogenic mechanisms, and consequences of acute atelectasis in the postoperative patient. ASA, acetylsalicylic acid; BMI, body mass index; COPD, chronic obstructive pulmonary disease; V./Q., ventilation–perfusion ratio.

Clinical Manifestations

The development of atelectasis usually is insidious. Signs and symptoms include increasing dyspnea (shortness of breath), cough, and sputum production.

In acute atelectasis involving a large amount of lung tissue (lobar atelectasis), marked respiratory distress may be observed. In addition to the previously mentioned signs and symptoms, tachycardia, tachypnea, pleural pain, and **central cyanosis** (a bluish skin hue that is a late sign of hypoxemia) may be anticipated. Patients characteristically have difficulty breathing in the supine position and are anxious.

In chronic atelectasis, signs and symptoms are similar to those of acute atelectasis. The chronic nature of the alveolar collapse predisposes patients to infection distal to the obstruction. Therefore, the signs and symptoms of a pulmonary infection also may be present.

Assessment and Diagnostic Findings

When clinically significant atelectasis develops, it is generally characterized by increased work of breathing and **hypoxemia** (i.e., a decrease in oxygen tension in the arterial blood). Decreased breath sounds and crackles are heard over the affected area. A chest x-ray may suggest a diagnosis of atelectasis before clinical symptoms appear; the x-ray may reveal patchy infiltrates or consolidated areas. Depending on the degree of hypoxemia, pulse oximetry (SpO_2) may demonstrate a low saturation of hemoglobin with oxygen (less than 90%) or a lower-than-normal partial pressure of arterial oxygen (PaO_2).

Quality and Safety Nursing Alert

Tachypnea, dyspnea, and mild-to-moderate hypoxemia are hallmarks of the severity of atelectasis.

Prevention

Nursing measures to prevent atelectasis include frequent turning, early mobilization, and strategies to expand the lungs and to manage secretions. Voluntary deep-breathing maneuvers (at least every 2 hours) assist in preventing and treating atelectasis. The performance of these maneuvers requires the patient to be alert and cooperative. Patient education and reinforcement are key elements to the success of these interventions. The use of incentive spirometry or voluntary deep breathing enhances lung expansion, decreases the potential for airway closure, and may generate a cough. **Incentive spirometry** is a method of deep breathing that provides visual feedback to encourage the patient to inhale slowly and deeply to maximize lung inflation and prevent or reduce atelectasis. The purpose of an incentive spirometer is to ensure that the volume of air inhaled is increased gradually as the patient takes deeper and deeper breaths.

Incentive spirometers are available in two types: volume or flow. In the volume type, the tidal volume is set using the manufacturer's instructions. The patient takes a deep breath through the mouthpiece, pauses at peak lung inflation, and then relaxes and exhales. Taking several normal breaths before attempting another with the incentive spirometer helps avoid fatigue. The volume is periodically increased as tolerated.

In the flow type, the volume is not preset. The spirometer contains a number of movable balls that are pushed up by the force of the breath and held suspended in the air while the patient inhales. The amount of air inhaled and the flow of the air are estimated by how long and how high the balls are suspended (see Chart 19-1).

Secretion management techniques include directed cough, suctioning, aerosol nebulizer treatments followed by chest physiotherapy (CPT; see Figs. 20-6 and 20-7 and further discussion of CPT principles in Chapter 20), and bronchoscopy. In some settings, a pressurized metered-dose inhaler (pMDI) is used to dispense a bronchodilator rather than an aerosolized, small-volume nebulizer (SVN) (see Chapter 20 for further discussion of pMDIs and SVNs). Chart 19-2 summarizes measures used to prevent atelectasis.

Chart 19-1 **PATIENT EDUCATION**

Performing Incentive Spirometry

The inspired air helps inflate the lungs. The ball or weight in the spirometer rises in response to the intensity of the intake of air. The higher the ball rises, the deeper the breath.

The nurse instructs the patient to:

- Assume a semi-Fowler position or an upright position before initiating therapy.
- Use diaphragmatic breathing.
- Place the mouthpiece of the spirometer firmly in the mouth, breathe air in (inspire) slowly through the mouth, and hold the breath at the end of inspiration for about 3 seconds to maintain the ball/indicator between the lines. Exhale slowly through the mouthpiece.
- Cough during and after each session. Splint the incision when coughing postoperatively.
- Perform the procedure approximately 10 times in succession, repeating the 10 breaths with the spirometer each hour during waking hours.

Chart 19-2

Preventing Atelectasis

- Change patient's position frequently, especially from supine to upright position, to promote ventilation and prevent secretions from accumulating.
- Encourage early mobilization from bed to chair followed by early ambulation.
- Encourage appropriate deep breathing and coughing to mobilize secretions and prevent them from accumulating.
- Educate/reinforce appropriate technique for incentive spirometry.
- Administer prescribed opioids and sedatives judiciously to prevent respiratory depression.
- Perform postural drainage and chest percussion, if indicated.
- Institute suctioning to remove tracheobronchial secretions, if indicated.

Management

The goal of the treatment is to improve ventilation and remove secretions. Strategies to prevent atelectasis, which include frequent turning, early ambulation, lung volume expansion maneuvers (e.g., deep-breathing exercises and incentive spirometry), and coughing, also serve as the first-line measures to minimize or treat atelectasis by improving ventilation. Multidisciplinary, evidence-based standardized intervention programs that incorporate ICOUGH℠ (see Chart 19-3) can prevent atelectasis (Moore, Conway, Thomas, et al., 2017; Smetana, 2018).

In patients who do not respond to first-line measures or who cannot perform deep-breathing exercises, other treatments such as **positive end-expiratory pressure** (**PEEP**; a simple mask and one-way valve system that provides varying amounts of expiratory resistance, usually 10 to 15 cm H_2O), continuous positive airway breathing, or bronchoscopy may be used. Before initiating more complex, costly, and labor-intensive therapies, the nurse should ask several questions:

- Has the patient been given an adequate trial of deep-breathing exercises?

Chart 19-3

ICOUGH[SM] Program

- **I**ncentive spirometry
- **C**oughing and deep breathing
- **O**ral care (brushing teeth and using mouthwash twice a day)
- **U**nderstanding (patient and staff education)
- **G**etting out of bed at least three times daily
- **H**ead-of-bed elevation

Adapted from Boston University School of Medicine. (2019). ICOUGHSM. Retrieved on 8/22/2019 at: www.bumc.bu.edu/surgery/quality-safety/i-cough

- Has the patient received adequate education, supervision, and coaching to carry out the deep-breathing exercises?
- Have other factors been evaluated that may impair ventilation or prevent a good patient effort (e.g., lack of turning, mobilization; excessive pain; excessive sedation)?

If the cause of atelectasis is bronchial obstruction from secretions, the secretions must be removed by coughing or suctioning to allow air to reenter that portion of the lung. CPT and postural drainage may also be used to mobilize secretions. SVN treatments with a bronchodilator may be used to assist patients in the expectoration of secretions. If respiratory care measures fail to remove the obstruction, a bronchoscopy is performed. Although bronchoscopy is an excellent measure to acutely remove secretions and increase ventilation, it is imperative for the nurse to assist the patient with maintaining the patency of the airways after bronchoscopy, using the traditional techniques of deep breathing, coughing, and suctioning. Severe or massive atelectasis may lead to acute respiratory failure, especially in patients with underlying lung disease. Endotracheal (ET) intubation and mechanical ventilation may be necessary.

If the cause of atelectasis is compression of lung tissue, the goal is to decrease the compression. With a large pleural effusion that is compressing lung tissue and causing alveolar collapse, treatment may include **thoracentesis** (removal of the fluid by needle aspiration) or insertion of a chest tube. The measures to increase lung expansion described previously also are used.

Management of chronic atelectasis focuses on removing the cause of the obstruction of the airways or the compression of the lung tissue. For example, bronchoscopy may be used to open an airway obstructed by lung cancer or a nonmalignant lesion, and the procedure may involve cryotherapy or laser therapy. If the atelectasis is a result of obstruction caused by lung cancer, an airway stent or radiation therapy to shrink a tumor may be used to open the airways and provide ventilation to the collapsed area. However, reopening the

airways and reaerating the area of the lung may not be possible in patients who have experienced chronic, long-term collapse. In some cases, surgical management may be indicated.

Acute Tracheobronchitis

Acute tracheobronchitis, an acute inflammation of the mucous membranes of the trachea and the bronchial tree, often follows infection of the upper respiratory tract usually as a result of a viral infection (see Chapter 18). Patients with viral infections have decreased resistance and can readily develop a secondary bacterial infection. Adequate treatment of upper respiratory tract infection is one of the major factors in the prevention of acute tracheobronchitis.

Pathophysiology

In acute tracheobronchitis, the inflamed mucosa of the bronchi produces mucopurulent sputum, often in response to infection by *Streptococcus pneumoniae, Haemophilus influenzae,* or *Mycoplasma pneumoniae.* A fungal infection (e.g., *Aspergillus*) may also cause tracheobronchitis. A sputum culture is essential to identify the specific causative organism. In addition to infection, inhalation of physical and chemical irritants, gases, or other air contaminants can also cause acute bronchial irritation (File, 2019a).

Clinical Manifestations

Initially, the patient has a dry, irritating cough and expectorates a scanty amount of mucoid sputum. The patient may report sternal soreness from coughing and have fever or chills, night sweats, headache, and general malaise. As the infection progresses, the patient may be short of breath, have noisy inspiration and expiration (inspiratory stridor and expiratory wheeze), and produce **purulent** (pus-filled) sputum. In severe tracheobronchitis, blood-streaked secretions may be expectorated as a result of the irritation of the mucosa of the airways.

Medical Management

Antibiotic treatment for an infection may be indicated depending on the symptoms, sputum purulence, and results of the sputum culture and sensitivity. Antihistamines usually are not prescribed, because they can cause excessive drying and make secretions more difficult to expectorate. Fluid intake is increased to thin viscous and tenacious secretions. Copious, purulent

secretions that cannot be cleared by coughing place patients at risk for increasing airway obstruction and the development of more severe lower respiratory tract infections, such as pneumonia. Suctioning and bronchoscopy may be needed to remove secretions. Rarely, ET intubation may be necessary in cases of acute tracheobronchitis leading to acute respiratory failure, such as in patients who are severely debilitated or who have coexisting diseases that impair the respiratory system.

In most cases, treatment of tracheobronchitis is largely symptomatic. Increasing the vapor pressure (moisture content) in the air reduces airway irritation. Cool vapor therapy or steam inhalations may help relieve laryngeal and tracheal irritation. Moist heat to the chest may relieve the soreness and pain, and mild analgesics may be prescribed.

Nursing Management

Acute tracheobronchitis is usually treated in the home setting. A primary nursing function is to encourage bronchial hygiene, such as increased fluid intake and directed coughing to remove secretions. The nurse encourages and assists the patient to sit up frequently to cough effectively and to prevent retention of mucopurulent sputum. If the patient is taking antibiotics for an underlying bacterial infection, the need to complete the full course of antibiotics prescribed is emphasized. Fatigue is a consequence of tracheobronchitis; therefore, the nurse cautions the patient against overexertion, which can induce a relapse or exacerbation of the infection. The patient is advised to rest (File, 2019a).

Pneumonia

Pneumonia is an inflammation of the lung parenchyma caused by various microorganisms, including bacteria, mycobacteria, fungi, and viruses. *Pneumonitis* is a more general term that describes an inflammatory process in the lung tissue that may predispose or place the patient at risk for microbial invasion. Pneumonia and influenza are the most common causes of death from infectious diseases in the United States. Pneumonia and influenza accounted for 55,672 deaths in the United States in 2017 (Centers for Disease Control and Prevention [CDC], 2017a). Together, these diseases were the eighth leading cause of death in the United States in 2017, accounting for 5.9% of all deaths (CDC, 2017a).

Chart 19-4

Classifications and Definitions of Pneumonias

- *Community-acquired pneumonia (CAP):* Pneumonia occurring in the community or ≤48 hours after hospital admission or institutionalization of patients who do not meet the criteria for health care–associated pneumonia (HCAP)
- *Health care–associated pneumonia (HCAP):* Pneumonia occurring in a nonhospitalized patient with extensive health care contact with one or more of the following:
  - Hospitalization for ≥2 days in an acute care facility within 90 days of infection
  - Residence in a nursing home or long-term care facility
  - Antibiotic therapy, chemotherapy, or wound care within 30 days of current infection
  - Hemodialysis treatment at a hospital or clinic
  - Home infusion therapy or home wound care
  - Family member with infection due to multidrug-resistant bacteria
- *Hospital-acquired pneumonia (HAP):* Pneumonia occurring ≥48 hours after hospital admission that did not appear to be incubating at the time of admission
- *Ventilator-associated pneumonia (VAP):* A type of HAP that develops ≥48 hours after endotracheal tube intubation

Adapted from Klompas, M., File, T. M., & Bond, S. (2019). Treatment of hospital-acquired, ventilator-associated and healthcare-associated pneumonia in adults. *UpToDate.* Retrieved on 8/22/2019 at: www.uptodate.com/contents/treatment-of-hospital-acquired-ventilator-associated-and-healthcare-associated-pneumonia-in-adults

Classification

Pneumonia can be classified into four types: community-acquired pneumonia (CAP), health care–associated pneumonia (HCAP), hospital-acquired pneumonia (HAP), and ventilator-associated pneumonia (VAP) (American Thoracic Society & Infectious Diseases Society of America, 2005; Klompas, 2019a). HCAP was conceived as a specific category in order to identify patients at increased risk for multidrug-resistant organisms (MDRO) versus community-acquired organisms (Klompas, 2019a). Chart 19-4 describes the different classifications and definitions of pneumonias. Other subcategories of HCAPs are those in the immunocompromised host and aspiration pneumonia. There is overlap in how specific pneumonias are classified, because they may occur in differing settings. Risk factors associated for specific pathogens are shown in Chart 19-5.

Community-Acquired Pneumonia

CAP, a common infectious disease, occurs either in the community setting or within the first 48 hours after hospitalization or institutionalization. The need for hospitalization for CAP depends on the severity of the pneumonia. The causative pathogens for CAP by site of care are shown in Table 19-1. The specific etiologic pathogen is identified in about 50% of cases. The rate of CAP increases with age, with 2000 per 100,000 adults 65 years of age and older hospitalized with CAP each year (Ramirez, 2019).

Chart 19-5 RISK FACTORS

Pneumonia Based upon Pathogen Type

Risk Factors for Infection with Penicillin-Resistant and Drug-Resistant Pneumococci

- Age >65 years
- Alcoholism
- Beta-lactam therapy (e.g., cephalosporins) in past 3 months
- Immunosuppressive disorders
- Multiple medical comorbidities
- Exposure to a child in a day care facility

Risk Factors for Infection with Enteric Gram-Negative Bacteria

- Residency in a long-term care facility
- Underlying cardiopulmonary disease
- Multiple medical comorbidities
- Recent antibiotic therapy

Risk Factors for Infection with *Pseudomonas aeruginosa*

- Structural lung disease (e.g., bronchiectasis)
- Corticosteroid therapy
- Broad-spectrum antibiotic therapy (>7 days in the past month)
- Malnutrition

Adapted from Ramirez, J. A. (2019). Overview of community acquired pneumonia in adults. *UpToDate*. Retrieved on 9/23/2019 at: www.uptodate.com/contents/overview-of-community-acquired-pneumonia-in-adults

S. pneumoniae (pneumococcus) is the most common bacterial cause of CAP in people younger than 60 years without comorbidity and in those 60 years and older with comorbidity (Baer, 2019; Ramirez, 2019). *S. pneumoniae,* a gram-positive organism that resides naturally in the upper respiratory tract, colonizes

the upper respiratory tract and can cause disseminated invasive infections, pneumonia and other lower respiratory tract infections, and upper respiratory tract infections such as otitis media and rhinosinusitis. It may occur as a lobar or bronchopneumonic form in patients of any age and may follow a recent respiratory illness.

TABLE 19-1 Community-Acquired Pneumonia Microbial Causes by Site of Care[a]

Outpatients	Hospitalized Patients	
	Non-ICU	ICU
Streptococcus pneumoniae	*S. pneumoniae*	*S. pneumoniae*
Mycoplasma pneumoniae	*M. pneumoniae*	*Staphylococcus aureus*
Haemophilus influenzae	*Chlamydophila pneumoniae*	*Legionella*
C. pneumoniae	*H. influenzae*	Gram-negative bacilli
Respiratory viruses	*Legionella*	*H. influenzae*

ICU, intensive care unit.

Adapted from Klompas, M. (2019b). Treatment of hospital-acquired and ventilator-associated pneumonia in adults. *UpToDate*. Last updated: July 10, 2019. Retrieved on 9/23/2019 at: www.uptodate.com/contents/treatment-of-hospital-acquired-and-ventilator-associated-pneumonia-in-adults/print

H. influenzae causes a type of CAP that frequently affects older adults and those with comorbid illnesses (e.g., chronic obstructive pulmonary disease [COPD], alcoholism, diabetes). The presentation is indistinguishable from that of other forms of bacterial CAP and may be subacute, with cough or low-grade fever for weeks before diagnosis.

Mycoplasma pneumonia is caused by *M. pneumoniae.* Mycoplasma pneumonia is spread by infected respiratory droplets through person-to-person contact. Patients can be tested for mycoplasma antibodies. The inflammatory infiltrate is primarily interstitial rather than alveolar. It spreads throughout the entire respiratory tract, including the bronchioles, and has the characteristics of a bronchopneumonia. Earache and bullous myringitis are common. Impaired ventilation and diffusion may occur.

Viruses are the most common cause of pneumonia in infants and children. Until the advent of the coronavirus disease 2019 (COVID-19) pandemic, viruses were relatively uncommon causes of CAP in adults (see later discussion). Pre-COVID-19, cytomegalovirus was the most commonly implicated viral pathogen in adults with compromised immune systems, followed by herpes simplex virus, adenovirus, and respiratory syncytial virus. The acute stage of a viral respiratory infection occurs within the ciliated cells of the airways, followed by infiltration of the tracheobronchial tree. With

pneumonia, the inflammatory process extends into the alveolar area, resulting in edema and exudation. The clinical signs and symptoms of a viral pneumonia are often difficult to distinguish from those of a bacterial pneumonia.

Health Care–Associated Pneumonia

An important distinction of HCAP is that the causative pathogens are often MDROs because of prior contact with a health care environment. Consequently, identifying this type of pneumonia in areas such as the emergency department is crucial. Because HCAP is often difficult to treat, initial antibiotic treatment must not be delayed. Initial antibiotic treatment of HCAP is often different from that for CAP due to the possibility of MDROs (Ramirez, 2019).

Hospital-Acquired Pneumonia

HAP develops 48 hours or more after hospitalization and does not appear to be incubating at the time of admission. VAP can be considered a subtype of HAP, as the only differentiating factor is the presence of an ET tube (see later discussion of VAP). Certain factors may predispose patients to HAP because of impaired host defenses (e.g., severe acute or chronic illness), a variety of comorbid conditions, supine positioning and aspiration, coma, malnutrition, prolonged hospitalization, hypotension, metabolic disorders. Hospitalized patients are also exposed to potential bacteria from other sources (e.g., respiratory therapy devices and equipment, transmission of pathogens by the hands of health care personnel). Numerous intervention-related factors also may play a role in the development of HAP (e.g., therapeutic agents leading to central nervous system depression with decreased ventilation, impaired removal of secretions, or potential aspiration; prolonged or complicated thoracoabdominal procedures, which may impair mucociliary function and cellular host defenses; ET intubation [VAP]; prolonged or inappropriate use of antibiotics; the use of nasogastric tubes). In addition, patients with compromised immune systems are at particular risk. HAP is associated with a high mortality rate, in part because of the virulence of the organisms, the resistance to antibiotics, and the patient's underlying disorder. It is the most common cause of death among all patients with hospital-acquired infections, with mortality rates up to 33% (Cunha, 2018; Klompas, 2019a).

The common organisms responsible for HAP include the *Enterobacter* species, *Escherichia coli, H. influenzae, Klebsiella pneumoniae*, *Pseudomonas aeruginosa, Acinetobacter* species, methicillin-sensitive or methicillin-resistant *Staphylococcus aureus* (MRSA), and *S. pneumoniae.* Most patients with HAP are colonized by multiple organisms. Pseudomonal pneumonia occurs in patients who are debilitated, those with altered mental status, and those with prolonged intubation or with tracheostomy. Staphylococcal

pneumonia can occur through inhalation of the organism or spread through the hematogenous route. It is often accompanied by sepsis and positive blood cultures. Its mortality rate is high. Specific strains of staphylococci are resistant to many available antimicrobial agents; notable exceptions include vancomycin and linezolid (Klompas, 2019b). Overuse and misuse of antimicrobial agents are major risk factors for the emergence of these resistant pathogens. Because MRSA is highly virulent, steps must be taken to prevent its spread. Patients with MRSA are isolated in a private room, and contact precautions (gown, gloves, and antibacterial soap or alcohol-based hand rub) are used. The number of people in contact with affected patients is minimized, and appropriate precautions must be taken when transporting these patients within or between facilities.

The usual presentation of HAP is a new pulmonary infiltrate on chest x-ray combined with evidence of infection such as fever, respiratory symptoms, purulent sputum, or leukocytosis. Pneumonias from *Klebsiella* or other gram-negative organisms are characterized by the destruction of lung structure and alveolar walls, **consolidation** (tissue that solidifies as a result of collapsed alveoli or infectious process such as pneumonia), and sepsis. Older adult patients and those with alcoholism, chronic lung disease, or diabetes are at increased risk (Klompas, 2019a). Development of a cough or increased cough and sputum production are common presentations, along with low-grade fever and general malaise. In patients who are debilitated or dehydrated, sputum production may be minimal or absent. Pleural effusion, high fever, and tachycardia are common.

Ventilator-Associated Pneumonia

As noted previously, VAP can be thought of as a subtype of HAP; however, in such cases, the patient has been endotracheally intubated and has received mechanical ventilatory support for at least 48 hours (see later discussions on ET intubation and mechanical ventilation). VAP is a complication in as many as 27% of patient who require mechanical ventilation (Gamache, 2019). The incidence of VAP increases with the duration of mechanical ventilation and the mortality rate is variable, depending upon the complexity of the underlying illness. The etiologic bacteriologic agents associated with VAP typically differ based on the timing of the occurrence of the infection relative to the start of mechanical ventilation. VAP occurring within 96 hours of the onset of mechanical ventilation is usually due to antibiotic-sensitive bacteria that colonize the patient prior to hospital admission, whereas VAP developing after 96 hours of ventilatory support is more often associated with MDROs. Prevention remains the key to reducing the burden of VAP (Klompas, File, & Bond, 2019; Timsit, Esaied, Neuville, et al., 2017). See Chart 19-6 for an overview of bundled interventions aimed at preventing VAP.

Chart 19-6

Collaborative Practice Interventions to Prevent Ventilator-Associated Pneumonia

Current best practices can include the implementation of specific evidence-based bundle interventions that, when used together (i.e., as a "bundle"), improve patient outcomes. This chart outlines specific parameters for the ventilator-bundled collaborative interventions that have been found to reduce ventilator-associated pneumonia (VAP).

What are the five key elements of the VAP bundle?

- Elevation of the head of the bed (30° to 45°)
- Daily "sedation vacations" and assessment of readiness to extubate (see below)
- Peptic ulcer disease prophylaxis
- Deep venous thrombosis (DVT) prophylaxis (see below)
- Daily oral care with chlorhexidine (0.12% oral rinses)

What is meant by daily "sedation vacations," and how does this tie into assessing readiness to extubate?

- Protocols should be developed so that sedative doses are purposely decreased at a time of the day when it is possible to assess the patient's neurologic readiness for extubation.
- Vigilance must be employed during the time that sedative doses are lower to ensure that the patient does not self-extubate.

What effect does DVT prophylaxis have on preventing VAP?

- The exact relationship is unclear. However, when appropriate, evidence-based methods to ensure DVT prophylaxis are applied (see Chapter 26); then the rates of VAP also drop.

Adapted from Institute for Healthcare Improvement. (2012). How-to guide: Prevent ventilator-associated pneumonia. Cambridge, MA: Institute for Healthcare Improvements. Retrieved on 3/6/2020 at: www.ihi.org/resources/Pages/Tools/HowtoGuidePreventVAP.aspx

Pneumonia in the Immunocompromised Host

Due to advances in immunosuppressive therapy, prevalence of MDROs, and improvements in diagnostic studies, there is an increased incidence of pneumonia in patients who are immunocompromised. Common causative organisms include *Pneumocystis* pneumonia (PCP), fungal pneumonias, and *Mycobacterium tuberculosis.* The organism that causes PCP is now known as *Pneumocystis jiroveci* instead of *Pneumocystis carinii.* The acronym PCP still applies because it can be read "***P****neumo****c****ystis* **p**neumonia."

Pneumonia in the immunocompromised host can occur with the use of corticosteroids or other immunosuppressive agents, chemotherapy, nutritional

depletion, the use of broad-spectrum antimicrobial agents, acquired immune deficiency syndrome (AIDS), genetic immune disorders, and long-term advanced life support technology (mechanical ventilation). It is seen with increasing frequency because affected patients constitute a growing portion of the population; however, pneumonias that typically occur in people who are immunocompromised may also occur in those who are immunocompetent. Pneumonia carries a higher morbidity and mortality rate in patients who are immunocompromised than in those who are immunocompetent (Zhao & Shin, 2019). Patients with compromised immune systems commonly develop pneumonia from organisms of low virulence. In addition, increasing numbers of patients with impaired defenses develop HAP from gram-negative bacilli (*Klebsiella, Pseudomonas, E. coli,* Enterobacteriaceae, *Proteus, Serratia*) (Zhao & Shin, 2019).

Whether patients are immunocompromised or immunocompetent, the clinical presentation of pneumonia is similar. PCP has a subtle onset, with progressive dyspnea, fever, and a nonproductive cough.

Aspiration Pneumonia

Aspiration pneumonia refers to the pulmonary consequences resulting from entry of endogenous or exogenous substances into the lower airway. The most common form of aspiration pneumonia is bacterial infection from aspiration of bacteria that normally reside in the upper airways. Aspiration pneumonia may occur in the community or hospital setting. Common pathogens are anaerobes, *S. aureus, Streptococcus* species, and gram-negative bacilli (Bartlett, 2019a). Substances other than bacteria may be aspirated into the lung, such as gastric contents, exogenous chemical contents, or irritating gases. This type of aspiration or ingestion may impair the lung defenses, cause inflammatory changes, and lead to bacterial growth and a resulting pneumonia (see later discussion of aspiration).

Pathophysiology

Normally, the upper airway prevents potentially infectious particles from reaching the sterile lower respiratory tract. Pneumonia arises from normal flora present in patients whose resistance has been altered or from aspiration of flora present in the oropharynx; patients often have an acute or chronic underlying disease that impairs host defenses. Pneumonia may also result from bloodborne organisms that enter the pulmonary circulation and are trapped in the pulmonary capillary bed.

Pneumonia affects both ventilation and diffusion. An inflammatory reaction can occur in the alveoli, producing an exudate that interferes with the diffusion of oxygen and carbon dioxide. White blood cells, mostly neutrophils, also migrate into the alveoli and fill the normally air-filled spaces. Areas of the

lung are not adequately ventilated because of secretions and mucosal edema that cause partial occlusion of the bronchi or alveoli, with a resultant decrease in alveolar oxygen tension. Bronchospasm may also occur in patients with reactive airway disease. Because of hypoventilation, a **ventilation–perfusion** (V./Q.) mismatch occurs in the affected area of the lung. V./Q. refers to the ratio between ventilation and perfusion in the lung, which is normally approximately 4 to 5, or 0.8; matching of ventilation to perfusion optimizes gas exchange. Venous blood entering the pulmonary circulation passes through the underventilated area and travels to the left side of the heart poorly oxygenated. The mixing of oxygenated and unoxygenated or poorly oxygenated blood eventually results in arterial hypoxemia.

If a substantial portion of one or more lobes is involved, the disease is referred to as lobar pneumonia. The term *bronchopneumonia* is used to describe pneumonia that is distributed in a patchy fashion, having originated in one or more localized areas within the bronchi and extending to the adjacent surrounding lung parenchyma. Bronchopneumonia is more common than lobar pneumonia (see Fig. 19-2).

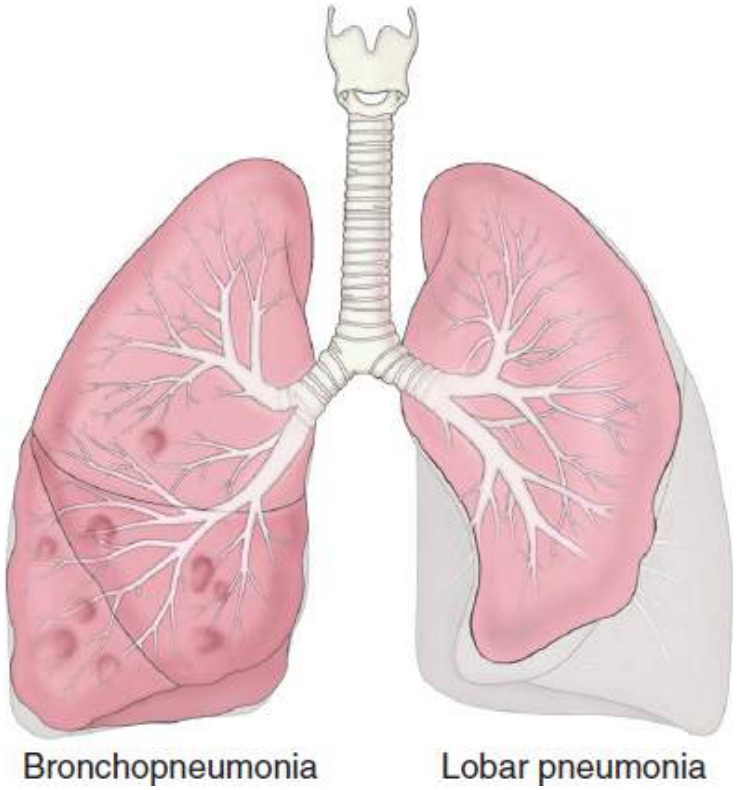

Figure 19-2 • Distribution of lung involvement in bronchial and lobar pneumonia. In bronchopneumonia (*left*), patchy areas of consolidation occur. In lobar pneumonia (*right*), an entire lobe is consolidated.

Risk Factors

Being knowledgeable about the factors and circumstances that commonly predispose people to pneumonia helps identify patients at high risk for the disease (Bartlett, 2019a). Table 19-2 describes risk factors for pneumonia; additional risk factors are travel or exposure to certain environments and residence in a long-term care facility. Increasing numbers of patients who have compromised defenses against infections are susceptible to pneumonia. Some types of pneumonia, such as those caused by viral infections, occur in previously healthy people, often after a viral illness.

Pneumonia occurs in patients with certain underlying disorders such as heart failure, diabetes, alcoholism, COPD, and AIDS (Klompas, 2019a). Certain diseases also have been associated with specific pathogens. For example, staphylococcal pneumonia has been noted after epidemics of influenza, and patients with COPD are at increased risk for development of pneumonia caused by pneumococci or *H. influenzae.* In addition, cystic fibrosis is associated with respiratory infection caused by pseudomonal and staphylococcal organisms, and PCP has been associated with AIDS. Pneumonias occurring in hospitalized patients often involve organisms not usually found in CAP, including enteric gram-negative bacilli and *S. aureus.*

TABLE 19-2 Risk Factors and Preventive Measures for Pneumonia

Risk Factor	Preventive Measure
Conditions that produce mucus or bronchial obstruction and interfere with normal lung drainage (e.g., cancer, cigarette smoking, chronic obstructive pulmonary disease)	Promote coughing and expectoration of secretions. Encourage smoking cessation
Patients who are immunosuppressed or neutropenic (low neutrophil count)	Initiate special precautions against infection
Smoking (cigarette smoke disrupts both mucociliary and macrophage activity)	Encourage smoking cessation
Prolonged immobility and shallow breathing pattern	Reposition frequently and promote lung expansion exercises and coughing. Initiate suctioning and chest physical therapy if indicated
Depressed cough reflex (due to medications, a debilitated state, or weak respiratory muscles); aspiration of foreign material into the lungs during a period of unconsciousness (head injury, anesthesia, depressed level of consciousness), or abnormal swallowing mechanism	Reposition frequently to prevent aspiration and administer medications judiciously, particularly those that increase risk for aspiration. Perform suctioning and chest physical therapy if indicated
Nothing-by-mouth (NPO) status; placement of nasogastric, orogastric, or endotracheal tube	Promote frequent oral hygiene. Minimize risk for aspiration by checking placement of tube and proper positioning of patient
Supine positioning in patients unable to protect their airway	Elevate head of bed at least 30 degrees
Antibiotic therapy (in people who are very ill, the oropharynx is likely to be colonized by gram-negative bacteria)	Monitor patients receiving antibiotic therapy for signs and symptoms of pneumonia
Alcohol intoxication (because alcohol suppresses the body's reflexes, may be associated with aspiration, and decreases white cell mobilization and tracheobronchial ciliary motion)	Encourage reduced or moderate alcohol intake (in case of alcohol stupor, position patient to prevent aspiration)
General anesthetic, sedative, or opioid preparations that promote respiratory depression, which causes a shallow breathing pattern and predisposes to the pooling of bronchial secretions and potential development of pneumonia	Observe the respiratory rate and depth during recovery from general anesthesia and before giving medications. If respiratory depression is apparent, withhold the medication and contact the primary provider
Advanced age, because of possible depressed cough and glottic reflexes and nutritional depletion	Promote frequent turning, early ambulation and mobilization, effective coughing, breathing exercises, and nutritious diet

Respiratory therapy with improperly cleaned equipment	Make sure that respiratory equipment is cleaned properly; participate in continuous quality improvement monitoring with the respiratory care department
Transmission of organisms from health care providers	Use strict hand hygiene and gloves. Implement health care provider education

Adapted from Ramirez, J. A. (2019). Overview of community acquired pneumonia in adults. *UpToDate*. Retrieved on 9/23/2019 at: www.uptodate.com/contents/overview-of-community-acquired-pneumonia-in-adults

Clinical Manifestations

Pneumonia varies in its signs and symptoms depending on the type, causal organism, and presence of underlying disease. However, it is not possible to diagnose a specific form or classification of pneumonia by clinical manifestations alone. The patient with streptococcal (pneumococcal) pneumonia usually has a sudden onset of chills, rapidly rising fever (38.5° to 40.5°C [101° to 105°F]), and pleuritic chest pain that is aggravated by deep breathing and coughing. The patient is severely ill, with marked tachypnea (25 to 45 breaths/min), accompanied by other signs of respiratory distress (e.g., shortness of breath and the use of accessory muscles in respiration) (Weinberger, Cockrill, & Mandel, 2019). A relative bradycardia (a pulse–temperature deficit in which the pulse is slower than that expected for a given temperature) may suggest viral infection, mycoplasma infection, or infection with a *Legionella* organism.

Some patients exhibit an upper respiratory tract infection (nasal congestion, sore throat), and the onset of symptoms of pneumonia is gradual and nonspecific. The predominant symptoms may be headache, low-grade fever, pleuritic pain, myalgia, rash, and pharyngitis. After a few days, mucoid or mucopurulent sputum is expectorated. In severe pneumonia, the cheeks are flushed and the lips and nail beds demonstrate central cyanosis (a late sign of hypoxemia).

The patient may exhibit **orthopnea** (shortness of breath when reclining or in the supine position), preferring to be propped up or sitting in bed leaning forward (orthopneic position) in an effort to achieve adequate gas exchange without coughing or breathing deeply. Appetite is poor, and the patient is diaphoretic and tires easily. Sputum is often purulent; however, this is not a reliable indicator of the etiologic agent. Rusty, blood-tinged sputum may be expectorated with streptococcal (pneumococcal), staphylococcal, and *Klebsiella* pneumonia.

Signs and symptoms of pneumonia may also depend on a patient's underlying condition. Different signs occur in patients with conditions such as

cancer, and in those who are undergoing treatment with immunosuppressant medications, which decrease the resistance to infection. Such patients have fever, crackles, and physical findings that indicate consolidation of lung tissue, including increased tactile fremitus (vocal vibration detected on palpation), percussion dullness, bronchial breath sounds, egophony (when auscultated, the spoken "E" becomes a loud, nasal-sounding "A"), and whispered pectoriloquy (whispered sounds are easily auscultated through the chest wall). These changes occur because sound is transmitted better through solid or dense tissue (consolidation) than through normal air-filled tissue; these sounds are described in Chapter 17.

Purulent sputum or slight changes in respiratory symptoms may be the only sign of pneumonia in patients with COPD. Determining whether an increase in symptoms is an exacerbation of the underlying disease process or an additional infectious process may be difficult.

Assessment and Diagnostic Findings

The diagnosis of pneumonia is made by history (particularly of a recent respiratory tract infection), physical examination, chest x-ray, blood culture (bloodstream invasion [bacteremia] occurs frequently), and sputum examination. The sputum sample is obtained by having patients rinse the mouth with water to minimize contamination by normal oral flora, breathe deeply several times, cough deeply, and expectorate the raised sputum into a sterile container.

More invasive procedures may be used to collect specimens. Sputum may be obtained by nasotracheal or orotracheal suctioning with a sputum trap or by fiberoptic bronchoscopy (see Chapter 17). Bronchoscopy is often used in patients with acute severe infection, in patients with chronic or refractory infection, in patients with compromised immune systems when a diagnosis cannot be made from an expectorated or induced specimen, and in patients who are mechanically ventilated. Bronchoscopic techniques may include a protected brush specimen or bronchoalveolar lavage.

Unfolding Patient Stories: Kenneth Bronson • Part 1

Kenneth Bronson, a 27-year-old man, has a history of fatigue, high fever, and a productive cough for a week and arrives in the emergency department with difficulty breathing. A chest x-ray reveals a right lower lobe pneumonia. What are the clinical manifestations and assessment findings associated with a right lower lobe pneumonia that the nurse should investigate when evaluating the patient? (Kenneth Bronson's story continues in Chapter 22.)

Care for Kenneth and other patients in a realistic virtual environment: vSim (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Prevention

Pneumococcal vaccination reduces the incidence of pneumonia, hospitalizations for cardiac conditions, and deaths in the older adult population. There are two types of pneumococcal vaccine recommended for adults: a pneumococcal conjugate vaccine (PCV13) and a pneumococcal polysaccharide vaccine (PPSV23) (CDC, 2017c).

PCV13 protects against 13 types of pneumococcal bacteria. PCV13 is recommended for all adults 65 years of age or older as well as adults 19 years or older with conditions that weaken the immune system, such as HIV infection, organ transplantation, leukemia, lymphoma, chronic kidney disease, and asplenism, or with cerebrospinal fluid leak or with cochlear implants (CDC, 2017b). PPSV23 is a newer vaccine and protects against 23 types of pneumococcal bacteria. It is recommended for all adults 65 years of age or older and for those adults 19 through 64 years of age who smoke cigarettes or who have chronic heart, lung, or liver disease, or alcoholism (CDC, 2017b). Most patients who have previously received PCV13 should receive PPSV23. In particular, all adults 65 years of age or older who previously received the PCV13 should receive the PPSV23 vaccine. For immunocompetent adults age 65 or older who have not received PCV13, a dose of PCV13 should be given followed by PPSV23 at least 1 year later. These two vaccines should not be co-administered (CDC, 2017b). As pneumococcal vaccination guidelines may change from year to year, it is important to consult the CDC web site for the most current recommendations. Other preventive measures are summarized in Table 19-2.

Medical Management

Medical management of patients with pneumonia includes prescribing appropriate antibiotics for bacterial pneumonias; assisting the patient to get adequate rest and hydration; and managing complications if they occur. In some patients, supplemental oxygenation may be prescribed.

Pharmacologic Therapy

The treatment of pneumonia includes administration of the appropriate antibiotic as determined by the results of a culture and sensitivity. However, the causative organism is not identified in half of CAP cases when therapy is initiated (File, 2019b). Guidelines are used to guide antibiotic choice; however, the resistance patterns, prevalence of causative organisms, patient risk factors, treatment setting (inpatient vs. outpatient), and costs and availability of newer antibiotic agents must all be considered. See Table 19-3 for the treatment of patients with pneumonia due to specific pathogens.

Inpatients should be switched from intravenous (IV) to oral therapy when they are hemodynamically stable, are improving clinically, are able to take medications/fluids by mouth, and have a normally functioning gastrointestinal tract. As soon as patients are clinically stable, have no medical problems, and have a safe environment for continued care, they should be discharged from the hospital. Clinical stability is defined as temperature less than or equal to 37.8°C (100°F), heart rate less than or equal to 100 bpm, respiratory rate less than or equal to 24 breaths/min, systolic blood pressure greater than or equal to 90 mm Hg, and oxygen saturation greater than or equal to 90%, with ability to maintain oral intake and normal (baseline) mental status.

TABLE 19-3 Commonly Encountered Pneumonias

Type (Causal Organism)	Epidemiology	Clinical Features	Treatment	Complications/ Comments
Community-Acquired Pneumonia				
Streptococcal pneumonia (*Streptococcus pneumoniae*)	Most prevalent in winter months More frequent occurrence in African Americans Incidence greatest in older adults and in patients with COPD, heart failure, alcoholism, asplenia, diabetes, and after influenza Leading infectious cause of illness worldwide among young children, people with underlying chronic health conditions, and older adults Mortality rate (in hospitalized adults with invasive disease): 14%	Abrupt onset, toxic appearance, pleuritic chest pain; usually involves ≥1 lobes Lobar infiltrate common on chest x-ray or bronchopneumonia pattern	Severity determines type of antibiotic and route (IV vs. oral) PCN sensitive: PCN, amoxicillin, ceftriaxone, cefotaxime, cefpodoxime, cefprozil or a macrolide PCN resistant: levofloxacin, moxifloxacin, vancomycin, or linezolid	Shock, pleural effusion, superinfections, pericarditis, and otitis media
Haemophilus influenzae (*Haemophilus influenzae*)	Incidence greatest in patients with alcoholism, older adults, patients in long-term care facilities and nursing homes, patients with diabetes or COPD, and children <5 yrs of age Accounts for 5–20% of community-acquired pneumonias Mortality rate: 30%	Frequently insidious onset associated with upper respiratory tract infection 2–6 wks before onset of illness; fever, chills, productive cough; usually involves ≥1 lobes Sepsis is common. Infiltrate, occasional bronchopneumonia pattern on chest x-ray	Severity determines type of antibiotic and route (IV vs. oral) doxycycline, third-generation cephalosporin (ceftriaxone) or a fluoroquinolone	Lung abscess, pleural effusion, meningitis, arthritis, pericarditis, epiglottitis
Legionnaires disease (*Legionella pneumophila*)	Highest occurrence in summer and fall May cause disease sporadically or as part of an epidemic Incidence greatest in middle-aged and older men, people who smoke, patients with chronic diseases, those receiving immunosuppressive therapy, and those in close proximity to excavation sites Accounts for 15% of community-acquired pneumonias Mortality rate: 15–50%	Flulike symptoms; high fevers, mental confusion, headache, pleuritic pain, myalgias, dyspnea, productive cough, hemoptysis, leukocytosis Bronchopneumonia, unilateral or bilateral disease, lobar consolidation	Severity determines type of antibiotic and route (IV vs. oral) Azithromycin, moxifloxacin, or a fluoroquinolone	Hypotension, shock, and acute kidney injury
Mycoplasma pneumoniae (*Mycoplasma pneumoniae*)	Increase in fall and winter Responsible for epidemics of respiratory illness Most common type of atypical pneumonia Accounts for 20% of community-acquired pneumonias; more common in children and young adults Mortality rate: <0.1%	Onset is usually insidious. Patients not usually as ill as in other pneumonias. Sore throat, nasal congestion, ear pain, headache, low-grade fever, pleuritic pain, myalgias, diarrhea, erythematous rash, pharyngitis. Interstitial infiltrates on chest x-ray	Severity determines type of antibiotic and route (IV vs. oral) Macrolides, combination drugs (macrolide plus ampicillin and sulbactam) or tetracyclines (doxycycline)	Aseptic meningitis, meningoencephalitis, transverse myelitis, cranial nerve palsies, pericarditis, myocarditis
Viral pneumonia (influenza virus types A, B adenovirus, parainfluenza, cytomegalovirus, coronavirus, varicella-zoster)	Incidence greatest in winter months Epidemics occur every 2–3 yrs. Most common causative organisms in adults; other organisms in children (e.g., cytomegalovirus and respiratory syncytial virus) Accounts for 20% of community-acquired pneumonias	Patchy infiltrate, small pleural effusion on chest x-ray In most patients, influenza begins as an acute upper respiratory infection; others have bronchitis, pleurisy, and so on, and still others develop gastrointestinal symptoms	Treated symptomatically; treat in high-risk patients; oseltamivir or zanamivir (+ other agents depending upon dominant strain [type of virus]) Does not respond to treatment with currently available antimicrobials	Superimposed bacterial infection, bronchopneumonia

Chlamydial pneumonia (*Chlamydophila pneumoniae*)	Reported mainly in college students, military recruits, and older adults May be a common cause of community-acquired pneumonia or observed in combination with other pathogens Mortality rate is low because the majority of cases are relatively mild. Older adults with coexistent infections, comorbidities, and reinfections may require hospitalization	Hoarseness, fever, chills, pharyngitis, rhinitis, nonproductive cough, myalgias, arthralgias Single infiltrate on chest x-ray; pleural effusion possible	Macrolide or doxycycline	Reinfection and acute respiratory failure
Hospital-Acquired and Health Care–Associated Pneumonias				
Pseudomonas pneumonia (*Pseudomonas aeruginosa*)	Incidence greatest in those with preexisting lung disease, cancer (particularly leukemia); those with homograft transplants; burns; people who are debilitated; and patients receiving antimicrobial therapy and treatments such as tracheostomy, suctioning, and in postoperative settings. Almost always of nosocomial origin Accounts for 15% of hospital-acquired pneumonias Mortality rate: 40–60%	Diffuse consolidation on chest x-ray; toxic appearance: fever, chills, productive cough, relative bradycardia, leukocytosis	Sensitivity tests guide choice and severity determines type of antibiotic and route (IV vs. oral): ceftazidime, ciprofloxacin, cefepime, aztreonam, imipenem/cilastatin, meropenem, piperacillin, +/– an aminoglycoside	Lung cavitation; has capacity to invade blood vessels, causing hemorrhage and lung infection; usually requires hospitalization
Staphylococcal pneumonia (*Staphylococcus aureus*)	Incidence greatest in immunocompromised patients, IV drug users, and as a complication of epidemic influenza Commonly nosocomial in origin Accounts for 10–30% of hospital-acquired pneumonias Mortality rate: 25–60% MRSA may also cause community-based infection	Severe hypoxemia, cyanosis, necrotizing infection. Sepsis is common	Severity determines type of antibiotic and route (IV vs. oral) MSSA: oxacillin or nafcillin MRSA or PCN allergy: vancomycin or linezolid	Pleural effusion/pneumothorax, lung abscess, empyema, meningitis, endocarditis Frequently requires hospitalization. Treatment must be vigorous and prolonged because disease tends to destroy lung tissue
Klebsiella pneumonia (*Klebsiella pneumoniae* [Friedländer's bacillus—encapsulated gram-negative aerobic bacillus])	Incidence greatest in older adults; patients with alcoholism; patients with chronic disease, such as diabetes, heart failure, COPD; patients in chronic care facilities and nursing homes Accounts for 2–5% of community-acquired and 10–30% of hospital-acquired pneumonias Mortality rate: 40–50%	Tissue necrosis occurs rapidly. Toxic appearance: fever, cough, sputum production, bronchopneumonia, lung abscess. Lobar consolidation, bronchopneumonia pattern on chest x-ray	Severity determines type of antibiotic and route (IV vs. oral) Hospital acquired: cefepime, ceftazidime, imipenem, meropenem, or piperacillin/tazobactam plus an aminoglycoside or a fluoroquinolone; Community acquired: a levofloxacin plus ciprofloxacin or nitrofurantoin or nitrofurantoin macrocrystals	Multiple lung abscesses with cyst formation, empyema, pericarditis, pleural effusion; may be fulminating, progressing to fatal outcome
Pneumonia in the Immunocompromised Host				
Pneumocystis pneumonia (*Pneumocystis jirovecii*)	Incidence greatest in patients with AIDS and patients receiving immunosuppressive therapy for cancer, organ transplantation, and other disorders Frequently seen with cytomegalovirus infection Mortality rate 15–20% in hospitalized patients and fatal if not treated	Pulmonary infiltrates on chest x-ray; nonproductive cough, fever, dyspnea	Severity determines type of antibiotic and route (IV vs. oral) Trimethoprim/sulfamethoxazole	Respiratory failure

Fungal pneumonia (*Aspergillus fumigatus*)	Incidence greatest in patients who are immunocompromised or neutropenic Mortality rate: 15–20%	Cough, hemoptysis, infiltrates, fungus ball on chest x-ray	Severity determines type of antibiotic and route (IV vs. oral) Voriconazole, for invasive disease; amphotericin B or liposomal amphotericin B or caspofungin Lobectomy for fungus ball	Dissemination to brain, myocardium, and thyroid gland
Tuberculosis (*Mycobacterium tuberculosis*)	Incidence increased in indigent, immigrant, and prison populations; people with AIDS; and people who are homeless Mortality rate: <1% (depending on comorbidity)	Weight loss, fever, night sweats, cough, sputum production, hemoptysis, nonspecific infiltrate (lower lobe), hilar node enlargement, pleural effusion on chest x-ray	Isoniazid + rifampin + ethambutol + pyrazinamide (see section on TB and Table 10-4)	Reinfection and acute respiratory infection
Pneumonia from Aspiration				
Anaerobic bacteria (*S. pneumoniae*, *H. influenzae*, *S. aureus*)	Risk: reduced consciousness, dysphagia, disorders of upper GI tract, mechanical disruption of glottic closure (endotracheal tube, tracheostomy, nasogastric feeding)	Abrupt onset of dyspnea, low-grade fever, cough, predisposing condition for aspiration	Severity determines type of antibiotic and route (IV vs. oral) Clindamycin +/– a fluoroquinolone	Identification of potential aspirate is important for treatment

AIDS, acquired immune deficiency syndrome; COPD, chronic obstructive pulmonary disease; GI, gastrointestinal; IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *Staphylococcus aureus*; PCN, penicillin; TB, tuberculosis

Adapted from Gilbert, D. N., Chambers, H. F., Eliopoulos, G. M., et al. (2018). *The Sanford guide to antimicrobial therapy 2018* (48th ed.). Sperryville, VA: Antimicrobial Therapy, Inc.

In suspected HAP, treatment is usually initiated with a broad-spectrum IV antibiotic and may be monotherapy or combination therapy. For patients with no known multidrug resistance, monotherapy with ceftriaxone, ampicillin/sulbactam, levofloxacin, or ertapenem is used. With known multidrug resistance, a three-drug combination therapy may be used; this drug regimen may include an antipseudomonal cephalosporin or ceftazidime or antipseudomonal carbapenem or piperacillin/tazobactam plus antipseudomonal fluoroquinolone or aminoglycoside plus linezolid or vancomycin. The patient's status must be assessed 72 hours after the initiation of therapy, and antibiotics should be discontinued or modified based on the culture results. Of concern is the rampant rise in respiratory pathogens that are resistant to available antibiotics. Examples include vancomycin-resistant enterococcus (VRE), MRSA, and drug-resistant *S. pneumoniae*. Providers tend to prescribe antibiotics aggressively in the presence of suspected infection. Mechanisms to monitor and minimize the inappropriate use of antibiotics are in place. In response to antibiotic resistant organisms, the CDC recommends all acute care hospitals participate in an antibiotic stewardship program (CDC, 2019b). Antibiotic stewardship refers to a set of coordinated strategies to improve the use of antimicrobial medications with the goal of enhancing patient health outcomes, reducing resistance to antibiotics, and decreasing unnecessary costs (CDC, 2019a; Nathwani, Varghese, Stephens, et al., 2019). Education of clinicians about the use of evidence-based guidelines in the treatment of respiratory infection is important, and some institutions have implemented algorithms to assist clinicians in choosing the appropriate antibiotics. Monitoring and surveillance of susceptibility patterns for pathogens are also important.

Other Therapeutic Regimens

Antibiotics are ineffective in viral upper respiratory tract infections and pneumonias, and their use may be associated with adverse effects. Antibiotics are indicated with a viral respiratory infection *only* if a secondary bacterial pneumonia, bronchitis, or rhinosinusitis is present. With the exception of the use of antimicrobial therapy, treatment of viral pneumonia is generally the same as that for bacterial pneumonia; however, different treatments have been used for the patient who develops pneumonia as a result of infection with the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the virion implicated in COVID-19 (Kim & Gandhi, 2020) (see later discussion).

Treatment of viral pneumonia is primarily supportive. Hydration is a necessary part of therapy, because fever and tachypnea may result in insensible fluid losses. Antipyretic agents may be used to treat headache and fever; antitussive medications may be used for the associated cough. Warm, moist inhalations are helpful in relieving bronchial irritation. Antihistamines may provide benefit with reduced sneezing and rhinorrhea. Nasal decongestants may also be used to treat symptoms and improve sleep; however, excessive use can cause rebound nasal congestion. Bed rest is prescribed until the infection shows signs of clearing. If hospitalized, the patient is observed carefully until the clinical condition improves.

If hypoxemia develops, oxygen is administered. Pulse oximetry or arterial blood gas analysis is used to determine the need for oxygen and to evaluate the effectiveness of the therapy. Arterial blood gases may be used to obtain a baseline measure of the patient's oxygenation and acid–base status; however, pulse oximetry is used to continuously monitor the patient's oxygen saturation and response to therapy. More aggressive respiratory support measures include administration of high concentrations of oxygen (**fraction of inspired oxygen [FiO_2]**, or the concentration of oxygen that is delivered), ET intubation, and mechanical ventilation. Different modes of mechanical ventilation may be required. Modes of mechanical ventilation are discussed later in this chapter.

Gerontologic Considerations

Pneumonia in older adult patients may occur as a primary diagnosis or as a complication of a chronic disease. Pulmonary infections in older adults frequently are difficult to treat and result in a higher mortality rate than in younger people (Ramirez, 2019). General deterioration, weakness, abdominal symptoms, anorexia, confusion, tachycardia, and tachypnea may signal the onset of pneumonia. The diagnosis of pneumonia may be missed because the classic symptoms of cough, chest pain, sputum production, and fever may be absent or masked in older adult patients. In addition, the presence of some signs may be misleading. Abnormal breath sounds, for example, may be caused by microatelectasis that occurs as a result of decreased mobility, decreased lung volumes, or other respiratory function changes. Chest x-rays

may be needed to differentiate chronic heart failure, which is often seen in older adults, from pneumonia as the cause of clinical signs and symptoms.

Supportive treatment includes hydration (with caution and with frequent assessment because of the risk of fluid overload in older adults); supplemental oxygen therapy; and assistance with deep breathing, coughing, frequent position changes, and early ambulation. All of these are particularly important in the care of older adult patients with pneumonia. To reduce or prevent serious complications of pneumonia in older adults, vaccination against pneumococcal and influenza infections is recommended.

COVID-19 Considerations

SARS-CoV-2 is a community-acquired coronavirus whose primary pathologic evolution occurs within the respiratory system. Viral transmission is presumed to occur through direct person-to-person contact via respiratory droplets, although it is hypothesized that fomite transmission (i.e., transmission from inanimate surfaces that carry the virus) might be possible (Cascella, Rajnik, Cuomo, et al., 2020; Kim & Gandhi, 2020). SARS-CoV-2 enters host cells through ACE2 cellular surface receptors where it replicates; these ACE2 receptors are particularly abundant in type II alveolar and vascular endothelial cells within the pulmonary vascular circuit (see Chapter 27, Fig. 27-2 for an illustration of viral transmission and replication; see Chapter 66 for a discussion of risks of SAR-CoV-2).

At the time of this writing, although it is believed that some patients infected with SARS-CoV-2 may remain asymptomatic, others exhibit signs and symptoms consistent with a type of viral upper respiratory tract infection that may lead to viral pneumonia. Clinical manifestations consistent with mild COVID-19 may include fever, nonproductive cough, sore throat, fatigue, myalgias (muscle aches), nasal congestion, nausea, vomiting, diarrhea, anosmia (loss of smell), and ageusia (loss of taste) (Cascella et al., 2020; CDC, 2020). Data derived from epidemiologic studies in China, where the COVID-19 pandemic originated, suggest that approximately 81% of patients with COVID-19 have mild illness, with either mild viral pneumonia or no pneumonia (Wu & McGoogan, 2020).

Ideally, the diagnosis of COVID-19 is confirmed by patient self-administered bilateral nasal swabbing for viral antigen or nucleic acid. Self-swabbing minimizes risk of person-to-person transmission of respiratory droplets. The act of patient self-swabbing ideally should be observed by a health care provider to assure it is performed properly (CDC, 2020).

Most patients with known or suspected mild COVID-19 may be managed on an outpatient basis within their homes, which conserves hospital resources and diminishes likelihood of exposure to others, including health care workers

(Kim & Gandhi, 2020). At the present time, no specific medications are prescribed to either treat COVID-19 or mitigate its effects in patients with mild disease who are managed at home. The therapeutic regimens that patients with mild COVID-19 are advised to follow mirror those for other viral respiratory illnesses. Patients are advised to rest, hydrate, take antipyretic agents (e.g., acetaminophen) and monitor their symptoms. However, given the virulence of SARS-CoV-2, these patients must be capable of maintaining self-quarantine/isolation at home until all of the following criteria are met (CDC, 2020):

- At least 72 hours have transpired since the patient had a fever and the patient has not taken any antipyretic agents during that timeframe;
- The patient reports an improvement in any respiratory manifestations of COVID-19; and
- At least 10 days have elapsed since the patient first noted clinical manifestations suggestive of COVID-19.

Clinicians and others in contact with patients with suspected or known COVID-19 should observe infection control and prevention measures and utilize appropriate personal protective equipment (PPE; CDC, 2020) (see Chapter 66 for further discussion).

Patients with moderate COVID-19 should be hospitalized so that they may be closely observed on an ongoing basis, because many of these patients may rapidly deteriorate to severe COVID-19 and respiratory failure. These patients have clear evidence of viral pneumonia that may be diagnosed based upon clinical examination, chest x-ray or CT scan findings but have SpO_2 levels >93% on room air, suggesting adequate oxygenation (Cascella et al., 2020; National Institutes of Health COVID-19 Treatment Guidelines Panel [NIH], 2020). These patients may or may not have dyspnea. Laboratory tests upon admission include a CBC with differential, a complete metabolic panel, creatine kinase (CK), lactate dehydrogenase (LDH), C-reactive protein (CRP), ferritin, and D-dimer. Notable findings may include leukopenia (low white blood cell count), lymphopenia (low lymphocyte count), and elevated CK, LDH, CRP, ferritin, and D-dimer levels (Cascella et al., 2020).

It appears at the present time that few patients with COVID-19 have a superinfection with bacterial pathogens (i.e., concomitant bacterial pneumonia); therefore, antibiotic agents are not routinely prescribed for the patient hospitalized to manage moderate COVID-19 pneumonia. However, if it is believed that the patient has a bacterial pneumonia or sepsis, then antibiotic agents indicated to treat CAP are prescribed (Kim & Gandhi, 2020; NIH, 2020) (see previous discussion). Most patients are prescribed anticoagulant agents as prophylaxis, as they have a higher risk of venous thromboembolism (VTE) (see Chapter 26 for further discussion of VTE). The typical agents

prescribed are low-molecular-weight heparins (e.g., enoxaparin, dalteparin), administered twice daily (Kim & Gandhi, 2020).

Currently, there is insufficient evidence to support prescribing any antiviral or immunomodulating agents to manage patients with moderate COVID-19 pneumonia (NIH, 2020). If a patient must be prescribed an inhaled medication (e.g., to manage a preexisting chronic respiratory disease), then to the extent possible, that medication should be administered by a pMDI rather than an SVN, to minimize the likelihood of aerosolizing the patient's respiratory droplets into the ambient air. Ideally, patients hospitalized with moderate COVID-19 pneumonia should be placed in airborne infection isolation rooms, with limitations enforced so that clinicians enter only as necessary, wearing appropriate PPE (NIH, 2020) (see Chapter 66 for further discussion). For instance, the nurse caring for the patient might arrange activities so that assessments are performed and medications are administered at the same time (see Chart 19-7).

The patient with severe COVID-19 pneumonia has SpO_2 ≤93% on room air with tachypnea and requires supplemental oxygen, perhaps with ET intubation and mechanical ventilation (see later discussions on ET intubation and mechanical ventilation). Chest x-ray findings typically show diffuse, bilateral, "ground-glass" opacities (Cascella et al., 2020). Some patients have severe dyspnea, while others report no dyspnea and have been referred to as the *happy hypoxemics* by Caputo, Strayer, and Levitan (2020). Reportedly, many patients deteriorate rapidly and without clear prodromal clinical indicators from moderate to severe disease (Cascella et al., 2020).

Chart 19-7 **ETHICAL DILEMMA**

Is It Ever Ethical to Refuse to Care for a Patient?

Case Scenario

You are a staff nurse in a medical intensive care unit (MICU). Within the past week, there has been a significantly increased incidence of patients infected with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) in two counties that border the county where your hospital is located. Your nurse manager holds an emergency mandatory staff meeting, and informs all staff present that preparations are being made for the hospital to receive and treat a large volume of patients with coronavirus disease 2019 (COVID-19). The MICU where you work has been designated to exclusively treat these patients who are critically ill, while the surgical ICU (SICU) in the hospital will admit all patients who are critically ill but do not have COVID-19. The MICU nurse manager describes hospital administration's plans to manage the distribution and rationing of personal protective equipment (PPE) for MICU staff and identifies new policies that have been emergently put in place to guide their usage, conservation, and disposal. H.S., a MICU staff nurse who works with you, turns to you and says "I am not going to take care of patients with COVID-19! They can find another safer place for me to work in this hospital or I will quit. I did not sign up to be a nurse here to risk my life."

Discussion

Nurses who work in MICUs confront risks to their health on a continuing basis by being in contact with patients who have infectious diseases. Prior to the COVID-19 pandemic, most of these health risks to nurses were minimal. Most pathogens that caused infectious diseases in patients in MICUs could be effectively treated pharmacologically (e.g., with antibiotics) in people with healthy immune systems. Many patients in MICUs who were critically ill with these infectious diseases had comorbid disorders that hampered their immune responses; however, a healthy nurse who became exposed to the pathogen would likely not become infected. Yet if the nurse did become ill, the nurse could have expected an expedient recovery to health after treatment was instituted. The personal risk to the nurse changes dramatically during pandemics, when the nurse is confronted with a novel aggressive contagious pathogen that can cause life-threatening illness in the previously healthy person, without the benefit of clearly effective evidence-based treatment strategies.

Analysis

- Identify the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Should the principle of beneficence have preeminence during pandemics? Can the desire to do the greatest good for the greatest number of people ever be given greater moral credence than ensuring that individual rights are preserved?

- Assume that H.S. is a healthy 24-year-old woman without any known risk factors for COVID-19. Now assume she is 62 years old, with diabetes and hypertension, and that her 88-year-old mother resides with her. Do these factors make a difference in whether or not you would support her desire to not care for patients with COVID-19?
- Do you and H.S. have a professional obligation to care for patients with COVID-19 who are critically ill? Do you have the right to refuse to care for these patients? How might your viewpoint change, depending upon the availability or lack of availability of appropriate PPE? How would you evaluate the new policies put in place that guide the usage, conservation, and disposal of PPE in the MICU? What resources are available for you to evaluate the soundness of this policy, to ensure that you, H.S., and your MICU colleagues are not placed at undue risk? Identify professional resources that might help you to resolve this dilemma.

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

The Centers for Disease Control and Prevention (CDC). (2020). Optimizing supply of PPE and other equipment during shortages. Retrieved on 8/6/2020 at: www.cdc.gov/coronavirus/2019-ncov/hcp/ppe-strategy/index.html

Although patients with severe COVID-19 pneumonia were nearly universally managed with ET intubation and mechanical ventilation during the first weeks of the pandemic, case fatality rates were reportedly much higher than anticipated (Caputo et al., 2020). That observation, along with actual or anticipated shortages of mechanical ventilators, led some providers to try managing patients with other strategies, including trials of placing nonintubated hospitalized patients with COVID-19 in the prone position at periodic intervals, along with administering high flow oxygen therapy. Although not universally effective, data from preliminary research suggest that periodic prone positioning with high flow oxygen therapy can prevent eventual ET intubation in some patients with severe COVID-19 pneumonia (Caputo et al., 2020).

At the present time, there are no immunomodulating agents that are recommended to treat severe COVID-19 pneumonia, although interleukin-6 (IL-6) antagonists (e.g., tocizilumab) are currently under investigation. IL-6 is believed to be a key cytokine responsible for propagating the haywire inflammatory response called cytokine release syndrome (CRS) or the "cytokine storm" that occurs in some patients with severe COVID-19 (NIH, 2020) (see Chapter 12 for further discussion of CRS). Another therapy that is under investigation and approved for emergency use is using convalescent plasma, which transfuses antibodies from patients recovered from COVID-19 into patients with severe disease (Kim & Gandhi, 2020).

It is recommended that the antiviral agent remdesivir be prescribed to treat patients with severe COVID-19 pneumonia as it has demonstrated promising results in clinical trials, notably improved recovery times and overall outcomes (Beigel, Tomashek, Dodd, et al., 2020; NIH, 2020; Wang, Zhang, Du, et al., 2020). Among patients with severe COVID-19 pneumonia, a frequent and serious complication is acute respiratory distress syndrome (ARDS), which is commonly managed with ET intubation and mechanical ventilation (see later discussion). Among patients with COVID-19 and ARDS, the mortality rate is reported at 50% (Anesi, 2020).

Complications

Shock and Respiratory Failure

Severe complications of pneumonia include hypotension and septic shock and respiratory failure (especially with gram-negative bacterial disease or with SARS-CoV-2 infection in older adult patients). These complications are encountered chiefly in patients who have received no specific treatment or inadequate or delayed treatment or in patients at risk for severe COVID-19. These complications are also encountered when the infecting organism is resistant to therapy, when a comorbid disease complicates the pneumonia, or when the patient is immune compromised. (See Chapter 11 for further discussion of management of the patient with septic shock.)

Pleural Effusion

A pleural effusion is an accumulation of pleural fluid in the pleural space (space between the parietal and visceral pleurae of the lung). A parapneumonic effusion is any pleural effusion associated with bacterial pneumonia, lung abscess, or bronchiectasis. After the pleural effusion is detected on a chest x-ray, a thoracentesis may be performed to remove the fluid, which is sent to the laboratory for analysis. There are three stages of parapneumonic pleural effusions based on pathogenesis: uncomplicated, complicated, and thoracic

empyema. An **empyema** occurs when thick, purulent fluid accumulates within the pleural space, often with fibrin development and a loculated (walled-off) area where the infection is located (see later discussion). A chest tube may be inserted to treat pleural infection by establishing proper drainage of the empyema. Sterilization of the empyema cavity requires 4 to 6 weeks of antibiotics, and sometimes surgical management is required.

NURSING PROCESS

The Patient with Bacterial Pneumonia

Assessment

Nursing assessment is critical in detecting pneumonia. Fever, chills, or night sweats in a patient who also has respiratory symptoms should alert the nurse to the possibility of bacterial pneumonia. Respiratory assessment further identifies the clinical manifestations of pneumonia: pleuritic-type pain, fatigue, tachypnea, the use of accessory muscles for breathing, bradycardia or relative bradycardia, coughing, and purulent sputum. The nurse monitors the patient for the following: changes in temperature and pulse; amount, odor, and color of secretions; frequency and severity of cough; degree of tachypnea or shortness of breath; changes in physical assessment findings (primarily assessed by inspecting and auscultating the chest); and changes in the chest x-ray findings.

In addition, it is important to assess older adult patients for unusual behavior, altered mental status, dehydration, excessive fatigue, and concomitant heart failure.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired airway clearance associated with copious tracheobronchial secretions
- Fatigue and activity intolerance associated with impaired respiratory function
- Risk for hypovolaemia associated with fever and a rapid respiratory rate
- Impaired nutritional status
- Lack of knowledge about the treatment regimen and preventive measures

Collaborative Problems/Potential Complications

Based on the assessment data, collaborative problems or potential complications that may occur include the following:

- Continuing symptoms after initiation of therapy
- Sepsis and septic shock
- Respiratory failure
- Atelectasis
- Pleural effusion

- Delirium

Planning and Goals

The major goals may include improved airway patency, increased activity, maintenance of proper fluid volume, maintenance of adequate nutrition, an understanding of the treatment protocol and preventive measures, and absence of complications.

Nursing Interventions

Improving Airway Patency

Removing secretions is important because retained secretions interfere with gas exchange and may slow recovery. The nurse encourages hydration (2 to 3 L/day), because adequate hydration thins and loosens pulmonary secretions. Humidification may be used to loosen secretions and improve ventilation. A high-humidity facemask (using either compressed air or oxygen) delivers warm, humidified air to the tracheobronchial tree, helps liquefy secretions, and relieves tracheobronchial irritation. Coughing can be initiated either voluntarily or by reflex. Lung expansion maneuvers, such as deep breathing with an incentive spirometer, may induce a cough. To improve airway patency, the nurse encourages the patient to perform an effective, directed cough, which includes correct positioning, a deep inspiratory maneuver, glottic closure, contraction of the expiratory muscles against the closed glottis, sudden glottic opening, and an explosive expiration. In some cases, the nurse may assist the patient by placing both hands on the lower rib cage (either anterior or posterior) to focus the patient on a slow deep breath, and then manually assisting the patient by applying constant, external pressure during the expiratory phase.

CPT is important in loosening and mobilizing secretions (see Figs. 20-6 and 20-7 and further discussion in Chapter 20). Indications for CPT include sputum retention not responsive to spontaneous or directed cough, a history of pulmonary problems previously treated with chest physiotherapy, continued evidence of retained secretions (decreased or abnormal breath sounds, change in vital signs), abnormal chest x-ray findings consistent with atelectasis or infiltrates, and deterioration in oxygenation. The patient is placed in the proper position to drain the involved lung segments, then the chest is percussed and vibrated either manually or with a mechanical percussor. The nurse may consult the respiratory therapist for volume expansion protocols and secretion management protocols that help direct the respiratory care of the patient and match the patient's needs with appropriate treatment schedules.

After each position change, the nurse encourages the patient to breathe deeply and cough. If the patient is too weak to cough effectively, the nurse may need to remove the mucus by nasotracheal suctioning. It may take time for secretions to mobilize and move into the central airways for

expectoration. Therefore, it is important for the nurse to monitor the patient for cough and sputum production after the completion of CPT.

The nurse also administers and titrates oxygen therapy as prescribed or via protocols. The effectiveness of oxygen therapy is monitored by improvement in clinical signs and symptoms, patient comfort, and adequate oxygenation values as measured by pulse oximetry or arterial blood gas analysis.

Promoting Rest and Conserving Energy

The nurse encourages the patient who is debilitated to rest and avoid overexertion and possible exacerbation of symptoms. The patient should assume a comfortable position to promote rest and breathing (e.g., semi-Fowler position) and should change positions frequently to enhance secretion clearance and pulmonary ventilation and perfusion. Outpatients must be instructed to avoid overexertion and to engage in only moderate activity during the initial phases of treatment.

Promoting Fluid Intake

The respiratory rate of patients with pneumonia increases because of the increased workload imposed by labored breathing and fever. An increased respiratory rate leads to an increase in insensible fluid loss during exhalation and can lead to dehydration. Therefore, unless contraindicated, increased fluid intake (at least 2 L/day) is encouraged. Hydration must be achieved more slowly and with careful monitoring in patients with preexisting conditions such as heart failure (see Chapter 25).

Maintaining Nutrition

Many patients with shortness of breath and fatigue have a decreased appetite and consume only fluids. Fluids with electrolytes (commercially available drinks, such as Gatorade) may help provide fluid, calories, and electrolytes. Other nutritionally enriched drinks such as oral nutritional supplements may be used to supplement calories. Small, frequent meals may be advisable. In addition, IV fluids and nutrients may be given if necessary.

Promoting Patients' Knowledge

The patient and family are educated about the cause of pneumonia, management of symptoms, signs and symptoms that should be reported to the primary provider or nurse, and the need for follow-up. The patient also needs information about factors (both patient risk factors and external factors) that may have contributed to the development of pneumonia and strategies to promote recovery and prevent recurrence. If the patient is hospitalized, they are instructed about the purpose and importance of management strategies that have been implemented and about the importance of adhering to them during and after the hospital stay.

Explanations should be given simply and in language that the patient can understand. If possible, written instructions and information should be provided, and alternative formats should be provided for patients with hearing or vision loss, if necessary. Because of the severity of symptoms, the patient may require that instructions and explanations be repeated several times.

Monitoring and Managing Potential Complications

Continuing Symptoms After Initiation of Therapy. The patient is observed for response to antibiotic therapy; patients usually begin to respond to treatment within 24 to 48 hours after antibiotic therapy is initiated. If the patient started taking antibiotics before evaluation by culture and sensitivity of the causative organisms, antibiotics may need to be changed once the results are available. The patient is monitored for changes in physical status (deterioration of condition or resolution of symptoms) and for persistent recurrent fever, which may be a result of medication allergy (signaled possibly by a rash); medication resistance or slow response (greater than 48 hours) of the susceptible organism to therapy; pleural effusion; or pneumonia caused by an unusual organism, such as *P. jiroveci* or *Aspergillus fumigatus*. Failure of the pneumonia to resolve or persistence of symptoms despite changes on the chest x-ray raises the suspicion of other underlying disorders, such as lung cancer. As described previously, lung cancers may invade or compress airways, causing an obstructive atelectasis that may lead to pneumonia.

In addition to monitoring for continuing symptoms of pneumonia, the nurse also monitors for other complications, such as septic shock and multiple organ dysfunction syndrome (MODS) and atelectasis, which may develop during the first few days of antibiotic treatment.

Shock and Respiratory Failure. The nurse assesses for signs and symptoms of septic shock and respiratory failure by evaluating the patient's vital signs, pulse oximetry values, and hemodynamic monitoring parameters. The nurse reports signs of deteriorating patient status and assists in administering IV fluids and medications prescribed to combat shock. Intubation and mechanical ventilation may be required if respiratory failure occurs. (Sepsis and septic shock are described in detail in Chapter 11, and care of the patient receiving mechanical ventilation is described later in this chapter.)

Pleural Effusion. If pleural effusion develops and thoracentesis is performed to remove fluid, the nurse assists in the procedure and explains it to the patient. After thoracentesis, the nurse monitors the patient for pneumothorax or recurrence of pleural effusion. If a chest tube needs to be inserted, the nurse monitors the patient's respiratory status (see discussion on chest tubes later in this chapter).

For the procedural guidelines for assisting the patient undergoing a thoracentesis, go to thepoint.lww.com/Brunner15e.

Delirium. A patient with pneumonia is assessed for delirium and other more subtle changes in cognitive status; this is especially true in the older adult. The Confusion Assessment Method (CAM) is a commonly used screening tool (see Chapter 8, Chart 8-7). Confusion, suggestive of delirium, and other changes in cognitive status resulting from pneumonia are poor prognostic signs (File, 2019b). Delirium may be related to hypoxemia, fever, dehydration, sleep deprivation, or developing sepsis. The patient's underlying comorbid conditions may also play a part in the development of confusion. Addressing and correcting underlying factors as well as ensuring patient safety are important nursing interventions.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Depending on the severity of the pneumonia, treatment may occur in the hospital or in the outpatient setting. Patient education is crucial regardless of the setting, and the proper administration of antibiotics is important. In some instances, the patient may be treated initially with IV antibiotics as an inpatient and then discharged to continue the IV antibiotics at home. A seamless system of care must be maintained for the patient from hospital to home; this includes communication between the nurses caring for the patient in both settings.

If oral antibiotics are prescribed, the nurse educates the patient about their proper administration and potential side effects. The patient should be educated about symptoms that require contacting the primary provider: difficulty breathing, worsening cough, recurrent/increasing fever, and medication intolerance.

After the fever subsides, the patient may gradually increase activities. Fatigue and weakness may be prolonged after pneumonia, especially in older adults. The nurse encourages breathing exercises to promote secretion clearance and volume expansion. A patient who is being treated as an outpatient should be contacted by the health care team or instructed to contact the primary provider 24 to 48 hours after starting therapy. The patient is also instructed to return to the clinic or primary provider's office for a follow-up chest x-ray and physical examination. Often, improvement in chest x-ray findings lags behind improvement in clinical signs and symptoms.

The nurse encourages the patient who smokes to stop smoking. Smoking inhibits tracheobronchial ciliary action, which is the first line of defense of the lower respiratory tract. Smoking also irritates the mucous cells of the bronchi and inhibits the function of alveolar macrophage (scavenger) cells. The patient is instructed to avoid stress, fatigue, sudden changes in temperature, and excessive alcohol intake, all of which lower resistance to pneumonia. The nurse reviews with the patient the principles of adequate nutrition and rest, because one episode of pneumonia may make a patient susceptible to recurring respiratory tract infections.

Continuing and Transitional Care. Patients who are severely debilitated or who cannot care for themselves may require referral for home, transitional, or community-based care. During home visits, the nurse assesses the patient's physical status, monitors for complications, assesses the home environment, and reinforces previous education. The patient's adherence to the therapeutic regimen is evaluated (i.e., taking medications as prescribed; performing breathing exercises; consuming adequate fluid and dietary intake; and avoiding smoking, alcohol, and excessive activity). The nurse stresses to the patient and family the importance of monitoring for complications or exacerbation of the pneumonia. The patient is encouraged to obtain an influenza vaccination at the prescribed times, because influenza increases susceptibility to secondary bacterial pneumonia, especially that caused by staphylococci, *H. influenzae,* and *S. pneumoniae.* The patient also is urged to receive the pneumococcal vaccine(s) according to CDC recommendations (see previous discussion).

Evaluation

Expected patient outcomes may include the following:

1. Demonstrates improved airway patency, as evidenced by adequate oxygenation by pulse oximetry or arterial blood gas analysis, normal temperature, normal breath sounds, and effective coughing
2. Rests and conserves energy by limiting activities and remaining in bed while symptomatic and then slowly increasing activities
3. Maintains adequate hydration, as evidenced by an adequate fluid intake and urine output and normal skin turgor
4. Consumes adequate dietary intake, as evidenced by maintenance or increase in body weight without excess fluid gain
5. Verbalizes increased knowledge about management strategies
6. Adheres to management strategies
7. Exhibits no complications
    a. Exhibits acceptable vital signs, pulse oximetry, and arterial blood gas measurements
    b. Reports productive cough that diminishes over time

c. Has absence of signs or symptoms of sepsis, septic shock, respiratory failure, or pleural effusion
d. Remains oriented and aware of surroundings

8. Maintains or increases weight
9. Adheres to treatment protocol and prevention strategies

Aspiration

Aspiration is inhalation of foreign material (e.g., oropharyngeal or stomach contents) into the lungs. It is a serious complication that can cause pneumonia and result in the following clinical picture: tachycardia, dyspnea, central cyanosis, hypertension, hypotension, and potentially death. It can occur when the protective airway reflexes are decreased or absent due to a variety of factors (see Chart 19-8). Studies suggest that aspiration pneumonia accounts for 5% to 15% of CAP (Gamache, 2019).

Pathophysiology

The primary factors responsible for death and complications after aspiration are the volume and character of the aspirated contents. Aspiration pneumonia develops after inhalation of colonized oral or pharyngeal material. The pathologic process involves an acute inflammatory response to bacteria and bacterial products. Most commonly, the causative organisms in community-acquired aspiration pneumonia may include *S. aureus*, *S. pneumoniae*, *H. influenzae*, and *Enterobacter* species (Gamache, 2019).

Chart 19-8 RISK FACTORS

Aspiration

- Seizure activity
- Brain injury
- Decreased level of consciousness from trauma, drug or alcohol intoxication, excessive sedation, or general anesthesia
- Flat body positioning
- Stroke
- Swallowing disorders
- Cardiac arrest

Adapted from American Association of Critical-Care Nurses. (2017b). AACN practice alert: Prevention of aspiration in adults. *Critical Care Nurse*, *37*(3), 88; Bartlett, J. (2019a). Aspiration pneumonia in adults. *UpToDate*. Retrieved on 9/23/2019 at: www.uptodate.com/contents/aspiration-pneumonia-in-adults

A full stomach contains solid particles of food. If these are aspirated, the problem then becomes one of mechanical blockage of the airways and secondary infection. During periods of fasting, the stomach contains acidic gastric juice, which, if aspirated, can be very destructive to the alveoli and capillaries. Fecal contamination (more likely seen in intestinal obstruction) increases the likelihood of death, because the endotoxins produced by intestinal organisms may be absorbed systemically, or the thick proteinaceous material found in the intestinal contents may obstruct the airway, leading to atelectasis and secondary bacterial invasion.

Esophageal conditions may also be associated with aspiration pneumonia. These include dysphagia, esophageal strictures, neoplasm or diverticula, tracheoesophageal fistula, and gastroesophageal reflux disease.

Prevention

The risk of aspiration is indirectly related to the level of consciousness of the patient. Aspiration of small amounts of material from the buccal (oral) cavity is not uncommon, particularly during sleep; however, disease as a result of aspiration does not occur in healthy people because the material is cleared by the mucociliary tree and the macrophages. Witnessed aspiration of large volumes occurs occasionally; however, small-volume clinically silent aspiration is more common. Prevention is the primary goal when caring for patients at risk for aspiration (American Association of Critical Care Nurses [AACN], 2017b).

Quality and Safety Nursing Alert

When a nonfunctioning nasogastric tube allows the gastric contents to accumulate in the stomach, a condition known as silent aspiration may result. Silent aspiration often occurs unobserved and may be more common than suspected. If untreated, massive inhalation of gastric contents develops in a period of several hours.

Compensating for Absent Reflexes

Aspiration may occur if the patient cannot adequately coordinate protective glottic, laryngeal, and cough reflexes. This hazard is increased if the patient has a distended abdomen, is supine, has the upper extremities immobilized in any manner, receives local anesthetic agents to the oropharyngeal or laryngeal area for diagnostic procedures, has been sedated, or has had long-term intubation. Clinical interventions are key to preventing aspiration (see Chart 19-9).

For patients with known swallowing dysfunction or those recently extubated following prolonged ET intubation, a swallowing screen is necessary. Patients deemed at risk are then assessed by a speech therapist. Besides positioning the patient semirecumbent or upright prior to eating, other helpful techniques may include suggesting a soft diet and encouraging the patient to take small bites. The patient should be instructed to keep the chin tucked and the head turned with repeated swallowing. Straws should not be used.

Chart 19-9

Clinical Practices That Prevent Aspiration

- Maintain head-of-bed elevation at an angle of 30 to 45 degrees, unless contraindicated
- Use sedatives as sparingly as possible
- Before initiating enteral tube feeding, confirm the tip location
- For patients receiving tube feedings, assess placement of the feeding tube at 4-hour intervals, assess for gastrointestinal residuals (<150 mL before next feeding) to the feedings at 4-hour intervals
- For patients receiving tube feedings, avoid bolus feedings in those at risk for aspiration
- Consult with primary provider about obtaining a swallowing evaluation before oral feedings are started for patients who were recently extubated but were previously intubated for >2 days
- Maintain endotracheal cuff pressures at an appropriate level, and ensure that secretions are cleared from above the cuff before it is deflated.

American Association of Critical Care Nurses (AACN). (2017b). AACN practice alert: Prevention of aspiration in adults. *Critical Care Nurse*, *37*(3), 88.

When vomiting, people can normally protect their airway by sitting up or turning on the side and coordinating breathing, coughing, gag, and glottic reflexes. If these reflexes are active, an oral airway should not be inserted. If an airway is in place, it should be pulled out the moment the patient gags so as not to stimulate the pharyngeal gag reflex and promote vomiting and aspiration. Suctioning of oral secretions with a catheter should be performed with minimal pharyngeal stimulation.

For patients with an ET tube and feeding tube, the ET cuff pressure should be maintained at greater than 20 cm H_2O (but less than 30 cm H_2O to minimize injury) to prevent leakage of secretions from around the cuff into the lower respiratory tract. In addition, hypopharyngeal suctioning is recommended before the cuff is deflated (AACN, 2017a).

Assessing Feeding Tube Placement

Tube feedings must be given only when it is certain that the feeding tube is positioned correctly in the stomach. Many patients receive enteral feeding directly into the duodenum through a small-bore flexible feeding tube or surgically implanted tube. (See Chapter 39 for discussion of enteral tube feedings.)

Identifying Delayed Stomach Emptying

A full stomach can cause aspiration because of increased intragastric or extragastric pressure. The following may delay emptying of the stomach: intestinal obstruction; increased gastric secretions in gastroesophageal reflex disease; increased gastric secretions during anxiety, stress, or pain; and abdominal distention due to paralytic ileus, ascites, peritonitis, the use of opioids or sedatives, severe illness, or vaginal delivery. (See Chapter 39 for discussion of management of patients receiving gastric tube feedings.)

Managing Effects of Prolonged Intubation

Prolonged ET intubation or tracheostomy (see later discussions) can depress the laryngeal and glottic reflexes because of disuse. Patients with prolonged tracheostomies are encouraged to phonate and exercise their laryngeal muscles. For patients who have had long-term intubation or tracheostomies, it may be helpful to have a speech therapist experienced in swallowing disorders work with the patient to address swallowing problems, as noted previously.

Pulmonary Tuberculosis

Tuberculosis (TB) is an infectious disease that primarily affects the lung parenchyma. It also may be transmitted to other parts of the body, including the meninges, kidneys, bones, and lymph nodes. The primary infectious agent, *M. tuberculosis,* is an acid-fast aerobic rod that grows slowly and is sensitive to heat and ultraviolet light. *Mycobacterium bovis* and *Mycobacterium avium* have rarely been associated with the development of a TB infection.

TB is a worldwide public health problem that is closely associated with poverty, malnutrition, overcrowding, substandard housing, and inadequate health care. Mortality and morbidity rates continue to rise; *M. tuberculosis* infects an estimated one third of the world's population and remains the leading cause of death from infectious disease in the world. In 2017, 10 million people were sick with TB throughout the world, and there were 1.3 million TB-related deaths (CDC, 2018b).

In the United States, 9105 cases of TB were reported in 2017, which is a 2.3% decrease from 2016 (CDC, 2018b). Factors that prevent elimination of TB in the United States include the prevalence of TB among foreign-born residents, delays in detecting and reporting cases of TB, the lack of protection of contacts of people with infectious cases of TB, the presence of a substantial number of people with latent TB, and barriers to supporting clinical and public health expertise in this disease (CDC, 2018b).

Transmission and Risk Factors

TB spreads from person to person by airborne transmission. An infected person releases droplet nuclei (usually particles 1 to 5 mcm in diameter) through talking, coughing, sneezing, laughing, or singing. Larger droplets settle; smaller droplets remain suspended in the air and are inhaled by a susceptible person. Chart 19-10 lists risk factors for TB. Chart 19-11 summarizes the CDC's recommendations for the prevention of TB transmission in health care settings.

Pathophysiology

TB begins when a susceptible person inhales mycobacteria and becomes infected. The bacteria are transmitted through the airways to the alveoli, where they are deposited and begin to multiply. The bacilli also are transported via the lymph system and bloodstream to other parts of the body (kidneys, bones, cerebral cortex) and other areas of the lungs (upper lobes). The body's immune system responds by initiating an inflammatory reaction. Phagocytes (neutrophils and macrophages) engulf many of the bacteria, and TB-specific lymphocytes lyse (destroy) the bacilli and normal tissue. This tissue reaction results in the accumulation of exudate in the alveoli, causing bronchopneumonia. The initial infection usually occurs 2 to 10 weeks after exposure.

Granulomas, new tissue masses of live and dead bacilli, are surrounded by macrophages, which form a protective wall. They are then transformed to a fibrous tissue mass, the central portion of which is called a *Ghon tubercle.* The material (bacteria and macrophages) becomes necrotic, forming a cheesy mass. This mass may become calcified and form a collagenous scar. At this point, the bacteria become dormant, and there is no further progression of active disease.

Chart 19-10 **RISK FACTORS**

Tuberculosis

- Close contact with someone who has active TB. Inhalation of airborne nuclei from a person who is infected is proportional to the amount of time spent in the same air space, the proximity of the person, and the degree of ventilation.
- Immunocompromised status (e.g., those with HIV infection, cancer, transplanted organs, and prolonged high-dose corticosteroid therapy).
- Substance use disorder (individuals who use IV/injection drug or abuse alcohol).
- Any person without adequate health care (those experiencing homelessness; those who are impoverished; and racial–ethnic minorities, particularly children <15 years and young adults between ages 15 and 44 years).
- Preexisting medical conditions or special treatment (e.g., diabetes, chronic kidney disease, malnourishment, select malignancies, hemodialysis, transplanted organ, gastrectomy, and jejunoileal bypass).
- Immigration from or recent travel to countries with a high prevalence of TB (southeastern Asia, Africa, Latin America, Caribbean).
- Institutionalization (e.g., long-term care facilities, psychiatric institutions, prisons).
- Living in overcrowded, substandard housing.
- Being a health care worker performing high-risk activities: administration of aerosolized pentamidine and other medications, sputum induction procedures, bronchoscopy, suctioning, coughing procedures, caring for patients who are immune suppressed, home care with the high-risk population, and administering anesthesia and related procedures (e.g., intubation, suctioning).

TB, tuberculosis.

Adapted from Centers for Disease Control and Prevention (CDC). (2018b). *TB fact sheets-infection control and prevention*; *TB in specific populations*. Retrieved on 9/26/2019 at: www.cdc.gov/tb/statistics/default.htm

After initial exposure and infection, active disease may develop because of a compromised or inadequate immune system response. Active disease also may occur with reinfection and activation of dormant bacteria. In this case, the *Ghon tubercle* ulcerates, releasing the cheesy material into the bronchi. The bacteria then become airborne, resulting in the further spread of the disease. Then, the ulcerated tubercle heals and forms scar tissue. This causes the infected lung to become more inflamed, resulting in the further development of bronchopneumonia and tubercle formation.

Unless this process is arrested, it spreads slowly downward to the hilum of the lungs and later extends to adjacent lobes. The process may be prolonged and is characterized by long remissions when the disease is arrested, followed

by periods of renewed activity. Approximately 10% of people who are initially infected develop active disease (Pozniak, 2019). Some people develop reactivation TB (also called *adult-type progressive TB*). The reactivation of a dormant focus occurring during the primary infection is the cause.

Chart 19-11

Centers for Disease Control and Prevention Recommendations for Preventing Transmission of Tuberculosis in Health Care Settings

1. Early identification and treatment of people with active TB
   a. Maintain a high index of suspicion for TB to identify cases rapidly.
   b. Promptly initiate effective multidrug anti-TB therapy based on clinical and drug-resistance surveillance data.
2. Prevention of spread of infectious droplet nuclei by source control methods and by reduction of microbial contamination of indoor air
   a. Initiate AFB isolation precautions immediately for all patients who are suspected or confirmed to have active TB and who may be infectious. AFB isolation precautions include the use of a private room with negative pressure in relation to surrounding areas and a minimum of six air exchanges per hour. Air from the room should be exhausted directly to the outside. The use of ultraviolet lamps or high-efficiency particulate air filters to supplement ventilation may be considered.
   b. People entering the AFB isolation room should use disposable particulate respirators that fit snugly around the face.
   c. Continue AFB isolation precautions until there is clinical evidence of reduced infectiousness (i.e., cough has substantially decreased and the number of organisms on sequential sputum smears is decreasing). If drug resistance is suspected or confirmed, continue AFB precautions until the sputum smear is negative for AFB.
   d. Use special precautions during cough-inducing procedures.
3. Surveillance for TB transmission
   a. Maintain surveillance for TB infection among health care workers (HCWs) by routine, periodic tuberculin skin testing. Recommend appropriate preventive therapy for HCWs when indicated.
   b. Maintain surveillance for TB cases among patients and HCWs.
   c. Promptly initiate contact investigation procedures among HCWs, patients, and visitors exposed to a patient with infectious TB who is untreated, or ineffectively treated, and for whom appropriate AFB procedures are not in place. Recommend appropriate therapy or preventive therapy for contacts with disease or TB infection without current disease. Therapeutic regimens should be chosen based on the clinical history and local drug-resistance surveillance data.

AFB, acid-fast bacilli; TB, tuberculosis.

Adapted from Centers for Disease Control and Prevention (CDC). (2018b). *TB fact sheets-infection control and prevention*; *TB in specific populations*. Retrieved on 9/26/2019 at: www.cdc.gov/tb/statistics/default.htm

Clinical Manifestations

The signs and symptoms of pulmonary TB are insidious. Most patients have a low-grade fever, cough, night sweats, fatigue, and weight loss. The cough may

be nonproductive, or mucopurulent sputum may be expectorated. **Hemoptysis** (i.e., coughing up blood) also may occur. Both the systemic and the pulmonary symptoms are chronic and may have been present for weeks to months. Older adult patients usually present with less pronounced symptoms than younger patients. Extrapulmonary disease occurs in up to 20% of cases in the United States (Bernardo, 2019). In patients infected with HIV, extrapulmonary disease is more prevalent.

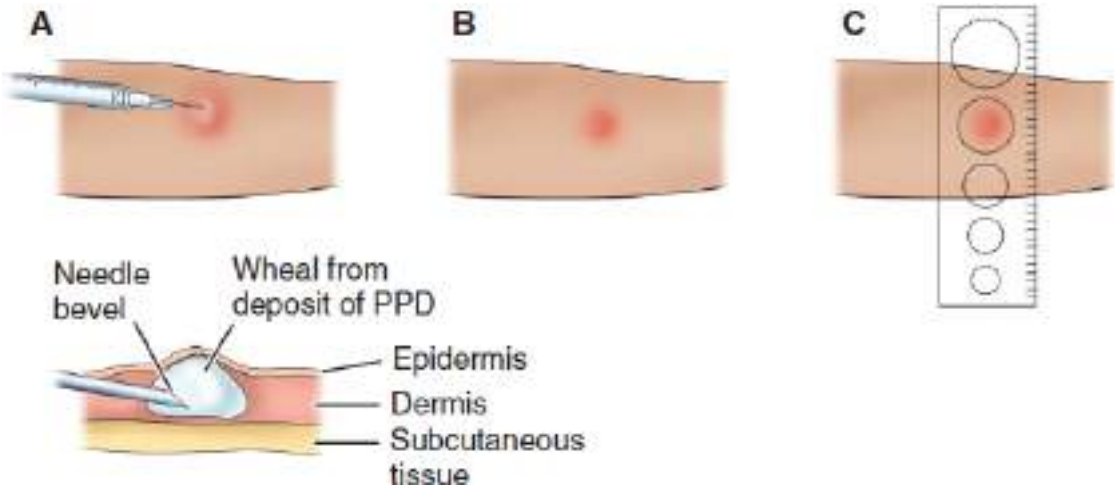

Figure 19-3 • The Mantoux test for tuberculosis. **A.** Correct technique for inserting the needle involves depositing the purified protein derivative (PPD) subcutaneously with the needle bevel facing upward. **B.** The reaction to the Mantoux test usually consists of a wheal, a hivelike, firm welt. **C.** To determine the extent of the reaction, the wheal is measured using a commercially prepared gauge. Interpretation of the Mantoux test is discussed in the text.

Assessment and Diagnostic Findings

Once a patient presents with a positive skin test, blood test, or sputum culture for acid-fast bacilli (AFB; see later discussion on these), additional assessments must be done. These tests include a complete history, physical examination, tuberculin skin test, chest x-ray, and drug susceptibility testing.

Clinical manifestations of fever, anorexia, weight loss, night sweats, fatigue, cough, and sputum production prompt a more thorough assessment of respiratory function—for example, assessing the lungs for consolidation by evaluating breath sounds (diminished, bronchial sounds; crackles), fremitus, and egophony. If the patient is infected with TB, the chest x-ray usually reveals lesions in the upper lobes. For all patients, the initial *M. tuberculosis* isolate should be tested for drug resistance. Drug susceptibility patterns should be repeated at 3 months for patients who do not respond to therapy (Sterling, 2019).

Tuberculin Skin Test

The Mantoux method is used to determine whether a person has been infected with the TB bacillus and is used widely in screening for latent *M. tuberculosis* infection. The Mantoux method is a standardized, intracutaneous injection procedure and should be performed only by those trained in its administration and reading. Tubercle bacillus extract (tuberculin), purified protein derivative (PPD), is injected into the intradermal layer of the inner aspect of the forearm, approximately 4 inches below the elbow (see Fig. 19-3). Intermediate-strength PPD, in a tuberculin syringe with a half-inch 26- or 27-gauge needle, is used. The needle, with the bevel facing up, is inserted beneath the skin. Then, 0.1 mL of PPD is injected, creating an elevation in the skin, a well-demarcated wheal 6 to 10 mm in diameter. The site, antigen name, strength, lot number, date, and time of the test are recorded. The test result is read 48 to 72 hours after injection. Tests read after 72 hours tend to underestimate the true size of **induration** (raised hard area or swelling). A delayed localized reaction indicates that the person is sensitive to tuberculin.

A reaction occurs when both induration and erythema (redness) are present. After the area is inspected for induration, it is lightly palpated across the injection site, from the area of normal skin to the margins of the induration. The diameter of the induration (not erythema) is measured in millimeters at its widest part (see Fig. 19-3), and the size of the induration is documented. Erythema without induration is not considered significant.

The size of the induration determines the significance of the reaction. A reaction of 0 to 4 mm is considered not significant. A reaction of 5 mm or greater may be significant in people who are considered to be at risk. It is defined as positive in patients who are HIV positive or have HIV risk factors and are of unknown HIV status, in those who are close contacts of someone with active TB, and in those who have chest x-ray results consistent with TB. An induration of 10 mm or greater is usually considered significant in people who have normal or mildly impaired immunity. A significant reaction indicates past exposure to *M. tuberculosis* or vaccination with bacille Calmette-Guérin (BCG) vaccine. The BCG vaccine is given to produce a greater resistance to development of TB. The BCG vaccine is used in Europe and Latin America but not routinely in the United States.

A significant (positive) reaction does not necessarily mean that active disease is present in the body. More than 90% of people who are tuberculin-significant reactors do not develop clinical TB (CDC, 2018b). However, all significant reactors are candidates for active TB. In general, the more intense the reaction, the greater the likelihood of an active infection. Additional testing is needed to determine if the person has latent TB infection or active TB.

A nonsignificant (negative) skin test means the person's immune system did not react to the test and that latent TB infection or TB disease is not likely. It does not exclude TB infection or disease, because patients who are

immunosuppressed cannot develop an immune response that is adequate to produce a positive skin test. This is referred to as anergy.

QuantiFERON-TB Gold® Plus and T-SPOT®

There are two TB blood tests (called interferon–gamma release assays or IGRAs) available in the United States: the QuantiFERON-TB Gold® Plus (QFT-Plus) test and the T-SPOT®. TB blood tests are the preferred diagnostic tests for patients who have received the BCG vaccine and for patients who are not likely to return for a second appointment to look for a reaction to the tuberculin skin test. The results of both of these tests are available within 24 to 36 hours. A positive IGRA signifies that the patient has been infected with TB bacteria and additional tests are needed. A negative IGRA means that the patient's blood did not react to the test and a latent or active TB infection is not likely (CDC, 2019d; Theel, Hilgart, Breen-Lyles, et al., 2018).

Sputum Culture

A sputum specimen may be used to screen for TB. The presence of AFB on a sputum smear may indicate disease but does not confirm the diagnosis of TB because some AFB are not *M. tuberculosis.* A culture is done to confirm the diagnosis. For all patients, the initial *M. tuberculosis* isolate should be tested for drug resistance (Sterling, 2019).

Gerontologic Considerations

TB may have atypical manifestations in older adult patients, whose symptoms may include unusual behavior and altered mental status, fever, anorexia, and weight loss. In many older adult patients, the tuberculin skin test produces no reaction (loss of immunologic memory) or delayed reactivity for up to 1 week (recall phenomenon). A second skin test is performed in 1 to 2 weeks. Older adults who live in long-term care facilities are at increased risk for primary and reactivated TB as compared to those in the community (Rajagopalan, 2016).

Medical Management

Pulmonary TB is treated primarily with anti-TB agents for 6 to 12 months. A prolonged treatment duration is necessary to ensure eradication of the organisms and to prevent relapse. The continuing and increasing resistance of *M. tuberculosis* to TB medications is a worldwide concern and challenge in TB therapy. Drug resistance must be considered when planning effective therapy, including the following:

- *Multidrug resistance (MDR TB):* Resistance to two agents, isoniazid and rifampin. The populations at greatest risk for multidrug

resistance are those who are HIV positive, institutionalized, or homeless.

- *Extensively drug resistant (XDR TB)*: Resistance to isoniazid and rifampin, in addition to any fluroquinolone, and at least one of three injectable second-line agents (i.e., amikacin, kanamycin, or capreomycin). The populations at greatest risk are those with HIV infection or other immunocompromised conditions (CDC, 2019d).

The increasing prevalence of drug resistance points out the need to begin TB treatment with four or more medications, to ensure completion of therapy, and to develop and evaluate new anti-TB medications.

TABLE 19-4 First-Line Antituberculosis Medications for Active Disease

Commonly Used Agents	Adult Daily Dosage[a]	Most Common Side Effects	Drug Interactions[b]	Nursing Considerations[c]
Isoniazid	5 mg/kg (300 mg maximum daily)	Peripheral neuritis, hepatic enzyme elevation, hepatitis, hypersensitivity	Phenytoin—synergistic Antabuse Alcohol	Bactericidal Pyridoxine is used as prophylaxis for neuritis. Monitor AST and ALT
Rifampin	10 mg/kg (600 mg maximum daily)	Hepatitis, febrile reaction, purpura (rare), nausea, vomiting	Rifampin increases metabolism of oral contraceptives, quinidine, corticosteroids, coumarin derivatives and methadone, digoxin, oral hypoglycemics. PAS may interfere with absorption of rifampin	Bactericidal Orange urine and other body secretions Discoloring of contact lenses Monitor AST and ALT
Rifabutin	5 mg/kg (300 mg maximum daily)		Avoid protease inhibitors	
Rifapentine	10 mg/kg (600 mg twice weekly)	Hepatotoxicity, thrombocytopenia		Orange-red coloration of body secretions, contact lenses, dentures Use with caution in older adults or in those with renal disease
Pyrazinamide	15–30 mg/kg (2 g maximum daily)[d]	Hyperuricemia, hepatotoxicity, skin rash, arthralgias, GI distress		Bactericidal Monitor uric acid, AST, and ALT
Ethambutol	15–25 mg/kg (1.6 g maximum daily dose)[d]	Optic neuritis (may lead to blindness; very rare at 15 mg/kg), skin rash		Bacteriostatic Use with caution with renal disease or when eye testing is not feasible. Monitor visual acuity, color, and discrimination[e]
Combinations: isoniazid + rifampin	150-mg and 300-mg caps (2 caps daily)			

ALT, alanine transaminase; AST, aspartate transaminase; GI, gastrointestinal; PAS, para-aminosalicylic acid.
[a]Check product labeling for detailed information on dose, contraindications, drug interactions, adverse reactions, and monitoring.
[b]Refer to current literature, particularly on rifampin, because it increases hepatic microenzymes and therefore interacts with many drugs.
[c]Initial examination should be performed at start of treatment.
Adapted from Gilbert, D. N., Chambers, H. F., Eliopoulos, G. M., et al. (2018). *The Sanford guide to antimicrobial therapy 2018* (48th ed.). Sperryville, VA: Antimicrobial Therapy, Inc.

In current TB therapy, four first-line medications are used (see Table 19-4): isoniazid, rifampin, pyrazinamide, and ethambutol. Combination medications, such as isoniazid and rifampin or isoniazid, pyrazinamide, and rifampin and medications given twice a week (e.g., rifapentine) are available to help improve patient adherence. However, these medications are more costly.

Multidrug-resistant TB is difficult to treat. Treatment is guided by sputum specimen culture and sensitivity testing as the patient typically is resistant to isoniazid and rifampin. The World Health Organization (WHO, 2019) recently

published recommendations for treatment consisting of multiple medications to combat drug-resistant organisms. It is important to consult current recommendations for treatment (WHO, 2019).

Recommended treatment guidelines for newly diagnosed cases of pulmonary TB have two phases: an initial treatment phase and a continuation phase (CDC, 2019d). The initial phase consists of a multiple-medication regimen of isoniazid, rifampin, pyrazinamide, and ethambutol plus vitamin B_6 50 mg. All are taken once a day and are oral medications. This initial intensive-treatment regimen is given daily for 8 weeks, after which options for the continuation phase of treatment include isoniazid and rifampin or isoniazid and rifapentine. The continuation regimen lasts for an additional 4 or 7 months. The 4-month period is used for the large majority of patients. The 7-month period is recommended for patients with cavitary pulmonary TB whose sputum culture after the initial 2 months of treatment is positive, for those whose initial phase of treatment did not include pyrazinamide, and for those being treated once weekly with isoniazid and rifapentine whose sputum culture is positive at the end of the initial phase of treatment. People are considered noninfectious after 2 to 3 weeks of continuous medication therapy. The total number of doses taken, not simply the duration of treatment, more accurately determines whether a course of therapy has been completed (CDC, 2019d).

Isoniazid also may be used as a prophylactic (preventive) measure for people who are at risk for significant disease, including:

- Household family members of patients with active disease
- Patients with HIV infection who have a PPD test reaction with 5 mm of induration or more
- Patients with fibrotic lesions suggestive of old TB detected on a chest x-ray and a PPD reaction with 5 mm of induration or more
- Patients whose current PPD test results show a change from former test results, suggesting recent exposure to TB and possible infection (skin test converters)
- Patients who use IV/injection drugs who have PPD test results with 10 mm of induration or more
- Patients with high-risk comorbid conditions and a PPD result with 10 mm of induration or more

Other candidates for preventive isoniazid therapy are those 35 years or younger who have PPD test results with 10 mm of induration or more and one of the following criteria:

- Individuals who are foreign-born from countries with a high prevalence of TB
- Populations that are high-risk and medically underserved
- Patients living in institutions

Prophylactic isoniazid treatment involves taking daily doses for 6 to 12 months. Liver enzymes, blood urea nitrogen (BUN), and creatinine levels are monitored monthly. Sputum culture results are monitored for AFB to evaluate the effectiveness of treatment and the patient's adherence to the treatment regimen.

Nursing Management

Nursing management includes promoting airway clearance, advocating adherence to the treatment regimen, promoting activity and nutrition, and preventing transmission.

Promoting Airway Clearance

Copious secretions obstruct the airways in many patients with TB and interfere with adequate gas exchange. Increasing the fluid intake promotes systemic hydration and serves as an effective expectorant. The nurse instructs the patient about correct positioning to facilitate airway drainage, referred to as postural drainage (see Chapter 20). Postural drainage allows the force of gravity to assist in the removal of bronchial secretions.

Promoting Adherence to Treatment Regimen

Adherence to the prescribed treatment regimen is key in treating the disease and controlling the spread of infection. The multiple-medication regimen that the patient must follow can be quite complex. Understanding of the medications, schedule, and side effects is important. The nurse educates the patient that TB is a communicable disease and that taking medications is the most effective means of preventing transmission. The major reason treatment fails is that patients do not take their medications regularly and for the prescribed duration. This may be due to side effects or the complexity of the treatment regimen. Risk factors for nonadherence to the drug regimen include patients who have previously failed to complete the course of therapy; patients who are physically, emotionally, or mentally challenged; patients unable to pay for medication; patients actively abusing illicit substances; and patients who do not understand the importance of treatment (Reichman & Lardizabal, 2019).

The nurse educates the patient to take the medication either on an empty stomach or at least 1 hour before meals, because food interferes with medication absorption (although taking medications on an empty stomach frequently results in gastrointestinal upset). Patients taking isoniazid should avoid foods that contain tyramine and histamine (tuna, aged cheese, red wine, soy sauce, yeast extracts), because eating them while taking isoniazid may result in headache, flushing, hypotension, lightheadedness, palpitations, and

diaphoresis. Patients should also avoid alcohol because of the high potential for hepatoxic effects.

In addition, rifampin can alter the metabolism of certain other medications, making them less effective. These medications include beta-blockers, oral anticoagulants such as warfarin, digoxin, quinidine, corticosteroids, oral hypoglycemic agents, oral contraceptives, theophylline, and verapamil. This issue should be discussed with the primary provider and pharmacist so that medication dosages can be adjusted accordingly. The nurse informs the patient that rifampin may discolor contact lenses and that the patient may want to wear eyeglasses during treatment. The nurse monitors for other side effects of anti-TB medications, including hepatitis, neurologic changes (hearing loss, neuritis), and rash. Liver enzymes, BUN, and serum creatinine levels are monitored to detect changes in liver and kidney function. Sputum culture results are monitored for AFB to evaluate the effectiveness of the treatment regimen and adherence to therapy.

The nurse educates the patient about the risk of drug resistance if the medication regimen is not strictly and continuously followed. The nurse carefully monitors vital signs and observes for spikes in temperature or changes in the patient's clinical status. Caregivers of patients who are not hospitalized are taught to monitor the patient's temperature and respiratory status. Changes in the patient's respiratory status are reported to the primary provider.

For patients at risk for nonadherence, programs used in the community setting may include comprehensive case management and directly observed therapy (DOT). In case management, each patient with TB is assigned a case manager who coordinates all aspects of the patient's care. DOT consists of a health care provider or other responsible person who directly observes that the patient ingests the prescribed medications. Although successful, DOT is a resource intensive program (Herchline, 2020).

Promoting Activity and Adequate Nutrition

Patients with TB are often debilitated from prolonged chronic illness and impaired nutritional status. The nurse plans a progressive activity schedule that focuses on increasing activity tolerance and muscle strength. Anorexia, weight loss, and malnutrition are common in patients with TB. The patient's willingness to eat may be altered by fatigue from excessive coughing; sputum production; chest pain; generalized debilitated state; or cost, if the patient has few resources. Identifying facilities (e.g., shelters, soup kitchens, Meals on Wheels) that provide meals in the patient's neighborhood may increase the likelihood that the patient with limited resources and energy will have access to a more nutritious intake. A nutritional plan that allows for small, frequent meals may be required. Liquid nutritional supplements may assist in meeting basic caloric requirements.

Preventing Transmission of Tuberculosis Infection

To prevent transmission of TB to others, the nurse carefully educates the patient about important hygiene measures, including mouth care, covering the mouth and nose when coughing and sneezing, proper disposal of tissues, and hand hygiene. TB is a disease that must be reported to the health department so that people who have been in contact with the affected patient during the infectious stage can undergo screening and possible treatment, if indicated.

In addition to the risk of transmission of TB infection to other people, it can also be spread to other parts of the body of affected patients. Spread or dissemination of TB infection to nonpulmonary sites of the body is known as miliary TB. Miliary TB is seen in approximately 1.5% of all patients with TB (Lessnau, 2019). It is the result of invasion of the bloodstream by the tubercle bacillus. Usually, it results from late reactivation of a dormant infection in the lung or elsewhere. The origin of the bacilli that enter the bloodstream is either a chronic focus that has ulcerated into a blood vessel or multitudes of miliary tubercles lining the inner surface of the thoracic duct. The organisms migrate from these foci into the bloodstream, are carried throughout the body, and disseminate throughout all tissues, with tiny miliary tubercles developing in the lungs, spleen, liver, kidneys, meninges, and other organs.

The clinical course of miliary TB may vary from an acute, rapidly progressive infection with high fever to a slowly developing process with low-grade fever, anemia, and debilitation. At first, there may be no localizing signs except an enlarged spleen and a reduced number of leukocytes. However, within a few weeks, the chest x-ray reveals small densities scattered diffusely throughout both lung fields; these are the miliary tubercles, which gradually grow.

The possibility of spread to nonpulmonary sites in the body requires careful monitoring for this very serious form of TB. The nurse monitors vital signs and observes for spikes in temperature as well as changes in renal and cognitive function. Few physical signs may be elicited on physical examination of the chest, but at this stage, the patient has a severe cough and dyspnea. Treatment of miliary TB is the same as for pulmonary TB.

Lung Abscess

A lung abscess is a localized collection of pus caused by microbial infection (Kamangar, 2018). It is generally caused by aspiration of anaerobic bacteria. By definition, in a lung abscess, the chest x-ray demonstrates a cavity of at least 2 cm. Patients who are at risk for aspiration of foreign material and development of a lung abscess include those with impaired cough reflexes who cannot close the glottis and those with swallowing difficulties. Other patients at risk include those with central nervous system disorders (e.g., seizure,

stroke), substance use disorder, esophageal disease, or compromised immune function; patients without teeth and those receiving nasogastric tube feedings; and patients with an altered state of consciousness due to anesthesia (Bartlett, 2019a).

Pathophysiology

Most lung abscesses are a complication of bacterial pneumonia or are caused by aspiration of oral anaerobes into the lung. Abscesses also may occur secondary to mechanical or functional obstruction of the bronchi by a tumor, foreign body, or bronchial stenosis, or from necrotizing pneumonias, TB, pulmonary embolism (PE), or chest trauma.

Most lung abscesses are found in areas of the lung that may be affected by aspiration. The site of the lung abscess is related to gravity and is determined by position. For patients who are confined to bed, the posterior segment of an upper lobe and the superior segment of the lower lobe are the most common areas. However, atypical presentations may occur, depending on the position of the patient when the aspiration occurred.

Initially, the cavity in the lung may or may not extend directly into a bronchus. Eventually, the abscess becomes surrounded, or encapsulated, by a wall of fibrous tissue. The necrotic process may extend until it reaches the lumen of a bronchus or the pleural space and establishes communication with the respiratory tract, the pleural cavity, or both. If the bronchus is involved, the purulent contents are expectorated continuously in the form of sputum. If the pleura is involved, the result is an empyema. A communication or connection between the bronchus and pleura is known as a bronchopleural fistula. The organisms frequently associated with lung abscesses are anaerobic; however, aerobic organisms may be involved as well. The organisms vary depending on the underlying predisposing factors (Kamangar, 2018).

Clinical Manifestations

The clinical manifestations of a lung abscess may vary from a mild productive cough to acute illness. Most patients have a fever and a productive cough with moderate to copious amounts of foul-smelling, sometimes bloody, sputum. The fever and cough may develop insidiously and may have been present for several weeks before diagnosis. Leukocytosis may be present. Pleurisy or dull chest pain, dyspnea, weakness, anorexia, and weight loss are common.

Assessment and Diagnostic Findings

Physical examination of the chest may reveal dullness on percussion and decreased or absent breath sounds with an intermittent **pleural friction rub**

(grating or creaking sound) on auscultation. Crackles may be present. Confirmation of the diagnosis is made by chest x-ray, sputum culture, and, in some cases, fiberoptic bronchoscopy. The chest x-ray reveals an infiltrate with an air–fluid level. A computed tomography (CT) scan of the chest may be required to provide more detailed images of different cross-sectional areas of the lung.

Prevention

The following measures reduce the risk of lung abscess:

- Appropriate antibiotic therapy before any dental procedures in patients who must have teeth extracted while their gums and teeth are infected
- Adequate dental and oral hygiene, because anaerobic bacteria play a role in the pathogenesis of lung abscess
- Appropriate antimicrobial therapy for patients with pneumonia

Medical Management

The findings of the history, physical examination, chest x-ray, and sputum culture indicate the type of organism and the treatment required. Adequate drainage of the lung abscess may be achieved through postural drainage and chest physiotherapy. Patients should be assessed for an adequate cough. Some patients require insertion of a percutaneous chest catheter for long-term drainage of the abscess. Therapeutic use of bronchoscopy to drain an abscess is uncommon. A diet high in protein and calories is necessary, because chronic infection is associated with a catabolic state, necessitating increased intake of calories and protein to facilitate healing. Surgical intervention is rare, but pulmonary resection (lobectomy) is performed if massive hemoptysis occurs or if there is little or no response to medical management.

IV antimicrobial therapy depends on the results of the sputum culture and sensitivity and is given for an extended period. Standard treatment of an anaerobic lung infection is clindamycin, ampicillin-sulbactam, or carbapenem (Bartlett, 2019b). Large IV doses are usually required, because the antibiotic must penetrate the necrotic tissue and the fluid in the abscess. The duration of treatment with IV antibiotics is not well studied and remains controversial (Bartlett, 2019b). Treatment with IV antibiotics may continue for 3 weeks and longer, depending upon the clinical severity and organism involved. Improvement is demonstrated by normal temperature, decreased white blood cell count, and improvement on chest x-ray (resolution of surrounding infiltrate, reduction in cavity size, and absence of fluid). Once improvement is demonstrated, IV antibiotics are discontinued and oral administration of

antibiotic therapy is continued for an additional 4 to 12 weeks and sometimes longer. If treatment is stopped too soon, a relapse may occur (Bartlett, 2019b).

Nursing Management

The nurse administers antibiotics and IV treatments as prescribed and monitors for adverse effects. CPT is initiated as prescribed to facilitate drainage of the abscess. The patient is educated on how to perform deep-breathing and coughing exercises to help expand the lungs. To ensure proper nutritional intake, the nurse encourages a diet that is high in protein and calories. The nurse also offers emotional support, because the abscess may take a long time to resolve.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

A patient who has had surgery may return home before the wound closes entirely or with a drain or tube in place. In these cases, the nurse educates the patient or caregivers about how to change the dressings to prevent skin excoriation and odor, how to monitor for signs and symptoms of infection, and how to care for and maintain the drain or tube. The nurse also reminds the patient to perform deep-breathing and coughing exercises every 2 hours during the day and shows caregivers how to perform chest percussion and postural drainage to facilitate expectoration of lung secretions.

Continuing and Transitional Care

A patient whose condition requires therapy at home may need referral for home, transitional, or community-based care. During home visits, the nurse assesses the patient's physical condition, nutritional status, and home environment, as well as the ability of the patient and family to carry out the therapeutic regimen. Patient education is reinforced, and nutritional counseling is provided with the goal of attaining and maintaining an optimal state of nutrition. To prevent relapses, the nurse emphasizes the importance of completing the antibiotic regimen and of following suggestions for rest and appropriate activity. If IV antibiotic therapy is to continue at home, the services of home health nurses may be arranged to initiate IV therapy and to evaluate its administration by the patient or family.

Although most outpatient IV therapy is given in the home setting, the patient may visit a nearby clinic or provider's office for this treatment. In some cases, patients with lung abscess may have ignored their health. Therefore, the nurse should use this opportunity to address health promotion strategies and health screening with the patient.

Sarcoidosis

Sarcoidosis is a type of interstitial lung disease that is also an inflammatory, multisystem, granulomatous disease of unknown etiology (King, 2019a). Although 90% of patients demonstrate thoracic involvement, any organ may be affected. Sarcoidosis usually presents between 20 and 40 years of age and is slightly more common in women than in men (Weinberger et al., 2019). In the United States, the disease is more common in African Americans, and the estimated prevalence is 10 to 20 per 100,000 people (King, 2019a).

Pathophysiology

Sarcoidosis is thought to be a hypersensitivity response to one or more exogenous agents (bacteria, fungi, virus, chemicals) in people with an inherited or acquired predisposition to the disorder. The hypersensitivity response and inflammation result in the formation of a noncaseating granuloma, which is a noninfectious organized collection of macrophages that appear as a nodule. In the lung, granuloma infiltration and fibrosis may occur, resulting in low lung compliance, impaired diffusing capacity, and reduced lung volumes (King, 2019a).

Clinical Manifestations

Hallmarks of sarcoidosis are its insidious onset and lack of prominent clinical signs or symptoms. The clinical picture depends on the systems affected. The lung is most commonly involved; signs and symptoms may include dyspnea, cough, hemoptysis, and congestion. Other signs include uveitis; joint pain; fever; and granulomatous lesions of the skin, liver, spleen, kidney, and central nervous system. With multisystem involvement, patients may also have fatigue, fever, anorexia, and weight loss. The granulomas may disappear or gradually convert to fibrous tissue.

Assessment and Diagnostic Findings

Chest x-rays and CT scans are used to assess pulmonary adenopathy. These may show hilar adenopathy and disseminated miliary and nodular lesions in the lungs. A mediastinoscopy or **transbronchial** biopsy (in which a tissue specimen is obtained through the bronchial wall) may be used to confirm the diagnosis. In rare cases, an open lung biopsy is performed. Diagnosis is confirmed by a biopsy that shows noncaseating granulomas. Pulmonary function test results are abnormal if there is restriction of lung function (reduction in total lung capacity). Arterial blood gas measurements may be

normal or may show hypoxemia (reduced oxygen levels) and hypercapnia (increased carbon dioxide levels).

Medical Management

Many patients undergo remission without specific treatment. Corticosteroids may be beneficial because of their anti-inflammatory effects. Oral corticosteroids have been the most commonly used agents for the relief of symptoms and control of potentially disabling respiratory impairment from pulmonary sarcoidosis. Once begun, corticosteroid therapy is usually continued in tapering doses for 12 months, and longer if the patient has recurrence of symptoms and chest x-ray indications (i.e., continued pulmonary adenopathy) (King, 2019b). Corticosteroids (e.g., prednisone) have been shown to be useful in patients with ocular and myocardial involvement, skin involvement, extensive pulmonary disease that compromises pulmonary function, hepatic involvement, and hypercalcemia. However, it is not known if corticosteroids alter the long-term course of the disease (King, 2019b). When there is inadequate response to prednisone or the dose cannot be decreased, an immune modulator may be added (e.g., methotrexate, azathioprine, leflunomide, mycophenolate). No single test monitors the progression or recurrence of sarcoidosis; multiple tests are used to monitor involved systems.

Nursing Management

The role of the nurse in the care of patients with sarcoidosis includes supporting the medical regimen and providing education and psychosocial support. Since treatment is aimed at reducing inflammation, patients should be educated on the effects and correct usage of corticosteroids. Patients should be instructed to notify their primary provider if symptoms do not improve or respiratory symptoms worsen. Sarcoidosis is a chronic illness warranting follow-ups at 3 to 6 month intervals to assess disease progression. Patients should be encouraged to contact the Foundation for Sarcoidosis Research to identify additional community resources that can be of assistance to them (see Resources section at the end of the chapter).

PLEURAL DISORDERS

Pleural disorders involve the membranes covering the lungs (visceral pleura) and the surface of the chest wall (parietal pleura) or disorders affecting the pleural space.

Pleurisy

Pleurisy (pleuritis) refers to inflammation of both layers of the pleurae (parietal and visceral). Pleurisy may develop in conjunction with pneumonia or an upper respiratory tract infection, TB, or collagen disease; after trauma to the chest, pulmonary infarction, or PE; in patients with primary or metastatic cancer; and after thoracotomy. The parietal pleura has nerve endings, and the visceral pleura does not. When the inflamed pleural membranes rub together during respiration (intensified on inspiration), the result is severe, sharp, knifelike pain.

Clinical Manifestations

The key characteristic of pleuritic pain is its relationship to respiratory movement. Taking a deep breath, coughing, or sneezing worsens the pain. Pleuritic pain is limited in distribution rather than diffuse; it usually occurs only on one side. The pain may become minimal or absent when the breath is held. It may be localized or radiate to the shoulder or abdomen. Later, as pleural fluid develops, the pain decreases (Weinberger et al., 2019).

Assessment and Diagnostic Findings

In the early period, when little fluid has accumulated, a pleural friction rub can be heard with the stethoscope, only to disappear later as more fluid accumulates and separates the inflamed pleural surfaces. Diagnostic tests may include chest x-rays, sputum analysis, thoracentesis to obtain a specimen of pleural fluid for examination, and, less commonly, a pleural biopsy.

Medical Management

The objectives of treatment are to discover the underlying condition causing the pleurisy and to relieve the pain. As the underlying disease (pneumonia, infection) is treated, the pleuritic inflammation usually resolves. At the same time, the patient must be monitored for signs and symptoms of pleural effusion, such as shortness of breath, pain, assumption of a position that decreases pain, and decreased chest wall excursion.

Prescribed analgesic agents and topical applications of heat or cold provide symptomatic relief. A nonsteroidal anti-inflammatory drug may provide pain relief while allowing the patient to take deep breaths and cough more effectively. If the pain is severe, an intercostal nerve block may be required (Weinberger et al., 2019).

Nursing Management

Because the patient has pain on inspiration, the nurse offers suggestions to enhance comfort, such as turning frequently onto the affected side to splint the chest wall and reduce the stretching of the pleurae. The nurse also educates the patient to use the hands or a pillow to splint the rib cage while coughing.

Pleural Effusion

Pleural effusion, a collection of fluid in the pleural space, is rarely a primary disease process; it is usually secondary to other diseases. Normally, the pleural space contains a small amount of fluid (5 to 15 mL), which acts as a lubricant that allows the pleural surfaces to move without friction (see Fig. 19-4). Pleural effusion may be a complication of heart failure, TB, pneumonia, pulmonary infections (particularly viral infections), nephrotic syndrome, connective tissue disease, PE, and neoplastic tumors. The most common malignancy associated with a pleural effusion is bronchogenic carcinoma.

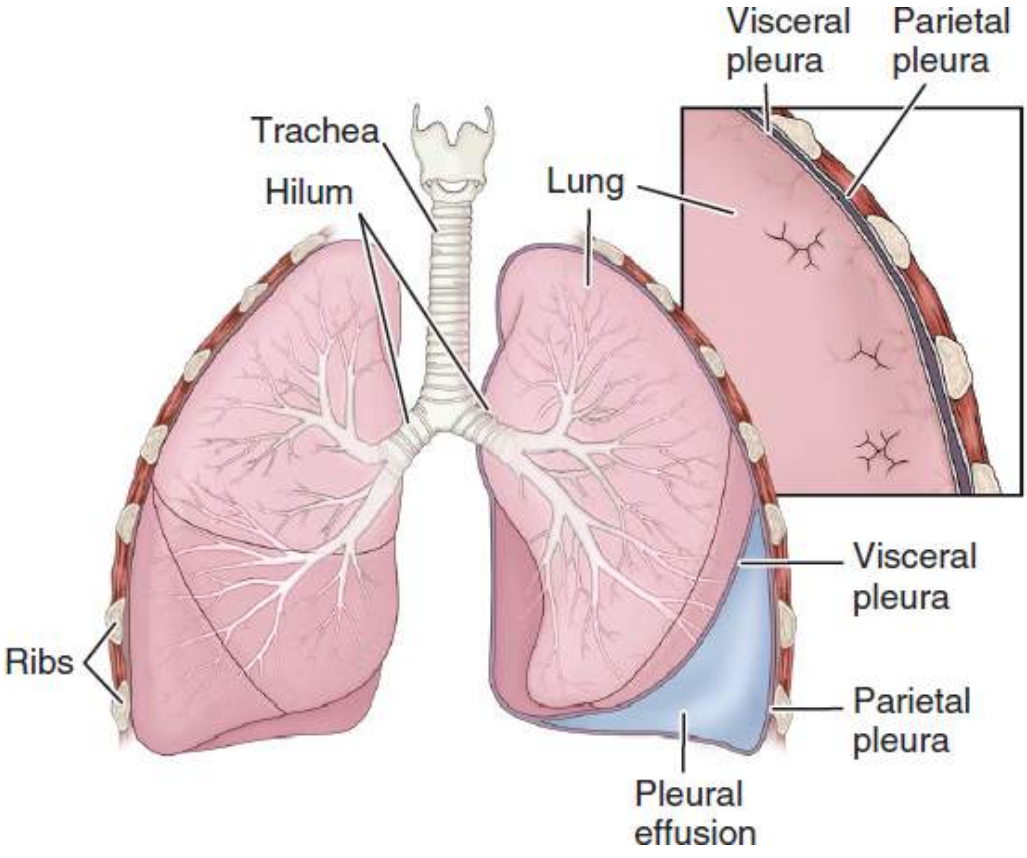

Figure 19-4 • In pleural effusion, an abnormal volume of fluid collects in the pleural space, causing pain and shortness of breath. Pleural effusion is usually secondary to other disease processes.

Pathophysiology

In certain disorders, fluid may accumulate in the pleural space to a point at which it becomes clinically evident. This almost always has pathologic significance. The effusion can be a relatively clear fluid, or it can be bloody or purulent. An effusion of clear fluid may be a transudate or an exudate. A transudate (filtrate of plasma that moves across intact capillary walls) occurs when factors influencing the formation and reabsorption of pleural fluid are altered, usually by imbalances in hydrostatic or oncotic pressures. The finding of a transudative effusion generally implies that the pleural membranes are not diseased. A transudative effusion most commonly results from heart failure. An exudate (extravasation of fluid into tissues or a cavity) usually results from inflammation by bacterial products or tumors involving the pleural surfaces (Heffner, 2019a).

Clinical Manifestations

Usually, the clinical manifestations are caused by the underlying disease. Pneumonia causes fever, chills, and pleuritic chest pain, whereas a malignant effusion may result in dyspnea, difficulty lying flat, and coughing. The severity of symptoms is determined by the size of the effusion, the speed of its formation, and the underlying lung disease. A large pleural effusion causes dyspnea. A small-to-moderate pleural effusion causes minimal or no dyspnea.

Assessment and Diagnostic Findings

Assessment of the area of the pleural effusion reveals decreased or absent breath sounds; decreased fremitus; and a dull, flat sound on percussion. In the case of an extremely large pleural effusion, the assessment reveals a patient in acute respiratory distress. Tracheal deviation away from the affected side may also be apparent.

Physical examination, chest x-ray, chest CT, and thoracentesis confirm the presence of fluid. In some instances, a lateral decubitus x-ray is obtained. For this x-ray, the patient lies on the affected side in a side-lying position. A pleural effusion can be diagnosed because this position allows for the “layering out” of the fluid, and an air–fluid line is visible.

Pleural fluid is analyzed by bacterial culture, Gram stain, AFB stain (for TB), red and white blood cell counts, chemistry studies (glucose, amylase, LDH, and protein), cytologic analysis for malignant cells, and pH. A pleural biopsy also may be performed as a diagnostic tool.

Medical Management

The objectives of treatment are to discover the underlying cause of the pleural effusion; to prevent reaccumulation of fluid; and to relieve discomfort,

dyspnea, and respiratory compromise. Specific treatment is directed at the underlying cause (e.g., heart failure, pneumonia, cirrhosis). If the pleural fluid is an exudate, more extensive diagnostic procedures are performed to determine the cause. Treatment of the primary cause is then instituted.

Thoracentesis is performed to remove fluid, to obtain a specimen for analysis, and to relieve dyspnea and respiratory compromise (see Chapter 17). Thoracentesis may be performed under ultrasound guidance. Depending on the size of the pleural effusion, the patient may be treated by removing the fluid during the thoracentesis procedure or by inserting a chest tube connected to a water-seal drainage system or suction to evacuate the pleural space and re-expand the lung.

However, if the underlying cause is a malignancy, the effusion tends to recur within a few days or weeks. Repeated thoracenteses result in pain, depletion of protein and electrolytes, and sometimes pneumothorax. Once the pleural space is adequately drained, a chemical pleurodesis may be performed to obliterate the pleural space and prevent reaccumulation of fluid. Pleurodesis may be performed using either a thoracoscopic approach or a chest tube. A chemically irritating agent (e.g., talc or another chemical irritant) is instilled or aerosolized into the pleural space. With the chest tube approach, after the agent is instilled, the chest tube is clamped for 60 to 90 minutes and the patient is assisted to assume various positions to promote uniform distribution of the agent and to maximize its contact with the pleural surfaces (Heffner, 2019b). The tube is unclamped as prescribed, and chest drainage may be continued several days longer to prevent reaccumulation of fluid and to promote the formation of adhesions between the visceral and parietal pleurae.

Other treatments for pleural effusions caused by malignancy include surgical pleurectomy, insertion of a small catheter attached to a drainage bottle for outpatient management (e.g., PleurX® catheter), or implantation of a pleuroperitoneal shunt. A pleuroperitoneal shunt consists of two catheters connected by a pump chamber containing two one-way valves. Fluid moves from the pleural space to the pump chamber and then to the peritoneal cavity. The patient manually pumps on the reservoir daily to move fluid from the pleural space to the peritoneal space.

Nursing Management

The nurse's role in the care of a patient with a pleural effusion includes supporting the medical regimen. The nurse prepares and positions the patient for thoracentesis and offers support throughout the procedure. The nurse ensures the thoracentesis fluid amount is recorded and sent for appropriate laboratory testing. If a chest tube drainage and water-seal system is used, the system's function is monitored and the amount of drainage is recorded at

prescribed intervals (see later discussion). Nursing care related to the underlying cause of the pleural effusion is specific to the underlying condition.

Patients with a pleural effusion secondary to a malignancy may have a chest tube inserted to instill talc (Bhatnagar, Piotrowska, Laskawiec-Szkonter, et al., 2019). Pain management is a priority, and the nurse helps the patient assume positions that are the least painful. However, frequent turning and movement are important to facilitate adequate spreading of the talc over the pleural surface. The nurse evaluates the patient's pain level and administers analgesic agents as prescribed and as needed.

If the patient is to be managed as an outpatient with a pleural catheter for drainage, the nurse educates the patient and family about management and care of the catheter and drainage system.

Empyema

An empyema is an accumulation of thick, purulent fluid within the pleural space, often with fibrin development and a loculated (walled-off) area where infection is located (Strange, 2019).

Pathophysiology

Most empyemas occur as complications of bacterial pneumonia or lung abscess. They also result from penetrating chest trauma, hematogenous infection of the pleural space, nonbacterial infections, and iatrogenic causes (after thoracic surgery or thoracentesis). At first the pleural fluid is thin, with a low leukocyte count, but it frequently progresses to a fibropurulent stage and, finally, to a stage where it encloses the lung within a thick exudative membrane (loculated empyema).

Clinical Manifestations

The patient is acutely ill and has signs and symptoms similar to those of an acute respiratory infection or pneumonia (fever, night sweats, pleural pain, cough, dyspnea, anorexia, weight loss). If the patient is immunocompromised, the symptoms may be vague. If the patient has received antimicrobial therapy, the clinical manifestations may be less obvious.

Assessment and Diagnostic Findings

Chest auscultation demonstrates decreased or absent breath sounds over the affected area, and there is dullness on chest percussion as well as decreased

fremitus. The diagnosis is established by chest CT. Usually, a diagnostic thoracentesis is performed, often under ultrasound guidance.

Medical Management

The objectives of treatment are to drain the pleural cavity and to achieve complete expansion of the lung. The fluid is drained, and appropriate antibiotics (usually begun by the IV route) in large doses are prescribed based on the causative organism. Sterilization of the empyema cavity requires 4 to 6 weeks of antibiotics (Strange, 2019). Drainage of the pleural fluid depends on the stage of the disease and is accomplished by one of the following methods:

- Thoracentesis (needle aspiration) with a thin percutaneous catheter, if the volume is small and the fluid is not too purulent or too thick
- Tube thoracostomy (chest drainage using a large-diameter intercostal tube attached to water-seal drainage; see later discussion) with thrombolytic agents instilled through the chest tube in patients with loculated or complicated pleural effusions
- Open chest drainage via thoracotomy, including potential rib resection, to remove the thickened pleura, pus, and debris and to remove the underlying diseased pulmonary tissue

With long-standing inflammation, an exudate can form over the lung, trapping it and interfering with its normal expansion. This exudate must be removed surgically by decortication. The drainage tube is left in place until the pus-filled space is obliterated completely. The complete obliteration of the pleural space is monitored by serial chest x-rays, and the patient should be informed that treatment may be long term (weeks to months). Patients are frequently discharged from the hospital with a chest tube in place, with instructions to monitor fluid drainage at home.

Nursing Management

Resolution of empyema is a prolonged process. The nurse helps the patient cope with the condition and instructs the patient in lung-expanding breathing exercises to restore normal respiratory function. The nurse also provides care specific to the method of drainage of the pleural fluid (e.g., needle aspiration, closed chest drainage, rib resection, and drainage). When the patient is discharged home with a drainage tube or system in place, the nurse instructs the patient and family on care of the drainage system and drain site, measurement and observation of drainage, signs and symptoms of infection, and how and when to contact the primary provider (see later discussion).

Acute Respiratory Failure

Respiratory failure is a sudden and life-threatening deterioration of the gas exchange function of the lungs and indicates their failure to provide adequate oxygenation or ventilation for the blood. Acute respiratory failure is defined as hypoxemia (a decrease in arterial oxygen tension [PaO_2] to less than 60 mm Hg) and hypercapnia (an increase in arterial carbon dioxide tension [$PaCO_2$] to greater than 50 mm Hg), with acidosis (an arterial pH of less than 7.35) (Kaynar, 2018).

It is important to distinguish between acute and chronic respiratory failure. Chronic respiratory failure is defined as deterioration in the gas exchange function of the lungs that has developed insidiously or has persisted for a long period after an episode of acute respiratory failure. The absence of acute symptoms and the presence of a chronic respiratory acidosis suggest the chronicity of the respiratory failure. Two causes of chronic respiratory failure are COPD (discussed in Chapter 20) and neuromuscular diseases (discussed in Chapter 65). Patients with these disorders develop a tolerance to the gradually worsening hypoxemia and hypercapnia. However, patients with chronic respiratory failure can develop acute failure. For example, a patient with COPD may develop an exacerbation or infection that causes additional deterioration of gas exchange. The principles of management of acute versus chronic respiratory failure are different; the following discussion is limited to acute respiratory failure.

Pathophysiology

In acute respiratory failure, the ventilation or perfusion mechanisms in the lung are impaired. Some of the many ventilatory failure mechanisms leading to acute respiratory failure include impaired function of the central nervous system (e.g., drug overdose, head trauma, infection, hemorrhage, sleep apnea), neuromuscular dysfunction (e.g., myasthenia gravis, Guillain–Barré syndrome, amyotrophic lateral sclerosis, spinal cord trauma), musculoskeletal dysfunction (e.g., chest trauma, kyphoscoliosis, malnutrition), and pulmonary dysfunction (e.g., COPD, asthma, cystic fibrosis).

Oxygenation failure mechanisms leading to acute respiratory failure include pneumonia, ARDS, heart failure, COPD, PE, and **restrictive lung diseases** (diseases that cause decrease in lung volumes).

In the postoperative period, especially after major thoracic or abdominal surgery, inadequate ventilation and respiratory failure may occur because of several factors. During this period, for example, acute respiratory failure may be caused by the effects of anesthetic, analgesic, and sedative agents, which may depress respiration (as described earlier) or enhance the effects of opioids

and lead to hypoventilation. Pain may interfere with deep breathing and coughing. A V./Q. mismatch is the usual cause of respiratory failure after major abdominal, cardiac, or thoracic surgery.

Clinical Manifestations

Early signs are those associated with impaired oxygenation and may include restlessness, fatigue, headache, dyspnea, air hunger, tachycardia, and increased blood pressure. As the hypoxemia progresses, more obvious signs may be present, including confusion, lethargy, tachycardia, tachypnea, central cyanosis, diaphoresis, and finally respiratory arrest. Physical findings are those of acute respiratory distress, including the use of accessory muscles, decreased breath sounds if the patient cannot adequately ventilate, and other findings related specifically to the underlying disease process and cause of acute respiratory failure.

Medical Management

The objectives of treatment are to correct the underlying cause and to restore adequate gas exchange in the lungs. ET intubation and mechanical ventilation may be required to maintain adequate ventilation and oxygenation while the underlying cause is corrected (see later discussion on ET intubation and mechanical ventilation).

Nursing Management

Nursing management of patients with acute respiratory failure includes assisting with intubation and maintaining mechanical ventilation. Patients are usually managed in the intensive care unit (ICU). The nurse assesses the patient's respiratory status by monitoring the level of responsiveness, arterial blood gases, pulse oximetry, and vital signs. In addition, the entire respiratory system is assessed and strategies to prevent complications (e.g., turning schedule, mouth care, skin care, and range of motion of extremities) are implemented. The nurse also assesses the patient's understanding of the management strategies that are used and initiates some form of communication to enable the patient to express concerns and needs to the health care team.

Finally, the problems that led to the acute respiratory failure are addressed. As the patient's status improves, the nurse assesses the patient's knowledge of the underlying disorder and provides education as appropriate to address the disorder.

Endotracheal Intubation

Endotracheal intubation involves passing an ET tube through the nose or mouth into the trachea (see Fig. 19-5). The oral route is preferred since oral intubation is associated with less trauma and lesser rates of infection; furthermore, the oral route can typically accommodate a larger diameter ET tube than may be passed when the nasal route is used. Intubation provides a patent airway when the patient is having respiratory distress that cannot be treated with simpler methods and is the method of choice in emergency care. ET intubation is a means of providing an airway for patients who cannot maintain an adequate airway on their own (e.g., patients who are comatose and patients with upper airway obstruction), for patients needing mechanical ventilation, and for suctioning secretions from the pulmonary tree.

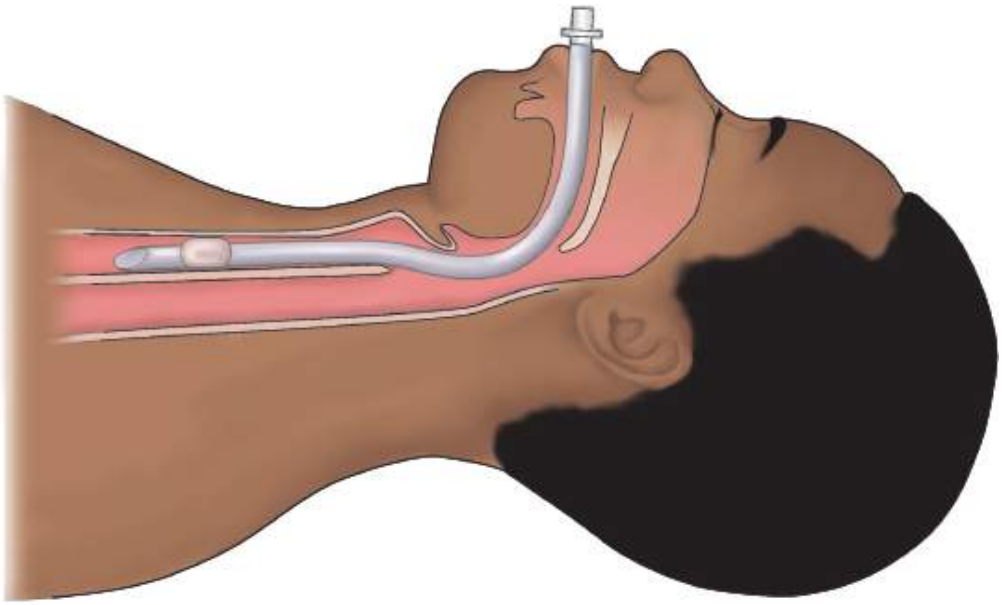

Figure 19-5 • Endotracheal tube in place. The tube has been inserted using the oral route. The cuff has been inflated to maintain the tube's position and to minimize the risk of aspiration.

An ET tube usually is passed with the aid of a laryngoscope by specifically trained medical, nursing, or respiratory therapy personnel. Once the tube is inserted and positioned about 2 cm above the carina, a cuff at the distal end of the ET tube is inflated with the use of a pilot balloon. Inflation of the cuff prevents air from leaking around the outer part of the tube in order to minimize the possibility of aspiration and secure the tube. The position of the ET tube is verified by checking end-tidal carbon dioxide levels and confirmed with chest x-ray. Chart 19-12 discusses the nursing care of the patient with an ET tube.

Complications can occur from pressure exerted by the cuff on the tracheal wall. Cuff pressures should be maintained between 20 and 25 mm Hg (24 and 30 cm H_2O) because high cuff pressure can cause tracheal bleeding, ischemia, and pressure necrosis, whereas low cuff pressure can increase the risk of

aspiration pneumonia. Routine deflation of the cuff is not recommended because of the increased risk of aspiration and **hypoxia** (i.e., decrease in oxygen supply to the tissues and cells) (Urden et al., 2018). Tracheobronchial secretions are suctioned through the tube. Warmed, humidified oxygen should always be introduced through the tube, whether the patient is breathing spontaneously or is receiving ventilatory support. ET intubation may be used for no longer than 14 to 21 days, by which time a tracheostomy must be considered to decrease irritation of and trauma to the tracheal lining, to reduce the incidence of vocal cord paralysis (secondary to laryngeal nerve damage), and to decrease the work of breathing (Wiegand, 2017).

ET and tracheostomy tubes have several disadvantages. The tubes cause discomfort. The cough reflex is depressed because glottis closure is hindered. Secretions tend to become thicker because the warming and humidifying effect of the upper respiratory tract has been bypassed. The swallowing reflexes (glottic, pharyngeal, and laryngeal reflexes) are depressed because of prolonged disuse and the mechanical trauma produced by the ET or tracheostomy tube, increasing the risk of aspiration as well as microaspiration and subsequent VAP (Urden et al., 2018). In addition, ulceration and stricture of the larynx or trachea may develop. Of great concern to the patient is the inability to talk and to communicate needs.

Tracheostomy

A **tracheotomy** is a surgical procedure in which an opening is made into the trachea. The indwelling tube inserted into the trachea is called a **tracheostomy tube** (see Fig. 19-6 for the different types of tracheostomy tubes). A tracheostomy (the stoma that is the product of the tracheotomy) may be either temporary or permanent.

Chart 19-12

Care of the Patient with an Endotracheal Tube

Immediately After Intubation

1. Check symmetry of chest expansion.
2. Auscultate breath sounds of anterior and lateral chest bilaterally.
3. Obtain capnography or end-tidal CO_2 as indicated.
4. Ensure chest x-ray obtained to verify proper tube placement.
5. Check cuff pressure every 6 to 8 hours.
6. Monitor for signs and symptoms of aspiration.
7. Ensure high humidity; a visible mist should appear in the T-piece or ventilator tubing.
8. Administer oxygen concentration as prescribed by the primary provider.
9. Secure the tube to the patient's face with tape, and mark the proximal end for position maintenance.
   a. Cut proximal end of tube if it is longer than 7.5 cm (3 inches) to prevent kinking.
   b. Insert an oral airway or mouth device if orally intubated to prevent the patient from biting and obstructing the tube.
10. Use sterile suction technique and airway care to prevent iatrogenic contamination and infection.
11. Continue to reposition patient every 2 hours and as needed to prevent atelectasis and to optimize lung expansion.
12. Provide oral hygiene and suction the oropharynx whenever necessary.

Extubation (Removal of Endotracheal Tube)

1. Explain procedure.
2. Have self-inflating bag and mask ready in case ventilatory assistance is required immediately after extubation.
3. Suction the tracheobronchial tree and oropharynx, remove tape, and then deflate the cuff.
4. Give 100% oxygen for a few breaths, then insert a new, sterile suction catheter inside tube.
5. Have the patient inhale. At peak inspiration, remove the tube, suctioning the airway through the tube as it is pulled out.

Note: In some hospitals, this procedure can be performed by respiratory therapists; in others, by nurses. Check hospital policy.

Care of Patient Following Extubation

1. Give heated humidity and oxygen by facemask and maintain the patient in a sitting or high-Fowler position.
2. Monitor respiratory rate and quality of chest excursions. Note stridor, color change, and change in mental alertness or behavior.
3. Monitor the patient's oxygen level using a pulse oximeter.

4. Keep patient NPO (nothing by mouth), or give only ice chips for next few hours.
5. Provide mouth care.
6. Educate the patient about how to perform coughing and deep-breathing exercises.

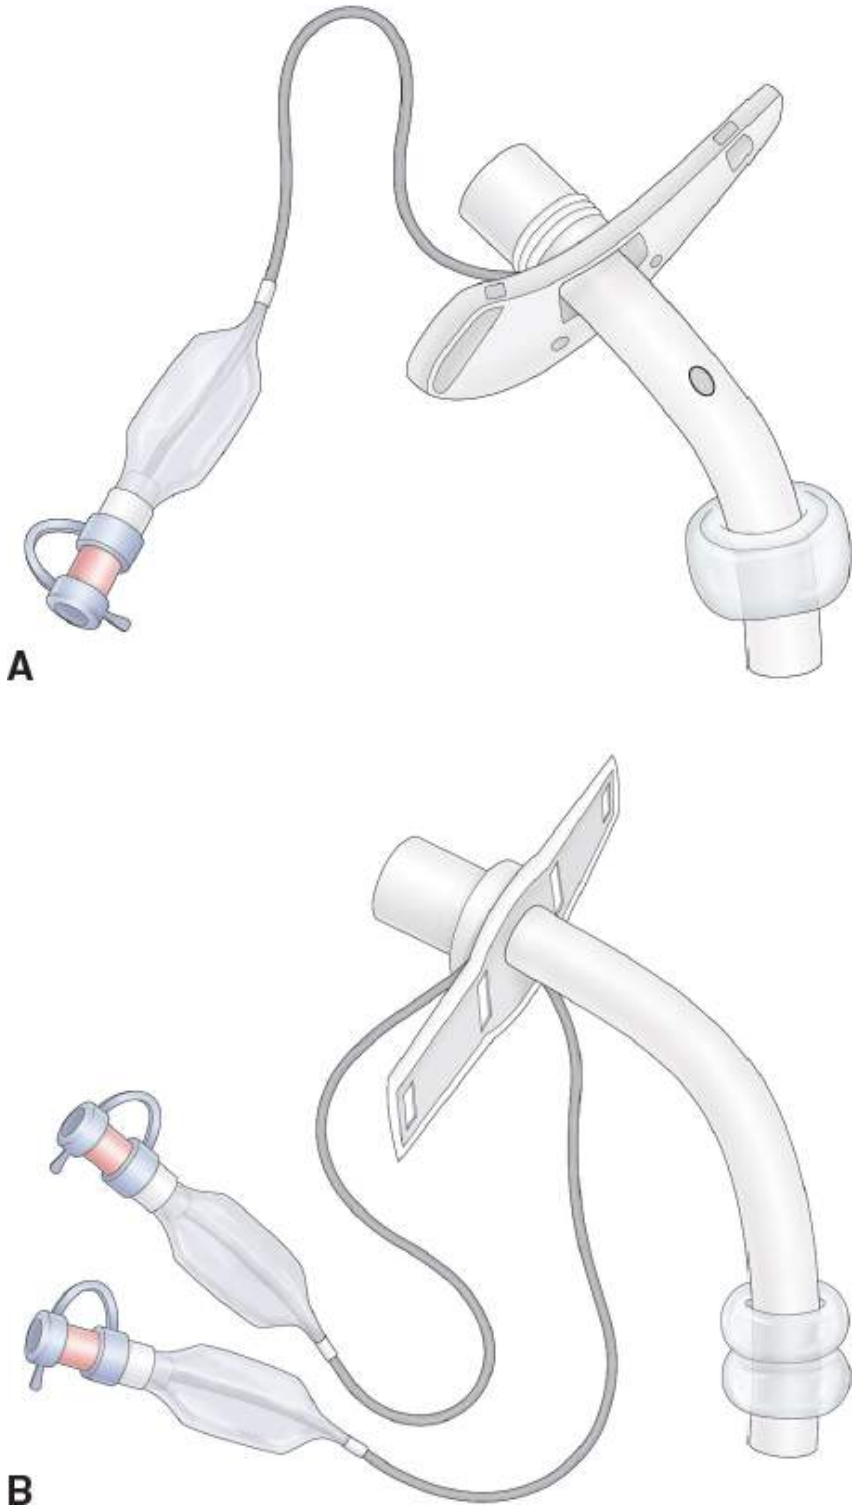

Figure 19-6 • Tracheostomy tubes. **A.** Fenestrated tube, which allows patient to talk. **B.** Double-cuffed tube. Inflating the two cuffs alternately can help prevent tracheal damage.

A tracheotomy is used to maintain a patent airway, bypass an upper airway obstruction, facilitate removal of tracheobronchial secretions, permit the long-term use of mechanical ventilation, replace an ET tube, and prevent aspiration

of oral or gastric secretions in the patient who is unconscious or paralyzed (by closing off the trachea from the esophagus). Many disease processes and emergency conditions make a tracheotomy necessary.

Tracheotomy

The tracheotomy procedure is usually performed in the operating room under general anesthesia, where the patient's ventilation can be well controlled and optimal aseptic technique can be maintained. A surgical opening is made between the second and third tracheal rings. After the trachea is exposed, a cuffed tracheostomy tube of an appropriate size is inserted. The cuff is an inflatable attachment to the tracheostomy tube that is designed to occlude the space between the tracheal walls and the tube, to permit effective mechanical ventilation, and to minimize the risk of aspiration.

For a patient who is intubated and mechanically ventilated, a newer surgical technique referred to as a percutaneous tracheostomy can be performed at the patient's bedside with the use of local anesthesia and sedation and analgesia. Using video-assisted guidance, a bronchoscope is passed down the ET tube. Following ET tube cuff deflation, the ET tube is withdrawn to the subglottic level. An opening is made in the skin between the second and third tracheal ring and enlarged with the use of dilators until the space is large enough to safely insert a tracheostomy tube. The ET tube and bronchoscope are then removed and the tracheostomy is secured into position (Lindman, 2018).

The tracheostomy tube is held in place by a velcro tube holder or twill tape ties fastened around the patient's neck. Usually, a square of sterile gauze is placed between the tube and the skin to absorb drainage and reduce the risk of infection.

Complications

Complications may occur early or late in the course of tracheostomy tube management. They may even occur years after the tube has been removed. Early complications include tube dislodgement, accidental decannulation, bleeding, pneumothorax, air embolism, aspiration, subcutaneous or mediastinal emphysema, recurrent laryngeal nerve damage, and posterior tracheal wall penetration. Long-term complications include airway obstruction from accumulation of secretions or protrusion of the cuff over the opening of the tube, infection, rupture of the innominate artery, dysphagia, tracheoesophageal fistula, tracheal dilation, tracheal ischemia, and necrosis. Tracheal stenosis may develop after the tube is removed. Chart 19-13 outlines measures nurses can take to prevent complications with use of ET and tracheostomy tubes.

Care of the Patient with an Endotracheal Tube or Tracheostomy

The patient requires continuous monitoring and assessment. The newly made opening must be kept patent by proper suctioning of secretions. After the vital signs are stable, the patient is placed in a semi-Fowler position to facilitate ventilation, promote drainage, minimize edema, and prevent strain on the suture lines. Analgesia and sedative agents must be given with caution because of the risk of suppressing the cough reflex.

Chart 19-13

Preventing Complications Associated with Endotracheal and Tracheostomy Tubes

- Administer adequate warmed humidity.
- Maintain cuff pressure at appropriate level.
- Suction as needed per assessment findings.
- Maintain skin integrity. Change tape and dressing as needed or per protocol.
- Auscultate lung sounds.
- Monitor for signs and symptoms of infection, including temperature and white blood cell count.
- Administer prescribed oxygen and monitor oxygen saturation.
- Monitor for cyanosis.
- Maintain adequate hydration of the patient.
- Use sterile technique when suctioning and performing tracheostomy care.

Major objectives of nursing care are to ensure a patent airway, monitor the patient's respiratory status, assess for complications, alleviate the patient's apprehension, and provide an effective means of communication. The nurse keeps paper and pencil or a Magic Slate® or a cellular device and the call light within the patient's reach at all times to ensure a means of communication.

For the procedural guidelines for nursing care of a patient with a tracheostomy tube, go to thepoint.lww.com/Brunner15e.

Suctioning the Tracheostomy or Endotracheal Tube

When a tracheostomy or ET tube is in place, it is usually necessary to suction the patient's secretions because of the decreased effectiveness of the cough mechanism. Tracheal suctioning is performed when adventitious breath sounds are detected or whenever secretions are obviously present. Unnecessary

suctioning can initiate bronchospasm and cause mechanical trauma to the tracheal mucosa.

All equipment that comes into direct contact with the patient's lower airway must be sterile to prevent sepsis.

For the procedural guidelines for suctioning a patient with a tracheostomy tube, go to thepoint.lww.com/Brunner15e.

In patients who are mechanically ventilated (see later discussion), an in-line suction catheter may be used to allow rapid suction when needed and to minimize cross-contamination by airborne pathogens. An in-line suction device allows the patient to be suctioned without being disconnected from the ventilator circuit. In-line suctioning (also called *closed suctioning*) decreases hypoxemia, sustains PEEP, and can decrease patient anxiety associated with suctioning (Wiegand, 2017). Because in-line suctioning protects staff from patient secretions, it can be performed in most cases without using personal protective gear. A notable exception is when the patient has COVID-19, when PPE must be used.

Managing the Cuff

The cuff on an ET or tracheostomy tube should be inflated if the patient requires mechanical ventilation or is at high risk for aspiration. The pressure within the cuff should be the lowest possible pressure (20 to 25 mm Hg) that allows delivery of adequate tidal volumes and prevents pulmonary aspiration (Urden et al., 2018). Cuff pressure must be monitored by the respiratory therapist or nurse at least every 8 hours by attaching a handheld pressure gauge to the pilot balloon of the tube or by using the minimal leak volume or minimal occlusion volume technique.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. If the patient is pending discharge to the home setting with a tracheostomy tube, the nurse should ensure that suction and other appropriate equipment is in place in the home prior to discharge. The nurse also educates the patient and family about daily care, including techniques to prevent infection, as well as measures to take in an emergency. The nurse provides the patient and family with a list of community contacts for education and support needs.

Continuing and Transitional Care. A referral for home, community-based, or transitional care is indicated for ongoing assessment of the patient and of the ability of the patient and family to provide appropriate and safe

care. The nurse assesses the patient's and family's ability to cope with the physical changes and psychological issues associated with having a tracheostomy. Minimizing the amount of dust or particles in the air and providing adequate humidification may make it easier for the patient to breathe. Dust and particles in the air can be decreased by removing drapes and upholstered furniture; using air filters; and washing floors, dusting, and vacuuming frequently. The nurse identifies resources and makes referrals for appropriate services to assist the patient and family to manage the tracheostomy tube at home.

Mechanical Ventilation

Mechanical ventilation may be required to manage acute respiratory failure. It may also be indicated for a variety of other reasons including to: control the patient's respirations during surgery or treatment, oxygenate the blood when the patient's ventilatory efforts are inadequate, and rest the respiratory muscles. Many patients placed on a ventilator can breathe spontaneously, although the effort needed to do so may be exhausting.

A **mechanical ventilator** is a positive- or negative-pressure breathing device that can maintain ventilation and oxygen delivery for a prolonged period.

Indications

If a patient has evidence of respiratory failure or a compromised airway, ET intubation and mechanical ventilation are indicated. This clinical evidence may be corroborated by a continuous decrease in PaO_2, an increase in $PaCO_2$, and a persistent acidosis (decreased pH); however, if the patient's status appears emergent, then waiting for these laboratory results prior to ensuring these ventilator support measures is imprudent. Conditions such as thoracic or abdominal surgery, drug overdose, neuromuscular disorders, inhalation injury, COPD, multiple trauma, shock, multisystem failure, and coma may lead to respiratory failure and the need for mechanical ventilation. General indications for mechanical ventilation are displayed in Chart 19-14.

Classification of Ventilators

Mechanical ventilators were traditionally classified according to the method by which they supported ventilation. The two general categories are negative- and positive-pressure ventilators. Figure 19-7 displays commonly used positive-pressure ventilators. Negative-pressure ventilators (e.g., "iron lungs," chest cuirass) are older modes of ventilatory support that are rarely utilized today.

Positive-Pressure Ventilators

Positive-pressure ventilators inflate the lungs by exerting positive pressure on the airway, pushing air in, similar to a bellows mechanism, and forcing the

alveoli to expand during inspiration. Expiration occurs passively. ET intubation or tracheostomy is usually necessary. These ventilators are widely used in the hospital setting and are increasingly used in the home for patients with primary lung disease. Three types of positive-pressure ventilators are classified by the method of ending the inspiratory phase of respiration: volume-cycled, pressure-cycled, and high-frequency oscillatory support. The fourth type, noninvasive positive-pressure ventilation (NIPPV), does not require intubation (Wiegand, 2017).

Chart 19-14

Indications for Mechanical Ventilation

Laboratory Values

PaO_2 <55 mm Hg
$PaCO_2$ >50 mm Hg and pH <7.32
Vital capacity <10 mL/kg
Negative inspiratory force <25 cm H_2O
FEV_1 <10 mL/kg

Clinical Manifestations

Apnea or bradypnea
Respiratory distress with confusion
Increased work of breathing not relieved by other interventions
Confusion with need for airway protection
Circulatory shock
Controlled hyperventilation (e.g., patient with a severe head injury)

Adapted from Amitai, A. (2018). Introduction to ventilator management. *Medscape.* Retrieved on 2/2/2020 at: emedicine.medscape.com/article/810126-overview

Volume-Cycled Ventilators. Volume-cycled ventilators deliver a preset volume of air with each inspiration. Once this preset volume is delivered to the patient, the ventilator cycles off and exhalation occurs passively. From breath to breath, the volume of air delivered by the ventilator is relatively constant, ensuring consistent, adequate breaths despite varying airway pressures. A major disadvantage to using volume-cycled ventilators is that patients may experience barotrauma (trauma to the trachea or alveoli secondary to positive pressure) because the pressures required to deliver the breaths may be excessive. This trauma causes damage to the alveolar capillary membrane and air to leak into the surrounding tissues (Urden et al., 2018).

Figure 19-7 • Positive-pressure ventilators. **A.** The AVEA can be used to both ventilate and monitor neonatal, pediatric, and adult patients. It can also deliver noninvasive ventilation with Heliox to adult and pediatric patients. Courtesy of Vyaire Medical Inc., Yorba Linda, CA. **B.** The Puritan-Bennett 840 Ventilator System has volume, pressure, and mixed modes designed for adult, pediatric, and infant ventilation. Courtesy of Tyco Healthcare/Nellcor Puritan Bennett, Pleasanton, CA.

Pressure-Cycled Ventilators. When the pressure-cycled ventilator cycles on, it delivers a flow of air (inspiration) until it reaches a preset pressure, and then cycles off, and expiration occurs. The major limitation is the volume of air or oxygen can vary as the patient's airway resistance or compliance changes. As a result, the **tidal volume** delivered (i.e., volume of air inspired and expired with each breath) may be inconsistent, possibly compromising ventilation.

High-Frequency Oscillatory Support Ventilators. These types of ventilators deliver very high respiratory rates (i.e., 180 to 900 breaths/min) that are accompanied by very low tidal volumes and high airway pressures (hence the name *high-frequency oscillatory support*). These small pulses of oxygen-enriched air move down the center of the airways, allowing alveolar air to exit the lungs along the margins of the airways. This ventilatory mode is used to open the alveoli in situations characterized by closed small airways, such as

atelectasis and ARDS and it is also thought to protect the lung from pressure injury (Wiegand, 2017).

Noninvasive Positive-Pressure Ventilation. NIPPV is a method of positive-pressure ventilation that can be given via facemasks that cover the nose and mouth, nasal masks, or other oral or nasal devices such as the nasal pillow (a small nasal cannula that seals around the nares to maintain the prescribed pressure). NIPPV eliminates the need for ET intubation or tracheostomy and decreases the risk of nosocomial infections such as pneumonia. The most comfortable mode for the patient is pressure-controlled ventilation with pressure support. This eases the work of breathing and enhances gas exchange. The ventilator can be set with a minimum backup rate for patients with periods of apnea.

Patients are candidates for NIPPV if they have acute or chronic respiratory failure, acute pulmonary edema, COPD, chronic heart failure, or a sleep-related breathing disorder. The technique also may be used at home to improve tissue oxygenation and to rest the respiratory muscles while patients sleep at night. NIPPV is contraindicated for those who have experienced respiratory arrest, serious arrhythmias, cognitive impairment, or head or facial trauma. NIPPV may also be used for obstructive sleep apnea, for patients at the end of life, and for those who do not want ET intubation but may need short- or long-term ventilatory support (Wiegand, 2017).

Continuous positive airway pressure (CPAP) provides positive pressure to the airways throughout the respiratory cycle. Although it can be used as an adjunct to mechanical ventilation with a cuffed ET tube or tracheostomy tube to open the alveoli, it is also used with a leak-proof mask to keep alveoli open, thereby preventing respiratory failure. CPAP is an effective treatment of obstructive sleep apnea because the positive pressure acts as a splint, keeping the upper airway and trachea open during sleep. To use CPAP, the patient must be breathing independently.

Bilevel positive airway pressure (BiPAP) ventilation offers independent control of inspiratory and expiratory pressures while providing pressure support ventilation (PSV). It delivers two levels of positive airway pressure provided via a nasal or oral mask, nasal pillow, or mouthpiece with a tight seal and a portable ventilator. Each inspiration can be initiated either by the patient or by the machine if it is programmed with a backup rate. The backup rate ensures that the patient receives a set number of breaths per minute. BiPAP is most often used for patients who require ventilatory assistance at night, such as those with severe COPD or sleep apnea. Tolerance is variable; BiPAP usually is most successful with patients who are highly motivated.

Ventilator Modes

Ventilator mode refers to how breaths are delivered to the patient. The most commonly used modes are controlled mechanical ventilation, continuous

mandatory ventilation, also known as assist–control (A/C), intermittent mandatory ventilation (IMV), synchronized intermittent mandatory ventilation (SIMV), PSV, and airway pressure release ventilation (APRV) (see Fig. 19-8).

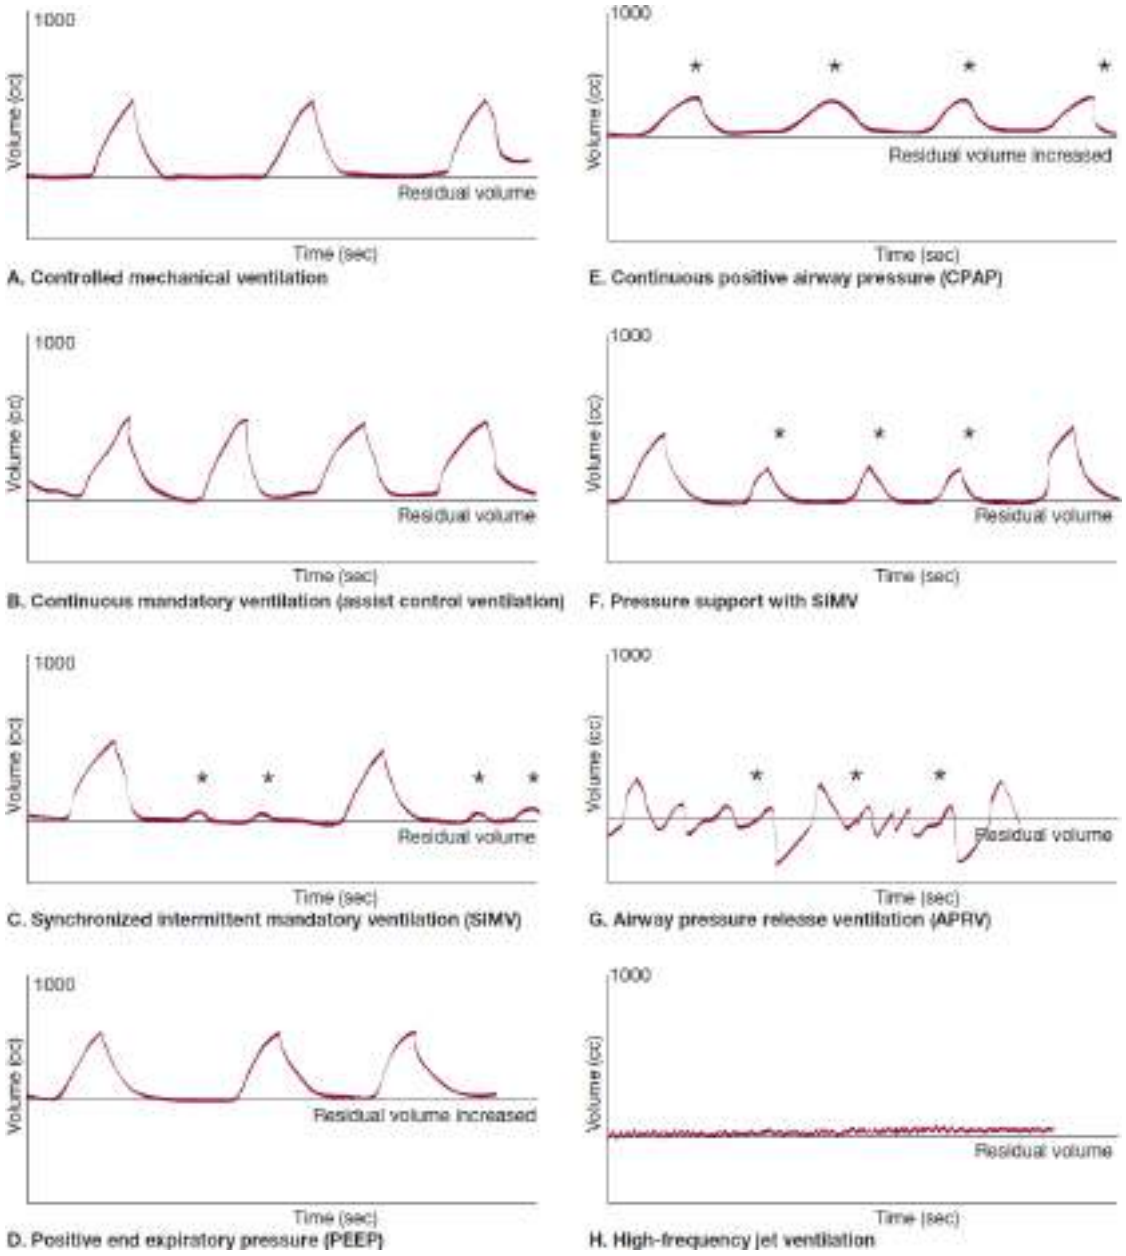

Figure 19-8 • Modes of mechanical ventilation with airflow waveforms. Inhalations marked with an asterisk (*) are spontaneous.

Controlled mechanical ventilation provides full ventilator support by delivering a preset tidal volume and respiratory rate. This mode of ventilation is indicated for patients who are apneic. In A/C ventilation, more commonly called **continuous mandatory (volume or pressure) ventilation (CMV)**, the ventilator delivers a preset tidal volume or pressure at a preset rate of

respirations. However, if the patient initiates a breath between the machine's breaths, the ventilator delivers at the preset volume or pressure (assisted breath). Therefore, every breath is the preset volume or pressure, regardless of whether it is initiated by the patient or the ventilator. Two variations to CMV include: pressure-regulated volume control ventilation (PRVCV) and pressure-controlled inverse ratio ventilation (PC-IRV). PRVCV delivers a preset tidal volume using the minimal amount of airway pressure in patients with rapidly changing airway resistance and lung compliance. PC-IRV provides prolonged inspiratory time in refractory to positive end-expiratory pressure (PEEP) in a patient with hypoxia.

Intermittent mandatory (volume or pressure) ventilation (IMV) provides a combination of mechanically assisted breaths and spontaneous breaths. Mechanical breaths are delivered at preset intervals and a preselected tidal volume, regardless of the patient's efforts. Although the patient can increase the respiratory rate by initiating inspiration between ventilator-delivered breaths, these spontaneous breaths are limited to the tidal volume generated by the patient. IMV allows patients to use their own muscles for ventilation to help prevent muscle atrophy. It lowers mean airway pressure, which can assist in preventing barotrauma. However, patient-ventilator dyssynchrony, evidenced by the patient "fighting the ventilator" or "bucking the ventilator" (i.e., trying to exhale when the ventilator is delivering a breath) may increase.

Synchronized intermittent mandatory ventilation (SIMV) also delivers a preset tidal volume and number of breaths per minute. Between ventilator-delivered breaths, the patient can breathe spontaneously with no assistance from the ventilator on those extra breaths. Because the ventilator senses patient breathing efforts and does not initiate a breath in opposition to the patient's efforts, patient-ventilator dyssynchrony is reduced. As the patient's ability to breathe spontaneously increases, the preset number of ventilator breaths is decreased and the patient does more of the work of breathing. Like IMV, SIMV can be used to provide full or partial ventilatory support. Nursing interventions for patients receiving IMV or SIMV include monitoring progress by recording respiratory rate, minute volume, spontaneous and machine-generated tidal volume, FiO_2, and arterial blood gas levels.

Pressure support ventilation (PSV) applies a pressure plateau to the airway throughout the patient-triggered inspiration to decrease resistance within the tracheal tube and ventilator tubing. Pressure support is reduced gradually as the patient's strength increases. An SIMV backup rate may be added for extra support. The nurse must closely observe the patient's respiratory rate and tidal volumes on initiation of PSV. It may be necessary to adjust the pressure support to avoid tachypnea or large tidal volumes.

An additional mode of ventilation used to facilitate weaning is volume-assisted pressure support ventilation (VAPSV) also referred to as pressure

augmentation (PA). This mode of ventilation ensures the patient receives a minimum tidal volume with each pressure support breath.

A newer mode of ventilation which requires an esophageal catheter to monitor electrical activity of the diaphragm is neurally adjusted ventilatory assist (NAVA). This mode delivers assisted breaths in synchrony with the patient's own breath. The esophageal catheter monitors electrical activity of the diaphragm and signals the ventilator when to initiate a breath.

Another unique mode of ventilation used in special circumstances is independent lung ventilation (ILV). This mode is used in patients with unilateral lung disease. Each lung is ventilated separately via a double lumen ET tube (Urden et al., 2018).

Airway pressure release ventilation (APRV) is a time-triggered, pressure-limited, time-cycled mode of mechanical ventilation that allows unrestricted, spontaneous breathing throughout the ventilatory cycle. The inflation period is long, and breaths may be initiated spontaneously as well as by the ventilator. APRV allows alveolar gas to be expelled through the lungs' natural recoil. APRV has the important advantages of causing less ventilator-induced lung injury and fewer adverse effects on cardiocirculatory function and being associated with lower need for sedation and neuromuscular blockade.

Proportional assist ventilation (PAV) provides partial ventilatory support in which the ventilator generates pressure in proportion to the patient's inspiratory efforts. With every breath, the ventilator synchronizes with the patient's ventilatory efforts. The more inspiratory pressure the patient generates, the more pressure the ventilator generates, amplifying the patient's inspiratory effort without any specific preselected target pressure or volume. It generally adds "additional muscle" to the patient's effort; the depth and frequency of breaths are controlled by the patient.

Other modes of mechanical ventilation that incorporate computerized control of ventilation include adaptive support ventilation (ASV), which adjusts minute ventilation and pressure support based on patient need (Urden et al., 2018).

With various modes of mechanical ventilation, the ventilator constantly monitors many variables and adjusts gas delivery during individual breaths; these within-breath adjustment systems include automatic tube compensation, volume-ensured pressure support, and proportional support ventilation. In other modes, the ventilator evaluates gas delivery during one breath and uses that information to adjust the next breath; these between-breath adjustment systems can be made to ensure a preset tidal volume by adjusting pressure, up to a preset maximum, and include pressure volume support, pressure-regulated volume control, and ASV.

Adjusting the Ventilator

The ventilator is adjusted so that the patient is comfortable and breathes synchronously (i.e., "in sync") with the machine. Minimal alteration of the normal cardiovascular and pulmonary dynamics is desired. If the volume ventilator is adjusted appropriately, the patient's arterial blood gas values will be satisfactory and there will be little or no cardiovascular compromise. Chart 19-15 describes initial ventilator settings.

Chart 19-15

Initial Ventilator Settings

The following guide is an example of the steps involved in operating a mechanical ventilator. The nurse, in collaboration with the respiratory therapist, always reviews the manufacturer's instructions, which vary according to the equipment, before beginning mechanical ventilation.

1. Set the machine to deliver the tidal volume required (6 to 10 mL/kg) or (4 to 8 mL/kg for patients with ARDS).
2. Adjust the machine to deliver the lowest concentration of oxygen to maintain normal PaO_2 (greater than 60 mm Hg) or an SpO_2 level greater than 92%. This setting may be high initially but will gradually be reduced based on arterial blood gas (ABG) results.
3. Record peak inspiratory pressure.
4. Set mode (continuous mandatory ventilation [also known as assist–control], or synchronized intermittent mandatory ventilation) and rate as prescribed by the primary provider. (See the glossary for definitions of modes of mechanical ventilation.) Set positive end-expiratory pressure (PEEP) and pressure support if prescribed.
5. Set sigh settings (usually set at 1.5 times the tidal volume and ranging from 1 to 3 per hour), if applicable.
6. Adjust sensitivity so that the patient can trigger the ventilator with a minimal effort (usually 2 mm Hg negative inspiratory force).
7. Record minute volume and obtain ABGs to measure carbon dioxide partial pressure ($PaCO_2$), pH, and PaO_2 after 20 minutes of continuous mechanical ventilation.
8. Adjust setting (FiO_2 and rate) according to results of ABG analysis to provide normal values or those set by the primary provider.
9. If there is poor coordination between the breathing rhythms of the patient and the ventilator (i.e., patient-ventilator dyssynchrony), assess for hypoxia and manually ventilate on 100% oxygen with a resuscitation bag.

NURSING PROCESS

The Patient Receiving Mechanical Ventilation

Nursing management of patients with acute respiratory failure includes assisting with intubation and maintaining mechanical ventilation. Furthermore, caring for a patient on mechanical ventilation has become an integral part of nursing care for many patients in critical care or general medical-surgical units, extended care facilities, and the home. Nurses, physicians, and respiratory therapists must understand each patient's specific pulmonary needs and work together to set realistic goals. Positive patient outcomes depend on an understanding of the principles of mechanical ventilation and the patient's care needs as well as open communication among members of the health care team about the goals of therapy, weaning plans, and the patient's tolerance of changes in ventilator settings.

Assessment

The nurse plays a vital role in assessing the patient's status and the functioning of the ventilator. In assessing the patient, the nurse evaluates the patient's physiologic status and how they are coping with mechanical ventilation. Physical assessment includes systematic assessment of all body systems, with an in-depth focus on the respiratory system. Respiratory assessment includes vital signs, respiratory rate and pattern, breath sounds, evaluation of spontaneous ventilatory effort, and potential evidence of hypoxia (e.g., skin color). Increased adventitious breath sounds may indicate a need for suctioning. The nurse maintains the patient's head of the bed so that it is elevated 30 degrees or higher unless contraindicated to prevent the risk of aspiration and VAP. The nurse verifies endotracheal tube position as applicable and evaluates the settings and functioning of the mechanical ventilator. Although the nurse may not be primarily responsible for adjusting the settings on the ventilator or measuring ventilator parameters (these are usually responsibilities of the respiratory therapist), the nurse is responsible for the patient and therefore needs to evaluate how the ventilator affects the patient's overall status.

When monitoring the ventilator, the nurse notes the following:

- Controlling mode (e.g., CMV ventilation and SIMV).
- Tidal volume and rate settings (tidal volume is usually set at 6 to 10 mL/kg [ideal body weight] or 4 to 8 mL/kg for the patient with ARDS [ideal body weight]; rate is usually set at 12 to 16 breaths/min).
- FiO_2 setting may be set between 21% and 100% to maintain an optimal PaO_2 level (e.g., greater than 60 mm Hg) or SpO_2 level greater than 92%.

- Peak inspiratory pressure (PIP) (normal is 15 to 20 cm H_2O; this increases if there is increased airway resistance or decreased compliance).
- Sensitivity (A 2 cm H_2O inspiratory force should trigger the ventilator).
- Inspiratory-to-expiratory ratio (usually 1:2 [1 second of inspiration to 2 seconds of expiration] unless inverse ratio is ordered).
- Minute volume (tidal volume × respiratory rate).
- Sigh settings (usually set at 1.5 times the tidal volume and ranging from 1 to 3 per hour), if applicable.
- Water in the tubing, disconnection or kinking of the tubing, which, if present, are corrected.
- Humidification (humidifier filled with water) and temperature.
- Alarms (turned on and functioning properly at all times per The Joint Commission [TJC] Alarm Safety Goal) (TJC, 2020).
- PEEP and pressure support level, if applicable.

As is true with any type of patient-sensitive life support equipment, mechanical ventilators have multiple alarms that are set to alert the health care team of potential patient problems. With the increased number of alarms and their high sensitivity to subtle changes, members of the health care team, including nurses, are at risk for experiencing alarm fatigue, which means that they may become desensitized to alarms and not respond to them with sufficient speed. According to the National Patient Safety Goals (TJC, 2020), measures must be instituted to prevent alarm fatigue.

Quality and Safety Nursing Alert

To prevent alarm fatigue associated with mechanical ventilators, nurses can manage the physical layout of the critical care unit (e.g., avoid locating patients on mechanical ventilators in close proximity); devise protocols for setting of alarms based upon best practices; and educate staff on how to set alarms and when and how to respond to them.

Assessment also addresses the patient's neurologic status and effectiveness of coping with the need for assisted ventilation and the changes that accompany it. The nurse assesses the patient's comfort level and ability to communicate as well. Because weaning from mechanical ventilation requires adequate nutrition, it is important to assess the patient's gastrointestinal system and nutritional status.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include:

- Impaired gas exchange associated with underlying illness, ventilator setting adjustments, or weaning
- Impaired airway clearance associated with increased mucus production associated with presence of the tube in trachea or continuous positive-pressure mechanical ventilation
- Risk for injury and infection associated with endotracheal intubation or tracheostomy
- Impaired mobility associated with ventilator dependency
- Impaired verbal communication associated with endotracheal tube or tracheostomy tube
- Difficulty coping associated with ventilator dependency

TABLE 19-5 Troubleshooting Problems with Mechanical Ventilation

Problem	Cause	Solution
Ventilator Problems		
Increase in peak airway pressure	Coughing or plugged airway tube	Suction airway for secretions; empty condensation fluid from circuit.
	Patient-ventilator dyssynchrony	Adjust sensitivity; consider administering sedatives as prescribed
	Decreasing lung compliance	Manually ventilate patient. Assess for hypoxia or bronchospasm. Check arterial blood gas values. Sedate only if necessary.
	Tubing kinked	Check tubing; reposition patient; insert oral airway if necessary.
	Pneumothorax	Manually ventilate patient; notify primary provider.
	Atelectasis or bronchospasm	Clear secretions.
Decrease in pressure or loss of volume	Increase in compliance	None.
	Leak in ventilator or tubing; cuff on tube/humidifier not tight	Check entire ventilator circuit for patency. Correct leak.
Patient Problems		
Cardiovascular compromise	Decrease in venous return due to application of positive pressure to lungs	Assess for adequate volume status by measuring heart rate, blood pressure, central venous pressure, pulmonary capillary wedge pressure, and urine output; notify primary provider if values are abnormal.
Barotrauma/pneumothorax	Application of positive pressure to lungs; high mean airway pressures lead to alveolar rupture	Notify primary provider. Prepare patient for chest tube insertion. Avoid high pressure settings for patients with COPD, ARDS, or history of pneumothorax.
Pulmonary infection	Bypass of normal defense mechanisms; frequent breaks in ventilator circuit; decreased mobility;	Use strict aseptic technique. Provide frequent mouth care. Optimize nutritional status.

	impaired cough reflex

ARDS, acute respiratory distress syndrome; COPD, chronic obstructive pulmonary disease.

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications may include the following (see Table 19-5):

- Ventilator problems (increase in peak airway pressure or decrease in pressure or loss of volume)
- Alterations in cardiac function
- Barotrauma and pneumothorax
- Pulmonary infection and sepsis (e.g., VAP; see Chart 19-6)
- Delirium and postintensive care syndrome

Planning and Goals

The major goals for the patient may include achievement of optimal gas exchange, maintenance of a patent airway, absence of injury or infection, attainment of optimal mobility, adjustment to nonverbal methods of communication, acquisition of successful coping measures, and absence of complications.

Nursing Interventions

Nursing care of the patient who is mechanically ventilated requires expert technical and interpersonal skills. Nursing interventions are similar regardless of the setting; however, the frequency of interventions and the stability of the patient vary from setting to setting. Nursing interventions for the patient who is mechanically ventilated are not uniquely different from those for patients with other pulmonary disorders, but astute nursing assessment and a therapeutic nurse–patient relationship are critical. The specific interventions used by the nurse are determined by the underlying disease process and the patient's response.

Two general nursing interventions that are important in the care of the patient who is mechanically ventilated are pulmonary auscultation and interpretation of arterial blood gas measurements. The nurse is often the first to note changes in physical assessment findings or significant trends in blood gases that signal the development of a serious problem (e.g., pneumothorax, tube displacement, pulmonary embolus).

Enhancing Gas Exchange

The purpose of mechanical ventilation is to optimize gas exchange by maintaining alveolar ventilation and oxygen delivery. The alteration in gas exchange may be caused by the underlying illness or by mechanical factors related to adjustment of the ventilator to the patient. The health care team,

including the nurse, physician, and respiratory therapist, continually assesses the patient for adequate gas exchange, signs and symptoms of hypoxia, and response to treatment. Therefore, the nursing diagnosis of impaired gas exchange is, by its complex nature, multidisciplinary and collaborative. The team members must share goals and information freely. All other goals directly or indirectly relate to this primary goal.

Nursing interventions to promote optimal gas exchange include judicious administration of analgesic agents to relieve pain without suppressing the respiratory drive and frequent repositioning to diminish the pulmonary effects of immobility. The nurse also monitors for adequate fluid balance by assessing for the presence of peripheral edema, calculating daily intake and output, and monitoring daily weights. The nurse administers medications prescribed to control the primary disease and monitors for their side effects.

Promoting Effective Airway Clearance

Continuous positive-pressure ventilation increases the production of secretions regardless of the patient's underlying condition. The nurse assesses for the presence of secretions by lung auscultation at least every 2 to 4 hours. Measures to clear the airway of secretions include suctioning, CPT, frequent position changes, and increased mobility as soon as possible. Frequency of suctioning should be determined by patient assessment. If excessive secretions are identified by inspection or auscultation techniques, suctioning should be performed. Sputum is not produced continuously or every 1 to 2 hours but as a response to a pathologic condition. Therefore, there is no rationale for routine suctioning of all patients every 1 to 2 hours. Although suctioning is used to aid in the clearance of secretions, it can damage the airway mucosa and impair cilia action.

The sigh mechanism on the ventilator may be adjusted to deliver at least 1 to 3 sighs per hour at 1.5 times the tidal volume if the patient is receiving A/C ventilation. Periodic sighs prevent atelectasis and the further retention of secretions. Because of the risk for hyperventilation and trauma to pulmonary tissue from excess ventilator pressure (barotrauma, pneumothorax), the sigh feature is not used frequently. If the SIMV mode is being used, the mandatory ventilations act as sighs because they are of greater volume than the patient's spontaneous breaths.

Humidification of the airway via the ventilator is maintained to help liquefy secretions so that they are more easily removed. Bronchodilators may be indicated to dilate the bronchioles in patients with acute lung injury or COPD and are classified as adrenergic or anticholinergic. Adrenergic bronchodilators (see Chapter 20, Table 20-4) are mostly inhaled and work by stimulating the beta-receptor sites, mimicking the effects of epinephrine in the body. The desired effect is smooth muscle relaxation, which dilates the constricted bronchial tubes. Anticholinergic bronchodilators (see

Chapter 20, Table 20-4) produce airway relaxation by blocking cholinergic-induced bronchoconstriction. Patients receiving bronchodilator therapy of either type should be monitored for adverse effects, including dizziness, nausea, decreased oxygen saturation, hypokalemia, increased heart rate, and urine retention. Mucolytic agents (e.g., acetylcysteine) may also be indicated in these patients to liquefy secretions so that they are more easily mobilized. Nursing management of patients receiving mucolytic therapy includes assessment of an adequate cough reflex, sputum characteristics, and (in patients not receiving mechanical ventilation) improvement in incentive spirometry. Side effects include nausea, vomiting, bronchospasm, stomatitis (oral ulcers), urticaria, and rhinorrhea (runny nose) (Karch, 2020).

Preventing Injury and Infection

Maintaining the endotracheal or tracheostomy tube is an essential part of airway management. Cuff pressure is monitored every 8 hours to maintain the pressure at 20 to 25 mm Hg (Urden et al., 2018). The nurse assesses for the presence of a cuff leak at the same time. The nurse positions the ventilator tubing so that there is minimal pulling or distortion of the tube in the trachea, reducing the risk of trauma to the trachea. Unintentional or premature removal of the tube is a potentially life-threatening complication of endotracheal intubation. Removal of the tube is a frequent problem in intensive care units (ICUs) and occurs mainly during nursing care or by the patient. Nurses must instruct and remind patients and family members about the purpose of the tube and the dangers of removing it. Baseline and ongoing assessment of the patient and of the equipment ensures effective care. Providing comfort measures, including opioid analgesia and sedation, can improve the patient's tolerance of the endotracheal tube.

Quality and Safety Nursing Alert

Inadvertent removal of an endotracheal tube can cause laryngeal swelling, hypoxemia, bradycardia, hypotension, and even death. Measures must be taken to prevent premature or inadvertent removal.

To prevent tube removal by the patient, the nurse should explain to the patient and family the purpose of the tube, distract the patient through one-to-one interaction or with television, and maintain comfort measures. If the patient cannot move the arms and hands to the endotracheal tube, restraints are not needed. If the patient is alert, oriented, able to follow directions, and cooperative to the point that it is highly unlikely that they will remove the endotracheal tube, restraints are not needed. However, if the nurse

determines there is a risk that the patient may try to remove the tube, the least invasive method of restraints (e.g., soft wrist restraints and hand mitts) may be appropriate as prescribed by the primary provider (check agency policy) (TJC, 2019). The rationale for use of restraints should be documented, and the patient's significant others should receive explanations why restraints are necessary. Close monitoring of the patient is essential to ensure safety and prevent harm.

Patients with an endotracheal or tracheostomy tube do not have the normal defenses of the upper airway. In addition, these patients frequently have multiple additional body system disturbances that lead to immune compromise. Tracheostomy care is performed at least every 8 hours, and more frequently if needed, because of the increased risk of infection. The ventilator circuit tubing and in-line suction tubing are replaced periodically, according to infection prevention guidelines, to decrease the risk of infection.

The nurse administers oral hygiene frequently because the oral cavity is a primary source of contamination of the lungs in the patient who is intubated. The presence of a nasogastric tube in the patient who is intubated can increase the risk of aspiration, leading to nosocomial pneumonia. The nurse positions the patient with the head elevated above the stomach as much as possible. Chart 19-6 provides an overview of strategies to prevent VAP.

Promoting Optimal Level of Mobility

Being connected to a ventilator limits the patient's mobility. Immobility in patients who are mechanically ventilated is associated with decreases in muscle strength and increases length of hospital stay, as well as increased mortality rates (Hodgson, Capell, & Tipping, 2018). The nurse helps the patient whose condition has become stable to get out of bed and move to a chair as soon as possible. If the patient is unable to get out of bed, the nurse encourages performance of active range-of-motion exercises at least every 6 to 8 hours. If the patient cannot perform these exercises, the nurse performs passive range-of-motion exercises at least every 8 hours to prevent contractures and venous stasis.

Promoting Optimal Communication

It is important to develop alternative methods of communication for the patient who is receiving mechanical ventilation. The nurse assesses the patient's communication abilities to evaluate for limitations. Questions to consider when assessing the ability of the patient who is ventilator dependent to communicate include the following:

- Is the patient conscious and able to communicate? Can the patient nod or shake their head?

- Is the patient's mouth unobstructed by the tube so that words can be mouthed?
- Is the patient's dominant hand strong and available for writing? For example, if the patient is right handed, the IV line should be placed in the left arm if possible so that the right hand is free.
- Is the patient a candidate for a fenestrated tracheostomy tube or a one-way speaking valve (such as Passy-Muir valve® or Olympic Trach-Talk®) that permits talking?

Once the patient's limitations are known, the nurse offers several appropriate communication approaches: lip or speech reading (use single key words), pad and pencil or Magic Slate®, iPad® or tablet, communication board, gesturing, sign language, or electric larynx. The use of a "talking" or fenestrated tracheostomy tube or one-way valve may be suggested to the primary provider, which would allow the patient to talk while on the ventilator. The nurse makes sure that the patient's eyeglasses, hearing aid, sign interpreter, and language translator are available if needed to enhance the patient's ability to communicate.

Some communication methods may be frustrating to the patient, family, and nurse; these need to be identified and minimized. A speech therapist can assist in determining the most appropriate method.

Promoting Coping Ability

Dependence on a ventilator is frightening to both the patient and the family and disrupts even the most stable families. Encouraging the family to verbalize their feelings about the ventilator, the patient's condition, and the environment in general is beneficial. Explaining procedures every time they are performed helps reduce anxiety and familiarizes the patient with ventilator procedures. To restore a sense of control, the nurse encourages the patient to use alternative methods of communication in order to participate in decisions about care, schedules, and treatment when possible. The patient may become withdrawn or depressed while receiving mechanical ventilation, especially if its use is prolonged. To promote effective coping, the nurse informs the patient about progress when appropriate. It is important to provide diversions such as watching television, playing music, or taking a walk (if appropriate and possible). Stress reduction techniques (e.g., a back rub, relaxation measures) relieve tension and help the patient deal with anxieties and fears about both the condition and the dependence on the ventilator.

Monitoring and Managing Potential Complications

Alterations in Cardiac Function. Alterations in cardiac output may occur as a result of positive-pressure ventilation. The positive intrathoracic pressure during inspiration compresses the heart and great vessels, thereby reducing venous return and cardiac output. This is usually corrected during

exhalation when the positive pressure is off. The patient may have decreased cardiac output and resultant decreased tissue perfusion and oxygenation.

To evaluate cardiac function, the nurse first observes for signs and symptoms of hypoxia (restlessness, apprehension, confusion, tachycardia, tachypnea, pallor progressing to cyanosis, diaphoresis, transient hypertension, and decreased urine output). If a pulmonary artery catheter is in place, cardiac output, cardiac index, and other hemodynamic values can be used to assess the patient's status (see Chapter 21).

Barotrauma and Pneumothorax. Excessive positive pressure can cause lung damage, or barotrauma, which may result in a spontaneous pneumothorax, which may quickly develop into a tension pneumothorax, further compromising venous return, cardiac output, and blood pressure (see later discussion). The nurse considers any sudden changes in oxygen saturation or the onset of respiratory distress to be a life-threatening emergency requiring immediate action.

Pulmonary Infection. The patient is at high risk for infection, as described earlier. The nurse reports fever or a change in the color or odor of sputum to the primary provider for follow-up (see earlier discussion of VAP). Subglottic secretions may increase the patients' risk for the development of VAP. Patients expected to be intubated for longer than 72 hours may benefit from the use of an endotracheal tube with a subglottic suction port. This extra port that is connected to continuous suction (20 to 30 cm H_2O) allows for the removal of secretions above the cuff (Urden et al., 2018).

Delirium and Postintensive Care Syndrome. Patients who are critically ill are at risk for delirium during their time in the ICU. They are also at risk for cognitive impairment at a level consistent with mild dementia that may persist for months after they are discharged to the home setting. This critical illness-associated cognitive impairment is called postintensive care syndrome (PICS). The *A*wakening and *B*reathing *C*oordination, *D*elirium monitoring and management, *E*arly mobility, *F*amily engagement and empowerment (ABCDEF) bundle proposes an interdisciplinary process using evidence-based practice to manage delirium and weakness in the patient who is critically ill. It is believed that implementing this bundle can mitigate risks for delirium and possibly PICS. The goals of this bundle are to improve communication among members of the health care team, standardize care related to the assessment and use of sedation, provide nonpharmacologic interventions in the management of delirium, provide early exercise and ambulation, and incorporate family's concerns and participation in care planning (see Chart 19-16) (Marra, Ely, Pandharipande, et al., 2017).

Chart 19-16

The ABCDEF Bundle

The *A*wakening and *B*reathing *C*oordination, *D*elirium monitoring and management, *E*arly mobility, *F*amily engagement and empowerment bundle

Overview: Typically, patients on mechanical ventilators require some form of sedation or analgesia during their hospital stay. Recent studies suggest a correlation between the use of potent sedatives and analgesia and ICU-acquired delirium, oversedation, prolonged mechanical ventilation, and postintensive care syndrome (PICS).

Key components of each of the categories of the ABCDEF Bundle include:

1. *Awakening and spontaneous breathing trials*

Using predefined criteria:

- The nurse determines if it is safe to stop sedation.
- If determined safe, the nurse will determine if patient tolerated the sedation interruption.
- If the patient tolerated the interruption, the respiratory therapist will determine if the patient is a candidate for a breathing trial.
- If the patient is a candidate for a breathing trial, the respiratory therapist and nurse will evaluate the patient's response.

2. *Monitoring and management of delirium*

- The nurse assesses the patient at least every 2 to 4 hours using a sedation assessment scale (e.g., the CAM-ICU, see Chapter 11).

3. *Early Mobility*

The nurse assesses the patient using the following criteria for mobility:

- The patient is able to respond to verbal stimuli.
- The patient is receiving less than 60% FiO_2 and less than 10 cm of PEEP.
- The patient has no circulatory or central catheters or injuries that may contraindicate mobility.

4. *Family Engagement*

- The nurse encourages engagement of family members and ensures unrestricted access for a designated family support person.

ICU, intensive care unit; PEEP, positive end-expiratory pressure.

Increasingly, patients are being cared for in extended care facilities or at home while receiving mechanical ventilation, with a tracheostomy tube, or receiving oxygen therapy. Patients receiving home ventilator care usually have a chronic neuromuscular condition or COPD. Providing the opportunity for patients who are ventilator dependent to return home to live with their families in familiar surroundings can be a positive experience. The ultimate goal of home ventilator therapy is to enhance the patient's quality of life, not simply to support or prolong life.

Educating Patients About Self-Care. Caring for the patient with mechanical ventilator support at home can be accomplished successfully. A home or transitional care team consisting of the nurse, physician, respiratory therapist, social service or home care agency, and equipment supplier is needed. The home is evaluated to determine whether the electrical equipment needed can be operated safely. Chart 19-17 summarizes the basic assessment criteria needed for successful home care.

Once the decision to initiate mechanical ventilation at home is made, the nurse prepares the patient and family for home care. The nurse educates the patient and family about the ventilator, suctioning, tracheostomy care, signs of pulmonary infection, cuff inflation and deflation, and assessment of vital signs. Education begins in the hospital and continues at home. Nursing responsibilities include evaluating the patient's and family's understanding of the information presented.

The nurse educates the family about cardiopulmonary resuscitation, including mouth-to-tracheostomy tube (instead of mouth-to-mouth) breathing. The family is also instructed how to handle a power failure, which usually involves converting the ventilator from an electrical power source to a battery power source. Conversion is automatic in most types of home ventilators and lasts approximately 1 hour. In addition, instructions are provided on the use of a manual self-inflation bag, should it be necessary. Chart 19-18 lists some of the patient's and family's responsibilities.

Chart 19-17

Criteria for Successful Home Ventilator Care

The decision to proceed with home ventilation therapy is usually based on the following parameters.

Patient Criteria

- The patient has a chronic underlying pulmonary or neuromuscular disorder.
- The patient's clinical pulmonary status is stable.
- The patient is willing to go home on mechanical ventilation.

Home Criteria

- The home environment is conducive to care of the patient.
- The electrical facilities are adequate to operate all equipment safely.
- The home environment is controlled, without drafts in cold weather and with proper ventilation in warm weather.
- Space is available for cleaning and storing ventilator equipment.

Family Criteria

- Family members are competent, dependable, and willing to spend the time required for proper training as primary caregivers.
- Family members understand the diagnosis and prognosis.
- Family has sufficient financial and supportive resources and can obtain professional support if necessary.

Chart 19-18 HOME CARE CHECKLIST

Ventilator Care

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed, as indicated, and how the patient's present status impacts physiologic functioning, ADLs, IADLs, relationships, and spirituality.
- State the name, dose, side effects, frequency, and schedule for all medications.
- State what types of changes are needed (if any) to maintain a clean home environment and prevent infection.
- State how to contact the primary provider, the team of home care professionals overseeing care, respiratory vendor and obtain supplies.
- Complete CPR training program for caregivers.
- Identify a plan for operation of ventilator and other devices during a power outage or other emergency.
- State proper care of patient on ventilator:
  - Observe physical signs such as color, secretions, breathing pattern, and state of consciousness.
  - Perform physical care such as suctioning, postural drainage, and ambulation.
  - Observe the tidal volume and pressure manometer regularly. Intervene when they are abnormal (i.e., suction if airway pressure increases).
  - Provide a communication method for the patient (e.g., pad and pencil, electric larynx, talking tracheostomy tube, and sign language).
  - Monitor vital signs as directed.
  - Use a predetermined signal to indicate when feeling short of breath or in distress.
- Care for and maintain equipment properly:
  - Check the ventilator settings twice each day and whenever the patient is removed from the ventilator.
  - Adjust the volume and pressure alarms if needed.
  - Fill humidifier as needed and check its level three times a day.
  - Empty water in tubing as needed.
  - Use a clean humidifier when circuitry is changed.
  - Keep exterior of ventilator clean and free of any objects.
  - Change external circuitry once a week or more often as indicated.
  - Report malfunction or strange noises immediately.

- Identify the contact details for support services for patients and their caregivers/families.

Resources

See Chapter 20, Figure 20-6 for additional information on postural drainage positions.

For the procedural guidelines for caring for a patient with a tracheostomy tube and performing tracheal suction, go to thepoint.lww.com/Brunner15e.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Continuing and Transitional Care. A home health or transitional care nurse monitors and evaluates how well the patient and family are adapting to providing care in the home. The nurse assesses the adequacy of the patient's ventilation and oxygenation as well as airway patency. The nurse addresses any unique adaptation problems that the patient may have and listens to the patient's and family's anxieties and frustrations, offering support and encouragement where possible. The nurse helps identify and contact community resources that may assist in home management of the patient with mechanical ventilation.

The technical aspects of the ventilator are managed by vendor follow-up. A respiratory therapist usually is assigned to the patient and makes home visits to evaluate the patient and perform a maintenance check of the ventilator as needed.

Transportation services are identified in case the patient requires transportation in an emergency. These arrangements must be made before an emergency arises.

Evaluation

Expected patient outcomes may include:

1. Exhibits adequate gas exchange, as evidenced by normal breath sounds, acceptable arterial blood gas levels, and vital signs
2. Demonstrates adequate ventilation with minimal mucus accumulation
3. Is free of injury or infection, as evidenced by normal temperature, white blood cell count, and clear sputum
4. Is mobile within limits of ability
   a. Gets out of bed to chair, bears weight, or ambulates as soon as possible
   b. Performs range-of-motion exercises every 6 to 8 hours

5. Communicates effectively through written messages, gestures, or other communication strategies
6. Copes effectively
    a. Verbalizes fears and concerns about condition and equipment
    b. Participates in decision making when possible
    c. Uses stress reduction techniques when necessary
7. Absence of complications
    a. Absence of cardiac compromise, as evidenced by stable vital signs and adequate urine output
    b. Absence of pneumothorax, as evidenced by bilateral chest excursion, normal chest x-ray, and adequate oxygenation
    c. Absence of pulmonary infection, as evidenced by normal temperature, clear pulmonary secretions, and negative sputum cultures
    d. Absence of delirium and of postintensive care syndrome, as evidenced by no patient-ventilator dyssynchrony, and being oriented to person, place, and time

Weaning the Patient from the Ventilator

Respiratory weaning, the process of withdrawing the patient from dependence on the ventilator, takes place in three stages: the patient is gradually removed from the ventilator, then from either the ET or tracheostomy tube, and finally from oxygen. Weaning from mechanical ventilation is performed at the earliest possible time consistent with patient safety. The decision must be made from a physiologic rather than a mechanical viewpoint. A thorough understanding of the patient's clinical status is required in making this decision. Weaning is started when the patient is physiologically and hemodynamically stable, demonstrates spontaneous breathing capability, recovering from the acute stage of medical and surgical problems, and when the cause of respiratory failure is sufficiently reversed (Wiegand, 2017). Chart 19-19 presents information about patient care during weaning from mechanical ventilation.

Successful weaning involves collaboration among the primary provider, respiratory therapist, and nurse. Each health care provider must understand the scope and function of other team members in relation to patient weaning to conserve the patient's strength, use resources efficiently, and maximize successful outcomes.

Criteria for Weaning

Careful assessment is required to determine whether the patient is ready to be removed from mechanical ventilation. If the patient is stable and showing signs of improvement or reversal of the disease or condition that caused the need for mechanical ventilation, weaning indices should be assessed (see Chart 19-19).

Stable vital signs and arterial blood gases are also important predictors of successful weaning. Once readiness has been determined, the nurse records baseline measurements of weaning indices to monitor progress.

Patient Preparation

To maximize the likelihood of success of weaning, the nurse must consider the patient as a whole, taking into account factors that impair the delivery of oxygen and elimination of carbon dioxide as well as those that increase oxygen demand (e.g., sepsis, seizures, thyroid imbalances) or decrease the patient's overall strength (e.g., inadequate nutrition, neuromuscular disease). Adequate psychological preparation is necessary before and during the weaning process.

Methods of Weaning

Successful weaning depends on the combination of adequate patient preparation, available equipment, and an interdisciplinary approach to solve patient problems (see Chart 19-19). All usual modes of ventilation can be used for weaning.

CPAP (also known as spontaneous mode ventilation in this context) allows the patient to breathe spontaneously while applying positive pressure throughout the respiratory cycle to keep the alveoli open and promote oxygenation. Providing CPAP during spontaneous breathing also offers the advantage of an alarm system and may reduce patient anxiety if the patient has been taught that the machine is keeping track of breathing. It also maintains lung volumes and improves the patient's oxygenation status. CPAP is often used in conjunction with PSV. Nurses should carefully assess for

tachypnea, tachycardia, reduced tidal volumes, decreasing oxygen saturations, and increasing carbon dioxide levels.

Chart 19-19

Care of the Patient Being Weaned from Mechanical Ventilation

1. Assess patient for weaning criteria:
   a. Vital capacity: 10 to 15 mL/kg
   b. Maximum inspiratory pressure (MIP) at least –20 cm H_2O
   c. Tidal volume: 7 to 9 mL/kg
   d. Minute ventilation: 6 L/min
   e. Rapid/shallow breathing index: Below 100 breaths/min/L; PaO_2 >60 mm Hg with FiO_2 <40%
2. Monitor activity level, assess dietary intake, and monitor results of laboratory tests of nutritional status. Reestablishing independent spontaneous ventilation can be physically exhausting. It is crucial that the patient have enough energy reserves to succeed.
3. Assess the patient's and family's understanding of the weaning process and address any concerns about the process. Explain that the patient may feel short of breath initially and provide encouragement as needed. Reassure the patient that they will be attended closely and that if the weaning attempt is not successful, it can be tried again later.
4. Implement the weaning method as prescribed (e.g., continuous positive airway pressure [CPAP] and T-piece).
5. Monitor vital signs, pulse oximetry, electrocardiogram, and respiratory pattern constantly for the first 20 to 30 minutes and every 5 minutes after that until weaning is complete. Monitoring the patient closely provides ongoing indications of success or failure.
6. Maintain a patent airway; monitor arterial blood gas levels and pulmonary function tests. Suction the airway as needed.
7. In collaboration with the primary provider, terminate the weaning process if adverse reactions occur. These include a heart rate increase of 20 bpm, systolic blood pressure increase of 20 mm Hg, a decrease in oxygen saturation to <90%, respiratory rate <8 or >20 breaths/min, ventricular arrhythmias, fatigue, panic, cyanosis, erratic or labored breathing, paradoxical chest movement.
8. If the weaning process continues, measure tidal volume and minute ventilation every 20 to 30 minutes; compare with the patient's desired values, which have been determined in collaboration with the primary provider.
9. Assess for psychological dependence if the physiologic parameters indicate that weaning is feasible and the patient still resists. Possible causes of psychological dependence include fear of dying and depression from chronic illness. It is important to address this issue before the next weaning attempt.

Adapted from Wiegand, D. J. L. (2017). *AACN procedure manual for critical care* (6th ed.). St. Louis, MO: Elsevier Saunders.

SIMV can also be used as a weaning method. The patient is placed on SIMV mode of ventilation and the rate is slowly decreased by 1 to 3 breaths/min until the patient is fully breathing on their own (Urden et al., 2018).

Furthermore, T-piece spontaneous breathing trials can also be used. When the patient can breathe spontaneously, weaning trials using a T-piece for the patient with an ET tube or tracheostomy mask for the patient with a tracheostomy tube (see Fig. 19-6) are normally conducted with the patient disconnected from the ventilator, receiving humidified oxygen only and performing all work of breathing. Because patients do not have to overcome the resistance of the ventilator, they may find this mode more comfortable, or they may become anxious as they breathe with no support from the ventilator. During these trial periods, the nurse monitors the patient closely and provides encouragement. This method of weaning is usually used when the patient is awake and alert, is breathing without difficulty, has good gag and cough reflexes, and is hemodynamically stable. During the weaning process, the patient is maintained on the same or a higher oxygen concentration than when receiving mechanical ventilation. While the patient is using the T-piece or tracheostomy mask, they are observed for signs and symptoms of hypoxia, increasing respiratory muscle fatigue, or systemic fatigue. These include restlessness, increased respiratory rate (greater than 35 breaths/min), the use of accessory muscles, tachycardia with premature ventricular contractions, and paradoxical chest movement (asynchronous breathing, chest contraction during inspiration and expansion during expiration). Fatigue or exhaustion is initially manifested by an increased respiratory rate associated with a gradual reduction in tidal volume; later there is a slowing of the respiratory rate.

If the patient appears to be tolerating the T-piece/tracheostomy mask trial, a second set of arterial blood gas measurements is drawn 20 minutes after the patient has been on spontaneous ventilation at a constant FiO_2 PSV. (Alveolar–arterial equilibration takes 15 to 20 minutes to occur.)

Signs of exhaustion and hypoxia correlated with deterioration in the blood gas measurements indicate the need for ventilatory support. The patient is placed back on the ventilator each time signs of fatigue or deterioration develop.

If clinically stable, the patient usually can be extubated within 2 or 3 hours after weaning and allowed spontaneous ventilation by means of a mask with humidified oxygen. Patients who have had prolonged ventilatory assistance usually require more gradual weaning; it may take days or even weeks. They are weaned primarily during the day and placed back on the ventilator at night to rest.

Because patients respond in different manners to weaning methods, there is no definitive way to assess which method is best. Regardless of the weaning method being used, ongoing assessment of respiratory status is essential to monitor patient progress.

Successful weaning from the ventilator is supplemented by intensive pulmonary care. The following methods are used: oxygen therapy; arterial blood gas evaluation; pulse oximetry; bronchodilator therapy; CPT; adequate nutrition, hydration, and humidification; blood pressure measurement; and incentive spirometry. Daily spontaneous breathing trials may be used to evaluate the patient's ability to breathe without ventilatory support. If the patient is receiving IV sedatives (e.g., propofol, dexmedetomidine), current guidelines recommend that the patient's sedative dose be decreased by 25% to 50% prior to weaning. In order to decrease agitation in patients who do not tolerate withdrawal of sedation, dexmedetomidine may be initiated for spontaneous breathing trials without causing significant respiratory depression (Devlin, Skrobik, Gélinas, et al., 2018; Urden et al., 2018). A patient may still have borderline

pulmonary function and need vigorous supportive therapy before their respiratory status returns to a level that supports activities of daily living.

Removal of the Tracheostomy Tube

Removal of the tracheostomy tube is considered when the patient can breathe spontaneously; maintain an adequate airway by effectively coughing up secretions, swallow, and move the jaw. Secretion clearance and aspiration risks are assessed to determine whether active pharyngeal and laryngeal reflexes are intact.

Once the patient can clear secretions adequately, a trial period of mouth breathing or nose breathing is conducted. This can be accomplished by several methods. The first method requires changing to a smaller size tube to increase the resistance to airflow or plugging the tracheostomy tube (deflating the cuff first). The smaller tube is sometimes replaced by a cuffless tracheostomy tube, which allows the tube to be plugged at lengthening intervals to monitor patient progress. A second method involves changing to a fenestrated tube (a tube with an opening or window in its bend). This permits air to flow around and through the tube to the upper airway and enables talking. A third method involves switching to a smaller tracheostomy button (stoma button). A tracheostomy button is a plastic tube approximately 1 inch long that helps keep the windpipe open after the larger tracheostomy tube has been removed. Finally, when the patient demonstrates the ability to maintain a patent airway, the tube can be removed. An occlusive dressing is placed over the stoma, which heals in several days to weeks.

Weaning from Oxygen

The patient who has been successfully weaned from the ventilator, cuff, and tube and has adequate respiratory function is then weaned from oxygen. The FiO_2 is gradually reduced until the PaO_2 is in the range of 70 to 100 mm Hg while the patient is breathing room air. If the PaO_2 is less than 70 mm Hg on room air, supplemental oxygen is recommended. To be eligible for financial reimbursement from the Centers for Medicare and Medicaid Services (CMS) for in-home oxygen, the patient must have a PaO_2 at or less than 55 mm Hg while awake and at rest or arterial oxygen saturation at or below 88%, breathing room air (American Association of Respiratory Care, 2007; CMS, 1993).

Nutrition

Success in weaning the patient who is long-term ventilator dependent requires early and aggressive but judicious nutritional support. The respiratory muscles (diaphragm and especially intercostals) become weak or atrophied after just a few days of mechanical ventilation and may be catabolized for energy, especially if nutrition is inadequate. Compensation for inadequate nutrition must be undertaken with care; excessive intake can increase the production of carbon dioxide and the demand for oxygen and lead to prolonged ventilator dependence and difficulty in weaning. Because the metabolism of fat produces less carbon dioxide than the metabolism of carbohydrates, it was long presumed that a high-fat and limited carbohydrate diet would be most therapeutic; however, evidence-based findings do not support its efficacy (Seres, 2020). Adequate protein intake is important in increasing respiratory muscle strength. Protein intake should be approximately 25% of total daily kilocalories, or 1.2 to 1.5 g/kg/day. Daily nutrition should be closely monitored.

Soon after the patient is admitted, a consultation with a dietitian or nutrition support team should be arranged to plan the best form of nutritional replacement. Adequate nutrition may decrease the duration of mechanical ventilation and prevent other complications, especially sepsis. Sepsis can occur if bacteria enter the bloodstream and release toxins that, in turn, cause vasodilation and hypotension, fever, tachycardia, increased respiratory rate, and coma. Aggressive treatment of sepsis is essential to reverse this threat to survival and to promote weaning from the ventilator when the patient's condition improves.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) can be thought of as a spectrum of disease, progressing from mild to moderate to its most severe, fulminant form. **Acute lung injury** is a term commonly used to describe mild ARDS. ARDS is a clinical syndrome characterized by a severe inflammatory process causing diffuse alveolar damage that results in sudden and progressive pulmonary edema, increasing bilateral infiltrates on chest x-ray, hypoxemia unresponsive to oxygen supplementation regardless of the amount of PEEP, and the absence of an elevated left atrial pressure (Siegel, 2019a). Patients often demonstrate reduced lung compliance. A wide range of factors are associated with the development of ARDS (see Chart 19-20), including direct injury to the lungs (e.g., smoke inhalation) or indirect insult to the lungs (e.g., shock). ARDS has been associated with a mortality rate ranging from 27% to 50%. Patients who survive the initial cause of ARDS may die later, commonly from HCAP or sepsis (Anesi, 2020; Siegel, 2019a).

Chart 19-20 RISK FACTORS

Acute Respiratory Distress Syndrome

- Aspiration (gastric secretions, drowning, hydrocarbons)
- COVID-19 pneumonia
- Drug ingestion and overdose
- Fat or air embolism
- Hematologic disorders (disseminated intravascular coagulation, massive transfusions, cardiopulmonary bypass)
- Localized infection (bacterial, fungal, viral pneumonia)
- Major surgery
- Metabolic disorders (pancreatitis, uremia)
- Prolonged inhalation of high concentrations of oxygen, smoke, or corrosive substances
- Sepsis
- Shock (any cause)
- Trauma (pulmonary contusion, multiple fractures, head injury)

COVID-19, coronavirus disease 2019.

Quality and Safety Nursing Alert

Be alert for the development of acute lung injury in the patient population using e-cigarettes, also known as vaping. This syndrome is called e-cigarette or vaping associated acute lung injury (EVALI). According to the CDC (2019c), patients diagnosed with EVALI have been identified in most states.

Pathophysiology

Inflammatory triggers initiate the release of cellular and chemical mediators, causing injury to the alveolar capillary membrane in addition to other structural damage to the lungs. Severe V./Q. mismatching occurs. Alveoli collapse because of the inflammatory infiltrate, blood, fluid, and surfactant dysfunction. Small airways are narrowed because of interstitial fluid and bronchial obstruction. Lung compliance may markedly decrease, resulting in decreased functional residual capacity and severe hypoxemia. The blood returning to the lung for gas exchange is pumped through the nonventilated, nonfunctioning areas of the lung, causing shunting. This means that blood is interfacing with nonfunctioning alveoli and gas exchange is markedly impaired, resulting in severe, refractory hypoxemia. Figure 19-9 shows the sequence of pathophysiologic events leading to ARDS.

Clinical Manifestations

Initially, ARDS closely resembles severe pulmonary edema. The acute phase of ARDS is marked by a rapid onset of severe dyspnea that usually occurs less than 72 hours after the precipitating event. Arterial hypoxemia that does not respond to supplemental oxygen is characteristic. ARDS is classified according to the severity of hypoxemia experienced by the patient as (Siegel, 2019a):

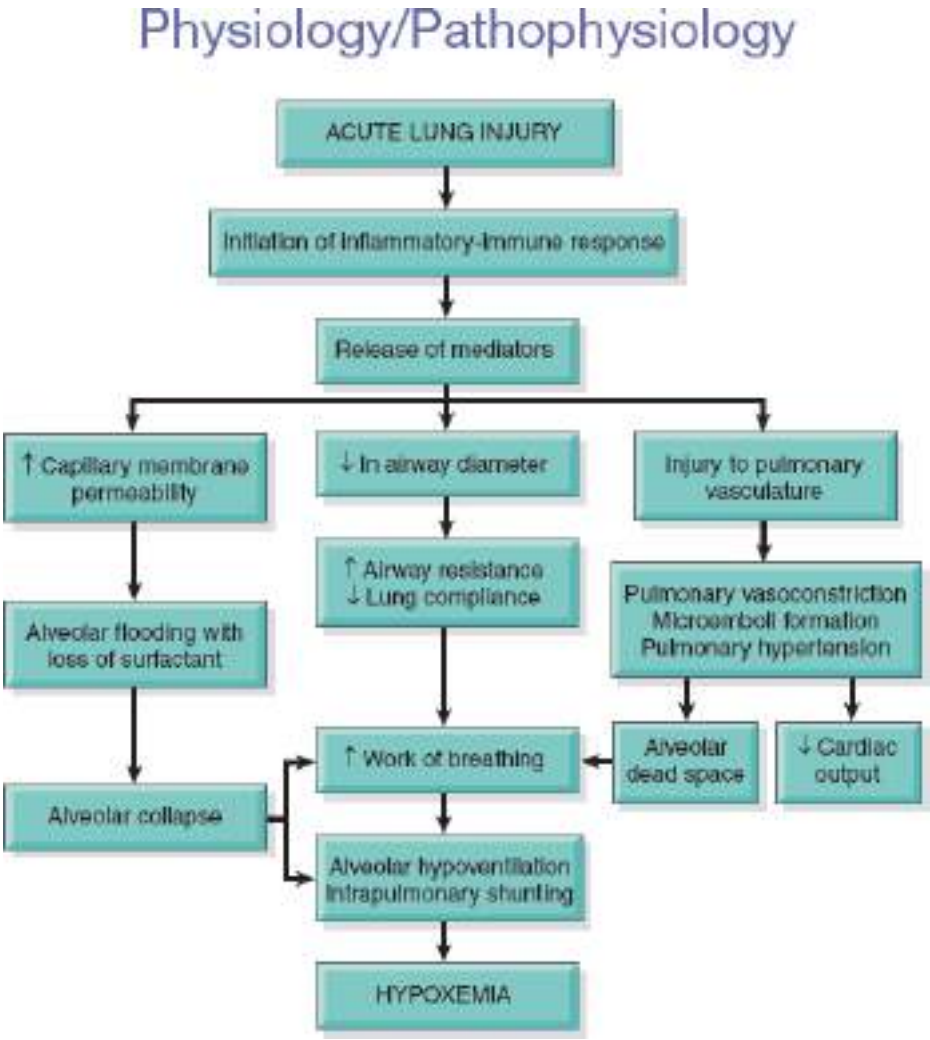

Figure 19-9 • Pathogenesis and pathophysiology of acute respiratory distress syndrome.

- mild ARDS, with arterial oxygen tension (PaO_2)/fraction of inspired oxygen (FIO_2) > 200 mm Hg but ≤300 mm Hg,
- moderate ARDS, with PaO_2/FIO_2 > 100 mm Hg but ≤200 mm Hg, or
- severe ARDS, with PaO_2/FIO_2 ≤ 100 mm Hg.

Findings on chest x-ray are similar to those seen with cardiogenic pulmonary edema and are visible as bilateral infiltrates that quickly worsen. Mild ARDS progresses to fibrosing alveolitis with persistent, severe hypoxemia. The patient also has increased alveolar dead space (ventilation to alveoli but poor perfusion) and typically has

decreased pulmonary compliance ("stiff lungs," which are difficult to ventilate). Clinically, the patient is thought to be in the recovery phase if the hypoxemia gradually resolves, the chest x-ray improves, and the lungs become more compliant.

Assessment and Diagnostic Findings

On physical examination, intercostal retractions and crackles may be present as the fluid begins to leak into the alveolar interstitial space. Common diagnostic tests performed in patients with potential ARDS include plasma brain natriuretic peptide (BNP) levels, echocardiography, and pulmonary artery catheterization. The BNP level is helpful in distinguishing ARDS from cardiogenic pulmonary edema. Transthoracic echocardiography may be used if the BNP is not conclusive.

Medical Management

The primary focus in the management of ARDS includes identification and treatment of the underlying condition. Aggressive, supportive care must be provided to compensate for the severe respiratory dysfunction. This supportive therapy almost always includes ET intubation and mechanical ventilation. In addition, circulatory support, adequate fluid volume, and nutritional support are important. Supplemental oxygen is used as the patient begins the initial spiral of hypoxemia. As the hypoxemia progresses, intubation and mechanical ventilation are instituted. The concentration of oxygen and ventilator settings and modes are determined by the patient's status. This is monitored by arterial blood gas analysis, pulse oximetry, and bedside pulmonary function testing.

Providing ventilatory PEEP support is a critical part of the treatment of ARDS. PEEP usually improves oxygenation, but it does not influence the natural history of the syndrome. The use of PEEP helps increase functional residual capacity and reverse alveolar collapse by keeping the alveoli open, resulting in improved arterial oxygenation and a reduction in the severity of the V./Q. imbalance. By using PEEP, a lower FiO_2 may be required. The goal is a PaO_2 greater than 60 mm Hg or an oxygen saturation level of greater than 90% at the lowest possible FiO_2.

Systemic hypotension may occur in ARDS as a result of hypovolemia secondary to leakage of fluid into the interstitial spaces and depressed cardiac output from high levels of PEEP therapy. Hypovolemia must be carefully treated without causing further overload. Inotropic or vasopressor agents may be required. Additional supportive treatments may include prone positioning, sedation, paralysis, and nutritional support (Siegel, 2019b).

Pharmacologic Therapy

There is no specific pharmacologic treatment of ARDS except supportive care. Neuromuscular blocking agents, sedatives, and analgesics may be used to improve patient–ventilator synchronization and help to decrease severe hypoxemia (see later discussion in Ventilator Considerations section). Inhaled nitric oxide (an endogenous vasodilator) was thought to reduce V./Q. mismatch and improve oxygenation; however, findings from clinical trials have not shown an improvement in mortality rates between patients who did and did not receive nitric oxide (Harman, 2018).

Nutritional Therapy

Adequate nutritional support is vital in the treatment of ARDS. Patients with ARDS require 35 to 45 kcal/kg/day to meet caloric requirements. Enteral feeding is the first consideration; however, parenteral nutrition also may be required.

Nursing Management

General Measures

A patient with ARDS is critically ill and requires close monitoring in an ICU. Respiratory modalities used in this situation include oxygen administration, nebulizer therapy, CPT, ET intubation or tracheostomy, mechanical ventilation, suctioning, and bronchoscopy. Frequent assessment of the patient's status is necessary to evaluate the effectiveness of treatment.

In addition to supporting the medical plan of care, the nurse considers other needs of the patient. Positioning is important. The nurse turns the patient frequently to improve ventilation and perfusion in the lungs and enhance secretion drainage. However, the nurse must closely monitor the patient for deterioration in oxygenation with changes in position. Oxygenation in patients with ARDS is sometimes improved in the prone position; this seems to be particularly true for patients with COVID-19 and ARDS (see later discussion). This position may be evaluated for improvement in oxygenation and used in special circumstances. Devices and specialty beds are available to assist the nurse in placing the patient in a prone position.

The patient is extremely anxious and agitated because of the increasing hypoxemia and dyspnea. It is important to reduce the patient's anxiety because anxiety increases oxygen expenditure by preventing rest. Rest is essential to limit oxygen consumption and reduce oxygen needs.

Ventilator Considerations

Several considerations must be addressed for the patient intubated and receiving mechanical ventilation with PEEP. PEEP, which causes increased end-expiratory pressure, is an unnatural pattern of breathing and feels strange to the patient. The patient may be anxious, and patient-ventilator dyssynchrony may be the consequence. Nursing assessment is important to identify problems with ventilation that may be causing the anxiety reaction: tube blockage by kinking or retained secretions, other acute respiratory problems (e.g., pneumothorax and pain), a sudden decrease in the oxygen level, the level of dyspnea, or ventilator malfunction. In some cases, sedation may be required to decrease the patient's oxygen consumption, allow the ventilator to provide full support of ventilation, and decrease the patient's anxiety. Sedatives that may be prescribed are lorazepam, midazolam, dexmedetomidine, propofol, and short-acting barbiturates.

If the PEEP level cannot be maintained despite the use of sedatives, neuromuscular blocking agents (paralytic agents) may be given to paralyze the patient. Examples of these agents include pancuronium, vecuronium, atracurium, and rocuronium. The resulting paralysis allows the patient to be ventilated more easily. With paralysis, the patient appears to be unconscious; loses motor function; and cannot breathe, talk, or blink independently. However, the patient retains sensation and is awake and able to

hear. The nurse must reassure the patient that the paralysis is a result of the medication and is temporary. Paralysis should be used for the shortest possible time and never without adequate sedation and pain management.

Peripheral nerve stimulators are used to assess nerve impulse transmissions at the neuromuscular junction of select skeletal muscles when neuromuscular blocking agents are used. A "train-of-four" test may be used to measure the level of neuromuscular blockade. With this test, four consecutive stimuli are delivered along the path of a nerve, and the response of the muscle is measured in order to evaluate whether or not stimuli are effectively blocked. Four equal muscle contractions, seen as "twitches," will result if there is no neuromuscular blockade. However, if neuromuscular blockade is present, there will be a loss of twitch height and number, which will indicate the degree of blockade. If all four stimulations result in an absence of twitches, it is estimated that 100% of the receptors are blocked (Wiegand, 2017).

The use of neuromuscular blocking agents has many dangers and side effects. The nurse must be sure the patient does not become disconnected from the ventilator, because respiratory muscles are paralyzed and the patient will be apneic. Consequently, the nurse ensures that the patient is closely monitored; all ventilator and patient alarms must be on at all times. Eye care is important as well, because the patient cannot blink, increasing the risk of corneal abrasions. Neuromuscular blockers predispose the patient to venous thromboembolism (VTE), muscle atrophy, foot drop, stress ulcers that may cause hemorrhage, and skin breakdown.

Quality and Safety Nursing Alert

Nursing assessment is essential to minimize the complications related to neuromuscular blockade. The patient may have discomfort or pain but cannot communicate these sensations. In addition, frequent oral care and suctioning may be needed.

Analgesia must be given concurrently with neuromuscular blocking agents (Saenz, 2019). The nurse must anticipate the patient's needs regarding pain and comfort. The nurse checks the patient's position to ensure it is comfortable without excessive pressure points and in normal alignment. Talking to and not about the patient while in the patient's presence is important.

In addition, the nurse must describe the purpose and effects of the neuromuscular blocking agents to the patient's family. If family members are unaware that these agents have been given, they may become distressed by the change in the patient's status.

COVID-19 Considerations

The most serious complication and most frequent cause of death among patients with COVID-19 is ARDS (Anesi, 2020). In China, where the SARS-CoV-2 virus first emerged, approximately one quarter of patients who were hospitalized in the early days of the pandemic required treatment in critical care units, the majority with respiratory

failure and ARDS. Of these, 52.4% died secondary to complications of ARDS (Niederman, Richeldi, Chotirmall, et al., 2020; Wu & McGoogan, 2020).

The pathogenesis of ARDS in patients with COVID-19 pneumonia appears to have some differences from other cases of ARDS. In particular, although there is evidence of damage to epithelial cells within alveoli, epithelial cells within the pulmonary endothelium are not damaged, resulting in less exudative pathologic changes than with other types of ARDS. In terms of clinical manifestations, some patients with severe COVID-19 pneumonia do not voice complaints of dyspnea but nonetheless may deteriorate rapidly into respiratory failure. Furthermore, some patients with COVID-19 and ARDS who are mechanically ventilated do not exhibit the poor lung compliance that is a classic manifestation of typical ARDS. In addition, the onset of most non-COVID-19 cases of ARDS is typically one week or less from the time of the causative insult; however, the median time from onset of COVID-19 symptoms to ARDS is longer, at between 8 to 12 days (Li & Ma, 2020).

The same classification system used to diagnosis other cases of ARDS is used to classify patients with COVID-19 pneumonia with ARDS (i.e., as having mild, moderate, or severe ARDS) (Cascella et al., 2020). Many of the same strategies used to manage patients without COVID-19 who have ARDS apply to the patient with COVID-19 and ARDS. For instance, it is recommended that the patient with COVID-19 and ARDS who is mechanically ventilated receive low tidal volumes (i.e., 4 to 8 mL/kg ideal body weight). However, there are some specific differences in the recommended treatment of the adult with COVID-19 and ARDS who is mechanically ventilated, which include the following (Alhazzani, Moller, Arabi, et al., 2020; Anesi, 2020):

- PEEP > 5 cm H_2O should be delivered (although the patient should be closely monitored for barotrauma if the PEEP is >10 cm H_2O);
- Low dosages of intravenous corticosteroids (e.g., dexamethasone, methylprednisolone) may be prescribed;
- Nitric oxide should not be routinely prescribed; however, for patients with severe ARDS refractory to other treatments, nitric oxide might be tried;
- For the patient with moderate or severe ARDS, prone positioning for 12 to 16 hours daily is recommended, if feasible; and
- For the patient with moderate or severe ARDS, intermittent boluses of neuromuscular blocking agents are preferred over continuous infusions, unless there is persistent patient-ventilator dyssynchrony.

Other treatments recommended for patients with severe COVID-19 pneumonia should also be followed (see previous discussion on COVID-19 pneumonia).

It has been reported that more patients with COVID-19 and ARDS who are mechanically ventilated have neurologic impairment (e.g., delirium, encephalopathy) than other patients with ARDS who are mechanically ventilated. Therefore, sedative requirements for these patients are reportedly higher than for most other patients with ARDS (Anesi, 2020). These neurologic manifestations are that much more difficult to manage because family members and friends, who may be a source of solace to the patient who is agitated, are typically not permitted to visit. Furthermore, the nurse caring for these patients must also practice isolation precautions and minimize interactions with the patient, which can serve to make the patient feel more isolated and agitated.

PULMONARY VASCULAR DISORDERS

Pulmonary Edema (Noncardiogenic)

Pulmonary edema is defined as abnormal accumulation of fluid in the lung tissue, the alveolar space, or both. It is a severe, life-threatening condition. Pulmonary edema can be classified as cardiogenic or noncardiogenic (see Chapter 25 for further discussion of cardiogenic pulmonary edema). Noncardiogenic pulmonary edema occurs due to damage of the pulmonary capillary lining. It may be due to direct injury to the lung (e.g., chest trauma, aspiration, and smoke inhalation), hematogenous injury to the lung (e.g., sepsis, pancreatitis, multiple transfusions, cardiopulmonary bypass), or injury plus elevated hydrostatic pressures. Management of noncardiogenic pulmonary edema mirrors that of cardiogenic pulmonary edema; however, hypoxemia may persist despite high concentrations of supplemental oxygen, due to the intrapulmonary shunting of blood.

Pulmonary Hypertension

Pulmonary hypertension (PH) is characterized by elevated pulmonary arterial pressure greater than 25 mm Hg at rest and greater than 30 mm Hg with exercise and secondary right heart ventricular failure (Rubin & Hopkins, 2019). It may be suspected in a patient with dyspnea with exertion without other clinical manifestations. Unlike systemic blood pressure, the pulmonary pressures cannot be measured indirectly. In the absence of these measurements, clinical recognition becomes the only indicator of PH. However, PH is a condition that is often not clinically evident until late in its progression. Patients are classified by the World Health Organization (WHO) into five groups based upon the mechanism of PH (Rubin & Hopkins, 2019) (see Chart 19-21).

Pathophysiology

Conditions such as collagen vascular disease, congenital heart disease, anorexigens (specific appetite depressants), chronic use of stimulants, portal hypertension, and HIV infection increase the risk of PH in susceptible patients. Vascular injury occurs with endothelial dysfunction and vascular smooth muscle dysfunction, which leads to disease progression (vascular smooth muscle hypertrophy, adventitial and intimal proliferation [thickening of the wall], and advanced vascular lesion formation). Normally, the pulmonary vascular bed can handle the blood volume delivered by the right ventricle. It has a low resistance to blood flow and compensates for increased blood volume by dilation of the vessels in the pulmonary circulation. However, if the pulmonary vascular bed is destroyed or obstructed, as in PH, the ability to handle whatever flow or volume of blood it receives is impaired, and the increased blood flow then increases the pulmonary artery pressure. As the pulmonary arterial pressure increases, the pulmonary vascular resistance also increases. Both pulmonary artery constriction (as in hypoxemia or hypercapnia) and a reduction of the pulmonary

vascular bed (which occurs with PE) result in increased pulmonary vascular resistance and pressure. This increased workload affects right ventricular function. The myocardium ultimately cannot meet the increasing demands imposed on it, leading to right ventricular hypertrophy (enlargement and dilation) and failure. Passive hepatic congestion may also develop.

Chart 19-21

Clinical Classification of Pulmonary Hypertension (PH)

Group 1: Pulmonary Arterial Hypertension (PAH)

- Sporadic idiopathic PAH
- Heritable idiopathic PAH
- Drug and toxin-induced PAH
- PAH due to diseases such as connective tissues disorders, HIV infection, portal hypertension, congenital heart disease

Group 2: PH due to left heart disease

- Systolic dysfunction
- Diastolic dysfunction
- Valvular heart disease

Group 3: PH due to chronic lung diseases and/or hypoxemia

- Chronic obstructive pulmonary disease
- Interstitial lung disease
- Mixed restrictive and obstructive lung disease
- Sleep disordered breathing

Group 4: Chronic thromboembolic pulmonary hypertension (CTEPH)

- Due to thromboembolic occlusion of the proximal or distal pulmonary vasculature

Group 5: PH with unclear multifactorial mechanisms

- Hematologic disorders
- Systemic disorders (e.g., sarcoidosis)
- Metabolic disorders

Adapted from Rubin, L., & Hopkins, W. (2019). Overview of pulmonary hypertension in adults. *UpToDate.* Retrieved on 8/22/2019 at: www.uptodate.com/contents/overview-of-pulmonary-hypertension-in-adults

Clinical Manifestations

Dyspnea, the main symptom of PH, occurs at first with exertion and eventually at rest. Substernal chest pain also is common. Other signs and symptoms include weakness, fatigue, syncope, occasional hemoptysis, and signs of right-sided heart failure (peripheral edema, ascites, distended neck veins, liver engorgement, crackles, heart murmur). Anorexia and abdominal pain in the right upper quadrant may also occur.

Assessment and Diagnostic Findings

Diagnostic testing is used to confirm that PH exists, determine its severity, and identify its causes. Initial diagnostic evaluation includes a history, physical examination, chest x-ray, pulmonary function studies, electrocardiogram (ECG), and echocardiogram. Echocardiography can be used to estimate the pulmonary artery systolic pressure and to assess right ventricular size, thickness, and function. It can also evaluate the right atrial size, left ventricular system, and diastolic function as well as valve function. Right heart catheterization is necessary to confirm the diagnosis of PH and to accurately assess the hemodynamic abnormalities. PH is confirmed with a mean pulmonary artery pressure greater than 25 mm Hg. If left heart disease is identified via echocardiography and correlates with the degree of estimated PH, then exercise testing and both a right and left heart catheterization may be done to determine the functional severity of the disease and the abnormalities in pressures (left heart filling, pulmonary vascular resistance, transpulmonary gradient) (Rubin & Hopkins, 2019).

Pulmonary function studies may be normal or show a slight decrease in vital capacity and lung compliance, with a mild decrease in the diffusing capacity. The PaO_2 also is decreased (hypoxemia). The ECG reveals right ventricular hypertrophy, right axis deviation, and tall peaked P waves in inferior leads; tall anterior R waves; and ST-segment depression, T-wave inversion, or both anteriorly. An echocardiogram can assess the progression of the disease and rule out other conditions with similar signs and symptoms. A V./Q. scan or pulmonary angiography detects defects in pulmonary vasculature, such as PE.

Medical Management

The primary goal of treatment is to manage the underlying condition related to PH if the cause is known. Recommendations regarding therapy are tailored to the patient's individual situation, functional New York Heart Association class, and specific needs (Rubin & Hopkins, 2019). All patients with PH should be considered for the following therapies: diuretics, oxygen, anticoagulation, digoxin, and exercise training. Diuretics and oxygen should be added as needed. Appropriate oxygen therapy reverses the vasoconstriction and reduces the PH in a relatively short time. Most patients with PH do not have hypoxemia at rest but require supplemental oxygen with exercise. Anticoagulation should be considered for patients at risk for intrapulmonary thrombosis. Digoxin may improve right ventricular ejection fraction in some patients and may help to control heart rate; however, patients must be monitored closely for potential complications (Rubin & Hopkins, 2019).

Pharmacologic Therapy

Recent advances in pharmacologic management and medication delivery options have offered more effective treatment regimens for patients affected with PH. Medications prescribed to treat PH include calcium channel blockers and specific pathogenetic therapies, including prostanoids, endothelin receptor antagonists, phosphodiesterase-5 inhibitors, and soluble guanylate cyclase stimulants. The choice of therapeutic agents is based on many facets, including the classification group status of the patient with PH (see Chart 19-21), as well as the cost and the patient's tolerance of the agents (Hopkins

& Rubin, 2019). In addition, a vasoreactivity test may be done to identify which medication is best suited for the patient with PH; this is done during cardiac catheterization using vasodilating medications such as inhaled nitric oxide, adenosine, or prostacyclin. A positive vasoreactivity test occurs when there is a decrease of at least 10 mm Hg in the pulmonary artery pressure with an overall pressure that is less than 40 mm Hg in the presence of both an increased or unchanged cardiac output and a minimally decreased or unchanged systemic blood pressure (Hopkins & Rubin, 2019).

Patients with a positive vasoreactivity test and who do not have right-sided heart failure may be prescribed calcium channel blockers. Calcium channel blockers have a significant advantage over some medications taken to treat PH in that they may be taken orally and are generally less costly; however, because calcium channel blockers are indicated in only a small percentage of patients, other treatment options, including prostanoids, are often necessary (Hopkins & Rubin, 2019).

Prostanoids mimic the effect of the prostaglandin prostacyclin. Prostacyclin relaxes vascular smooth muscle by stimulating the production of cyclic 3′,5′-adenosine monophosphate (AMP) and inhibits the growth of smooth muscle cells. Prostanoids used to treat PH include epoprostenol, iloprost, treprostinil, and selexipag. Limitations of the prostanoids include their short half-life and variable patient responses to therapy (Hopkins & Rubin, 2019). IV epoprostenol was the first FDA-approved prostanoid and is the most widely studied advanced therapy for PH. Epoprostenol has a half-life of less than 3 minutes and must be continuously delivered through a permanently implanted central venous catheter using a portable infusion pump in order to maintain therapeutic effectiveness. Although a useful therapy, it requires extensive patient education and caregiver support. An advantage to iloprostis over epoprostenol is that it is an inhaled preparation; however, it needs to be administered six to nine times daily. The first formulations of treprostinil could only be taken parenterally; however, it has recently been approved in an inhaled formulation, and an oral preparation is under development. Parenteral trepostinil can be administered IV or subcutaneously, although the subcutaneous method causes severe pain at the injection site (Hopkins & Rubin, 2019). Selexipag is the newest FDA-approved prostanoid. It is available in tablet form administered in twice-daily doses, a clear advantage over-the-other prostanoids. However, it is a costly medication and not all insurance plans cover all of its costs (Pulmonary Hypertension Association Scientific Leadership Council, 2016).

Endothelin receptor antagonists bind to vascular endothelin-1 receptors, effectively blocking constriction of the pulmonary arteries, resulting in vasodilation. Endothelin receptor antagonists used to treat PH include bosentan, ambrisentan, and macitentan. These medications are available as oral preparations. A disadvantage to them is that they are hepatotoxic. Liver function must be monitored in patients using these agents.

The oral medications sildenafil, tadalafil, and vardenafil are potent, specific phosphodiesterase-5 inhibitors that degrade cyclic 3′,5′-guanosine monophosphate (cGMP) and promotes pulmonary vasodilation. These drugs are also prescribed to treat erectile dysfunction (Hopkins & Rubin, 2019; Korokina, Zhernakova, Korokin, et al., 2018).

Soluble guanylate cyclase stimulants, which act on the nitrous oxide pathway, are currently undergoing clinical trials to target many cardiopulmonary diseases. Riociguat, a medication in this category, is newly FDA approved for use in PH. Riociguat, an oral preparation administered three times daily, is contraindicated in patients with liver or kidney disease (Tsai, Sung, & de Jesus Perez, 2016).

Surgical Management

Lung transplantation remains an option for a select group of patients with PH who are refractory to medical therapy. Bilateral lung or heart–lung transplantation is the procedure of choice. Atrial septostomy may be considered for select patients with severe disease (Hopkins & Rubin, 2019); this procedure results in shunting of blood from the right side of the heart to the left, decreasing the strain on the right side of the heart and maintaining left ventricular output.

Nursing Management

The major nursing goal is to identify patients at high risk for PH, such as those with COPD, PE, congenital heart disease, and mitral valve disease so that early treatment can commence. The nurse must be alert for signs and symptoms, administer oxygen therapy appropriately, and instruct the patient and family about the use of home oxygen therapy. In patients treated with some of the prostanoids, education about the need for central venous access (epoprostenol), subcutaneous infusion (treprostinil), proper administration and dosing of the medication, pain at the injection site, and potential severe side effects is extremely important. Emotional and psychosocial aspects of this disease must be addressed. It is important to provide contact details for support services for patients and families.

Pulmonary Heart Disease (Cor Pulmonale)

Cor pulmonale is a condition that results from PH, which causes the right side of the heart to enlarge because of the increased work required to pump blood against high resistance through the pulmonary vascular system. This causes right-sided heart failure (see Chapter 25 for further discussion of management of right-sided heart failure).

Pulmonary Embolism

PE refers to the obstruction of the pulmonary artery or one of its branches by a thrombus (or thrombi) that originates somewhere in the venous system or in the right side of the heart. Deep vein thrombosis (DVT), a related condition, refers to thrombus formation in the deep veins, usually in the calf or thigh, but sometimes in the arm, especially in patients with peripherally inserted central catheters. VTE is a term that includes both DVT and PE. (VTE and the medical and nursing management of patients with DVT and with PE are discussed in detail in Chapter 26.)

OCCUPATIONAL LUNG DISEASE: PNEUMOCONIOSES

Pneumoconiosis is a general term given to any lung disease caused by dusts that are breathed in and then deposited deep in the lungs causing damage. Pneumoconiosis is usually considered an occupational lung disease, and includes asbestosis, silicosis and coal workers' pneumoconiosis, also known as "Black Lung Disease" (American Lung Association [ALA], 2018a) (see Table 19-6). Pneumoconiosis refers to a non-

neoplastic alteration of the lung resulting from inhalation of mineral or inorganic dust (e.g., "dusty lung"). This alteration results in pulmonary fibrosis and parenchymal changes. Usually, extended exposure to irritating or toxic substances accounts for these changes, although severe single exposures may also lead to chronic lung disease. Occupational lung disease is the number one work-related illness in the United States based on its frequency, severity, and preventability (ALA, 2018a). Many people with early pneumoconiosis are asymptomatic, but advanced disease often is accompanied by disability and premature death.

TABLE 19-6 Occupational Lung Diseases: Pneumoconioses

Disease (Source)	Pathophysiology	Clinical Manifestations
Silicosis (glass manufacturing, foundry work, stone cutting)	Inhaled silica dust produces nodular lesions in the lungs. Nodules enlarge and coalesce. Dense masses form on upper portion of lungs, resulting in loss of pulmonary volume. Fibrotic destruction of pulmonary tissue can lead to restrictive lung disease, emphysema, pulmonary hypertension, and cor pulmonale	*Acute silicosis:* dyspnea, fever, cough, weight loss *Chronic silicosis:* progressive symptoms indicative of hypoxemia, severe airflow obstruction, and right-sided heart failure
Asbestosis (shipbuilding, building demolition)	Inhaled asbestos fibers enter alveoli and are surrounded by fibrous tissue. Fibrous changes can also affect the pleura, which thicken and develop plaque. These changes lead to restrictive lung disease, with a decrease in lung volume, diminished exchange of oxygen and carbon dioxide, hypoxemia, cor pulmonale, and respiratory failure. It also increases risk of lung cancer, mesothelioma, and pleural effusion	Progressive dyspnea; persistent, dry cough; mild-to-moderate chest pain; anorexia; weight loss; malaise; clubbing of the fingers
Coal worker's pneumoconiosis	Encompasses a variety of lung diseases; is also known as black lung disease. Inhaled dusts that are mixtures of coal, kaolin, mica, and silica are deposited in the alveoli and respiratory bronchioles. When macrophages that engulf the dust can no longer be cleared, they aggregate and fibroblasts appear. The bronchioles and alveoli become clogged with dust, dying macrophages, and fibroblasts, leading to formation of coal macules. Fibrotic lesions develop and subsequently localized emphysema develops, with cor pulmonale and respiratory failure	Chronic cough, dyspnea, and expectoration of black or gray sputum, especially in coal workers who smoke and who have cavitation in the lungs

Adapted from American Lung Association (ALA). (2018a). Lung health & diseases: Pneumoconiosis. Retrieved on 10/4/2019 at: www.lung.org/lung-health-and-diseases/lung-disease-lookup/pneumoconiosis

Diseases of the lungs occur in numerous occupations as a result of exposure to several different types of agents, such as mineral dusts, metal dusts, biologic dusts, and

toxic fumes. Smoking may compound the problem and may increase the risk of lung cancers in people exposed to the mineral asbestos and other potential carcinogens (ALA, 2018b). The effects of inhaling these materials depend on the composition of the substance, its concentration, its ability to initiate an immune response, its irritating properties, the duration of exposure, and the person's response or susceptibility to the irritant.

These diseases are not curable; however, they are preventable. Therefore, a major role for nurses, especially occupational health nurses, is that of advocate for employees. Nurses need to make every effort to promote measures to reduce the exposure of workers to industrial products. Strategies to control exposure should be identified and encouraged; these strategies include the use of protective devices (facemasks, hoods, industrial respirators) to minimize exposure and screening/monitoring of individuals at risk.

Key aspects of any assessment of patients with a potential occupational respiratory history include job and job activities, exposure levels, general hygiene, time frame of exposure, smoking history, effectiveness of respiratory protection used, and direct versus indirect exposures (Goldman, 2019). Specific information that should be obtained includes the following:

- Exposure to an agent known to cause an occupational disorder
- Length of time from exposure of agent to onset of symptoms
- Congruence of symptoms with those of known exposure-related disorder
- Lack of other more likely explanations of the signs and symptoms

More than one million workers are exposed to silica each year. Symptoms rarely develop in less than 5 years. Progression of the disease results in extreme shortness of breath, loss of appetite, chest pains, and potentially respiratory failure (ALA, 2018a). Asbestosis is progressive and causes severe scarring of the lung, which leads to fibrosis. The lungs become stiff, making it difficult to breathe or to oxygenate well. The disease may not evidence manifestations until 10 to 40 years after exposure (ALA, 2018a). Coal worker's pneumoconiosis is a collection of lung disease caused by exposure to inhaled dusts.

The nurse provides education about preventive measures to patients and their families, assesses patients for a history of exposure to environmental agents, and makes referrals so that pulmonary function can be evaluated and the patient can be treated early in the course of the disease. These diseases have no effective treatment because damage is irreversible. Supportive therapy is aimed at preventing infections and managing complications.

Veterans Considerations

Many American veterans who served in Iraq and Afghanistan are experiencing respiratory disorders as a result of exposure to pollutants in situations such as sand storms and car bombings. Their illnesses can range from a new onset of asthma to constrictive bronchiolitis (Harrington, Schmidt, Szema, et al., 2017). These veterans could also have been exposed to organic contamination within the sand that could further irritate airways. When providing care to a veteran, it is important to assess

exposure to airway irritants, particularly when the patient is complaining of chronic respiratory symptoms.

CHEST TUMORS

Tumors of the lung may be benign or malignant. A malignant chest tumor can be primary, arising within the lung, chest wall, or mediastinum or it can be a metastasis from a primary tumor site elsewhere in the body.

Lung Cancer (Bronchogenic Carcinoma)

Lung cancer is the leading cancer killer among men and women in the United States, with about 1 out of 4 cancer deaths from lung cancer; over 135,000 deaths were estimated in 2018 (Midthun, 2019). Each year, more people die of lung cancer than of colon, breast, and prostate cancers combined. Approximately 228,820 new cases of lung cancer are diagnosed annually; 13% of new cancers for men and women involve the lung or bronchus (American Cancer Society [ACS], 2019). In approximately 48.5% of patients with lung cancer, the disease has spread to regional lymphatics and other sites by the time of diagnosis. As a result, the long-term survival rate is low. Overall, the 5-year survival rate is 21.7% (ALA, 2020; Thomas & Gould, 2019).

Pathophysiology

The most common cause of lung cancer is inhaled carcinogens, most often cigarette smoke (>85%); other carcinogens include radon gas and occupational and environmental agents (ALA, 2020). Lung cancers arise from a single transformed epithelial cell in the tracheobronchial airways, in which the carcinogen binds to and damages the cell's DNA. This damage results in cellular changes, abnormal cell growth, and eventually a malignant cell. As the damaged DNA is passed on to daughter cells, the DNA undergoes further changes and becomes unstable. With the accumulation of genetic changes, the pulmonary epithelium undergoes malignant transformation from normal epithelium eventually to invasive carcinoma. Carcinoma tends to arise at sites of previous scarring in the lung (e.g., TB, fibrosis).

Classification and Staging

For purposes of staging and treatment, over 95% of lung cancers are classified into one of two major categories: small cell lung cancer (SCLC) and non-small cell lung cancer (NSCLC). SCLC represents approximately 13% of tumors, and includes small cell and combined small cell cancers. NSCLC represents approximately 84% of tumors, and these are further classified by cell type, including squamous cell (20%), large cell (5%), adenocarcinoma (41%), and others, some of which cannot be classified (18%) (ACS, 2019; Midthun, 2019).

TABLE 19-7 Five-Year Relative Survival Rates for Lung Cancer based on Surveillance, Epidemiology, End Results (SEER) Stage[a]

SEER Stage	5-Year Relative Survival Rate (%)
NSCLC	
Localized	60
Regional	33
Distant	6
All SEER stages combined	23
SCLC	
Localized	29
Regional	15
Distant	3
All SEER stages combined	6

[a]Data are for patients diagnosed between the years 2009 and 2015. The SEER database does not group patients by the TNM system; rather, SEER categorizes patients based upon whether or not cancer has spread to distant organs/tissues (*distant*), or to proximal tissues or lymph nodes (*regional)*, or has not spread outside the lung (*localized*).

NSCLC, non-small cell lung cancer; SCLC, small cell lung cancer; TNM system, a tumor staging system promulgated by the American Joint Committee on Cancer that stages cancer based upon evidence of the size of the tumor (*T*), extent of lymph node involvement (*N*), and whether or not metastasis has occurred (*M*).

Adapted from American Cancer Society (ACS). (2019). Lung cancer survival rates. Last updated 10/1/2019. Retrieved on 10/4/2019 at: www.cancer.org/cancer/lung-cancer/detection-diagnosis-staging/survival-rates.html

In terms of specific types of NSCLC, squamous cell cancer is usually more centrally located and arises more commonly in the segmental and subsegmental bronchi. Adenocarcinoma is the most prevalent carcinoma of the lung in both men and women; it occurs peripherally as peripheral masses or nodules and often metastasizes. Large cell carcinoma (also called *undifferentiated carcinoma*) is a fast-growing tumor that tends to arise peripherally. Bronchoalveolar cell cancer is found in the terminal bronchi and alveoli and is usually slower growing compared with other bronchogenic carcinomas.

In addition to classification according to cell type, lung cancers are staged using the TNM staging system. The stage of the tumor refers to the size of the tumor, its location, whether lymph nodes are involved, and whether the cancer has spread (ACS, 2019). NSCLC is staged as I to IV. Stage I is the earliest stage and has the highest cure rate, whereas stage IV designates metastatic spread. Survival rates for NSCLC are shown in Table 19-7. (Diagnostic tools and further information on staging are described in Chapter 12.)

Risk Factors

The National Comprehensive Cancer Network (NCCN; 2020) asserts that 85% to 90% of all lung cancer cases are caused by cigarette smoke, whether it is from voluntary or involuntary (secondhand) smoking. Other factors that have been associated with lung cancer include genetic predisposition, dietary deficits, and underlying respiratory

diseases, such as COPD and TB. Some familial predisposition to lung cancer exists. The incidence of lung cancer in close relatives of patients with lung cancer is two to three times higher than the general population, regardless of smoking status (ACS, 2019).

Tobacco Smoke

The risk of developing lung cancer is about 23 times higher in men who smoke and 13 times higher in women who smoke compared to individuals who have never smoked (ACS, 2019). Risk is determined by the pack-year history (number of packs of cigarettes used each day, multiplied by the number of years smoked), the age of initiation of smoking, the depth of inhalation, and the tar and nicotine levels in the cigarettes smoked. The younger a person is when they start smoking, the greater the risk of developing lung cancer. People who smoke and use smokeless products as a supplemental source of nicotine have an increased overall risk of lung cancer (ACS, 2019).

Almost all cases of SCLC are due to cigarette smoking. SCLC is rare in people who have never smoked. It is the most aggressive form of lung cancer, grows quickly, and usually starts in the airways in the center of the chest (ACS, 2019).

Electronic Nicotine Delivery Systems

Electronic nicotine delivery systems (ENDS) include e-cigarettes, e-pens, e-pipes, e-hookahs, and e-cigars. According to a 2018 survey of 44,000 high school adolescents, 37% of 12th graders self-reported use of e-cigarettes (NIH News in Health, 2019). The amounts of nicotine and other substances a person gets from each cartridge are also unclear and have been found to vary greatly even when comparing same brand cartridges from the same manufacturer. Since these ENDS products have only been available for about a decade, the link between their use and lung cancer is unclear at the present time (ACS, 2019).

Secondhand Smoke

Secondhand or involuntary smoking has been identified as a cause of lung cancer in people who do not smoke. People who are involuntarily exposed to tobacco smoke in a closed environment (house, automobile, building) have an increased risk of lung cancer when compared with unexposed individuals who do not smoke (CDC, 2018a; NCCN, 2020).

Environmental and Occupational Exposure

Various carcinogens have been identified in the atmosphere, including motor vehicle emissions and pollutants from refineries and manufacturing plants. Evidence suggests that the incidence of lung cancer is greater in urban areas as a result of the buildup of pollutants and motor vehicle emissions (ALA, 2018b).

Radon is a colorless, odorless gas found in soil and rocks. For many years, it has been associated with uranium mines, but it is now known to seep into homes through ground rock. High levels of radon have been associated with the development of lung cancer, especially when combined with cigarette smoking. Homeowners are advised to

have radon levels checked in their houses and to arrange for special venting if the levels are high.

Chronic exposure to industrial carcinogens, such as arsenic, asbestos, mustard gas, chromates, coke oven fumes, nickel, oil, and radiation, has been associated with the development of lung cancer. Laws have been passed to control exposure to these carcinogens in the workplace.

Genetic Mutations

Genetic mutations can cause certain changes in the DNA of lung cells. These changes can lead to abnormal cell growth and, sometimes, cancer. Acquired mutations in lung cells often result from exposure to factors in the environment, such as cancer-causing chemicals in tobacco smoke (ACS, 2019). The most common genetic mutations occur in *EGFR* (the gene that produces epidermal growth factor receptor) and the *K-RAS* or *ALK* oncogenes. *EGFR* is abnormal in about 50% of all patients with lung cancer. Abnormalities in *K-RAS* or *ALK* oncogenes are thought to be important in the development of NSCLC (ACS, 2019).

Clinical Manifestations

Often, lung cancer develops insidiously and is asymptomatic until late in its course. The signs and symptoms depend on the location and size of the tumor, the degree of obstruction, and the existence of metastases to regional or distant sites.

The most frequent symptom of lung cancer is cough or change in a chronic cough. People frequently ignore this symptom and attribute it to smoking or a respiratory infection. The cough may start as a dry, persistent cough, without sputum production. When obstruction of airways occurs, the cough may become productive due to infection.

Quality and Safety Nursing Alert

A cough that changes in character should arouse suspicion of lung cancer.

Dyspnea is prominent in patients early in their disease. Causes of dyspnea may include tumor occlusion of the airway or lung parenchyma, pleural effusion, pneumonia, or complications of treatment. Hemoptysis or blood-tinged sputum may be expectorated. Chest or shoulder pain may indicate chest wall or pleural involvement by a tumor. Pain also is a late manifestation and may be related to metastasis to the bone.

In some patients, a recurring fever is an early symptom in response to a persistent infection in an area of pneumonitis distal to the tumor. In fact, cancer of the lung should be suspected in people with repeated unresolved upper respiratory tract infections. If the tumor spreads to adjacent structures and regional lymph nodes, the patient may present with chest pain and tightness, hoarseness (involving the recurrent laryngeal nerve), dysphagia, head and neck edema, and symptoms of pleural or pericardial effusion. The most common sites of metastases are lymph nodes, bone, brain, contralateral lung, adrenal glands, and liver (see Fig. 19-10). Nonspecific

symptoms of weakness, anorexia, and weight loss also may be present (Eldridge, 2020).

Assessment and Diagnostic Findings

If pulmonary symptoms occur in individuals who currently smoke or who formerly smoked, or in people chronically exposed to secondhand smoke, cancer of the lung should be considered. A chest x-ray is performed to search for pulmonary density, a solitary pulmonary nodule (coin lesion), atelectasis, and infection. CT scans of the chest are used to identify small nodules not easily visualized on the chest x-ray and also to serially examine areas for lymphadenopathy. Additionally, the U.S. Preventive Services Task Force (USPSTF) recommends annual lung cancer screening using low dose CT (LDCT) for adults 55 to 80 years of age who have a 30 pack-year smoking history and either currently smoke or have quit smoking less than 15 years ago. Each pack-year is calculated based upon smoking one pack of cigarettes daily for 1 year; for instance, a 30 pack-year is defined as smoking one pack of cigarettes daily for 30 years, or 3 packs daily for 10 years (CDC, 2019e).

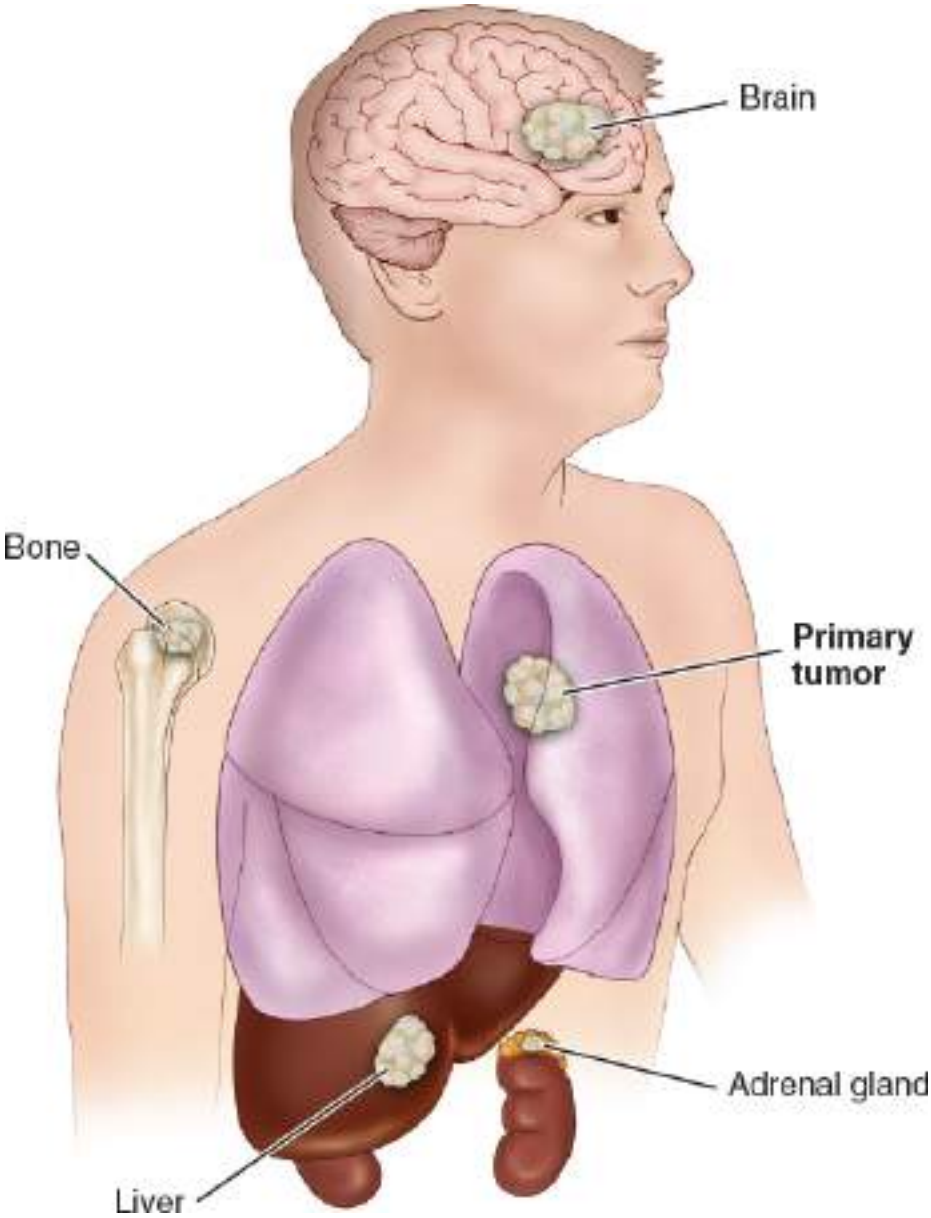

Figure 19-10 • Frequent sites of lung cancer metastasis.

Fiberoptic bronchoscopy is commonly used to diagnose lung cancer; it provides a detailed study of the tracheobronchial tree and allows for brushings, washings, and biopsies of suspicious areas. For peripheral lesions not amenable to bronchoscopic biopsy, a transthoracic fine-needle aspiration may be performed under CT guidance to aspirate cells from a suspicious area.

A variety of scans may be used to assess for metastasis of the cancer. These may include bone scans, abdominal scans, positron emission tomography (PET) scans, and liver ultrasound. CT scan of the brain, magnetic resonance imaging (MRI), and other neurologic diagnostic procedures are used to detect central nervous system metastases. Mediastinoscopy or mediastinotomy may be used to obtain biopsy samples from lymph nodes in the mediastinum. Endobronchial ultrasound biopsy of mediastinal nodes is also used. In some circumstances, an endoscopy with esophageal ultrasound may be used to obtain a transesophageal biopsy of enlarged subcarinal lymph nodes.

If surgery is a potential treatment, the patient is evaluated to determine whether the tumor is resectable and whether the patient can tolerate the physiologic impairment resulting from such surgery. Preoperative diagnostic studies provide a baseline for comparison during the postoperative period and detect additional abnormalities. Studies can be comprehensive and may include a bronchoscopic examination (a lighted scope is inserted into the airways to examine the bronchi), chest x-ray, MRI, ECG (for arteriosclerotic heart disease, conduction defects), nutritional assessment, determination of BUN and serum creatinine levels (to assess renal function), determination of glucose tolerance or blood glucose level (to check for diabetes), serum electrolytes and protein levels, blood volume determinations, complete blood cell count (CBC), pulmonary function tests, arterial blood gas analysis, V./Q. scans, and exercise testing.

Medical Management

The objective of management is to provide a cure, if possible. Treatment depends on the cell type, the stage of the disease, and the patient's physiologic status (particularly cardiac and pulmonary status). In general, treatment for patients with NSCLC may involve surgery, radiation therapy, chemotherapy, immunotherapy—or a combination of these. Immunotherapy specifically targets patients' immune cells so that they are primed to more effectively kill cancer cells. Gene therapy using agents that target specific genetic mutations including *EGFR* mutations and *ALK* and *ROS1* rearrangements have shown promising results (Eldridge, 2020).

Treatment for patients with SCLC may include surgery (but only if the cancer is in one lung and there is no metastasis), radiation therapy, laser therapy to open airways blocked by tumor growth, and endoscopic stent placement (to open an airway). Although the cancer cells are small, they grow very quickly and create large tumors. These tumors often metastasize (spread) rapidly to other parts of the body, including the brain, liver, and bone. Typically, by the time a patient is diagnosed with SCLC, it is late in the course of the disease and metastasis has occurred.

Surgical Management: Thoracotomy

A **thoracotomy** (creation of a surgical opening into the thoracic cavity) may be performed to treat lung cancer. As noted previously, surgery is primarily used for patients with NSCLC, because SCLC grows rapidly and metastasizes early and extensively. Surgical resection is the preferred method of treating patients with localized NSCLCs without evidence of metastatic spread, and with adequate cardiopulmonary function. However, coronary artery disease, pulmonary insufficiency, and other comorbidities may contraindicate surgical intervention. The cure rate of surgical resection depends on the type and stage of the cancer. Several different types of lung resection may be performed (see Chart 19-22). The most common surgical procedure for a small, apparently curable tumor of the lung is lobectomy (removal of a lobe of the lung). In some cases, pneumonectomy (removal of an entire lung) may be required.

Nursing Management of the Patient Having a Thoracotomy

Patients are typically admitted on the day of surgery. The nurse in the outpatient surgical clinic setting is responsible for performing the preoperative assessment and education and for alleviating the anxiety experienced by the patient and family members by providing them with anticipatory guidance. Postoperatively, the patient may be managed by the nurse in the ICU. Successfully managing transitions in care for the patient from the ICU to other inpatient acute care settings (e.g., medical-surgical unit, step-down unit) to the outpatient setting is a key nursing responsibility.

Educating the Patient Preoperatively

The nurse informs the patient about what to expect, from administration of anesthesia to thoracotomy, and the likely use of chest tubes and a drainage system in the postoperative period. The patient is also informed about the usual postoperative administration of oxygen to facilitate breathing and the possible use of a ventilator. It is essential to explain the importance of frequent turning to promote drainage of lung secretions. Instruction in the use of incentive spirometry begins before surgery to familiarize the patient with its correct use. The nurse educates the patient on the use of diaphragmatic and pursed-lip breathing, and the patient should begin practicing these techniques (see Chapter 20, Chart 20-5).

Because a coughing schedule is necessary in the postoperative period to promote the clearance or removal of secretions, the nurse instructs the patient in the technique of coughing and warns the patient that the coughing routine may be uncomfortable. The nurse educates the patient about how to splint the incision with the hands, a pillow, or a folded towel.

Encouraging the use of forced expiratory technique (FET) may be helpful for the patient with diminished expiratory flow rates or for the patient who refuses to cough because of severe pain. FET is the expulsion of air through an open glottis. This technique stimulates pulmonary expansion and assists in alveolar inflation (Kacmarek, Stoller, Heuer, et al., 2017). The nurse instructs the patient as follows:

- Take a deep diaphragmatic breath and exhale forcefully against the hand in a quick, distinct pant, or huff.
- Practice doing small huffs and progress to one strong huff during exhalation.

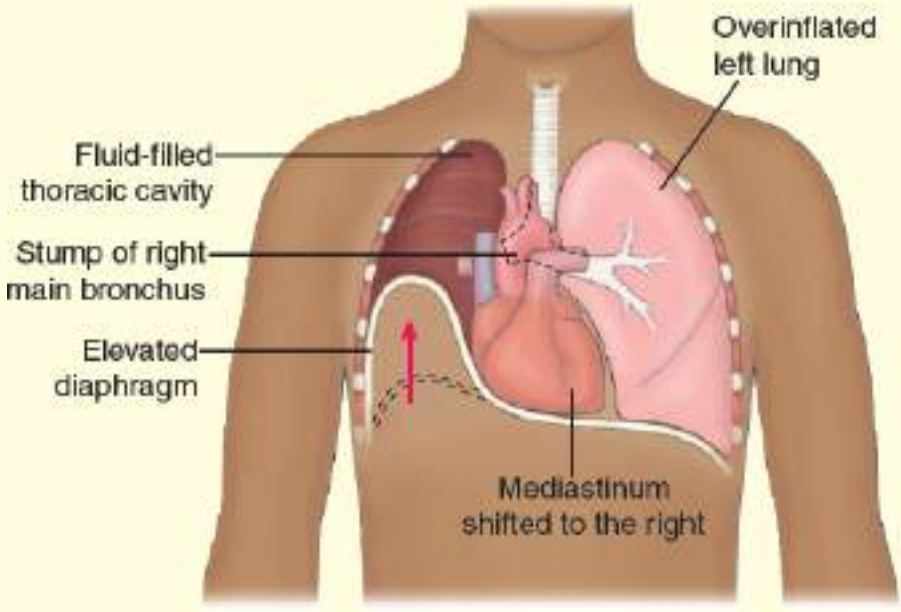
Patients should be informed preoperatively that blood and other fluids may be given, oxygen will be given, and vital signs will be checked often for several hours after surgery. If a chest tube is indicated (see later discussion on Chest Drainage Systems), the patient should be informed that it will drain the fluid and air that normally accumulate after chest surgery. The patient and family are informed that the patient may be admitted to the ICU for 1 to 2 days after surgery, that the patient may experience pain at the incision site, and that medication is available to relieve pain and discomfort.

Chart 19-22

Pneumonectomy

The removal of an entire lung, referred to as pneumonectomy, is performed chiefly for cancer when the lesion cannot be removed by a less extensive procedure. It also may be performed for lung abscesses, bronchiectasis, or extensive unilateral tuberculosis. The removal of the right lung is riskier than the removal of the left, because the right lung has a larger vascular bed and its removal imposes a greater physiologic burden.

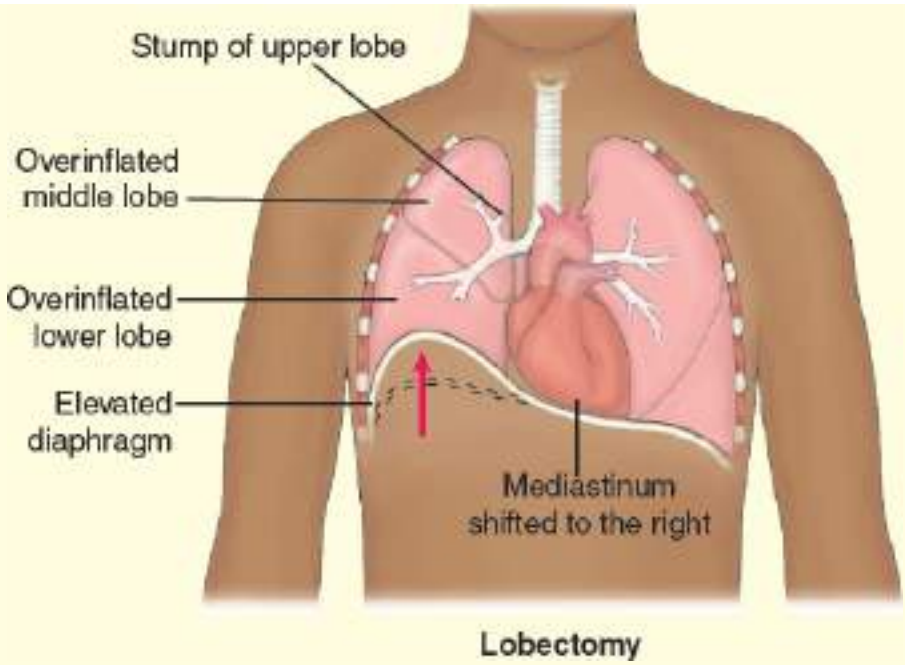
A posterolateral or anterolateral thoracotomy incision is made, sometimes with resection of a rib. The pulmonary artery and the pulmonary veins are ligated and severed. The main bronchus is divided and the lung removed. The bronchial stump is stapled, and usually no drains are used because the accumulation of fluid in the empty hemithorax prevents mediastinal shift.



Pneumonectomy

Lobectomy

When the pathology is limited to one area of a lung, a lobectomy (removal of a lobe of a lung) is performed. Lobectomy, which is more common than pneumonectomy, may be carried out for bronchogenic carcinoma, giant emphysematous blebs or bullae, benign tumors, metastatic malignant tumors, bronchiectasis, and fungal infections.



Lobectomy

The surgeon makes a thoracotomy incision. Its exact location depends on the lobe to be resected. When the pleural space is entered, the involved lung collapses and the lobar vessels and the bronchus are ligated and divided. After the lobe is removed, the remaining lobes of the lung are re-expanded. Usually, two chest catheters are inserted for drainage. The upper tube is for air removal; the lower one is for fluid drainage. Sometimes, only one catheter is needed. The chest tube is connected to a chest drainage apparatus for several days.

Segmentectomy (Segmental Resection)

Some lesions are located in only one segment of the lung. Bronchopulmonary segments are subdivisions of the lung that function as individual units. They are held together by delicate connective tissue. Disease processes may be limited to a single segment. Care is used to preserve as much healthy and functional lung tissue as possible, especially in patients who already have limited cardiopulmonary reserve. Single segments can be removed from any lobe; the right middle lobe, which has only two small segments, invariably is removed entirely. On the left side, corresponding to a middle lobe, is a “lingular” segment of the upper lobe. This can be removed as a single segment or by lingulectomy. This segment frequently is involved in bronchiectasis.

Wedge Resection

A wedge resection of a small, well-circumscribed lesion may be performed without regard to the location of the intersegmental planes. The pleural cavity usually is drained because of the possibility of an air or blood leak. This procedure is performed for diagnostic lung biopsy and for the excision of small peripheral nodules.

Bronchoplastic or Sleeve Resection

Bronchoplastic resection is a procedure in which only one lobar bronchus, together with a part of the right or left bronchus, is excised. The distal bronchus is reanastomosed to the proximal bronchus or trachea.

Lung Volume Reduction

Lung volume reduction is a surgical procedure involving the removal of 20% to 30% of a patient's lung through a midsternal incision or video thoracoscopy. The diseased lung tissue is identified on a lung perfusion scan. This surgery leads to significant improvements in dyspnea, exercise capacity, quality of life, and survival of a subgroup of people with end-stage emphysema.

Video Thoracoscopy

A video thoracoscopy is an endoscopic procedure that allows the surgeon to look into the thorax without making a large incision. The procedure is performed to obtain specimens of tissue for biopsy, to treat recurrent spontaneous pneumothorax, and to diagnose either pleural effusions or pleural masses. Thoracoscopy has also been found to be an effective diagnostic and therapeutic alternative for the treatment of mediastinal disorders. Some advantages of video thoracoscopy are rapid diagnosis and treatment of some conditions, a decrease in postoperative complications, and a shortened hospital stay.

Adapted from Urden, L. D., Stacy, K. M., & Lough, M. E. (2018). *Critical care nursing: Diagnosis and management* (8th ed.). St. Louis, MO: Elsevier Mosby.

The nurse listens to the patient and family to evaluate their feelings about the illness and proposed treatment. The nurse also determines the patient's motivation to return to normal or baseline function. The patient may reveal significant concerns: fear of hemorrhage because of bloody sputum, fear of discomfort from a chronic cough and chest pain, fear of ventilator dependence, or fear of death because of dyspnea and the underlying disease.

The nurse helps the patient to address fears and to cope with the stress of surgery by correcting any misconceptions, supporting the patient's decision to undergo surgery, and dealing honestly with questions about pain and discomfort and the patient's treatment. The management and control of pain begin before surgery, when the nurse informs the patient that many postoperative problems can be overcome by following certain routines related to deep breathing, coughing, turning, and moving. Nonopioid preemptive analgesic agents (e.g., acetaminophen and nonsteroidal anti-inflammatory drugs [NSAIDs]) may also be prescribed to help decrease the dose of postoperative opioid agents. This also helps to facilitate deep-breathing techniques and return to normal respiratory function. If patient-controlled analgesia (PCA) or patient-controlled epidural analgesia (PCEA) is to be used after surgery, the nurse instructs the patient in its use.

Postoperative Management

After surgery, the vital signs are checked frequently. Oxygen is given by a mechanical ventilator, nasal cannula, or mask for as long as necessary. A reduction in lung capacity requires a period of physiologic adjustment, and fluids may be given at a low hourly rate to prevent fluid overload and pulmonary edema. After the patient has recovered from anesthesia and the vital signs have stabilized, the head of the bed may be elevated 30 to 45 degrees. Careful positioning of the patient is important. After pneumonectomy, a patient is usually turned every hour from the back to the operative side and should not be completely turned to the unoperated side. This allows the fluid left in the space to consolidate and prevents the remaining lung and the heart from

shifting (mediastinal shift) toward the operative side. The patient with a lobectomy may be turned to either side, and a patient with a segmental resection usually is not turned onto the operative side unless the surgeon prescribes this position (see Chart 19-23: Plan of Nursing Care: Care of the Patient After Thoracotomy).

Complications after thoracic surgery are always possible and must be identified and managed early. The nurse monitors the patient at regular intervals for signs of respiratory distress or developing respiratory failure, arrhythmias, bronchopleural fistula, hemorrhage and shock, atelectasis, and incisional or pulmonary infection. Arrhythmias are often related to the effects of hypoxia or the surgical procedure. They are treated with antiarrhythmic medication and supportive therapy (see Chapter 22). Pulmonary infections or effusion, often preceded by atelectasis, may occur a few days into the postoperative course.

Pneumothorax may occur after thoracic surgery if there is an air leak from the surgical site to the pleural cavity or from the pleural cavity to the environment. Failure of the chest drainage system prevents return of negative pressure in the pleural cavity and results in pneumothorax. In the patient who is postoperative, pneumothorax is often accompanied by hemothorax. The nurse maintains the chest drainage system and monitors the patient for signs and symptoms of pneumothorax (see later discussions): increasing shortness of breath, tachycardia, increased respiratory rate, and increasing respiratory distress. Bronchopleural fistula is a serious but rare complication that prevents the return of negative intrathoracic pressure and lung re-expansion. Depending on its severity, it is treated with continued closed chest drainage and mechanical ventilation.

Hemorrhage and shock are managed by treating the underlying cause, whether by reoperation or by administration of blood products or fluids. Pulmonary edema from overinfusion of IV fluids is a significant danger. Early symptoms are dyspnea; crackles; tachycardia; and pink, frothy sputum. This constitutes an emergency and must be reported and treated immediately (see Chapter 25 for further discussion).

Medication for pain is needed for several days after surgery; it is usually a combination of epidural analgesia, PCA, and scheduled or as-needed oral analgesics. Because coughing can be painful, the patient should be encouraged to splint the chest as taught in the preoperative period. Exercises are resumed early in the postoperative period to facilitate lung ventilation. The nurse assesses for signs of complications, including cyanosis, dyspnea, and acute chest pain. These may indicate atelectasis and should be reported immediately. Increased temperature or white blood cell count may indicate an infection, and pallor and increased pulse may indicate internal hemorrhage. Dressings are assessed for fresh bleeding.

Promoting Home, Community-Based, and Transitional Care

The nurse educates the patient and family about postoperative care that will be continued in the community setting and at home.

Educating Patients About Self-Care

The nurse explains signs and symptoms that should be reported to the primary provider. These include the following:

- Change in respiratory status, such as increasing shortness of breath, fever, increased restlessness or other changes in mental or cognitive status, increased respiratory rate, change in respiratory pattern, change in amount or color of sputum
- Bleeding or other drainage from the surgical incision or chest tube exit sites
- Increased chest pain

In addition, respiratory care and other treatment modalities (oxygen; incentive spirometry; CPT; and oral, inhaled, or IV medications) may be continued at home. Therefore, the nurse needs to instruct the patient and family in their correct and safe use.

The nurse emphasizes the importance of progressively increased activity. The patient is instructed to ambulate within limits and informed that return of strength is likely to be very gradual. Another important aspect of patient education addresses shoulder exercises. The patient is instructed to do these exercises five times daily (see Chart 19-24). Additional patient education is described in Chart 19-25.

Chart 19-23 PLAN OF NURSING CARE

Care of the Patient After Thoracotomy

NURSING DIAGNOSIS: Impaired gas exchange associated with lung impairment and surgery
Goal: Improvement of gas exchange and breathing

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor pulmonary status as directed and as needed. a. Auscultate breath sounds. b. Check rate, depth, and pattern of respirations. c. Assess blood gases for signs of hypoxemia or CO_2 retention. d. Evaluate patient's color for cyanosis. 2. Monitor and record blood pressure, apical pulse, and temperature every 2 to 4 hours, and central venous pressure (if indicated) every 2 hours. 3. Monitor continuous electrocardiogram for pattern and arrhythmias. 4. Elevate head of bed 30° to 40° when patient is oriented and hemodynamic status is stable. 5. Encourage deep-breathing exercises and effective use of incentive spirometer. 6. Encourage and promote an effective cough routine to be performed every hour during first 24 hours. 7. Assess and monitor the chest drainage system.[a] a. Assess for leaks and patency as needed (see procedural guidelines for setting up and managing chest drainage systems at thepoint.lww.com/Brunner15e). b. Monitor amount and character of drainage and document every 2 hours. Notify primary provider if drainage is ≥150 mL/h.	1. Changes in pulmonary status indicate improvement or onset of complications. 2. Vital signs aid in evaluating effect of surgery on cardiac status. 3. Arrhythmias (especially atrial fibrillation and atrial flutter) are more frequently seen after thoracic surgery. A patient with total pneumonectomy is especially prone to cardiac irregularity. 4. Maximum lung excursion is achieved when patient is as close to upright as possible. 5. Helps to achieve maximal lung inflation and to open closed airways 6. Coughing is necessary to remove retained secretions. 7. System is used to eliminate any residual air or	• Lungs are clear on auscultation. • Respiratory rate is within acceptable range with no episodes of dyspnea. • Vital signs are stable. • Arrhythmias are not present or are treated effectively. • Demonstrates deep, controlled, effective breathing to allow maximal lung expansion. • Uses incentive spirometer every 2 hours while awake. • Demonstrates deep, effective coughing technique. • Lungs are expanded to capacity (evidenced by chest x-ray).

	fluid after thoracotomy.	

NURSING DIAGNOSIS: Impaired airway clearance associated with lung impairment, anesthesia, and pain
Goal: Improvement of airway clearance and achievement of a patent airway

Nursing Interventions	Rationale	Expected Outcomes
1. Maintain an open airway. 2. Perform endotracheal suctioning until patient can cough effectively. 3. Assess and medicate for pain. Encourage deep-breathing and coughing exercises. Help splint incision during coughing. 4. Monitor amount, viscosity, color, and odor of sputum. Notify primary provider if sputum is excessive or contains bright-red blood. 5. Administer humidification and small-volume nebulizer therapy as prescribed. 6. Perform postural drainage, percussion, and vibration as prescribed. Do not percuss or vibrate directly over operative site. 7. Auscultate both sides of chest to determine changes in breath sounds.	1. Provides for adequate ventilation and gas exchange. 2. Endotracheal secretions are present in excessive amounts in patients who are postthoracotomy due to trauma to the tracheobronchial tree during surgery, diminished lung ventilation, and cough reflex. 3. Helps to achieve maximal lung inflation and to open closed airways. Coughing is painful; incision needs to be supported. 4. Changes in sputum suggest presence of infection or change in pulmonary status. Colorless sputum is not unusual; opacification or coloring of sputum may indicate	• Airway is patent. • Coughs effectively. • Splints incision while coughing. • Sputum is clear or colorless. • Lungs are clear on auscultation.

	dehydration or infection. 5. Secretions must be moistened and thinned if they are to be raised from the chest with the least amount of effort. 6. Chest physiotherapy uses gravity to help remove secretions from the lung. 7. Indications for tracheal suctioning are determined by chest auscultation.	
NURSING DIAGNOSIS: Acute pain associated with incision, drainage tubes, and the surgical procedure **Goal:** Relief of pain and discomfort		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Evaluate location, character, quality, and severity of pain. Administer analgesic medication as prescribed and as needed. Observe for respiratory effect of opioid. Note if patient seems too somnolent to cough or if respirations are depressed. 2. Maintain care postoperatively in positioning the patient. a. Place patient in semi-Fowler position. b. Patients with limited respiratory reserve may not be able to turn on unoperated side. c. Assist or turn patient every 2 hours. 3. Assess incision area every 8 hours for redness, heat,	1. Pain limits chest excursions and thereby decreases ventilation. 2. The patient who is comfortable and free of pain will be less likely to splint the chest while breathing. A semi-Fowler position permits residual air in the pleural space to rise to upper portion of pleural space	• Asks for pain medication but verbalizes that they expect some discomfort while deep breathing and coughing. • Verbalizes that they are comfortable and not in acute distress. • No signs of incisional infection evident.

induration, swelling, separation, and drainage. 4. Request order for patient-controlled analgesia pump if appropriate for patient.	and be removed via the upper chest catheter. 3. These signs indicate possible infection. 4. Encouraging patient control over frequency and dose improves comfort and adherence with treatment regimen.	
NURSING DIAGNOSIS: Anxiety associated with outcomes of surgery, pain, technology **Goal:** Reduction of anxiety to a manageable level		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Explain all procedures in understandable language. 2. Assess for pain and medicate, especially before potentially painful procedures. 3. Silence all *unnecessary* alarms on technology (monitors, ventilators). 4. Encourage and support patient while increasing activity level. 5. Mobilize resources (family, clergy, social worker) to help patient cope with outcomes of surgery (diagnosis, change in functional abilities).	1. Explaining what can be expected in understandable terms decreases anxiety and increases cooperation. 2. Premedication before painful procedures or activities improves comfort and minimizes undue anxiety. 3. *Unnecessary* alarms increase the risk of sensory overload and may increase anxiety. *Essential* alarms must be turned on at all times.	• States that anxiety is at a manageable level. • Participates with health care team in treatment regimen. • Uses appropriate coping skills (verbalization; pain relief strategies; the use of support systems such as family, clergy). • Demonstrates basic understanding of technology used in care.

	4. Positive reinforcement improves patient motivation and independence. 5. A multidisciplinary approach promotes the patient's strengths and coping mechanisms.	
NURSING DIAGNOSIS: Impaired mobility of the upper extremities associated with thoracic surgery **Goal:** Increased mobility of the affected shoulder and arm		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Assist patient with normal range of motion and function of shoulder and trunk. a. Educate about use of breathing exercises to mobilize thorax. b. Encourage skeletal exercises to promote abduction and mobilization of shoulder (see Chart 19-23). c. Assist out of bed to chair as soon as pulmonary and circulatory systems are stable (usually by evening of surgery). 2. Encourage progressive activities according to level of fatigue.	1. Necessary to regain normal mobility of arm and shoulder and to speed recovery and minimize discomfort 2. Increases patient's use of affected shoulder and arm	• Demonstrates arm and shoulder exercises and verbalizes intent to perform them on discharge. • Regains previous range of motion in shoulder and arm.

NURSING DIAGNOSIS: Risk for hypovolaemia associated with the surgical procedure
Goal: Maintenance of adequate fluid volume

Nursing Interventions	Rationale	Expected Outcomes

1. Monitor and record hourly intake and output. Urine output should be at least 0.5 mL/kg/h over 6 hours and at least 400 mL in 24 hours after surgery.
2. Administer blood component therapy and parenteral fluids and diuretics as prescribed to restore and maintain fluid volume.
	1. Fluid management may be altered before, during, and after surgery, and patient's response to and need for fluid management must be assessed.
	2. Pulmonary edema due to transfusion or fluid overload is an ever-present threat; after pneumonectomy, the pulmonary vascular system has been greatly reduced.
		• Patient is adequately hydrated, as evidenced by:
		  • Urine output >0.5 mL/kg/h over 6 hours, and >400 mL in 24 hours
		  • Vital signs stable, heart rate, and central venous pressure approaching normal
		  • No excessive peripheral edema

NURSING DIAGNOSIS: Lack of knowledge of home care procedures
Goal: Increased ability to carry out care procedures at home

Nursing Interventions	Rationale	Expected Outcomes
1. Encourage patient to practice arm and shoulder exercises 5 times daily at home. 2. Instruct patient to practice assuming a functionally erect position	1. Exercise accelerates recovery of muscle function and reduces long-term pain and discomfort. 2. Practice will help restore normal posture. 3. Knowing what to expect facilitates recovery.	• Demonstrates arm and shoulder exercises. • Verbalizes need to try to assume an erect posture. • Verbalizes the importance of relieving discomfort, alternating walking and rest, performing breathing exercises, avoiding heavy lifting, avoiding undue fatigue, avoiding bronchial irritants, preventing colds or lung infections, getting influenza

	in front of a full-length mirror.	vaccine, keeping follow-up visits, and stopping smoking.
3.	Instruct patient about home care (see Chart 19-25).	

[a]A patient with a pneumonectomy usually does not have water-seal chest drainage because it is desirable that the pleural space fill with an effusion, which eventually obliterates this space. Some surgeons do use a modified water-seal system.

Continuing and Transitional Care

Depending on the patient's physical status and the availability of family assistance, a referral for home, community-based, or transitional care may be indicated. The home health nurse assesses the patient's recovery from surgery, with special attention to respiratory status, the surgical incision, chest drainage, pain control, ambulation, and nutritional status. The patient's use of respiratory modalities is assessed to ensure that they are being used correctly and safely. In addition, the nurse assesses the patient's adherence to the postoperative treatment plan and identifies acute or late postoperative complications.

The recovery process may take longer than the patient had expected, and providing support to the patient is an important task for the nurse. Because of shorter hospital stays, follow-up appointments with the primary provider are essential. The nurse educates the patient about the importance of keeping follow-up appointments and completing laboratory tests as prescribed to assist the primary provider in evaluating recovery. The nurse provides continuous encouragement and education to the patient and family during the process. As recovery progresses, the patient and family are reminded about the importance of participating in health promotion activities and recommended health screening.

Radiation Therapy

Radiation therapy may offer cure in a small percentage of patients with lung cancer. It is useful in controlling neoplasms that cannot be surgically resected but are responsive to radiation. Irradiation also may be used to reduce the size of a tumor, to make an inoperable tumor operable, or to relieve the pressure of the tumor on vital structures. It can reduce symptoms of spinal cord metastasis and superior vena caval compression. In addition, prophylactic brain irradiation is used in certain patients to treat microscopic metastases to the brain. Radiation therapy may help relieve cough, chest pain, dyspnea, hemoptysis, and bone and liver pain. Relief of symptoms may last from a few weeks to many months and is important in improving the quality of the remaining period of life. Stereotactic ablative radiotherapy (SABR) is a treatment option that delivers higher-than-typical doses of radiation directly to the tumor. This treatment is given over 1 to 5 days and is indicated for early stages of lung cancers in

patients who either elect to not have surgery or are considered ineligible for surgery (ACS, 2019).

Chart 19-24 PATIENT EDUCATION

Performing Arm and Shoulder Exercises

Arm and shoulder exercises are performed after thoracic surgery to restore movement, prevent painful stiffening of the shoulder, and improve muscle power. The nurse instructs the patient to perform these exercises as follows:

Hold hand of the affected side with the other hand, palms facing in. Raise the arms forward, upward, and then overhead, while taking a deep breath. Exhale while lowering the arms. Repeat five times.

Raise arm sideward, upward, and downward in a waving motion.

Place arm at side. Raise arm sideward, upward, and then overhead. Repeat five times. These exercises can also be performed while lying in bed.

Extend the arm up and back, out to the side and back, down at the side, and back.

Place hands in small of back. Push elbows as far back as possible.

Sit erect in an armchair; place the hands on arms of the chair. Press down on hands, consciously pulling the abdomen in and stretching up from the waist. Inhale while raising the body until elbows are extended completely. Hold this position a moment, and begin exhaling while lowering the body slowly to the original position.

Radiation therapy usually is toxic to normal tissue within the radiation field, and this may lead to complications such as esophagitis, pneumonitis, and radiation lung fibrosis, although the incidence of these complications has decreased over time with improvements in delivery of radiation therapy (ACS, 2019). These complications may impair ventilatory and diffusion capacity and significantly reduce pulmonary reserve. The patient's nutritional status, psychological outlook, fatigue level, and signs of

anemia and infection are monitored throughout the treatment (see Chapter 12 for management of the patient receiving radiation therapy).

Chart 19-25 HOME CARE CHECKLIST

The Patient with a Thoracotomy

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Identify interventions and strategies (e.g., durable medical equipment, oxygen, and adaptive equipment) used in adapting to any permanent changes in structure or function.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., walking and breathing exercises) and to limit or avoid (e.g., lifting weights, driving a car, and contact sports).
  - Alternate walking and other activities with frequent rest periods, expecting weakness and fatigue for the first 3 weeks.
  - Walk at a moderate pace, gradually and persistently extending walking time and distance.
  - Perform arm and shoulder exercises as prescribed.
  - Perform breathing exercises several times daily for the first few weeks at home.
  - Avoid lifting >20 lb until complete healing has taken place; the chest muscles and incision may be weaker than normal for 3 to 6 months after surgery.
  - Use local heat and oral analgesia to relieve intercostal pain.
  - Immediately stop any activity that causes undue fatigue, increased shortness of breath, or chest pain.
  - Avoid bronchial irritants (smoke, fumes, air pollution, aerosol sprays).
  - Avoid others with known colds or lung infections.
- Describe signs and symptoms of complications (e.g., increased shortness of breath, fever, restlessness, mental status changes, change in rate or pattern of respiration, increased pain, or bleeding from incision).
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up appointments.
- Obtain an annual influenza vaccine, and discuss vaccination against pneumonia with the primary provider.
- State understanding of community resources and referrals (if any).
- Identify the need for health promotion (e.g., weight reduction, smoking cessation, and stress management), disease prevention and screening activities

Resources

See Chapter 20, Chart 20-7 for additional information on oxygen therapy at home and Chart 19-23 for additional information on performing arm and shoulder exercises.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Chemotherapy

Chemotherapy is used to alter tumor growth patterns, to treat distant metastases or small cell cancer of the lung, and as an adjunct to surgery or radiation therapy. Chemotherapy may provide relief, especially of pain, but it does not usually cure the disease or prolong life to any great degree. Chemotherapy is also accompanied by side effects. It is valuable in reducing pressure symptoms of lung cancer and in treating brain, spinal cord, and pericardial metastasis (see Chapter 12 for a discussion of chemotherapy for the patient with cancer).

The choice of agent depends on the growth of the tumor cell and the specific phase of the cell cycle that the medication affects. In combination with surgery, chemotherapy may be given before surgery (neoadjuvant therapy) or after surgery (adjuvant therapy). Specific guidelines are available for the treatment of differing stages of NSCLC and SCLC through the NCCN (2020).

Immunotherapy

Advances in immunotherapy have provided additional options for the treatment of advanced NSCLC and SCLC. Immunotherapy drugs referred to as checkpoint inhibitors are indicated for the treatment of unresectable stage III tumors in addition to lung cancers that have metastasized. These agents target programmed cell death proteins such as PD-1 or PD-L1 on T cells that prevent T cells from attacking other cells in the body. By blocking these PD proteins, the T cells are able to mount a better immune response against the tumor cells, more quickly and effectively killing them. Four checkpoint inhibitors are FDA-approved for use with lung cancer. The first three, pembrolizumab, nivolumab, and atezolizumab, are approved for use in metastatic lung cancer (Hellman & West, 2020; Yang, Zhang, & Wang, 2019). In addition, penbrolizumab combined with chemotherapy may be used as a first-line treatment for metastatic NSCLC. Durvalumab is the only agent approved for nonoperable stage III NSCLC (Hellmann & West, 2020). Checkpoint inhibitors are delivered by IV infusion every 2, 3, or 4 weeks over several months or up to 1 year. They are generally well tolerated with few adverse effects, particularly as compared to chemotherapeutic agents. Side effects include fatigue, rashes, and diarrhea (ACS, 2019).

Palliative Care

Palliative care, concurrent with standard oncologic care for lung cancer, should be considered early in the course of illness for any patient with metastatic cancer or high symptom burden. In lung cancer, palliative therapy may include radiation therapy to shrink the tumor to provide pain relief, a variety of bronchoscopic interventions to open a narrowed bronchus or airway, and pain management and other comfort measures. Evaluation and referral for hospice care are important in planning for comfortable and dignified end-of-life care for the patient and family (see Chapter 13 for further discussion).

Complications

A variety of complications may occur as a result of treatment of lung cancer. Surgical resection may result in respiratory failure, particularly if the cardiopulmonary system is compromised before surgery. Surgical complications and prolonged mechanical

ventilation are potential outcomes. Despite advances in improved delivery of radiation therapy, complications may still ensue, including diminished cardiopulmonary function and other complications, such as pulmonary fibrosis, pericarditis, myelitis, and cor pulmonale (Benveniste, Gomez, Brett, et al., 2019). Chemotherapy, particularly in combination with radiation therapy, can cause pneumonitis. Pulmonary toxicity is a potential side effect of chemotherapy.

Nursing Management

Nursing care of patients with lung cancer is similar to that for other patients with cancer (see Chapter 12, Chart 12-6) and addresses the physiologic and psychological needs of the patient. The physiologic problems are primarily due to the respiratory manifestations of the disease. Nursing care includes strategies to ensure relief of pain and discomfort and to prevent complications.

Managing Symptoms

The nurse educates the patient and family about the potential side effects of the specific treatment and strategies to manage them. Strategies for managing such symptoms as dyspnea, fatigue, nausea and vomiting, and anorexia help the patient and family cope with therapeutic measures.

Relieving Breathing Problems

Airway clearance techniques are key to maintaining airway patency through the removal of excess secretions. This may be accomplished through deep-breathing exercises, chest physiotherapy, directed cough, suctioning, and in some instances bronchoscopy. Bronchodilator medications may be prescribed to promote bronchial dilation. As the tumor enlarges or spreads, it may compress a bronchus or involve a large area of lung tissue, resulting in an impaired breathing pattern and poor gas exchange. At some stage of the disease, supplemental oxygen will probably be necessary.

Nursing measures focus on decreasing dyspnea by encouraging the patient to assume positions that promote lung expansion and to perform breathing exercises for lung expansion and relaxation. Patient education about energy conservation and airway clearance techniques is also necessary. Many of the techniques used in pulmonary rehabilitation can be applied to patients with lung cancer. Depending on the severity of disease and the patient's wishes, a referral to a pulmonary rehabilitation program may be helpful in managing respiratory symptoms.

Reducing Fatigue

Fatigue is a devastating symptom that affects quality of life in patients with cancer. It is commonly experienced by patients with lung cancer and may be related to the disease itself, the cancer treatment and complications (e.g., anemia), sleep disturbances, pain and discomfort, hypoxemia, poor nutrition, or the psychological ramifications of the disease (e.g., anxiety and depression) (see Chapter 12 for nursing strategies to reduce fatigue).

Providing Psychological Support

Another important part of the nursing care of patients with lung cancer is provision of psychological support and identification of potential resources for the patient and family. Often, the nurse must help the patient and family deal with the following:

- The poor prognosis and relatively rapid progression of this disease
- Informed decision making regarding the possible treatment options
- Methods to maintain the patient's quality of life during the course of this disease
- End-of-life treatment options

Oncology nurses are employed as *nurse navigators* in oncology practice settings to help patients and their families manage and coordinate the many challenging aspects of cancer care. Jeyathevan, Lemonde, and Cooper Brathwaite (2017) studied the effectiveness of the oncology nurse navigator role in helping patients and families deal with the complexities of a diagnosis of lung cancer (see Nursing Research Profile in Chart 19-26).

Gerontologic Considerations

At the time of diagnosis of lung cancer, most patients are older than 65 years and have stage III or IV disease (Midthun, 2019). In older patients, the management of a cancer is complex and challenging. Although age is not a significant prognostic factor for overall survival and response to treatment of either NSCLC or SCLC, older patients have specific needs. The presence of comorbidities and the patient's cognitive, functional, nutritional, and social status are important issues to consider with the patient of advanced age. Depending on the comorbidities and functional status of older adult patients, chemotherapy agents, doses, and cycles may need to be adjusted to maintain quality of life.

Tumors of the Mediastinum

Tumors of the mediastinum include neurogenic tumors, tumors of the thymus, lymphomas, germ cell tumors, cysts, and mesenchymal tumors. These tumors may be malignant or benign. They are usually described in relation to location: anterior, middle, or posterior masses or tumors.

Clinical Manifestations

Nearly all symptoms of mediastinal tumors result from the pressure of the mass against important intrathoracic organs. Symptoms may include cough, wheezing, dyspnea, anterior chest or neck pain, bulging of the chest wall, heart palpitations, angina, other circulatory disturbances, central cyanosis, superior vena cava syndrome (i.e., swelling of the face, neck, and upper extremities), marked distention of the veins of the neck and the chest wall (evidence of the obstruction of large veins of the mediastinum by extravascular compression or intravascular invasion), and dysphagia and weight loss from pressure or invasion into the esophagus (Berry, 2019).

Assessment and Diagnostic Findings

Chest x-rays are the major method used initially to diagnose mediastinal tumors and cysts. A CT scan is the standard diagnostic test for the assessment of the mediastinum and surrounding structures. MRI, as well as PET, may be used in some circumstances (Berry, 2019).

Chart 19-26 **NURSING RESEARCH PROFILE**

The Role of the Oncology Nurse Navigator

Jeyathevan, G., Lemonde, M., & Cooper Brathwaite, A. (2017). The role of oncology nurse navigators in facilitating continuity of care within the diagnostic phase for adult patients with lung cancer. *Canadian Oncology Nursing Journal*, *27*(1), 74–87.

Purpose

An emerging trend in the effective management of cancer care and treatment is the use of nurse navigators. The purpose of this phenomenologic qualitative research study was to explore the effectiveness of the oncology nurse navigator (ONN) in facilitating the care of the patient with lung cancer during the diagnostic period. Through the lens of both the ONN and the patient, the researchers explored the organizational and clinical component of the role and the impact on continuity of care and patient empowerment. This published report focused on continuity of care through the dimensions of informational, management, and relational continuity.

Design

A Bi-Dimensional Framework examining the organization and clinical role of the ONN guided this study. Using a phenomenologic approach, the "lived experience" of the patient and the ONN were explored. Purposive sampling yielded eight participants, four patients, and four ONNs. Criteria for patient participation in the study included: adults 18 years of age and older, symptoms suspicious of lung cancer, English speaking, and at least two prior contacts with the ONN. Criteria for nurse navigator participation in the study included: certification in oncology nursing, completion of courses specific to lung disease, and employed in the lung cancer diagnostic department as a nurse navigator. Semi-structured individual interviews were conducted with each participant; in addition, the ONNs participated in a focus group.

Findings

Five major themes emerged through an iterative process of thematic analysis from the perspective of the patient with lung cancer and the ONN. Themes identified included: patient focused care, needs assessment, shared decision making, accessibility, and eliminating barriers. These themes correspond to the continuity of care related to informational, management, and relational continuity.

Nursing Implications

Little is known about the impact of nurse navigators on the patient experience during the diagnostic and cancer treatment periods. This research provides empirical evidence on the importance of this role throughout the diagnostic period of cancer as perceived by both patients and ONNs. Patient-focused care was enhanced through the provision of timely, personalized information which aided in the patients' understanding of diagnostic tests and subsequent follow-up. Telephone needs assessment proved to be vital as the ONN explored not only medical symptoms and social aspects, but also included an assessment of cultural concerns prior to the patients' first visit to the cancer center. These interactions supported the theme of shared decision making; the participants felt empowered, rather than powerless, as the ONN involved them in their care. Empathy and therapeutic communication were expressed through the theme of accessibility. Participants acknowledged the "professional-personal" connection with the ONN. Through the trusting relationship that was formed, barriers were eliminated, and all aspects of care could be addressed during this phase of care. This research supports best practice standards

for the role of the nurse navigator and provides a framework for continued study in other specialties of care.

Medical Management

If the tumor is malignant and has infiltrated the surrounding tissue and complete surgical removal is not feasible, radiation therapy, chemotherapy, or both are used.

Many mediastinal tumors are benign and operable. The location of the tumor (anterior, middle, or posterior compartment) in the mediastinum dictates the type of incision. The common incision used is a median sternotomy; however, a thoracotomy may be used, depending on the location of the tumor. Additional approaches include a bilateral anterior thoracotomy (clamshell incision) and video-assisted thoracoscopic surgery. The care is the same as for any patient undergoing thoracic surgery. Major complications include hemorrhage, injury to the phrenic or recurrent laryngeal nerve, and infection.

Chest Trauma

Thoracic injuries occurred in over 194,622 patients and accounted for 22.58% of the types of trauma recently recorded in a national trauma database (American College of Surgeons, 2016). Four of the top 10 complications in trauma patients were related to the respiratory system: pneumonia, DVT/PE, unplanned extubation, and acute lung injury/ARDS (American College of Surgeons, 2016). Major chest trauma may occur alone or in combination with multiple other injuries. Chest trauma is classified as either blunt or penetrating. Blunt chest trauma results from sudden compression or positive pressure inflicted to the chest wall. Penetrating trauma occurs when a foreign object penetrates the chest wall.

Blunt Trauma

Overall, blunt thoracic injuries are directly responsible for 20% to 25% of all trauma deaths (Mancini, 2018). Although blunt chest trauma is more common than penetrating trauma, it is often difficult to identify the extent of the damage because the symptoms may be generalized and vague. In addition, patients may not seek immediate medical attention, which may complicate the problem.

Pathophysiology

The most common causes of blunt chest trauma are motor vehicle crashes (trauma from steering wheel, seat belt), falls, and bicycle crashes (trauma from handlebars). Types of blunt chest trauma include chest wall fractures, dislocations, and barotraumas (including diaphragmatic injuries); injuries of the pleura, lungs, and aerodigestive tracts; and blunt injuries of the heart, great arteries, veins, and lymphatics (Mancini,

2018). Injuries to the chest are often life-threatening and result in one or more of the following pathologic states:

- Hypoxemia from disruption of the airway; injury to the lung parenchyma, rib cage, and respiratory musculature; massive hemorrhage; collapsed lung; and pneumothorax
- Hypovolemia from massive fluid loss from the great vessels, cardiac rupture, or hemothorax
- Cardiac failure from cardiac tamponade, cardiac contusion, or increased intrathoracic pressure

These pathologic states frequently result in impaired V./Q. leading to acute kidney injury, hypovolemic shock, and death.

Assessment and Diagnostic Findings

Because time is critical in treating chest trauma, the patient must be assessed immediately to determine the following: time elapsed since injury occurred, mechanism of injury, level of responsiveness, specific injuries, estimated blood loss, recent drug or alcohol use, and prehospital treatment. Initial assessment of thoracic injuries includes assessment of airway obstruction, tension pneumothorax, open pneumothorax, massive hemothorax, flail chest, and cardiac tamponade. These injuries are life-threatening and require immediate treatment. Secondary assessment includes assessment of simple pneumothorax, hemothorax, pulmonary contusion, traumatic aortic rupture, tracheobronchial disruption, esophageal perforation, traumatic diaphragmatic injury, and penetrating wounds to the mediastinum. Although listed as secondary, these injuries may be life-threatening as well.

The physical examination includes inspection of the airway, thorax, neck veins, and breathing difficulty. Specifics include assessing the rate and depth of breathing for abnormalities such as stridor, cyanosis, nasal flaring, the use of accessory muscles, drooling, and overt trauma to the face, mouth, or neck. The chest is assessed for symmetric movement, symmetry of breath sounds, open chest wounds, entrance or exit wounds, impaled objects, tracheal shift, distended neck veins, subcutaneous emphysema, and paradoxical chest wall motion. In addition, the chest wall is assessed for bruising, petechiae, lacerations, and burns. The vital signs and skin color are assessed for signs of shock. The thorax is palpated for tenderness and crepitus, and the position of the trachea is also assessed.

The initial diagnostic workup includes a chest x-ray, CT scan, complete blood count, clotting studies, type and cross-match, electrolytes, oxygen saturation, arterial blood gas analysis, and ECG. The patient is completely undressed to avoid missing additional injuries that may complicate care. Many patients with injuries involving the chest have associated head and abdominal injuries that require attention. Ongoing assessment is essential to monitor the patient's response to treatment and to detect early signs of clinical deterioration.

Medical Management

The goals of treatment are to evaluate the patient's condition and to initiate aggressive resuscitation. An airway is immediately established with oxygen support and, in some

cases, ET intubation and ventilatory support. Reestablishing fluid volume and negative intrapleural pressure and draining intrapleural fluid and blood are essential.

The potential for massive blood loss and exsanguination with blunt or penetrating chest injuries is high because of injury to the great blood vessels. Many patients die at the scene of the injury or are in shock by the time help arrives. Agitation and irrational and combative behavior are signs of decreased oxygen delivery to the cerebral cortex. Strategies to restore and maintain cardiopulmonary function include ensuring an adequate airway and ventilation; stabilizing and reestablishing chest wall integrity; occluding any opening into the chest (open pneumothorax); and draining or removing any air or fluid from the thorax to relieve pneumothorax, hemothorax, or cardiac tamponade. Hypovolemia and low cardiac output must be corrected. Many of these treatment efforts, along with the control of hemorrhage, are carried out simultaneously at the scene of the injury or in the emergency department. Depending on the success of efforts to control the hemorrhage in the emergency department, the patient may be taken immediately to the operating room. Principles of management are essentially those pertaining to care of the postoperative thoracic patient (Urden et al., 2018).

Sternal and Rib Fractures

Sternal fractures are most common in motor vehicle crashes with a direct blow to the sternum via the steering wheel. Rib fractures are the most common type of chest trauma with blunt chest injury (Mancini, 2018). Most rib fractures are benign and are treated conservatively; ribs 4 through 10 are most frequently involved. Fractures of the first three ribs are rare but can result in a high mortality rate because they are associated with laceration of the subclavian artery or vein. Fractures of the lower ribs are associated with injury to the spleen and liver, which may be lacerated by fragmented sections of the rib. Older adult patients with three or more rib fractures have been shown to have a fivefold increased mortality rate and a fourfold increased incidence of pneumonia (Mancini, 2018).

Clinical Manifestations

Patients with sternal fractures have anterior chest pain, overlying tenderness, ecchymosis, crepitus, swelling, and possible chest wall deformity. For patients with rib fractures, clinical manifestations are similar: severe pain, point tenderness, and muscle spasm over the area of the fracture that are aggravated by coughing, deep breathing, and movement. The area around the fracture may be bruised. To reduce the pain, the patient splints the chest by breathing in a shallow manner and avoids sighs, deep breaths, coughing, and movement. This reluctance to move or breathe deeply results in diminished ventilation, atelectasis (collapse of unaerated alveoli), pneumonitis, and hypoxemia. Respiratory insufficiency and failure can be the outcomes of such a cycle.

Assessment and Diagnostic Findings

The patient must be closely evaluated for underlying cardiac injuries. A crackling, grating sound in the thorax (subcutaneous crepitus) may be detected with auscultation. The diagnostic workup may include a chest x-ray, rib films of a specific area, ECG, continuous pulse oximetry, and arterial blood gas analysis.

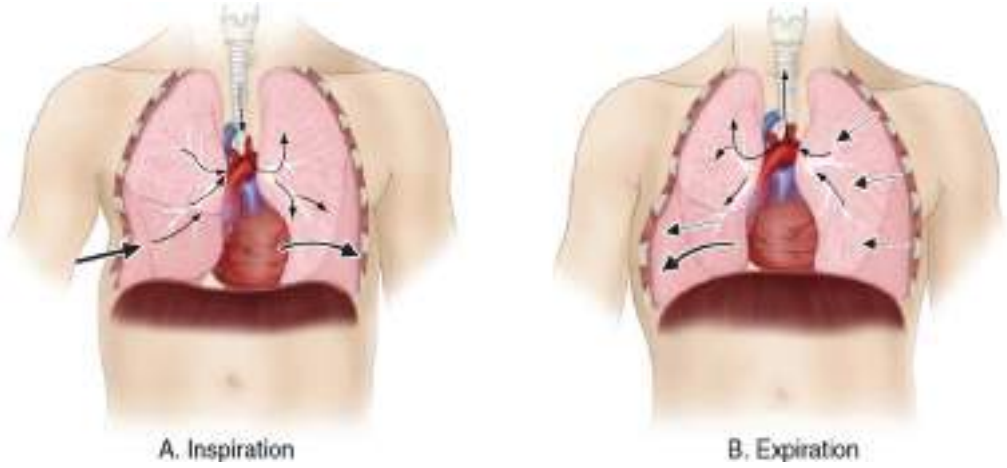


Figure 19-11 • Flail chest is caused by a free-floating segment of rib cage resulting from multiple rib fractures. **A.** Paradoxical movement on inspiration occurs when the flail rib segment is sucked inward and the mediastinal structures shift to the unaffected side. The amount of air drawn into the affected lung is reduced. **B.** On expiration, the flail segment bulges outward and the mediastinal structures shift back to the affected side.

Medical Management

Medical management is directed toward relieving pain, avoiding excessive activity, and treating any associated injuries. Surgical fixation is rarely necessary unless fragments are grossly displaced and pose a potential for further injury.

The goals of treatment of rib fractures are to control pain and to detect and treat the injury. Sedation is used to relieve pain and to allow deep breathing and coughing. Care must be taken to avoid oversedation and suppression of respiratory drive. Alternative strategies to relieve pain include an intercostal nerve block and ice over the fracture site. A chest binder may be used as supportive treatment to provide stability to the chest wall and may decrease pain. The patient is instructed to apply the binder snugly enough to provide support, but not to impair respiratory excursion. Usually, the pain abates in 5 to 7 days, and discomfort can be relieved with epidural analgesia, PCA, or nonopioid analgesia. Most rib fractures heal in 3 to 6 weeks. The patient is monitored closely for signs and symptoms of associated injuries.

Flail Chest

Flail chest is frequently a complication of blunt chest trauma, which may occur from a steering wheel injury, motor vehicle crash involving a pedestrian or cyclist, a significant fall onto the chest, or an assault with a blunt weapon. The incidence of flail chest among patients with chest wall injury is 5% to 13% (Sarani, 2019). It occurs when three or more adjacent ribs (multiple contiguous ribs) are fractured at two or more sites, resulting in free-floating rib segments. It may also result as a combination fracture of ribs and costal cartilages or sternum. As a result, the chest wall loses stability, causing respiratory impairment and usually severe respiratory distress.

Pathophysiology

During inspiration, as the chest expands, the detached part of the rib segment (flail segment) moves in a paradoxical manner (pendelluft movement) in that it is pulled inward during inspiration, reducing the amount of air that can be drawn into the lungs. On expiration, because the intrathoracic pressure exceeds atmospheric pressure, the flail segment bulges outward, impairing the patient's ability to exhale. The mediastinum then shifts back to the affected side (see Fig. 19-11). This paradoxical action results in increased dead space, a reduction in alveolar ventilation, and decreased compliance. Retained airway secretions and atelectasis frequently accompany flail chest. The patient has hypoxemia, and if gas exchange is greatly compromised, respiratory acidosis develops as a result of carbon dioxide retention. Hypotension, inadequate tissue perfusion, and metabolic acidosis often follow as the paradoxical motion of the mediastinum decreases cardiac output.

Medical Management

As with rib fracture, treatment of flail chest is usually supportive. Management includes providing ventilatory support, clearing secretions from the lungs, and controlling pain. Specific management depends on the degree of respiratory dysfunction. If only a small segment of the chest is involved, the objectives are to clear the airway through positioning, coughing, deep breathing, and suctioning to aid in the expansion of the lung, and to relieve pain by intercostal nerve blocks, high thoracic epidural blocks, or cautious use of IV opioids.

For mild-to-moderate flail chest injuries, the underlying pulmonary contusion is treated by monitoring fluid intake and appropriate fluid replacement while relieving chest pain. Pulmonary physiotherapy focusing on lung volume expansion and secretion management techniques is performed. The patient is closely monitored for further respiratory compromise.

For severe flail chest injuries, ET intubation and mechanical ventilation are required to provide internal pneumatic stabilization of the flail chest and to correct abnormalities in gas exchange. This helps to treat the underlying pulmonary contusion, serves to stabilize the thoracic cage to allow the fractures to heal, and improves alveolar ventilation and intrathoracic volume by decreasing the work of breathing. This treatment modality requires ET intubation and mechanical ventilator support. Differing modes of ventilation are used depending on the patient's underlying disease and specific needs.

Rib-specific plating systems may be used for three or more rib fractures or flail chest in order to achieve chest wall stabilization (CWS). These systems are inserted internally in the operating room, preferably within the first 72 hours of injury (see Fig. 19-12). The benefits of their use include decreased bleeding, less inflammation, and reduced chest wall deformities. Contraindications for CWS include traumatic brain injury and unstable spine fracture. With coexisting pulmonary contusion the overall efficacy of CWS remains controversial (Milanez de Campos & White, 2018).

Figure 19-12 • Chest wall stabilization (CWS) plating system provides chest wall stability for multiple fractures or a flail chest. Reproduced from Moya, M., Nirula, R., & Biffl, W. (2017). Rib fixation: Who, What, When? *Trauma Surgery & Acute Care Open*, *2*(1):e000059. Copyright © The American Association for the Surgery of Trauma with permission from BMJ Publishing Group Ltd. doi:10.1136/tsaco-2016-000059.

Regardless of the type of treatment, the patient is carefully monitored by serial chest x-rays, arterial blood gas analysis, pulse oximetry, and bedside pulmonary function monitoring. Pain management is key to successful treatment. PCA, intercostal nerve blocks, epidural analgesia, and intrapleural administration of opioids may be used to relieve or manage thoracic pain.

Pulmonary Contusion

Pulmonary contusion is a common thoracic injury and is frequently associated with flail chest. It is defined as damage to the lung tissues resulting in hemorrhage and localized edema. It is associated with chest trauma when there is rapid compression and decompression to the chest wall (i.e., blunt trauma). Pulmonary contusion represents a spectrum of lung injury characterized by the development of infiltrates and various degrees of respiratory dysfunction and sometimes respiratory failure. It is often cited as the most common potentially life-threatening chest injury; however, mortality is often attributed to other associated injuries. Pulmonary contusion may not be evident initially on examination but develops in the posttraumatic period; it may involve a small portion of one lung, a massive section of a lung, one entire lung, or both lungs. Depending on the extent of injury, this type of trauma may be associated with a mortality rate greater than 50% (Mancini, 2018).

Pathophysiology

The primary pathologic defect is an abnormal accumulation of fluid in the interstitial and intra-alveolar spaces. It is thought that injury to the lung parenchyma and its capillary network results in a leakage of serum protein and plasma. The leaking serum protein exerts an osmotic pressure that enhances loss of fluid from the capillaries. Blood, edema, and cellular debris (from cellular response to injury) enter the lung and accumulate in the bronchioles and alveoli, where they interfere with gas exchange. An increase in pulmonary vascular resistance and pulmonary artery pressure occurs. The patient has hypoxemia and carbon dioxide retention.

Clinical Manifestations

Pulmonary contusion may be mild, moderate, or severe. The clinical manifestations vary from decreased breath sounds, tachypnea, tachycardia, chest pain, hypoxemia, and blood-tinged secretions to more severe tachypnea, tachycardia, crackles, frank bleeding, severe hypoxemia (cyanosis), and respiratory acidosis. Changes in sensorium, including increased agitation or combative irrational behavior, may be signs of hypoxemia.

In addition, patients with moderate pulmonary contusion have a large amount of mucus, serum, and frank blood in the tracheobronchial tree; patients often have a constant cough but cannot clear the secretions. Patients with severe pulmonary contusion have signs and symptoms that mirror ARDS, which may include central cyanosis; agitation; combativeness; and productive cough with frothy, bloody secretions.

Assessment and Diagnostic Findings

The efficiency of gas exchange is determined by pulse oximetry and arterial blood gas measurements. Pulse oximetry is also used to measure oxygen saturation continuously. The initial chest x-ray may show no changes; changes may not appear for 1 or 2 days after the injury and appear as pulmonary infiltrates on chest x-ray.

Medical Management

Treatment priorities include maintaining the airway, providing adequate oxygenation, and controlling pain. In mild pulmonary contusion, adequate hydration via IV fluids and oral intake is important to mobilize secretions. However, fluid intake must be closely monitored to avoid hypervolemia. Volume expansion techniques, postural drainage, physiotherapy including coughing, and ET suctioning are used to remove the secretions. Pain is managed by intercostal nerve blocks or by opioids via PCA or other methods. Usually, antimicrobial therapy is given because the damaged lung is susceptible to infection. Supplemental oxygen is usually given by mask or cannula for 24 to 36 hours.

In patients with moderate pulmonary contusion, bronchoscopy may be required to remove secretions. Intubation and mechanical ventilation with PEEP may also be necessary to maintain the pressure and keep the lungs inflated. A nasogastric tube is inserted to relieve gastrointestinal distention.

In patients with severe contusion, who may develop respiratory failure, aggressive treatment with ET intubation and ventilatory support, diuretics, and fluid restriction

may be necessary. Antimicrobial medications may be prescribed for the treatment of pulmonary infection. This is a common complication of pulmonary contusion (especially pneumonia in the contused segment) because the fluid and blood that extravasate into the alveolar and interstitial spaces serve as an excellent culture medium.

Penetrating Trauma

Any organ or structure within the chest is potentially susceptible to traumatic penetration. These organs include the chest wall, lung and pleura, tracheobronchial system, esophagus, diaphragm, and major thoracic blood vessels, as well as heart and other mediastinal structures. The clinical consequence of penetrating trauma to the chest depends on the mechanism of injury, location, associated injuries, and underlying illnesses (Shahani, 2017). Common injuries include pneumothorax and cardiac tamponade.

Medical Management

The objective of immediate management is to restore and maintain cardiopulmonary function. After an adequate airway is ensured and ventilation is established, examination for shock and intrathoracic and intra-abdominal injuries is necessary. The patient is undressed completely so that additional injuries are not missed (see Chapter 67 for discussion of primary and secondary survey). There is a high risk of associated intra-abdominal injuries with stab wounds below the level of the fifth anterior intercostal space. Death can result from exsanguinating hemorrhage or intra-abdominal sepsis.

The diagnostic workup includes a chest x-ray, chemistry profile, arterial blood gas analysis, pulse oximetry, and ECG. The patient's blood is typed and cross-matched in case blood transfusion is required. After the status of the peripheral pulses is assessed, a large-bore IV line is inserted. An indwelling catheter is inserted to monitor urinary output. A nasogastric tube is inserted and connected to low suction to prevent aspiration, minimize leakage of abdominal contents, and decompress the gastrointestinal tract.

Hemorrhagic shock is treated simultaneously with colloid solutions, crystalloids, or blood, as indicated by the patient's condition. Diagnostic procedures are carried out as dictated by the needs of the patient (e.g., CT scans of chest or abdomen, flat plate x-ray of the abdomen) (see Chapter 11).

A chest tube is inserted into the pleural space in most patients with penetrating wounds of the chest to achieve rapid and continuing re-expansion of the lungs. The insertion of the chest tube frequently results in a complete evacuation of the blood and air. The chest tube also allows early recognition of continuing intrathoracic bleeding, which would make surgical exploration necessary. If the patient has a penetrating wound of the heart or great vessels, the esophagus, or the tracheobronchial tree, surgical intervention is required.

Pneumothorax

Pneumothorax occurs when the parietal or visceral pleura is breached and the pleural space is exposed to positive atmospheric pressure. Normally, the pressure in the pleural space is negative or subatmospheric; this negative pressure is required to maintain lung inflation. When either pleura is breached, air enters the pleural space, and the lung or a portion of it collapses.

Types of Pneumothorax

Types of pneumothorax include simple, traumatic, and tension pneumothorax.

Simple Pneumothorax

A simple, or spontaneous, pneumothorax occurs when air enters the pleural space through a breach of either the parietal or visceral pleura. Most commonly, this occurs as air enters the pleural space through the rupture of a bleb or a bronchopleural fistula. A spontaneous pneumothorax may occur in an apparently healthy person in the absence of trauma due to rupture of an air-filled bleb, or blister, on the surface of the lung, allowing air from the airways to enter the pleural cavity. It may be associated with diffuse interstitial lung disease and severe emphysema.

Traumatic Pneumothorax

A traumatic pneumothorax occurs when air escapes from a laceration in the lung itself and enters the pleural space or from a wound in the chest wall. It may result from blunt trauma (e.g., rib fractures), penetrating chest or abdominal trauma (e.g., stab wounds or gunshot wounds), or diaphragmatic tears. Traumatic pneumothorax may occur during invasive thoracic procedures (i.e., thoracentesis, transbronchial lung biopsy, and insertion of a subclavian line) in which the pleura is inadvertently punctured, or with barotrauma from mechanical ventilation.

A traumatic pneumothorax resulting from major injury to the chest is often accompanied by hemothorax (collection of blood in the pleural space resulting from torn intercostal vessels, lacerations of the great vessels, or lacerations of the lungs). Hemopneumothorax (both blood and air in the chest cavity) is also common after major trauma. Chest surgery can be classified as a traumatic pneumothorax as a result of the entry into the pleural space and the accumulation of air and fluid in the pleural space.

Open pneumothorax is one form of traumatic pneumothorax. It occurs when a wound in the chest wall is large enough to allow air to pass freely in and out of the thoracic cavity with each attempted respiration. Because the rush of air through the wound in the chest wall produces a sucking sound, such injuries are termed *sucking chest wounds.* In such patients, not only does the lung collapse, but the structures of the mediastinum (heart and great vessels) also shift toward the uninjured side with each inspiration and in the opposite direction with expiration. This is termed *mediastinal flutter* or *swing,* and it produces serious circulatory problems.

Quality and Safety Nursing Alert

Traumatic open pneumothorax calls for emergency interventions. Stopping the flow of air through the opening in the chest wall is a lifesaving measure.

Tension Pneumothorax

A **tension pneumothorax** occurs when air is drawn into the pleural space from a lacerated lung or through a small opening or wound in the chest wall. It may be a complication of other types of pneumothorax. In contrast to open pneumothorax, the air that enters the chest cavity with each inspiration is trapped; it cannot be expelled during expiration through the air passages or the opening in the chest wall. In effect, a one-way valve or ball valve mechanism occurs where air enters the pleural space but cannot escape. With each breath, tension (positive pressure) is increased within the affected pleural space. This causes the lung to collapse and the heart, the great vessels, and the trachea to shift toward the unaffected side of the chest (mediastinal shift). Both respiration and circulatory function are compromised because of the increased intrathoracic pressure, which decreases venous return to the heart, causing decreased cardiac output and impairment of peripheral circulation. In extreme cases, the pulse may be undetectable—this is known as pulseless electrical activity.

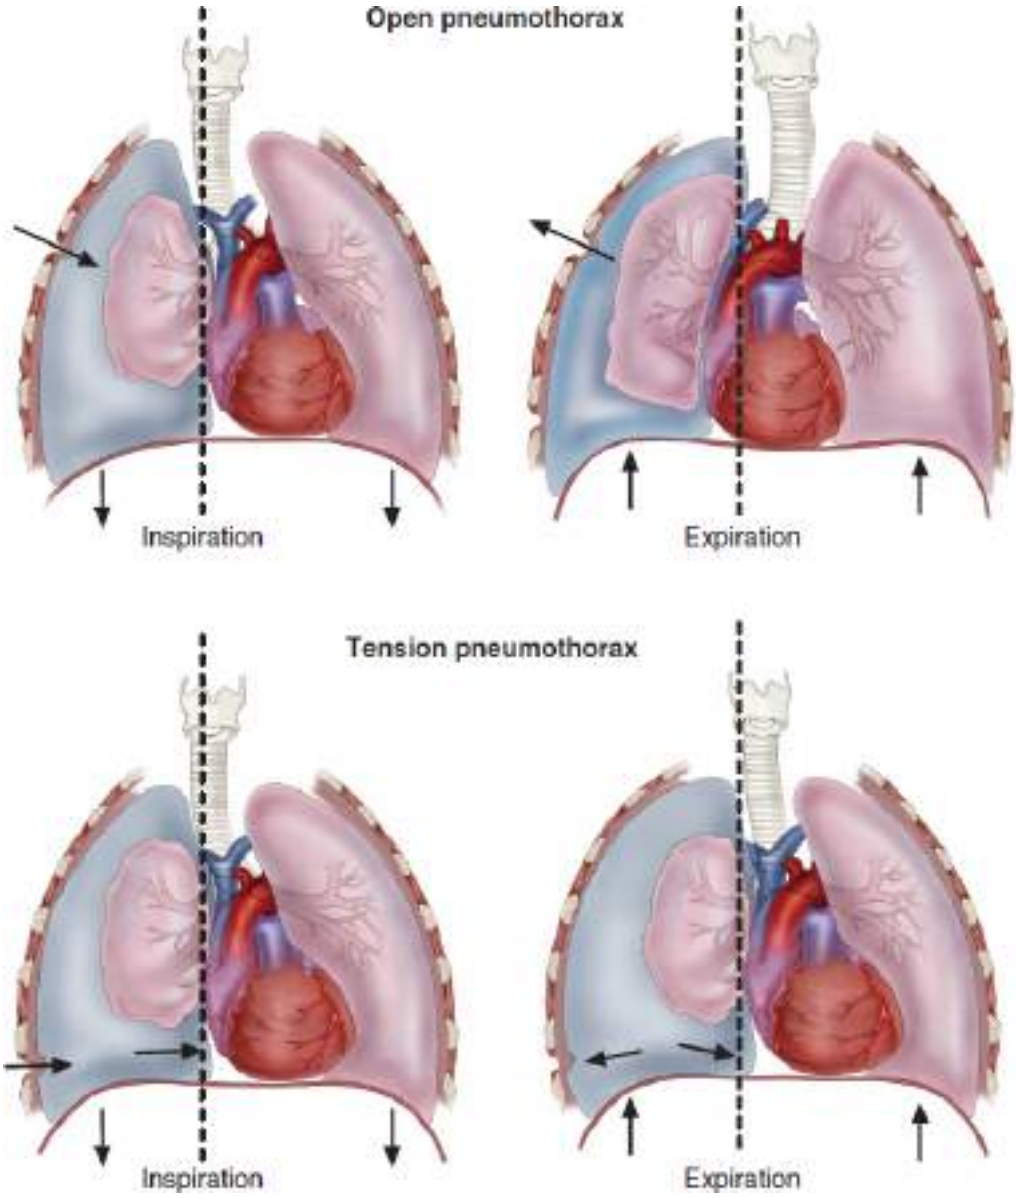

Figure 19-13 • Open pneumothorax (**top**) and tension pneumothorax (**bottom**). In open pneumothorax, air enters the chest during inspiration and exits during expiration. A slight shift of the affected lung may occur because of a decrease in pressure as air moves out of the chest. In tension pneumothorax, air enters but cannot leave the chest. As the pressure increases, the heart and great vessels are compressed and the mediastinal structures are shifted toward the opposite side of the chest. The trachea is pushed from its normal midline position toward the opposite side of the chest, and the unaffected lung is compressed.

Clinical Manifestations

The signs and symptoms associated with pneumothorax depend on its size and cause. Pain is usually sudden and may be pleuritic. The patient may have only minimal respiratory distress with slight chest discomfort and tachypnea with a small simple or uncomplicated pneumothorax. If the pneumothorax is large and the lung collapses totally, acute respiratory distress occurs. The patient is anxious, has dyspnea and air

hunger, has increased use of the accessory muscles, and may develop central cyanosis from severe hypoxemia.

In assessing the chest for any type of pneumothorax, the nurse assesses tracheal alignment, expansion of the chest, breath sounds, and percussion of the chest. In a simple pneumothorax, the trachea is midline, expansion of the chest is decreased, breath sounds may be diminished or absent, and percussion of the chest may reveal normal sounds or hyperresonance depending on the size of the pneumothorax. In a tension pneumothorax, the trachea is shifted away from the affected side, chest expansion may be decreased or fixed in a hyperexpansion state, breath sounds are diminished or absent, and percussion to the affected side is hyperresonant. The clinical picture is one of air hunger, agitation, increasing hypoxemia, central cyanosis, hypotension, tachycardia, and profuse diaphoresis. Figure 19-13 compares open and tension pneumothorax.

Medical Management

Medical management of pneumothorax depends on its cause and severity. The goal of treatment is to evacuate the air or blood from the pleural space. A small chest tube (28 Fr) is inserted near the second intercostal space; this space is used because it is the thinnest part of the chest wall, minimizes the danger of contacting the thoracic nerve, and leaves a less visible scar. If a patient also has a hemothorax, a large-diameter chest tube (32 Fr or greater) is inserted, usually in the fourth or fifth intercostal space at the midaxillary line. The tube is directed posteriorly to drain the fluid and air. Once the chest tube or tubes are inserted and suction is applied (usually to 20 mm Hg suction), effective decompression of the pleural cavity (drainage of blood or air) occurs.

If an excessive amount of blood enters the chest tube in a relatively short period, an autotransfusion may be needed. This technique involves taking the patient's own blood that has been drained from the chest, filtering it, and then transfusing it back into the vascular system.

In such an emergency, anything may be used that is large enough to fill the chest wound—a towel, a handkerchief, or the heel of the hand. If conscious, the patient is instructed to inhale and strain against a closed glottis. This action assists in re-expanding the lung and ejecting the air from the thorax. In the hospital, the opening is plugged by sealing it with gauze impregnated with petrolatum. A pressure dressing is applied. Usually, a chest tube connected to water-seal drainage is inserted to remove air and fluid. Antibiotics usually are prescribed to combat infection from contamination.

The severity of open pneumothorax depends on the amount and rate of thoracic bleeding and the amount of air in the pleural space. The pleural cavity can be decompressed by thoracentesis or by chest tube drainage of the blood or air. The lung is then able to re-expand and resume the function of gas exchange. As a rule of thumb, thoracotomy is performed if more than 1500 mL of blood is aspirated initially by thoracentesis (or is the initial chest tube output) or if chest tube output continues at greater than 200 mL/h (Shahani, 2017). The urgency with which the blood must be removed is determined by the degree of respiratory compromise. An emergency thoracotomy may also be performed in the emergency department if a cardiovascular injury secondary to chest or penetrating trauma is suspected. The patient with a possible tension pneumothorax should immediately be given a high concentration of supplemental oxygen to treat the hypoxemia, and pulse oximetry should be used to

monitor oxygen saturation. In an emergency situation, a tension pneumothorax can be decompressed or quickly converted to a simple pneumothorax by inserting a large-bore needle (14 gauge) at the second intercostal space, midclavicular line on the affected side. This relieves the pressure and vents the positive pressure to the external environment. A chest tube is then inserted and connected to suction to remove the remaining air and fluid, reestablish the negative pressure, and re-expand the lung. If the lung re-expands and air leakage from the lung parenchyma stops, further drainage may be unnecessary. If a prolonged air leak continues despite chest tube drainage to underwater seal, surgery may be necessary to close the leak.

Chest Drainage

Chest tubes and a closed drainage system are used to re-expand the involved lung and to remove excess air, fluid, and blood, and may be used in patients who have had a thoracotomy (see previous discussion). Chest drainage systems also are frequently indicated in the treatment of spontaneous pneumothorax and trauma resulting in pneumothorax. Table 19-8 describes and compares the main features of these systems.

For the procedural guidelines for setting up and managing chest drainage systems, go to thepoint.lww.com/Brunner15e.

The normal breathing mechanism operates on the principle of negative pressure. The pressure in the chest cavity normally is lower than the pressure of the atmosphere, causing air to move into the lungs during inspiration. Whenever the chest is opened, there is a loss of negative pressure, which results in collapse of the lung. The collection of air, fluid, or other substances in the chest can compromise cardiopulmonary function and can also cause the lung to collapse. Pathologic substances that can collect in the pleural space include fibrin or clotted blood, liquids (serous fluids, blood, pus, chyle), and gases (air from the lung, tracheobronchial tree, or esophagus).

Chest tubes may be inserted to drain fluid or air from any of the three compartments of the thorax (the right and left pleural spaces and the mediastinum). The pleural space, located between the visceral and parietal pleura, normally contains 20 mL or less of fluid, which helps lubricate the visceral and parietal pleura (Norris, 2019).

There are two types of chest tubes: small-bore and large-bore catheters. Small-bore catheters (7 Fr to 12 Fr) have a one-way valve apparatus to prevent air from moving back into the chest. They can be inserted through a small skin incision. Large-bore catheters, which range in size up to 40 Fr, are usually connected to a chest drainage system to collect any pleural fluid and monitor for air leaks. After the chest tube is positioned, it is sutured to the skin and connected to a drainage apparatus to remove the residual air and fluid from the pleural or mediastinal space. This results in the re-expansion of remaining lung tissue.

TABLE 19-8 Comparison of Chest Drainage Systems[a]

Types of Chest Drainage Systems	Description	Comments
Traditional Water Seal		
Also referred to as wet suction	Has three chambers: a collection chamber, water-seal chamber (middle chamber), and wet suction control chamber	Requires that sterile fluid be instilled into water seal and suction chambers Has positive- and negative-pressure release valves Intermittent bubbling indicates that the system is functioning properly. Additional suction can be added by connecting system to a suction source.
Dry Suction Water Seal		
Also referred to as dry suction	Has three chambers: a collection chamber, water-seal chamber (middle chamber), and suction regulator dial	Requires that sterile fluid be instilled in water-seal chamber at 2-cm level No fluid-filled suction chamber Suction pressure is set with a suction regulator dial. Has positive- and negative-pressure release valves Has an indicator to signify that the suction pressure is adequate Quieter than traditional water-seal systems
Dry Suction		
Also referred to as one-way valve system	Has a one-way mechanical valve that allows air to leave the chest and prevents air from moving back into the chest	No need to fill suction chamber with fluid; thus, can be set up quickly in an emergency Works even if knocked over, making it ideal for patients who are ambulatory

[a]If no fluid drainage is expected, a drainage collection device may not be needed.

Chest Drainage Systems

Chest drainage systems have a suction source, a collection chamber for pleural drainage, and a mechanism to prevent air from reentering the chest with inhalation (see Fig. 19-14). Various types of chest drainage systems are available for use in the removal of air and fluid from the pleural space and re-expansion of the lungs. Chest drainage systems come with either wet (water seal) or dry suction control. In wet suction systems, the amount of suction is determined by the amount of water instilled in the suction chamber. The amount of bubbling in the suction chamber indicates the strength of the suction. Wet systems use a water seal to prevent air from moving back into the chest on inspiration. Dry systems use a one-way valve and may have a suction

control dial in place of the water. Both systems can operate by gravity drainage, without a suction source.

Figure 19-14 • Chest drainage systems. **A.** The Atrium Ocean is an example of a water-seal chest drain system composed of a drainage chamber and water-seal chamber. The suction control is determined by the height of the water column in that chamber (usually 20 cm). *A,* suction control chamber; *B,* water-seal chamber; *C,* air leak zone; *D,* collection chamber. **B.** The Atrium Oasis is an example of a dry suction water-seal system that uses a mechanical regulator for vacuum control, a water-seal

chamber, and a drainage chamber. *A,* dry suction regulator; *B,* water-seal chamber; *C,* air leak monitor; *D,* collection chamber; *E,* suction monitor bellows. Photos used with permission from Atrium Medical Corporation, Hudson, NH.

Quality and Safety Nursing Alert

When the wall vacuum is turned off, the drainage system must be open to the atmosphere so that intrapleural air can escape from the system. This can be done by detaching the tubing from the suction port to provide a vent.

Water-Seal Systems

The traditional water-seal system (or wet suction) for chest drainage has three chambers: a collection chamber, a water-seal chamber, and a wet suction control chamber. The collection chamber acts as a reservoir for fluid draining from the chest tube. It is graduated to permit easy measurement of drainage. Suction may be added to create negative pressure and promote drainage of fluid and removal of air. The suction control chamber regulates the amount of negative pressure applied to the chest. The amount of suction is determined by the water level. It is usually set at 20 cm H_2O; adding more fluid results in more suction. After the suction is turned on, bubbling appears in the suction chamber. A positive-pressure valve is located at the top of the suction chamber that automatically opens with increases in positive pressure within the system. Air is automatically released through a positive-pressure relief valve if the suction tubing is inadvertently clamped or kinked.

The water-seal chamber has a one-way valve or water seal that prevents air from moving back into the chest when the patient inhales. There is an increase in the water level with inspiration and a return to the baseline level during exhalation; this is referred to as tidaling. Intermittent bubbling in the water-seal chamber is normal, but continuous bubbling can indicate an air leak. Bubbling and tidaling do not occur when the tube is placed in the mediastinal space; however, fluid may pulsate with the patient's heartbeat. If the chest tube is connected to gravity drainage only, suction is not used. The pressure is equal to the water seal only. Two-chamber chest drainage systems (water-seal chamber and collection chamber) are available for use with patients who need only gravity drainage.

The water level in the water-seal chamber reflects the negative pressure present in the intrathoracic cavity. A rise in the water level indicates negative pressure in the pleural or mediastinal space. Excessive negative pressure can cause trauma to tissue. Most chest drainage systems have an automatic means to prevent excessive negative pressure. By pressing and holding a manual high-negativity vent (usually located on the top of the chest drainage system) until the water level in the water-seal chamber returns to the 2-cm mark, excessive negative pressure is avoided, preventing damage to tissue.

Quality and Safety Nursing Alert

If the chest tube and drainage system become disconnected, air can enter the pleural space, producing a pneumothorax. To prevent pneumothorax if the chest tube is inadvertently disconnected from the drainage system, a temporary water seal can be established by immersing the chest tube's open end in a bottle of sterile water.

Dry Suction Water-Seal Systems

Dry suction water-seal systems, also referred to as dry suction, have a collection chamber for drainage, a water-seal chamber, and a dry suction control regulator. The water-seal chamber is filled with water to the 2-cm level. Bubbling in this area can indicate an air leak. The dry suction control regulator provides a dial that conveniently regulates vacuum to the chest drain. The system does not contain a suction control chamber filled with water. Without a water-filled suction chamber, the machine is quieter. However, if the container is knocked over, the water seal may be lost.

Once the tube is connected to the suction source, the regulator dial allows the desired level of suction to be set; the suction is increased until an indicator appears. The indicator has the same function as the bubbling in the traditional water-seal system—that is, it indicates that the vacuum is adequate to maintain the desired level of suction. Some drainage systems use a bellows (a chamber that can be expanded or contracted) or an orange-colored float device as an indicator of when the suction control regulator is set.

When the water in the water seal rises above the 2-cm level, intrathoracic pressure increases. Dry suction water-seal systems have a manual high-negativity vent located on top of the drain. The manual high-negativity vent is pressed until the indicator appears (either a float device or bellows) and the water level in the water seal returns to the desired level, indicating that the intrathoracic pressure is decreased.

Quality and Safety Nursing Alert

The manual vent should not be used to lower the water level in the water seal when the patient is on gravity drainage (no suction) because intrathoracic pressure is equal to the pressure in the water seal.

Dry Suction Systems with a One-Way Valve

A third type of chest drainage system is dry suction with a one-way mechanical valve. This system has a collection chamber, a one-way mechanical valve, and a dry suction control chamber. The valve permits air and fluid to leave the chest but prevents their movement back into the pleural space. This model lacks a water-seal chamber and therefore can be set up quickly in emergency situations, and the dry control drain still works even if it is knocked over. This makes the dry suction systems useful for the patient who is ambulating or being transported. However, without the water-seal chamber, there is no way to tell by inspection whether the pressure in the chest has changed, even though an air leak indicator is present so that the system can be checked. If an air leak is suspected, 30 mL of water is injected into the air leak indicator or the container is tipped so that fluid enters the air leak detection chamber. Bubbles will appear if a leak is present.

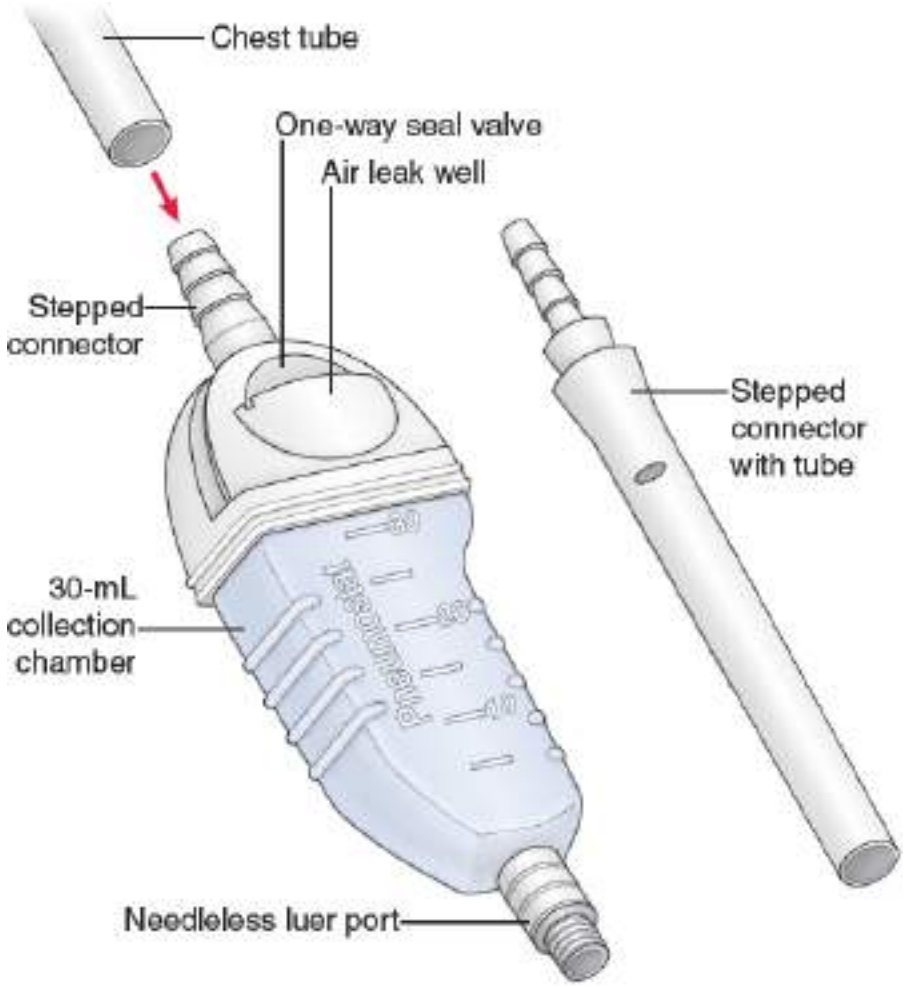

Figure 19-15 • One-way (Heimlich) valve, a disposable, single-use chest drainage system with 30-mL collection volume. Used when minimal volume of chest drainage is expected.

If the chest tube has been inserted to re-expand a lung after pneumothorax, or if very little fluid drainage is expected, a one-way valve (Heimlich valve) may be connected to the chest tube. This valve may be attached to a collection bag (see Fig. 19-15) or covered with a sterile dressing if no drainage is expected.

Cardiac Tamponade

Cardiac tamponade is compression of the heart resulting from fluid or blood within the pericardial sac. It usually is caused by blunt or penetrating trauma to the chest. A penetrating wound of the heart is associated with a high mortality rate. Cardiac tamponade also may follow diagnostic cardiac catheterization, angiographic procedures, and pacemaker insertion, which can produce perforations of the heart and great vessels. Pericardial effusion with fluid compressing the heart also may develop from metastases to the pericardium from malignant tumors of the breast, lung, or mediastinum and may occur with lymphomas and leukemias, kidney injury, TB, and high-dose radiation to the chest (see Chapter 25 for a detailed discussion of cardiac tamponade).

Subcutaneous Emphysema

No matter what kind of chest trauma a patient has, when the lung or the air passages are injured, air may enter the tissue planes and pass for some distance under the skin (e.g., neck and chest). The tissues give a crackling sensation when palpated, and the subcutaneous air produces an alarming appearance as the face, neck, body, and scrotum become misshapen by subcutaneous air. Subcutaneous emphysema is of itself usually not a serious complication. The subcutaneous air is spontaneously absorbed if the underlying air leak is treated or stops spontaneously. In severe cases in which there is widespread subcutaneous emphysema, a tracheostomy is indicated if airway patency is threatened by pressure of the trapped air on the trachea.

CRITICAL THINKING EXERCISES

1 ipc An 84-year-old male is brought to the ED by his daughter with reports of increasing shortness of breath over the past 2 days. You begin your assessment and note that the patient's vital signs include a BP of 110/72 mm Hg, heart rate of 92 bpm, RR of 26/min, and temperature is 38°C (100.4°F). The patient has marked inspiratory and expiratory wheezes that are audible upon auscultation. Oxygen saturation is 92% on room air. The patient denies chest pain; however, he admits to general fatigue, shortness of breath with exertion, and a moist unproductive cough. The daughter explains he resides at home with her and is wheelchair dependent. His past medical history includes an occipital stroke, open reduction internal fixation (ORIF) of right and left hip following fractures, bilateral pulmonary emboli, and paroxysmal atrial fibrillation. The patient's daughter tells you that he has difficulty with dentition with frequent episodes of coughing while eating. The patient admits he stopped taking his prescribed warfarin 6 months ago since he experienced several falls. What are the potential causes of his respiratory problem and what nursing interventions are important? What interdisciplinary team members warrant consultation in the care of the patient?

2 pq A 26-year-old male arrives via Emergency Medical Services (EMS) to the ED following a motor vehicle crash (MVC). The patient is awake and alert; however, he complains of sharp pain in his chest that extends to his back, neck, and shoulders. You begin your assessment and note that the patient's vital signs include a BP of 90/42 mm Hg, heart rate of 101 bpm, and RR of 32/min. He is pale and dyspneic with an oxygen saturation of 89% on 4 L of O_2 via nasal cannula. Inspection of the chest wall reveals areas of ecchymoses over the right shoulder and right anterior chest wall. The emergency medical technician (EMT) reports the patient was the sole driver of the automobile and bystanders stated the driver swerved to avoid a deer and hit a telephone pole. The patient was wearing a seatbelt; however, the air bags did not deploy. Auscultation of the chest reveals an absence of lung sounds on the right side with diminished lung sounds on the left side. What are the possible respiratory conditions associated with the clinical presentation of this patient? Describe your priorities of care.

3 ebp An 18-year-old female is admitted to the ICU from the ED with a diagnosis of acute respiratory failure. She is endotracheally intubated and placed on mechanical ventilation. Her past medical history includes a fractured left ulnar at the age of 10 but is otherwise unremarkable. She denies drug use; however, she admits to use of e-cigarettes since the 10th grade. The intensivist suspects EVALI. Forty-eight hours following intubation, diffuse hazy opacities are noted on chest x-ray throughout all lung fields. What evidence is available associating the use of electronic nicotine delivery systems (ENDS) with acute lung injury? What strategies should you implement to prevent ventilator-associated pneumonia (VAP) in this patient? What is the evidence base for the strategies that you consider? How would you evaluate the strength of the evidence?

20 Management of Patients with Chronic Pulmonary Disease

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the pathophysiology, clinical manifestations, treatment, and medical and nursing management of chronic pulmonary diseases, including chronic obstructive pulmonary disease, bronchiectasis, asthma, and cystic fibrosis.
2. Discuss the major risk factors for developing chronic obstructive pulmonary disease and nursing interventions to minimize or prevent these risk factors.
3. Use the nursing process as a framework for care of the patient with chronic obstructive pulmonary disease.
4. Develop an education plan for patients with chronic obstructive pulmonary disease.
5. Discuss nursing management of and patient education and transitions in care considerations for patients receiving oxygen therapy.
6. Describe asthma self-management strategies.

NURSING CONCEPTS

Oxygenation

GLOSSARY

air trapping: incomplete emptying of alveoli during expiration due to loss of lung tissue elasticity (emphysema), bronchospasm (asthma), or airway obstruction

alpha$_1$-antitrypsin deficiency: genetic disorder resulting from deficiency of alpha$_1$-antitrypsin, a protective agent for the lung; increases patient's risk for developing panacinar emphysema even in the absence of smoking

asthma: a heterogeneous disease, usually characterized by chronic airway inflammation; defined by history of symptoms such as wheeze, shortness of breath, chest tightness, and cough that vary over time and in intensity

bronchiectasis: chronic, irreversible dilation of the bronchi and bronchioles that results from the destruction of muscles and elastic connective tissue; dilated airways become saccular and are a medium for chronic infection

chest percussion: manually cupping hands over the chest wall and using vibration to mobilize secretions by mechanically dislodging viscous or adherent secretions in the lungs

chest physiotherapy (CPT): therapy used to remove bronchial secretions, improve ventilation, and increase the efficiency of the respiratory muscles; types include postural drainage, chest percussion, and vibration, and breathing retraining

chronic bronchitis: a disease of the airways defined as the presence of cough and sputum production for at least a combined total of 3 months in each of 2 consecutive years

chronic obstructive pulmonary disease (COPD): disease state characterized by airflow limitation that is not fully reversible; sometimes referred to as chronic airway obstruction or chronic obstructive lung disease

desaturate: a precipitous drop in the saturation of hemoglobin with oxygen

dry-powder inhaler (DPI): a compact, portable inspiratory flow–driven inhaler that delivers dry-powder medications into the patient's lungs

emphysema: a disease of the airways characterized by destruction of the walls of overdistended alveoli

flutter valve: portable handheld mucous clearance device; consisting of a tube with an oscillating steel ball inside; upon expiration, high-frequency oscillations facilitate mucous expectoration

fraction of inspired oxygen (FiO_2): concentration of oxygen delivered (e.g., 1.0 equals to 100% oxygen)

hypoxemia: decrease in arterial oxygen tension in the blood

hypoxia: decrease in oxygen supply to the tissues and cells

polycythemia: increase in the red blood cell concentration in the blood; in COPD, the body attempts to improve oxygen-carrying capacity by producing increasing amounts of red blood cells

postural drainage: positioning the patient to allow drainage from all lobes of the lungs and airways

pressurized metered-dose inhaler (pMDI): a compact, portable patient-activated pressurized medication canister that provides aerosolized medication that the patient inhales into the lungs

small-volume nebulizer (SVN): a handheld generator-driven medication delivery system that provides aerosolized liquid medication that the patient inhales into the lungs

spirometry: pulmonary function tests that measure specific lung volumes (e.g., FEV_1, FVC) and rates (e.g., $FEF_{25\%–75\%}$); may be measured before and after bronchodilator administration

vibration: a type of massage given by quickly tapping the chest with the fingertips or alternating the fingers in a rhythmic manner, or by using a mechanical device to assist in mobilizing lung secretions

Chronic pulmonary disorders are a leading cause of morbidity and mortality in the United States. Nurses care for patients with chronic pulmonary disease across the spectrum of care, from outpatient and home care to emergency department (ED), critical care, and hospice settings. To care for these patients, nurses not only need to have astute assessment and clinical management skills, but they also need knowledge of how these disorders can affect quality of life. In addition, the nurse's knowledge of palliative and end-of-life care is important for applicable patients. Patient and family education is an important nursing intervention to enhance self-management in patients with any chronic pulmonary disorder.

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is a preventable and treatable slowly progressive respiratory disease of airflow obstruction involving the airways, pulmonary parenchyma, or both (Global Initiative for Chronic Obstructive Lung Disease [GOLD], 2019). The parenchyma includes any form of lung tissue, including bronchioles, bronchi, blood vessels, interstitium, and alveoli. The airflow limitation or obstruction in COPD is not fully reversible. Most patients with COPD present with overlapping signs and symptoms of emphysema and chronic bronchitis, which are two distinct disease processes.

COPD may include diseases that cause airflow obstruction (e.g., emphysema, chronic bronchitis) or any combination of these disorders. Other

diseases such as cystic fibrosis (CF), bronchiectasis, and asthma are classified as chronic pulmonary disorders. Asthma is considered a distinct, separate disorder and is classified as an abnormal airway condition characterized primarily by reversible inflammation. COPD can coexist with asthma. Both of these diseases have the same major symptoms; however, symptoms are generally more variable in asthma than in COPD. This chapter discusses COPD as a disease and describes chronic bronchitis and emphysema as distinct disease states, providing a foundation for understanding the pathophysiology of COPD. Bronchiectasis, asthma, and CF are discussed separately.

While COPD and lower respiratory diseases are the fourth leading cause of death for people of all ages in the United States, they are the third leading cause of death for people ages 65 and over (Centers for Disease Control and Prevention [CDC], 2018a). In 2016, approximately 154,596 Americans died from COPD and lower respiratory diseases (CDC, 2017a). The CDC (2018b) reports that over 16 million Americans live with COPD. This number does not account for the millions of Americans who have COPD but are not diagnosed. Although the rate of hospitalizations for COPD is slowly decreasing, the Agency for Healthcare Research and Quality (AHRQ) reported in 2016 that there were still 501,849 hospitalizations that had COPD as a primary diagnosis (AHRQ, 2016). The cost of individual hospital admissions for patients with COPD is approximately $6245 more per year than admissions for patients without COPD. COPD's economic burden goes beyond the direct medical costs. Patients with COPD were 60% more likely to call in sick to work and 2.6 times more likely to incur short-term disability than patients without COPD (Patel, Coutinho, Lunacsek, et al., 2018).

Pathophysiology

People with COPD commonly become symptomatic during the middle adult years, and the incidence of the disease increases with age. Although certain aspects of lung function normally decrease with age—for example, vital capacity and forced expiratory volume in 1 second (FEV_1)—COPD accentuates and accelerates these physiologic changes as described later. In COPD, the airflow limitation is both progressive and associated with the lungs' abnormal inflammatory response to noxious particles or gases. The inflammatory response occurs throughout the proximal and peripheral airways, lung parenchyma, and pulmonary vasculature (GOLD, 2019). Because of the chronic inflammation and the body's attempts to repair it, changes and narrowing occur in the airways. In the proximal airways (trachea and bronchi greater than 2 mm in diameter), changes include increased numbers of goblet cells and enlarged submucosal glands, both of which lead to hypersecretion of mucus. In the peripheral airways (bronchioles less than 2 mm diameter),

inflammation causes thickening of the airway wall, peribronchial fibrosis, exudate in the airway, and overall airway narrowing (obstructive bronchiolitis). Over time, this ongoing injury-and-repair process causes scar tissue formation and narrowing of the airway lumen (GOLD, 2019). Inflammatory and structural changes also occur in the lung parenchyma (respiratory bronchioles and alveoli). Alveolar wall destruction leads to loss of alveolar attachments and a decrease in elastic recoil. Finally, the chronic inflammatory process affects the pulmonary vasculature and causes thickening of the lining of the vessel and hypertrophy of smooth muscle, which may lead to pulmonary hypertension (GOLD, 2019).

Processes related to imbalances of substances (proteinases and antiproteinases) in the lung may also contribute to airflow limitation. When activated by chronic inflammation, proteinases and other substances may be released, damaging the parenchyma of the lung. These parenchymal changes may also occur as a consequence of inflammation or environmental or genetic factors (e.g., alpha$_1$-antitrypsin deficiency).

Chronic Bronchitis

Chronic bronchitis, a disease of the airways, is defined as the presence of cough and sputum production for at least 3 months in each of 2 consecutive years. Although *chronic bronchitis* is a clinically and epidemiologically useful term, it does not reflect the major impact of airflow limitation on morbidity and mortality in COPD (GOLD, 2019). In many cases, smoke or other environmental pollutants irritate the airways, resulting in inflammation and hypersecretion of mucus. Constant irritation causes the mucus-secreting glands and goblet cells to increase in number, leading to increased mucus production. Mucus plugging of the airway reduces ciliary function. Bronchial walls also become thickened, further narrowing the bronchial lumen (Fig. 20-1). Alveoli adjacent to the bronchioles may become damaged and fibrosed, resulting in altered function of the alveolar macrophages. This is significant because the macrophages play an important role in destroying foreign particles, including bacteria. As a result, the patient becomes more susceptible to respiratory infection. A wide range of viral, bacterial, and mycoplasma infections can produce acute episodes of bronchitis. Exacerbations of chronic bronchitis are most likely to occur during the winter when viral and bacterial infections are more prevalent.

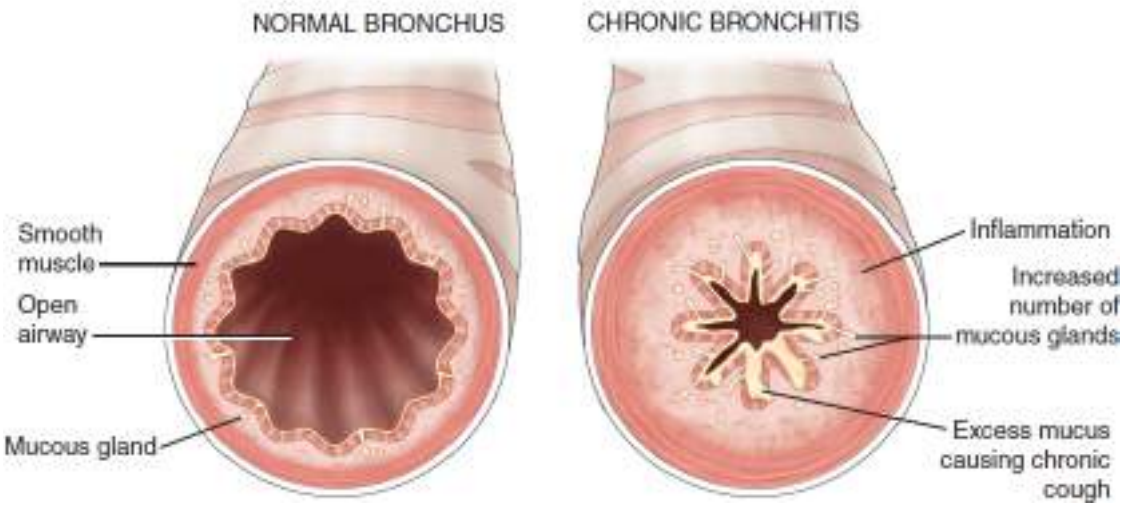

Figure 20-1 • Pathophysiology of chronic bronchitis as compared to a normal bronchus. The bronchus in chronic bronchitis is narrowed and has impaired airflow due to multiple mechanisms: inflammation, excess mucus production, and potential smooth muscle constriction (bronchospasm).

Emphysema

In **emphysema,** impaired oxygen and carbon dioxide exchange results from destruction of the walls of overdistended alveoli. *Emphysema* is a pathologic term that describes an abnormal distention of the airspaces beyond the terminal bronchioles and destruction of the walls of the alveoli (GOLD, 2019; Han, Dransfield, & Martinez, 2018). In addition, a chronic inflammatory response may induce disruption of the parenchymal tissues. This end-stage process progresses slowly for many years. As the walls of the alveoli are destroyed (a process accelerated by recurrent infections), the alveolar surface area in direct contact with the pulmonary capillaries continually decreases. This causes an increase in dead space (lung area where no gas exchange can occur) and impaired oxygen diffusion, which leads to hypoxemia. In the later stages of disease, carbon dioxide elimination is impaired, resulting in hypercapnia (increased carbon dioxide tension in arterial blood) leading to respiratory acidosis. As the alveolar walls continue to break down, the pulmonary capillary bed is reduced in size. Consequently, resistance to pulmonary blood flow is increased, forcing the right ventricle to maintain a higher blood pressure in the pulmonary artery. Hypoxemia may further increase pulmonary artery pressures (pulmonary hypertension). Cor pulmonale, one of the complications of emphysema, is right-sided heart failure brought on by long-term high blood pressure in the pulmonary arteries. This high pressure in the pulmonary arteries and right ventricle lead to back up of blood in the venous

system, resulting in dependent edema, distended neck veins, or pain in the region of the liver (see Chapter 25 for further discussion).

There are two main types of emphysema, based on the changes taking place in the lung (Fig. 20-2). Both types may occur in the same patient. In the panlobular (panacinar) type of emphysema, there is destruction of the respiratory bronchiole, alveolar duct, and alveolus. All airspaces within the lobule are essentially enlarged, but there is little inflammatory disease. A hyperinflated (hyperexpanded) chest, marked dyspnea on exertion, and weight loss typically occur. To move air into and out of the lungs, negative pressure is required during inspiration, and an adequate level of positive pressure must be attained and maintained during expiration. Instead of being an involuntary passive act, expiration becomes active and requires muscular effort.

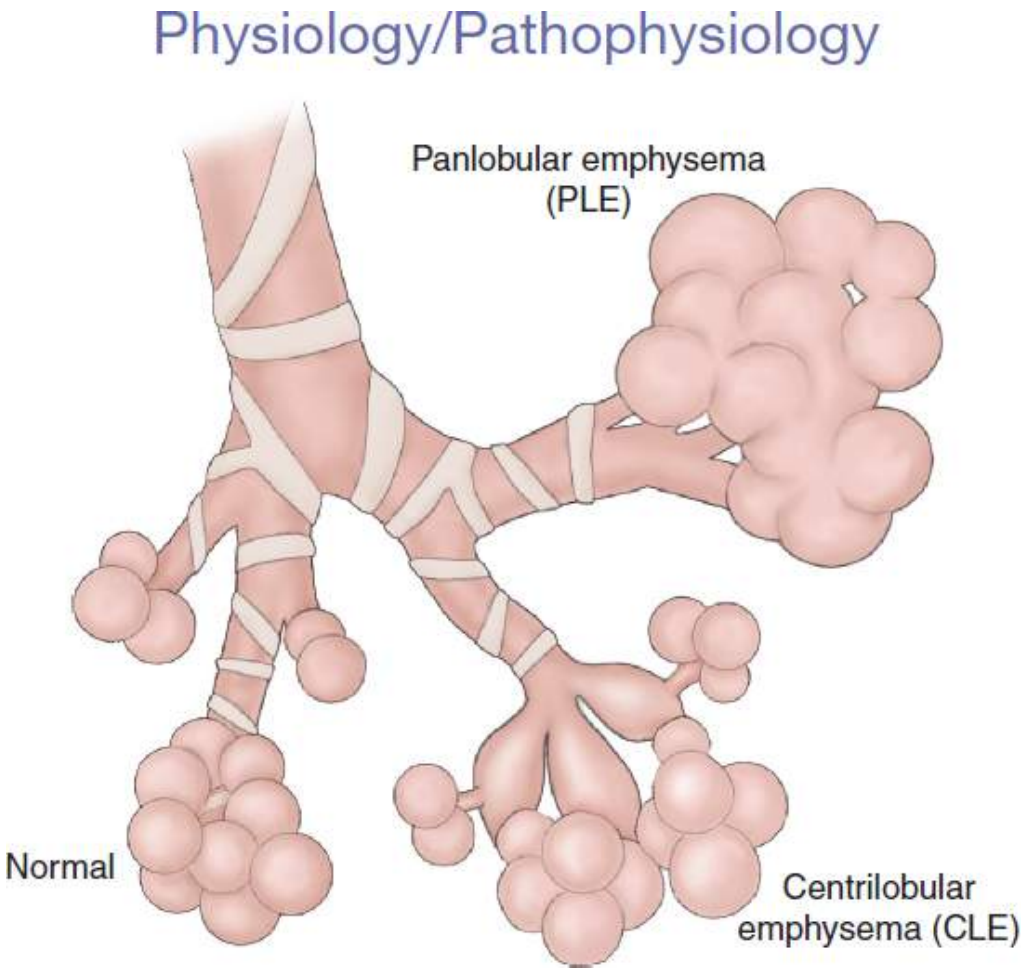

Figure 20-2 • Changes in alveolar structure in centrilobular and panlobular emphysema. In panlobular emphysema, the bronchioles, alveolar ducts, and alveoli are destroyed, and the airspaces within the lobule are enlarged. In centrilobular emphysema, the pathologic changes occur in the lobule, whereas the peripheral portions of the acinus are preserved.

In the centrilobular (centroacinar) form, pathologic changes take place mainly in the center of the secondary lobule, preserving the peripheral portions of the acinus (i.e., the terminal airway unit where gas exchange occurs). Frequently, there is a derangement of ventilation–perfusion ratios, producing chronic hypoxemia, hypercapnia, **polycythemia** (i.e., an increase in red blood cells), and episodes of right-sided heart failure. This leads to central cyanosis and respiratory failure. The patient also develops peripheral edema.

Risk Factors

Risk factors for COPD include environmental exposures and host factors (Chart 20-1). The most important environmental risk factor for COPD worldwide is cigarette smoking. A dose–response relationship exists between the intensity of smoking (pack-year history) and the decline in pulmonary function. Other environmental risk factors include smoking other types of tobacco (e.g., pipes, cigars) and marijuana. Secondhand smoke also contributes to respiratory symptoms and COPD (GOLD, 2019). Smoking depresses the activity of scavenger cells and affects the respiratory tract's ciliary cleansing mechanism, which keeps breathing passages free of inhaled irritants, bacteria, and other foreign matter. When smoking damages this cleansing mechanism, airflow is obstructed and air becomes trapped behind the obstruction. The alveoli greatly distend, which diminishes lung capacity. Smoking also irritates the goblet cells and mucous glands, causing an increased accumulation of mucus, which in turn produces more irritation, infection, and damage to the lung (U.S. Department of Health & Human Services [HHS], 2014). In addition, carbon monoxide (a by-product of smoking) combines with hemoglobin to form carboxyhemoglobin. Hemoglobin that is bound by carboxyhemoglobin cannot carry oxygen efficiently. Cigarette smoking is the best studied COPD risk factor; however, it is not the only risk factor and studies have demonstrated nonsmokers may also develop chronic airflow obstruction.

Chart 20-1 **RISK FACTORS**

Chronic Obstructive Pulmonary Disease

- Exposure to tobacco smoke accounts for an estimated 80–90% of cases of chronic obstructive pulmonary disease
- Secondhand smoke
- Increased age
- Occupational exposure—dust, chemicals
- Indoor and outdoor air pollution
- Genetic abnormalities, including a deficiency of alpha$_1$-antitrypsin, an enzyme inhibitor that normally counteracts the destruction of lung tissue by certain other enzymes

Adapted from Global Initiative for Chronic Obstructive Lung Disease (GOLD). (2019). Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease. Retrieved on 6/23/2019 at: www.goldcopd.org/wp-content/uploads/2018/11/GOLD-2019-v1.7-FINAL-14Nov2018-WMS.pdf

Other environmental risk factors for COPD include prolonged and intense exposure to occupational dusts and chemicals, indoor air pollution, and outdoor air pollution (GOLD, 2019). Recent studies indicate that the use of electronic nicotine delivery systems (ENDS; e.g., e-cigarettes, e-pens, e-pipes, e-hookahs, e-cigars) could increase the risk for developing COPD, but additional research is needed to better understand how their use causes changes similar to COPD in the lungs (Canistro, Vivarelli, Cirillo, et al., 2017; Evans, Burton, & Schwartz, 2018; Larcombe, Janka, Mullins, et al., 2017). Smoke from ENDS has been shown to trigger lung changes (i.e., airway hyperreactivity and lung tissue destruction) that are normally associated with the development of COPD (Garcia-Arcos, Geraghty, Baumlin, et al., 2016). Further research demonstrated that different flavored e-cigarette fluids, aerosols, and solvents can produce different patterns of cytotoxicity (Behar, Wang, & Talbot, 2018). The Surgeon General reported that more than one third of adults ages 18 to 24 years of age had tried e-cigarettes (HHS, 2016). Young adults who have used e-cigarettes report being attracted to them due to perceptions of low harm, the flavorings/tastes of the product, and curiosity (HHS, 2016).

Host risk factors include a person's genetic makeup. One well-documented genetic risk factor is a deficiency of alpha$_1$-antitrypsin, an enzyme inhibitor that protects the lung parenchyma from injury. This deficiency may lead to lung and liver disease. Worldwide, **alpha$_1$-antitrypsin deficiency** impacts between 1/1500 and 1/3000 people with European ancestry (U.S. National Library of Medicine [NLM], 2019). This genetic risk is uncommon in people of Asian descent (NLM, 2019). Approximately 2% of people with COPD have been diagnosed with this deficiency (Stoller, Barnes, & Hollingsworth, 2018).

This deficiency predisposes young people to rapid development of lobular emphysema, even in the absence of smoking. Among Caucasians, alpha$_1$-antitrypsin deficiency is one of the most common genetically linked lethal diseases. COPD may also result from gene–environment interactions (GOLD, 2019). People who are genetically susceptible are sensitive to environmental factors (e.g., smoking, air pollution, infectious agents, allergens) and eventually develop chronic obstructive symptoms. Carriers must be identified so that they can modify environmental risk factors to delay or prevent overt symptoms of disease. Genetic counseling should be offered. Alpha-protease inhibitor replacement therapy, which slows the progression of the disease, is available for patients with this genetic defect and for those with severe disease. However, this infusion therapy is costly and is required on an ongoing basis.

Other genetic risk factors may predispose a patient to COPD. Work is ongoing to identify specific variants of genes hypothesized to be involved in the development of COPD. These may include specific phenotypes to several chromosomal regions in families with multiple members developing early-onset COPD (see Chapter 17, Chart 17-8).

Age is often identified as a risk factor for COPD, but it is unclear whether healthy aging is an independent risk or whether the risk is related to cumulative exposures to risks over time (GOLD, 2019). There is a strong inverse relationship between COPD and lower socioeconomic status. However, perhaps it is not the lower socioeconomic status but how the socioeconomic status places the person at risk for increased patterns of exposure (indoor and outdoor pollutants, crowding, poor nutrition, infections, and increased smoking).

Clinical Manifestations

Although the natural history of COPD is variable, it is generally a progressive disease characterized by three primary symptoms: chronic cough, sputum production, and dyspnea (GOLD, 2019). These symptoms often worsen over time. Chronic cough and sputum production often precede the development of airflow limitation by many years. However, not all people with cough and sputum production develop COPD. The cough may be intermittent and may be unproductive in some patients (GOLD, 2019). Dyspnea may be severe and interfere with the patient's activities and quality of life. It is usually progressive, worse with exercise, and persistent. As COPD progresses, dyspnea may occur at rest. Weight loss is common, because dyspnea interferes with eating and the work of breathing is energy depleting. As the work of breathing increases over time, the accessory muscles are recruited in an effort to breathe. Patients with COPD are at risk for respiratory insufficiency and respiratory infections or COPD exacerbation, which in turn increase the risk of acute and chronic respiratory failure.

In patients with COPD who have a primary emphysematous component, chronic hyperinflation leads to the "barrel chest" thorax configuration. This configuration results from a more fixed position of the ribs in the inspiratory position (due to hyperinflation) and from loss of lung elasticity (Fig. 20-3). Retraction of the supraclavicular fossae occurs on inspiration, causing the shoulders to heave upward (Fig. 20-4). In advanced emphysema, the abdominal muscles may also contract on inspiration.

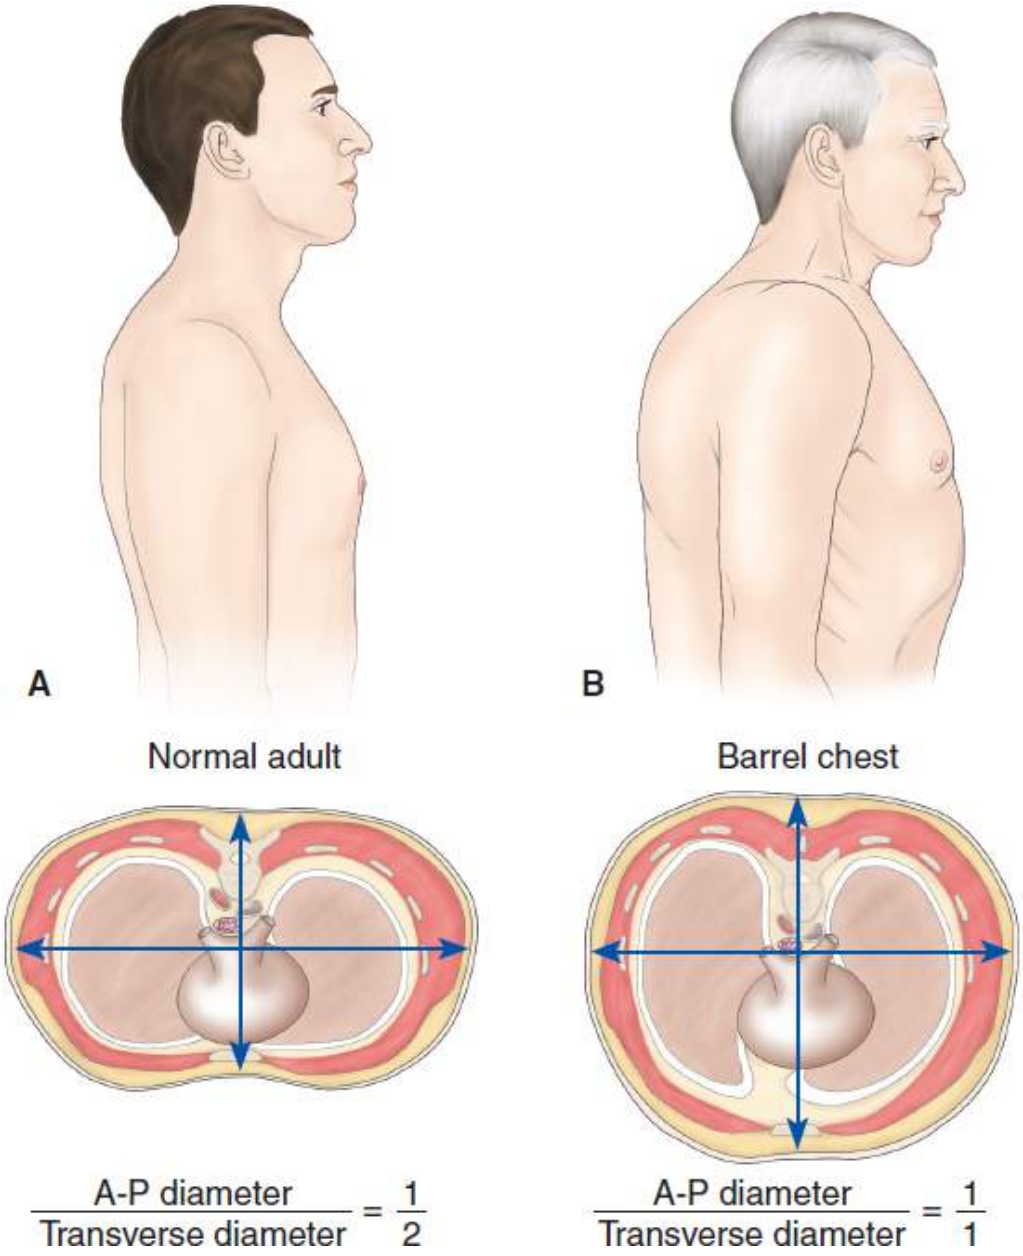

Figure 20-3 • Characteristics of normal chest wall and chest wall in emphysema. **A.** The normal chest wall and its cross-section. **B.** The barrel-shaped chest of emphysema and its cross-section.

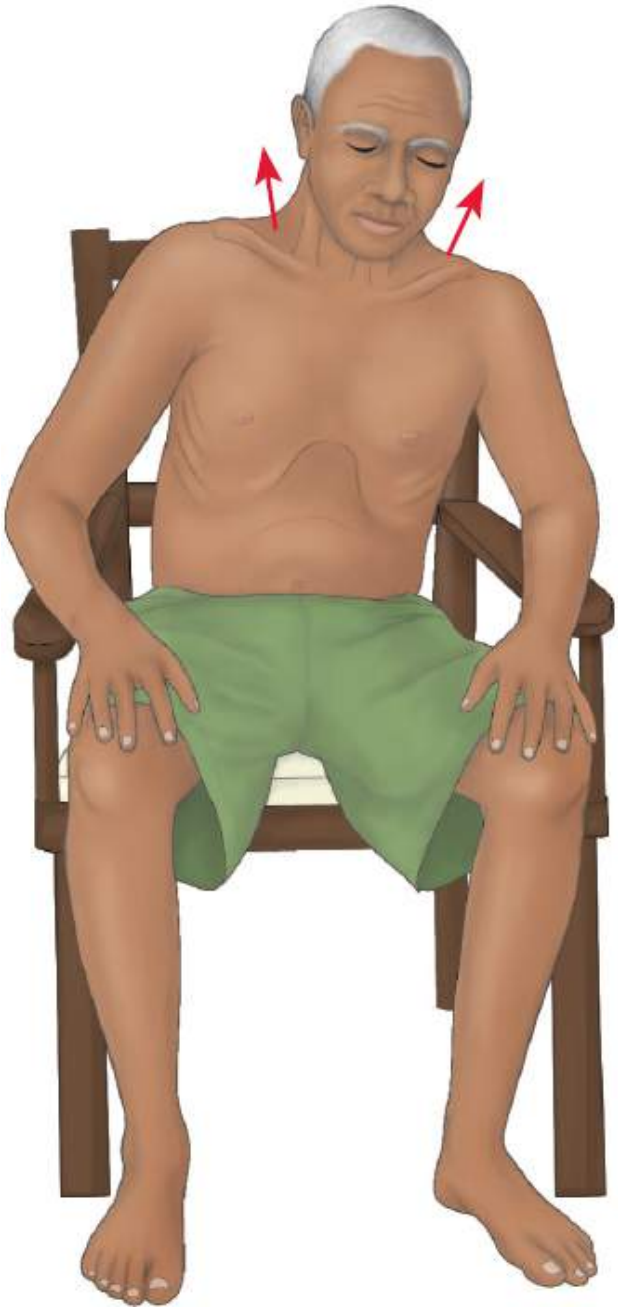

Figure 20-4 • Typical posture of a person with chronic obstructive pulmonary disease—primarily emphysema. The person tends to lean forward and uses the accessory muscles of respiration to breathe, forcing the shoulder girdle upward and causing the supraclavicular fossae to retract on inspiration.

There are systemic or extrapulmonary manifestations of COPD. These include musculoskeletal wasting (see Chapter 4 for discussion of nutrition assessment and Chapters 39 and 40 for discussion of nutrition therapy), metabolic disturbances, and depression (a frequent comorbidity that accompanies chronic debilitating illnesses). These clinical manifestations beyond the lungs must also be assessed and treated in order to decrease the

morbidity and improve the quality of life of the patient with COPD. For example, research has indicated that depression, metabolic syndrome, and diabetes are frequent comorbidities of COPD (Raherison, Ouaalaya, Bernady, et al., 2018). It is speculated that measures to promote healthy eating and activity that may ameliorate metabolic syndrome, diabetes, and depression may also deter the development of COPD.

Assessment and Diagnostic Findings

The nurse obtains a thorough health history from patients with known or potential COPD. Chart 20-2 lists the key factors to assess for patients with known or suspected COPD. Pulmonary function studies are used to help confirm the diagnosis of COPD, determine disease severity, and monitor disease progression. **Spirometry** is used to evaluate airflow obstruction, which is determined by the ratio of FEV_1 to forced vital capacity (FVC). Spirometric results are expressed as an absolute volume and as a percentage of the predicted value using appropriate normal values for gender, age, and height. With obstruction, the patient either has difficulty exhaling or cannot forcibly exhale air from the lungs, reducing the FEV_1. Spirometry is also used to determine reversibility of obstruction after the use of bronchodilators (GOLD, 2019). Spirometry is initially performed, the patient is given an inhaled bronchodilator treatment according to a standard protocol, and then spirometry is repeated. The patient demonstrates a degree of reversibility if the pulmonary function values improve after administration of the bronchodilator.

Chart 20-2 **ASSESSMENT**

Assessing Patients with Chronic Obstructive Pulmonary Disease

Health History

- Has the patient been exposed to risk factors (see Chart 20-1)? If so, inquire about types, intensity, and duration of exposure; for instance:
  - How much exposure has the patient had to secondhand smoke?
  - Is there occupational exposure to smoke or other pollutants?
- Does the patient have a past medical history of respiratory diseases/problems, including asthma, allergy, sinusitis, nasal polyps, or respiratory infections?
- Does the patient have a family history of chronic obstructive pulmonary disease or other chronic respiratory diseases?
- How long has the patient had respiratory difficulty?
- What is the pattern of symptom development?
- Does exertion increase the dyspnea? What type of exertion?
- What are the limits of the patient's tolerance for exercise?
- At what times during the day does the patient complain most of fatigue and shortness of breath?
- Does the patient describe any discomfort or pain in any part of the body? If so, where does it occur, how intense is this pain, when does it occur, and does it interfere with activities of daily living? Is there any intervention that helps to alleviate the pain or discomfort?
- Which eating and sleeping habits have been affected?
- What is the impact of respiratory disease on quality of life?
- What does the patient know about the disease and their condition?
- What is the patient's smoking history?
- Does the patient have a history of using electronic nicotine delivery systems (ENDS) (e.g., vaping, e-cigarettes, e-pens, e-pipes, e-hookah, e-cigars)?
- What are the triggering events (e.g., exertion, strong odors, dust, exposure to animals)?
- Does the patient have a history of exacerbations or previous hospitalizations for respiratory problems?
- Are comorbidities present?
- How appropriate are current medical treatments?
- Does the patient have available social and family support?
- What is the potential for reducing risk factors (e.g., smoking cessation)?

Physical Assessment

- What position does the patient assume during the interview?
- What are the pulse and the respiratory rates?
- What is the character of respirations? Even and without effort? Other?

- Can the patient complete a sentence without having to take a breath?
- Does the patient contract the abdominal muscles during inspiration?
- Does the patient use accessory muscles of the shoulders and neck when breathing?
- Does the patient take a long time to exhale (prolonged expiration)?
- Is central cyanosis evident?
- Are the patient's neck veins distended?
- Does the patient have peripheral edema?
- Is the patient coughing?
- What are the color, amount, and consistency of the sputum?
- Is clubbing of the fingers present?
- What types of breath sounds (i.e., clear, diminished or distant, crackles, wheezes) are heard? Describe and document findings and locations.
- Are there any sensory deficits?
- Is there short- or long-term memory impairment?
- Is there increasing stupor?
- Is the patient apprehensive?

Arterial blood gas measurements may also be obtained to assess baseline oxygenation and gas exchange and are especially important in advanced COPD. A chest x-ray may be obtained to exclude alternative diagnoses. A computed tomography (CT) chest scan is not routinely obtained in the diagnosis of COPD, but a high-resolution CT scan may help in the differential diagnosis. Screening for $alpha_1$-antitrypsin deficiency is suggested for all adults who are symptomatic, especially for patients younger than 45 years. Screening in young adults is important for those with a family history of COPD, particularly if they have a family history of blood relatives with $alpha_1$-antitrypsin deficiency or COPD that is primarily emphysematous in nature (Han et al., 2018).

COPD is classified into four grades depending on the severity measured by pulmonary function tests, as shown in Table 20-1 (GOLD, 2019). However, pulmonary function is not the only way to assess or classify COPD; pulmonary function is evaluated in conjunction with symptoms, health status impairment with COPD, and the potential for exacerbations. Factors that determine the clinical course and survival of patients with COPD include history of cigarette smoking, exposure to secondhand smoke, age, rate of decline of FEV_1, hypoxemia, pulmonary artery pressure, resting heart rate, weight loss, reversibility of airflow obstruction, and comorbidities.

In diagnosing COPD, several differential diagnoses must be ruled out. The primary differential diagnosis is asthma. It may be difficult to differentiate between a patient with COPD and one with chronic asthma. Other diseases

that must be considered in the differential diagnosis include heart failure, bronchiectasis, tuberculosis, obliterative bronchiolitis, and diffuse panbronchiolitis (GOLD, 2019). Key factors in determining the diagnosis are the patient's history, severity of symptoms, and responsiveness to bronchodilators.

TABLE 20-1 Grades of Chronic Obstructive Pulmonary Disease

Grade	Severity	Pulmonary Function
Grade I	Mild	FEV_1/FVC <70% FEV_1 ≥80% predicted
Grade II	Moderate	FEV_1/FVC <70% FEV_1 50–79% predicted
Grade III	Severe	FEV_1/FVC <70% FEV_1 30–49% predicted
Grade IV	Very severe	FEV_1/FVC <70% FEV_1 <30% predicted

FEV_1, forced expiratory volume in 1 s; FVC, forced vital capacity.

Adapted from Global Initiative for Chronic Obstructive Lung Disease (GOLD). (2019). Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease. Retrieved on 06/23/2019 at: www.goldcopd.org/wp-content/uploads/2018/11/GOLD-2019-v1.7-FINAL-14Nov2018-WMS.pdf

Complications

Respiratory insufficiency and failure are major life-threatening complications of COPD. The acuity of the onset and the severity of respiratory failure depend on baseline pulmonary function, pulse oximetry or arterial blood gas values, comorbid conditions, and the severity of other complications of COPD. Respiratory insufficiency and failure may be chronic (with severe COPD) or acute (with severe bronchospasm or pneumonia in a patient with severe COPD). Acute respiratory insufficiency and failure may necessitate ventilatory support until other acute complications, such as infection, can be treated. (See Chapter 19 for the management of the patient requiring ventilatory support.) Other complications of COPD include pneumonia, chronic atelectasis, pneumothorax, and pulmonary arterial hypertension (cor pulmonale).

Medical Management

Therapeutic strategies for the patient with COPD include promoting smoking cessation as appropriate, providing supplemental oxygen therapy as indicated, prescribing medications, and managing exacerbations. Some patients may

benefit from surgical interventions; whereas others with advanced COPD may benefit from palliative care.

Risk Reduction

For patients with stable disease, treatment aims to reduce risk and symptoms. The major risk factor associated with COPD is environmental exposure and it is modifiable. The most important environmental exposure is smoking. In 2017, over 34 million people in the United States reported that they were active smokers (CDC, 2018b). Smoking kills more than 480,000 people each year and costs the nation more than $300 billion in health care expenses and lost productivity annually (CDC, 2019a; CDC, 2019b). Smoking cessation is the single most cost-effective intervention to reduce the risk of developing COPD and to stop its progression (GOLD, 2019). However, smoking cessation is difficult to achieve and even more difficult to sustain in the long term. Factors associated with continued smoking vary among patients and may include the strength of the nicotine addiction, continued exposure to smoking-associated stimuli (at work or in social settings), stress, depression, and habit.

Because multiple factors are associated with continued smoking, successful cessation often requires multiple strategies. Health care providers should promote cessation by explaining the risks of smoking and personalizing the "at-risk" message to the patient. After giving a strong warning about smoking, health care providers should work with the patient to set a definite "quit date." Referral to a smoking cessation program may be helpful. Follow-up within 3 to 5 days after the quit date to review progress and to address any problems is associated with an increased rate of success; this should be repeated as needed. Continued reinforcement with a modality that is individualized to the patient and the patient's lifestyle (e.g., telephone calls, texting, e-mail, or clinic visits) is beneficial. Relapses should be analyzed, and the patient and health care provider should jointly identify possible solutions to prevent future backsliding. It is important to emphasize successes rather than failures. Nicotine replacement—a first-line pharmacotherapy that reliably increases long-term smoking abstinence rates—comes in a variety of forms (gum, inhaler, nasal spray, transdermal patch, sublingual tablet, or lozenge). Bupropion SR and nortriptyline, both antidepressants, may also increase long-term quit rates. Other pharmacologic agents include the antihypertensive agent clonidine; however, its side effects limit its use. Varenicline, a nicotinic acetylcholine receptor partial agonist, may assist in smoking cessation (GOLD, 2019). Patients who are not appropriate candidates for such pharmacotherapy include those with medical contraindications, light smokers (fewer than 10 cigarettes per day), pregnant women, and adolescent smokers.

Smoking cessation can begin in a variety of health care settings—outpatient clinic, nursing center, pulmonary rehabilitation center, community, hospital, and in the home. Regardless of the setting, nurses have the opportunity to

educate patients about the risks of smoking and the benefits of smoking cessation. Various materials, resources, and programs developed by several organizations (e.g., AHRQ, CDC, National Cancer Institute, American Lung Association, American Cancer Society) are available to assist with this effort.

General Principles of Oxygen Therapy

Oxygen therapy is the administration of oxygen at a concentration greater than that found in the environmental atmosphere. At sea level, the concentration of oxygen in room air is 21%. The goal of oxygen therapy is to provide adequate transport of oxygen in the blood while decreasing the work of breathing and reducing stress on the myocardium.

Oxygen transport to tissues depends on factors such as cardiac output, arterial oxygen content, concentration of hemoglobin, and metabolic requirements. These factors must be kept in mind when oxygen therapy is considered for use in all patients, regardless of underlying disorders.

Indications

A change in the patient's respiratory rate or pattern may be one of the earliest indicators of the need for oxygen therapy. These changes may result from hypoxemia or hypoxia. **Hypoxemia,** a decrease in the arterial oxygen tension in the blood, is manifested by changes in mental status (progressing through impaired judgment, agitation, disorientation, confusion, lethargy, and coma), dyspnea, increase in blood pressure, changes in heart rate, arrhythmias, central cyanosis (late sign), diaphoresis, and cool extremities. Hypoxemia usually leads to **hypoxia,** a decrease in oxygen supply to the tissues and cells that can also be caused by problems outside the respiratory system. Severe hypoxia can be life-threatening.

The signs and symptoms signaling the need for supplemental oxygen may depend on how suddenly this need develops. With rapidly developing hypoxia, changes occur in the central nervous system because the neurologic centers are very sensitive to oxygen deprivation. The clinical picture may resemble that of alcohol intoxication, with the patient exhibiting lack of coordination and impaired judgment. With long-standing hypoxia (as seen in patients with COPD as well as in patients with chronic heart failure), fatigue, drowsiness, apathy, inattentiveness, and delayed reaction time may occur. The need for oxygen is assessed by arterial blood gas analysis, pulse oximetry, and clinical evaluation.

Complications

Oxygen is a medication, and except in emergency situations it is given only when prescribed by a health care provider. As with other medications, the nurse administers oxygen with caution and carefully assesses its effects on each patient.

In general, a patient with any type of respiratory disorder is given oxygen therapy only to increase the partial pressure of arterial oxygen (PaO_2) back to the patient's normal baseline, which may vary from 60 to 95 mm Hg. In terms of the oxyhemoglobin dissociation curve (see Chapter 17), arterial hemoglobin at these levels is 80% to 98% saturated with oxygen; higher **fraction of inspired oxygen (FiO_2)** flow values add no further significant amounts of oxygen to the red blood cells or plasma. Instead of helping, increased amounts of oxygen may produce toxic effects on the lungs and central nervous system or may depress ventilation, which is a particularly lethal adverse effect in patients with COPD (see later discussion).

It is important to observe for subtle indicators of inadequate oxygenation when oxygen is given by any method. Therefore, the nurse assesses the patient frequently for confusion, restlessness progressing to lethargy, diaphoresis, pallor, tachycardia, tachypnea, and hypertension. Intermittent or continuous pulse oximetry is used to monitor oxygen levels.

Oxygen toxicity may occur when too high concentration of oxygen is given for an extended period (generally longer than 24 hours) (Kacmarek, Stoller, & Heuer, 2017). It is caused by overproduction of oxygen free radicals, which are by-products of cell metabolism. These free radicals then mediate a severe inflammatory response that can severely damage the alveolar capillary membrane leading to pulmonary edema and progressing to cell death. Clinical manifestations of oxygen toxicity causing lung damage are similar to acute respiratory distress syndrome (ARDS) (see Chapter 19).

Signs and symptoms of oxygen toxicity include substernal discomfort, paresthesias, dyspnea, restlessness, fatigue, malaise, progressive respiratory difficulty, refractory hypoxemia, alveolar atelectasis, and alveolar infiltrates evident on chest x-rays.

Using the lowest amount of oxygen needed to maintain an acceptable PaO_2 level and treating the underlying condition aids in the prevention of oxygen toxicity (Kacmarek et al., 2017).

An additional adverse effect of the administration of high concentrations of oxygen (greater than 50%) to patients who are sedated and breathing small tidal volumes of air (volume of air inspired and expired with each breath) is absorption atelectasis. Normally, 79% of room air is comprised of nitrogen. During inhalation, nitrogen, in addition to other gases, fills the alveoli and helps keep the alveoli open. With the administration of high concentrations of oxygen, nitrogen is diluted and replaced with oxygen. Oxygen in the alveoli is absorbed quickly into the bloodstream and not replaced rapidly enough in the alveoli to maintain patency. The alveoli collapse, causing atelectasis (Kacmarek et al., 2017).

Because oxygen supports combustion, there is always a danger of fire when it is used. It is important to post "No Smoking" signs when oxygen is in use. Oxygen therapy equipment is also a potential source of bacterial

contamination; therefore, the nurse (or respiratory therapist) changes the tubing according to infection prevention policy, manufacturer's recommendations, and the type of oxygen delivery equipment.

Gerontologic Considerations

The respiratory system changes throughout the aging process, and it is important for nurses to be aware of these changes when assessing older adult patients who are receiving oxygen therapy. As the respiratory muscles weaken and the large bronchi and alveoli become enlarged, the available surface area of the lungs decreases, resulting in reduced ventilation and respiratory gas exchange. The number of functional cilia is also reduced, decreasing ciliary action and the cough reflex. As a result of osteoporosis and calcification of the costal cartilages, chest wall compliance is decreased. Patients may display increased chest rigidity and respiratory rate and decreased PaO_2 and lung expansion. The older adult is at risk for aspiration and infection related to these changes. In addition, patient education regarding adequate nutrition is essential because appropriate dietary intake can help diminish the excess buildup of carbon dioxide and maintain optimal respiratory functioning (Meiner & Yeager, 2019).

Methods of Oxygen Administration

Oxygen is dispensed from a cylinder or a piped-in system. A reduction gauge is necessary to reduce the pressure to a working level, and a flow meter regulates the flow of oxygen in liters per minute (L/min). When oxygen is used at high flow rates, it should be moistened by passing it through a humidification system to prevent it from drying the mucous membranes of the respiratory tract.

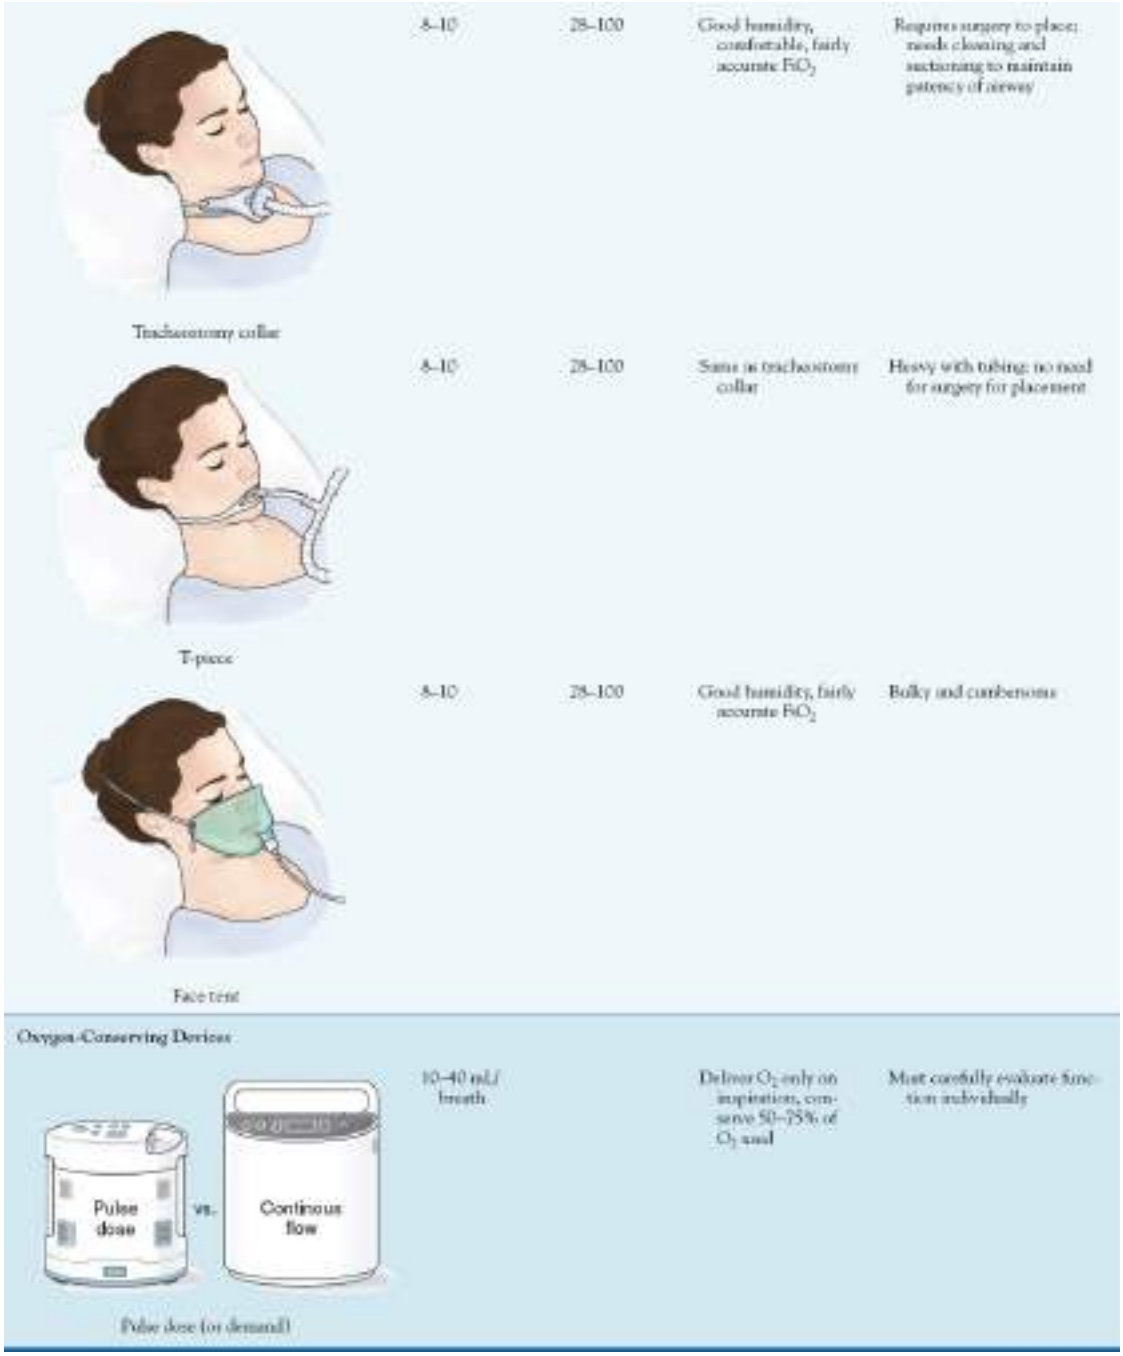
The use of oxygen concentrators is another means of providing varying amounts of oxygen, especially in the home setting. These devices are relatively portable, easy to operate, and cost-effective but require more maintenance than tank or liquid systems. These models can deliver oxygen flows from 1 to 10 L/min and provide an FiO_2 of about 40% (Cairo, 2018).

Many different oxygen devices are used (Table 20-2). The amount of oxygen delivered is expressed as a percentage concentration (e.g., 70%). The appropriate form of oxygen therapy is best determined by arterial blood gas levels (see Chapter 10), which indicate the patient's oxygenation status.

TABLE 20-2 Oxygen Administration Devices

Device	Suggested Flow Rate (L/min)	O_2 Percentage Setting	Advantages	Disadvantages
Low-Flow Systems				
Cannula (nasal and reservoir)	1–2 3–5 6	24–28 32–40 44	Lightweight, comfortable, inexpensive, continuous use with meals and activity	Easily dislodged, from nares, skin breakdown over ears or nares, nasal mucosal and/or pharyngeal mucosal drying, air swallowing, variable FiO_2
Nasal (oropharyngeal) catheter	1–6	24–44	Inexpensive, does not require a tracheostomy	Nasal mucosa irritation; catheter should be changed frequently to alternate nostril
Mask, simple	5–8	40–60	Simple to use, inexpensive	Poorly fitting, variable FiO_2, must remove to eat
Mask, partial rebreathing	8–11	50–75	Moderate O_2 concentration	Warm, poorly fitting, must remove to eat

Mask, nonrebreathing	10–15	80–95	High O_2 concentration	Poorly fitting, must remove to eat
High-Flow Systems				
Mask, Venturi	4–6 6–8	24, 26, 28 30, 35, 40	Provides low levels of supplemental O_2 Precise FiO_2, additional humidity available	Must remove to eat
Tracheostomal oxygen catheter	1/4–4	60–100	More comfortable than other high-flow systems, concealed by clothing, less oxygen liters per minute needed than nasal cannula	Requires frequent and regular cleaning, requires surgical intervention, with associated risk for surgical complications
Mask, aerosol	8–10	28–100	Good humidity, accurate FiO_2	Uncomfortable for some



Oxygen delivery systems are classified as low-flow systems (variable performance) or high-flow systems (fixed performance). Low-flow systems contribute partially to the inspired gas the patient breathes, which means that the patient breathes some room air along with the oxygen. These systems do not provide a constant or precise concentration of inspired oxygen. The amount of inspired oxygen changes as the patient's breathing changes. High-flow systems provide the total inspired air. A specific percentage of oxygen is delivered independent of the patient's breathing. High-flow systems are indicated for patients who require a constant and precise amount of oxygen (Cairo, 2018).

A nasal cannula is used when the patient requires a low to medium concentration of oxygen for which precise accuracy is not essential. This method allows the patient to move about in bed, talk, cough, and eat without interrupting oxygen flow. Although a nasal cannula can deliver up to 6 L/min, flow rates in excess of 4 L/min may lead to swallowing of air or may cause irritation and drying of the nasal and pharyngeal mucosa.

A reservoir cannula stores oxygen in a thin membrane during exhalation. When the patient's inspiration exceeds the flow rate into the cannula, the patient receives additional gas from the reservoir membrane. This reduces oxygen use because the patient can achieve adequate oxygenation with a lower flow rate than what would be used with a nasal cannula. The patient must exhale through the nose to reopen the reservoir. Any condition, such as pursed lipped breathing, that prevents nasal exhalation would limit the effectiveness of the device.

The nasal (oropharyngeal) catheter delivers low to moderate concentrations of oxygen and is rarely used. This method of delivering low-flow oxygen is usually reserved for use in special procedures, such as those that examine the patient's airways and lungs (bronchoscopy). When used during long procedures, the catheter should be changed frequently (e.g., every 8 hours), alternating nostrils to prevent nasal irritation and infection.

When oxygen is given via cannula or catheter, the percentage of oxygen reaching the lungs varies with the depth, rate, and technique of respirations. Anatomic occlusions in the nasal cavity, swollen nasal mucosa, and mouth breathing are examples of conditions that would alter the amount of gas the patient inhales.

Oxygen masks come in several forms. Each is used for different purposes (see Table 20-2). *Simple masks,* low-flow design, are used to administer low to moderate concentrations of oxygen. The body of the mask itself gathers and stores oxygen between breaths. The patient exhales directly through openings or ports in the body of the mask. If oxygen flow ceases, the patient can draw air in through these openings around the mask edges. Although widely used, these masks cannot be used for controlled oxygen concentrations and must be adjusted for proper fit. They should not press too tightly against the skin, because this can cause a sense of claustrophobia as well as skin breakdown; adjustable elastic bands are provided to ensure comfort and security.

Partial rebreathing masks have a reservoir bag that must remain inflated during both inspiration and expiration. The nurse adjusts the oxygen flow to ensure that the bag does not collapse during inhalation. A moderate concentration of oxygen can be delivered because both the mask and the bag serve as reservoirs for oxygen. Oxygen enters the mask through small-bore tubing that connects at the junction of the mask and bag. As the patient inhales, gas is drawn from the mask, from the bag, and potentially from room air through the exhalation ports. As the patient exhales, the first third of the

exhalation fills the reservoir bag. This is mainly dead space and does not participate in gas exchange in the lungs. Therefore, it has a high oxygen concentration. The remainder of the exhaled gas is vented through the exhalation ports. The actual percentage of oxygen delivered is influenced by the patient's ventilatory pattern (Kacmarek et al., 2017).

Nonrebreathing masks are similar in design to partial rebreathing masks except that they have additional valves. A one-way valve located between the reservoir bag and the base of the mask allows gas from the reservoir bag to enter the mask on inhalation but prevents gas in the mask from flowing back into the reservoir bag during exhalation. One-way valves located at the exhalation ports prevent room air from entering the mask during inhalation. They also allow the patient's exhaled gases to exit the mask on exhalation. As with the partial rebreathing mask, it is important to adjust the oxygen flow so that the reservoir bag does not completely collapse on inspiration. In theory, if the nonrebreathing mask fits the patient snugly and both side exhalation ports have one-way valves, it is possible for the patient to receive 100% oxygen, making the nonrebreathing mask a high-flow oxygen system. However, because it is difficult to get an exact fit from the mask on every patient, and some nonrebreathing masks have only one one-way exhalation valves, it is almost impossible to ensure 100% oxygen delivery, making it a low-flow oxygen system.

The *Venturi mask* is the most reliable and accurate method for delivering precise concentrations of oxygen through noninvasive means. The mask is constructed in a way that allows a constant flow of room air blended with a fixed flow of oxygen. It is used primarily for patients with COPD because it can accurately provide appropriate levels of supplemental oxygen, thus avoiding the risk of suppressing the hypoxic drive.

The Venturi mask uses the Bernoulli principle of air entrainment (trapping the air like a vacuum), which provides a high airflow with controlled oxygen enrichment. For each liter of oxygen that passes through a jet orifice, a fixed proportion of room air is entrained. Varying the size of the jet orifice and adjusting the flow of oxygen can deliver a precise volume of oxygen. Excess gas leaves the mask through the two exhalation ports, carrying with it the exhaled carbon dioxide. This method allows a constant oxygen concentration to be inhaled regardless of the depth or rate of respiration.

The mask should fit snugly enough to prevent oxygen from flowing into the patient's eyes. The nurse checks the patient's skin for irritation. It is necessary to remove the mask so that the patient can eat, drink, and take medications, at which time supplemental oxygen is provided through a nasal cannula.

Concept Mastery Alert

Oxygen delivery systems are classified as either low- or high-flow systems. Whereas a low-flow oxygen delivery system may imprecisely deliver high concentrations of oxygen (e.g., up to 100% via a nonrebreathing mask), the Venturi mask, which is a high-flow system, is specifically designed to deliver precise but lower concentrations of oxygen (less than 30% oxygen).

The *transtracheal oxygen catheter* requires minor surgery to insert a catheter through a small incision directly into the trachea. It is indicated for patients with chronic oxygen therapy needs. These catheters are more comfortable, less dependent on breathing patterns, and less obvious than other oxygen delivery methods. Because no oxygen is lost into the surrounding environment, the patient achieves adequate oxygenation at lower rates, making this method less expensive and more efficient.

Other oxygen devices include *aerosol masks, tracheostomy collars* (see Table 20-2), *T-pieces,* and *face tents,* all of which are used with aerosol devices (nebulizers) that can be adjusted for oxygen concentrations from 28% to 100% (0.28 to 1.00). If the gas mixture flow falls below patient demand, room air is pulled in, diluting the concentration. The aerosol mist must be available for the patient during the entire inspiratory phase.

Specific Considerations for the Patient with COPD Receiving Oxygen Therapy

Oxygen therapy can be given as long-term continuous therapy, during exercise, or to prevent acute dyspnea during an exacerbation (see later discussion). The goal of supplemental oxygen therapy in the patient with COPD is to increase the baseline resting partial pressure of arterial oxygen (PaO_2) to at least 60 mm Hg at sea level, which corresponds with an arterial oxygen saturation (SaO_2) of 90% (GOLD, 2019). Long-term oxygen therapy (more than 15 hours per day) has also been shown to improve quality of life, reduce pulmonary arterial pressure and dyspnea, and improve survival (GOLD, 2019). Long-term oxygen therapy is usually introduced in very severe COPD, and indications generally include a PaO_2 of 55 mm Hg or less or SaO_2 at or below 88% (GOLD, 2019). Other indications for long-term oxygen therapy include evidence of tissue hypoxia and organ damage such as cor pulmonale, secondary polycythemia, edema from right-sided heart failure, or impaired mental status (GOLD, 2019). For patients with exercise-induced hypoxemia, oxygen supplementation during exercise may improve dyspnea but will not diminish breathlessness in daily life (GOLD, 2019). Patients who are hypoxemic while awake are likely to be so during sleep. Therefore, nighttime oxygen therapy is recommended as well, and the prescription for oxygen therapy is for continuous, 24-hour use. Intermittent oxygen therapy is indicated for patients who **desaturate** (i.e., experience a precipitous drop in hemoglobin molecule saturation with oxygen) only during activities of daily living, exercise, or sleep.

The main objective in treating patients with hypoxemia and hypercapnia is to give sufficient oxygen to improve oxygenation. Patients with COPD who require oxygen may have respiratory failure that is caused primarily by a ventilation–perfusion mismatch. These patients respond to oxygen therapy and should be treated to keep the resting oxygen saturation at or above 90%, which is associated with a PaO_2 of 60 mm Hg or higher (GOLD, 2019). Nursing assessments of a patient with COPD on supplemental oxygen must include monitoring the respiratory rate and the oxygen saturation as measured by pulse oximetry (SpO_2) so that the patient has an adequate oxygen saturation (90%) on the lowest liter flow of oxygen (GOLD, 2019).

Administering too much oxygen can result in the retention of carbon dioxide. The high O_2 levels can then suppress CO_2 chemoreceptors, which in turn would depress the respiratory drive and disrupt ventilation–perfusion balance (Kacmarek et al., 2017). The resulting increased O_2 tension in the alveoli causes a ventilation–perfusion mismatch that presents as hypercapnia. Monitoring and assessment are essential in the care of patients with COPD on supplemental oxygen due to complications of oxygen supplementation. Although pulse oximetry is helpful in assessing response to oxygen therapy, it does not assess $PaCO_2$ levels. A SaO_2 of 88% or less warrants further evaluation with arterial blood gas analysis (GOLD, 2019). The nurse must evaluate for other factors and medications which could further decrease the respiratory drive—neurologic impairment, fluid and electrolyte issues, and opioids or sedatives.

Quality and Safety Nursing Alert

Oxygen therapy is variable in patients with COPD; its aim in COPD is to achieve an acceptable oxygen level without a fall in the pH (increasing hypercapnia).

Pharmacologic Therapy

Medication regimens used to manage COPD are based on disease severity. For grade I (mild) COPD, a short-acting bronchodilator may be prescribed. For grade II or III (moderate or severe) COPD, a short-acting bronchodilator and regular treatment with one or more long-acting bronchodilators may be used. For grade III or IV (severe or very severe) COPD, medication therapy includes regular treatment with long-acting bronchodilators and/or inhaled corticosteroids (ICSs) for repeated exacerbations.

Bronchodilators

Bronchodilators are key for symptom management in stable COPD (GOLD, 2019). The choice of bronchodilator depends on availability and individual response in terms of symptom relief and side effects. Long-acting bronchodilators are more convenient for patients to use, and combining bronchodilators with different durations of action and different mechanisms may optimize symptom management (GOLD, 2019). Long-acting bronchodilators are typically used for maintenance treatment for long-term symptom control. Short-acting bronchodilators are usually used for acute management of symptomatic flairs. Even patients who do not show a significant response to a short-acting bronchodilator test may benefit symptomatically from long-term bronchodilator treatment.

Bronchodilators relieve bronchospasm by improving expiratory flow through widening of the airways and promoting lung emptying with each breath. These medications alter smooth muscle tone and reduce airway obstruction by allowing increased oxygen distribution throughout the lungs and improving alveolar ventilation. Although regular use of bronchodilators that act primarily on the airway smooth muscle does not modify the decline of function or the prognosis of COPD, their use is central in the management of COPD (GOLD, 2019). These agents can be delivered through a pressurized metered-dose inhaler (pMDI), a dry-powder inhaler (DPI), by a small-volume nebulizer (SVN), or via the oral route in pill or liquid form. Bronchodilators are often given regularly throughout the day as well as on an as-needed basis. They may also be used prophylactically to prevent breathlessness by having the patient use them before participating in or completing an activity, such as eating or walking.

Several devices are available to deliver medication via the inhaled route. These may be categorized as pMDIs, DPIs, or SVNs, as noted previously (Cairo, 2018; Gregory, Elliott, & Dunne, 2013). The choice of an inhaler device will depend on availability, cost, prescribing provider, insurance coverage, and the skills and ability of the patient (GOLD, 2019). Key aspects of each are described in Table 20-3.

Both pMDIs and DPIs are small handheld devices that may be carried in a pocket or purse (Cairo, 2018; D'Urzo, Chapman, Donohue, et al., 2019). Attention to effective drug delivery and training in proper inhaler technique is essential when using a pMDI or DPI. A respiratory therapist is an excellent health care provider to consult on appropriate inhaler technique. **Pressurized metered-dose inhalers (pMDIs)** include conventional pMDIs or breath-actuated pMDIs; these may also feature spacer or valved-holding chambers (VHCs). They are pressurized devices that contain aerosolized powder of medications. A precise amount of medication is released with each activation of the pMDI canister. A spacer or VHC may also be indicated to enhance deposition of the medication in the lung and help the patient coordinate activation of the pMDI with inspiration. Spacers come in several designs, but

all are attached to the pMDI and have a mouthpiece on the opposite end (Fig. 20-5).

All pMDIs are designed so that they require coordination between the patient's inspiration and the mechanics of the inhaler. In contrast, **dry-powder inhalers (DPIs)** (see Fig. 20-5) rely solely on the patient's inspiration for medication delivery. While DPIs still require the user to press a lever or button to dispense the medication, these inhalers do not require the coordination necessary to administer pMDIs.

Because of the significant relationship between poor inhaler technique and lack of symptom control, issues that could affect proper inhaler use must be considered when assessing the effectiveness of these medications (GOLD, 2019). Conditions such as decreased hand–inhalation coordination, insufficient hand strength, and the inability to generate a sufficient inspiratory flow could impair the delivery of the medication, and thus, impair symptom control (D'Urzo et al., 2019). For example, patients with decreased hand–inhalation coordination could fail to exhale prior to administering pMDIs, which would prevent them from inhaling the proper amount of the medication. While DPIs minimize the need for hand–inhalation coordination, patients with severe COPD may not have the ability to generate a sufficient inspiratory flow necessary to deliver the proper dose (D'Urzo et al., 2019).

TABLE 20-3 Aerosol Delivery Devices

Devices/Drugs	Optimal Technique	Therapeutic Issues
Pressurized metered-dose inhaler (pMDI) Beta-2-adrenergic agonists Corticosteroids Anticholinergics	Actuation[a] during a slow (30 L/min or 3–5 s) deep inhalation, followed by 10-s breath-hold	Slow inhalation and coordination of actuation may be difficult for some patients. Patients may incorrectly stop inhalation at actuation. Deposition of 50–80% of actuated dose in the oropharynx. Mouth washing and spitting is effective in reducing the amount of drug swallowed and absorbed systemically
Breath-actuated pMDI Beta-2-adrenergic agonists	Tight seal around mouthpiece and slightly more rapid inhalation than standard pMDI (see above) followed by 10-s breath-hold	May be particularly useful for patients unable to coordinate inhalation and actuation. May also be useful for older patients. Patients may incorrectly stop inhalation at actuation. Cannot be used with currently available spacer/valved-holding chamber (VHC) devices
Spacer or VHC (*Note—this is an accessory to a pMDI*)	Slow (30 L/min or 3–5 s) deep inhalation, followed by 10-s breath-hold immediately following actuation. Actuate only once into spacer/VHC per inhalation. Rinse plastic VHCs once a month with low concentration of liquid household dishwashing detergent (1:5000 or 1–2 drops per cup of water) and let drip dry	Indicated for patients who have difficulty performing adequate pMDI technique. May be bulky. Simple tubes do not obviate coordinating actuation and inhalation. VHCs are preferred. Spacers or VHCs may increase delivery of inhalational corticosteroids to the lungs
Dry-powder inhaler (DPI) Beta-2-adrenergic agonists Corticosteroids Anticholinergics	Rapid (1–2 s) deep inhalation. Minimally effective inspiratory flow is device dependent	Dose is lost if patient exhales through device after actuating. Delivery may be greater or lesser than pMDIs, depending on device and technique. Delivery is more flow dependent in devices with highest internal resistance. Rapid inhalation promotes greater deposition in larger central airways. Mouth washing and spitting are effective in reducing amount of drug swallowed and absorbed systemically
Small-volume nebulizer (SVN) Beta-2-adrenergic agonists	Slow tidal breathing with occasional deep breaths. Tightly fitting facemask for those unable to use mouthpiece	Less dependent on patient's coordination and cooperation. May be expensive, time-consuming, and bulky; output depends on device and operating parameters (fill volume, driving gas flow);

Corticosteroids Anticholinergics	internebulizer and intranebulizer output variances are significant. The use of a facemask reduces delivery to lungs by 50%. Choice of delivery system depends on resources, availability, and clinical judgment of clinician caring for patient. There is potential for infections if device is not cleaned properly

[a]Actuation refers to release of dose of medication with inhalation.

Adapted from Cairo, J. M. (2018). *Mosby's respiratory care equipment* (10th ed.). St. Louis, MO: Elsevier Mosby.

Figure 20-5 • **A.** Examples of pressurized metered-dose inhalers (pMDIs) and spacers and a dry-powder inhaler (DPI). **B.** A pressurized metered-dose inhaler and spacer in use.

The **small-volume nebulizer (SVN)** is a handheld apparatus that is easier to use than a pMDI or a DPI but lacks the convenience of these inhalers as it requires a power source in order to operate. Common SVNs include single-use pneumatic jet nebulizers with reservoir tubes, which are most commonly used in hospitals, and electronic nebulizers, which may be used in the home-based setting (Gregory et al., 2013). SVNs are commonly prescribed when patients are challenged with being able to administer their medications through either a pMDI or a DPI; some reasons why this might happen have been described previously (Cairo, 2018). The SVN may also be a preferred option to other inhalers because the nebulized particles in an SVN are smaller and can better penetrate the airways. Diaphragmatic breathing (see later discussion under "Breathing Retraining") is a helpful technique to prepare for proper use of the SVN.

Several classes of bronchodilators are used that include beta-adrenergic agonists, muscarinic antagonists (anticholinergics) and combination agents. Beta-adrenergic agonists include short-acting beta-2-adrenergic agonists (SABAs) and long-acting beta-2 adrenergic agonists (LABAs). The anticholinergic agents include short-acting muscarinic antagonists (SAMAs) and long-acting muscarinic antagonists (LAMAs) (GOLD, 2018; GOLD, 2019). ICSs may also be combined with bronchodilators. These medications may be used in combination to optimize bronchodilation. LABA bronchodilators are more convenient for patient use as compared to short-acting $beta_2$-agonist bronchodilators. Examples of these medications are described in Table 20-4.

Fixed dose combinations of LABAs and LAMAs have become the foundation for treating COPD (D'Urzo et al., 2019). Combining these classes of medications in one inhaler has synergistic effects, so that the dosages of each medication may be lesser than if they were each administered separately (i.e., as monotherapy), without diminishing their effectiveness (GOLD, 2019). Furthermore, combination therapy is associated with less adverse reactions and promotes proper medication administration by avoiding the use of multiple inhaler devices (GOLD, 2019).

Corticosteroids

Although inhaled and systemic corticosteroids may improve the symptoms of COPD, they do not slow the decline in lung function. A short trial course of oral corticosteroids may be prescribed for patients to determine whether pulmonary function improves and symptoms decrease. Long-term treatment with oral corticosteroids is not recommended in COPD and can cause steroid myopathy, leading to muscle weakness, decreased ability to function, and, in advanced disease, respiratory failure (GOLD, 2019). ICSs are frequently prescribed in COPD.

Treatment of COPD with combination long-term $beta_2$-agonists plus corticosteroids in one inhaler may improve lung function (GOLD, 2018). Examples of these medications include formoterol/budesonide, vilanterol/fluticasone furoate, and salmeterol/fluticasone.

Other Medications

Other pharmacologic treatments that may be used in COPD include $alpha_1$-antitrypsin augmentation therapy, antibiotic agents, mucolytic agents, antitussive agents, vasodilators, and opioids. Vaccines are also effective in that they prevent exacerbations by thwarting respiratory infections. For instance, influenza vaccines can reduce serious illness and death in patients with COPD (GOLD, 2019). It is recommended that people limit their risk through influenza vaccination and smoking cessation. Pneumococcal vaccination also

reduces the incidence of community-acquired pneumonia in the general older adult population (GOLD, 2019).

Management of Exacerbations

An exacerbation of COPD is defined as an event in the natural course of the disease characterized by acute changes (worsening) in the patient's respiratory symptoms beyond the normal day-to-day variations. An exacerbation also leads to change in medication (GOLD, 2019). During an exacerbation, there is increased dyspnea that is a result of amplified hyperinflation and air trapping (GOLD, 2019). Primary causes of an acute exacerbation are usually related to viral infections, particularly human rhinovirus (i.e., the common cold). However, bacterial infections and environmental factors have also been linked to the development of acute exacerbations (GOLD, 2019). Roflumilast may be used as a treatment to reduce the risk of exacerbations in patients with severe COPD associated with chronic bronchitis and a history of exacerbations. Roflumilast is a selective phosphodiesterase-4 (PDE4) inhibitor and is taken as a tablet once daily.

TABLE 20-4 Common Types of Bronchodilator Medications for Chronic Obstructive Pulmonary Disease

	Method of Administration			
Class/Drug	Inhaler[a]	Nebulizer	Oral	Duration of Action[b]
Beta-2–Adrenergic Agonist Agents				
albuterol	X	X	X	SABA
levalbuterol	X	X		SABA
terbutaline	X			SABA
arformoterol	X			LABA
formoterol	X			LABA
salmeterol	X			LABA
indacaterol	X			LABA
olodaterol	X			LABA
Anticholinergic Agents				
ipratropium bromide	X	X		SAMA
tiotropium bromide	X			LAMA
umeclidinium	X			LAMA
Combination Short-Acting Beta-2–Adrenergic Agonist and Anticholinergic Agent				
albuterol/ipratropium	X			SABA/SAMA
Inhaled Corticosteroids (ICSs)				
beclomethasone dipropionate	X	X		
budesonide	X	X		
fluticasone propionate	X	X		
Combination Inhaled Corticosteroids and Long-Acting Beta-2–Adrenergic Agonist				
budesonide/formoterol	X			ICS/LABA
mometasone/formoterol	X			ICS/LABA
fluticasone/salmeterol	X			ICS/LABA
fluticasone furoate/vilanterol	X			ICS/LABA

[a]Inhaler may include pressurized metered-dose inhaler (pMDI) or dry-powder inhaler (DPI).
[b]Short acting, 4–6 h; long acting, 12+ h.
ICS, inhaled corticosteroid; LABA, long-acting beta-2 adrenergic agonist; LAMA, long-acting muscarinic antagonist; SABA, short-acting beta-2 adrenergic agonist; SAMA, short-acting muscarinic antagonist.
Adapted from Global Initiative for Chronic Obstructive Lung Disease (GOLD). (2019). Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease. Retrieved on 6/25/2019 at: www.goldcopd.org/wp-content/uploads/2018/11/GOLD-2019-v1.7-FINAL-14Nov2018-WMS.pdf

Treatment of an exacerbation requires identifying the primary cause (if possible) and administering the specific treatment. Optimization of bronchodilator medications is first-line therapy and involves identifying the best medication or combinations of medications taken on a regular schedule

for a specific patient. Depending on the signs and symptoms, corticosteroids, antibiotic agents, oxygen therapy, and intensive respiratory interventions may also be used. The GOLD (2019) guidelines provide indications for assessment, hospital admission, and possible critical-care admission for patients with exacerbations of COPD. Indications for hospitalization include marked increase in intensity of symptoms, severe underlying COPD, onset of new physical signs (e.g., the use of accessory muscles, paradoxical chest wall movement, worsening or new onset of central cyanosis, peripheral edema, signs of right heart failure, reduced alertness), failure to respond to initial medical management, older age, and insufficient home support. Patients requiring hospitalization for an exacerbation would exhibit severe dyspnea that does not respond adequately to initial therapy, confusion or lethargy, respiratory muscle fatigue, paradoxical chest wall movement, peripheral edema, worsening or new onset of central cyanosis, persistent or worsening hypoxemia, and the need for noninvasive or invasive assisted mechanical ventilation (GOLD, 2019). The outcome from an exacerbation of COPD is closely related to the development of respiratory acidosis, the presence of significant comorbidities, and the need for noninvasive or invasive positive pressure ventilatory support.

When the patient with an exacerbation of COPD arrives in an ED, the first line of treatment is supplemental oxygen therapy and rapid assessment to determine if the exacerbation is life-threatening (GOLD, 2019). A short-acting inhaled bronchodilator may be used to assess response to treatment. Oral or intravenous (IV) corticosteroids, in addition to bronchodilators, are recommended in the hospital management of a COPD exacerbation. The administration of antibiotics remains controversial, but in general, they should be administered when the patient has three cardinal symptoms of an exacerbation: increase in dyspnea, increase in sputum volume, and sputum purulence (GOLD, 2019).

Surgical Management

Surgical options might be appropriate for patients who do not demonstrate symptom improvement with nonsurgical therapies.

Bullectomy

A bullectomy is a surgical option for select patients with bullous emphysema. Bullae are enlarged airspaces that do not contribute to ventilation but occupy space in the thorax; these areas may be surgically excised. These bullae compress areas of the lung and may impair gas exchange. Bullectomy may help reduce dyspnea and improve lung function. It can be performed via a video-assisted thoracoscope or a limited thoracotomy incision (GOLD, 2019).

Lung Volume Reduction Surgery

Treatment options for patients with advanced or end-stage COPD (grade IV) with a primary emphysematous component are limited, although lung volume reduction surgery is a palliative surgical option. This includes patients with homogenous disease or disease that is focused in one area and not widespread throughout the lungs. Lung volume reduction surgery involves the removal of a portion of the diseased lung parenchyma. This reduces hyperinflation and allows the functional tissue to expand, resulting in improved elastic recoil of the lung and improved chest wall and diaphragmatic mechanics. This type of surgery does not cure the disease but may improve health status, exercise tolerance, and the patient's overall quality of life (GOLD, 2019).

Bronchoscopic lung volume reduction therapies are under investigation in clinical research protocols. These bronchoscopic procedures were developed to collapse areas of emphysematous lung and thus improve aeration of the functional lung tissue. Techniques include endobronchial placement of a one-way valve that allows air and mucus to exit the treated area but does not allow air to reenter. Another technique achieves biologic lung volume reduction through bronchoscopic instillation of nitinol coils into the airway of the hyperinflated lung tissue of patients with advanced emphysema. Because air can no longer enter the airway, the lung tissue beyond the sealed airway collapses over time. Patients receiving this procedure reported increased quality of life. However, there is insufficient evidence to determine the benefit–risk ratios, cost-effectiveness, and possible roles of these procedures in care of the patient with severe emphysema (GOLD, 2019).

Lung Transplantation

Lung transplantation is a viable option for definitive surgical treatment of severe COPD in select patients. It has been shown to improve quality of life and functional capacity in some patients with COPD. Limited not only by the shortage of donor organs, it is also a costly procedure with financial implications for months to years because of complications and the need for costly immunosuppressive medication regimens (GOLD, 2019).

Pulmonary Rehabilitation

Pulmonary rehabilitation, one of the most cost-effective treatment strategies, is a holistic intervention aimed at improving physical and psychological health of patients with COPD (GOLD, 2019). The primary goals of rehabilitation are to reduce symptoms, improve quality of life, and increase physical and emotional participation in everyday activities (GOLD, 2019). The benefits of this therapy include improvement of exercise capacity, reduction in the perceived intensity of breathlessness, improvement in health-related quality of life, reduction in the number of hospitalizations and days in the hospital, and reduction in the anxiety and depression associated with COPD (GOLD, 2019). Pulmonary rehabilitation services are multidisciplinary and include assessment, education,

smoking cessation, physical reconditioning, nutritional counseling, skills training, and psychological support. Patients are taught methods to alleviate symptoms. Breathing exercises, as well as retraining and exercise programs, are used to improve functional status.

Pulmonary rehabilitation is appropriate for most patients with COPD, particularly those with moderate or severe COPD (GOLD, 2019). Optimum benefits are achieved in programs that are 6 to 8 weeks in length (GOLD, 2019). Programs vary in duration and may be conducted in inpatient, outpatient, or home settings. Program selection depends on the patient's physical, functional, and psychosocial status; insurance coverage; availability of programs; and preference. Pulmonary rehabilitation may also be used therapeutically in other disorders besides COPD, including asthma, CF, lung cancer, interstitial lung disease, thoracic surgery, and lung transplantation. Despite their proven efficacy, comprehensive programs for patients with moderate to severe COPD are covered by Medicare only for those who meet specific criteria.

Patient Education

Nurses play a key role in identifying potential candidates for pulmonary rehabilitation and in facilitating and reinforcing the material learned in the rehabilitation program. Not all patients have access to a formal rehabilitation program. However, nurses can be instrumental in educating patients and families as well as facilitating specific services, such as respiratory therapy education, physical therapy for exercise and breathing retraining, occupational therapy for conserving energy during activities of daily living, and nutritional counseling. Patient education is a major component of pulmonary rehabilitation and includes a broad variety of topics. (See Chart 20-3, Nursing Research Profile: Managing Anxiety among Patients with Advanced COPD.)

Depending on the length and setting of the educational program, topics may include normal anatomy and physiology of the lung, pathophysiology and changes with COPD, medications and home oxygen therapy, nutrition, respiratory therapy treatments, symptom alleviation, smoking cessation, sexuality and COPD, coping with chronic disease, communicating with the health care team, and planning for the future (advance directives, living wills, informed decision making about health care alternatives). Education, including that relating to smoking cessation, should be incorporated into all aspects of care for COPD and in many settings (primary providers' offices, clinics, hospitals, home and community health care settings, and comprehensive rehabilitation programs).

Nutritional Therapy

Nutritional assessment and counseling are important for patients with COPD. Nutritional status is reflected in severity of symptoms, degree of disability, and prognosis. Significant weight loss is often a major problem; however, excessive weight can also be problematic, although it occurs less often. Most patients with COPD have difficulty gaining and maintaining weight. A thorough assessment of caloric needs and counseling about meal planning and supplementation is part of the rehabilitation process. Continual monitoring of weight and interventions as necessary are important parts of the care of patients with COPD.

Chart 20-3 **NURSING RESEARCH PROFILE**

Managing Anxiety among Patients with Advanced COPD

Bove, D. G., Midtgaard, G., Kaldan, D., et al. (2017). Home-based COPD psychoeducation: A qualitative study of the patients' experiences. *Journal of Psychosomatic Research, 98*, 71–77.

Purpose

This study was a nested posttrial qualitative study conducted in the context of a randomized controlled trial (RCT), *Efficacy of a Minimal Home-Based Psychoeducative Intervention in Patients with Advanced COPD.* Quantitative results from the RCT found that the nurse-led home-based intervention significantly reduced anxiety and increased mastery of dyspneic symptoms in patients with advanced COPD. The purpose of this qualitative study was to explore whether patients with advanced COPD who received this intervention found the intervention meaningful and applicable to their everyday lives.

Design

This qualitative study utilized the Interpretive Description methodology and collected data from 20 participants enrolled in the RCT. The participants accepted an invitation for the qualitative interview and signed informed consent to participate in the study. With one exception, all participants were interviewed at home. Interviews were conducted by researchers who did not previously meet the participants. All interviews were recorded and transcribed for data analysis.

Findings

Transcribed interviews revealed three main themes: (1) Making anxiety visible makes it manageable and provides relief; (2) Anxiety management is about getting control of cognitions; and (3) Being alone with anxiety and dyspnea. The first theme centered on recognition of anxiety as an aspect of COPD; nonetheless, participants expressed difficulty in talking about anxiety with relatives. Some participants felt that their spouses were annoyed when they talked about anxiety and dyspnea. They validated the usefulness of patient education materials that gave legitimacy to the problems they struggled with on a daily basis. The second theme focused on anxiety management and revealed that participants believed they had to deal with their anxiety privately. The behavioral cognitive intervention gave them the freedom to verbalize their thoughts and worries, especially thoughts of death and the dying process. The third theme revolved around feelings of isolation associated with anxiety and dyspnea. Participants verbalized that the psychoeducation intervention helped them establish a sense of control and self-preservation despite feeling alone during acute episodes.

Nursing Implications

This study validated that the nurse-led psychoeducation intervention that decreased anxiety and improved dyspneic symptoms among patients with advanced COPD also had the favorable effect of being perceived as meaningful and helpful to these participants. Participants in this study felt better equipped to manage their anxiety and dyspnea after having received the intervention, and found it valuable. They expressed relief that the intervention was focused upon their anxieties. These findings illustrate the importance of acknowledging and assessing anxiety during dyspneic episodes among patients with COPD. Legitimizing the anxiety experienced by patients with advanced COPD can establish a solid foundation for providing education to them and their spouses on the disease process and help them understand what to expect as the disease progresses. Increasing their knowledge on COPD and disease management will help them feel a sense of control that in turn could help diminish feelings of anxiety. Moreover, including family members in patient education could diminish feelings of isolation, which in turn will help decrease anxiety and ultimately improve disease management.

Palliative Care

Palliative care is integral for the patient with advanced COPD. Unfortunately, palliative care is often not considered until the disease is far advanced. The overall goals of palliative care are to manage symptoms and improve the quality of life for patients and families with advanced disease (GOLD, 2019). Areas addressed in palliative care include effective and empathetic communication with patients and families; close attention to pain, dyspnea, panic, anxiety, depression and other symptoms; psychosocial, spiritual and bereavement support; and coordination of the wide range of medical and social services required with this disease (GOLD, 2019). Palliative, hospice care, and end-of-life care are fundamental components of treatment for patients with advanced COPD (GOLD, 2019) (see Chapter 13).

Nursing Management

An overview of the nursing care of the patient with COPD is provided in Chart 20-4. Additional nursing considerations with regard to assessing the patient with COPD and promoting optimal nursing and collaborative outcomes are specified as follows.

Assessing the Patient

Assessment involves obtaining information about current symptoms as well as previous disease manifestations. See Chart 20-2 for sample questions that may be used to obtain a clear history of the disease process. In addition to the history, the nurse reviews the results of diagnostic tests.

Achieving Airway Clearance

Bronchospasm, which occurs in many pulmonary diseases, reduces the caliber of the small bronchi and may cause dyspnea, static secretions, and infection. Bronchospasm can sometimes be detected on auscultation with a stethoscope when wheezing or diminished breath sounds are heard. Increased mucus production, along with decreased mucociliary action, contributes to further reduction in the caliber of the bronchi and results in decreased airflow and decreased gas exchange. This is further aggravated by the loss of lung elasticity that occurs with COPD (GOLD, 2019). These changes in the airway require that the nurse monitor the patient for dyspnea and hypoxemia. The relief of bronchospasm is confirmed by measuring improvement in expiratory flow rates and volumes (the force of expiration, how long it takes to exhale, and the amount of air exhaled) as well as by assessing the dyspnea and making sure that it has lessened.

Chart 20-4 **PLAN OF NURSING CARE**

Care of the Patient with Chronic Obstructive Pulmonary Disease

Nursing Diagnosis: Impaired gas exchange and impaired airway clearance due to chronic inhalation of toxins
Goal: Improvement in gas exchange

Nursing Interventions	Rationale	Expected Outcomes
1. Evaluate current smoking status, educate regarding smoking cessation, and facilitate efforts to quit. a. Evaluate current smoking habits of patient and family. b. Educate regarding hazards of smoking and relationship to COPD. c. Evaluate previous smoking cessation attempts. d. Provide educational materials. e. Refer to a smoking cessation program or resource.	1. Smoking causes permanent damage to the lungs and diminishes the lungs' protective mechanisms. Airflow is obstructed, secretions are increased, and lung capacity is reduced. Continued smoking increases morbidity and mortality in COPD and is also a risk factor for lung cancer.	• Identifies the hazards of cigarette smoking • Identifies resources for smoking cessation, if appropriate • Enrolls in smoking cessation program, if appropriate • Reports success in stopping smoking
2. Evaluate current exposure to occupational toxins or pollutants and indoor/outdoor pollution. a. Emphasize primary prevention to occupational exposures. This	2. Chronic inhalation of both indoor and outdoor toxins causes damage to the airways and impairs gas exchange.	• Verbalizes types of inhaled toxins • Minimizes or eliminates exposures • Monitors public announcements regarding air quality and minimizes or eliminates exposures during episodes of severe pollution

is best achieved by elimination or reduction in exposures in the workplace. b. Educate regarding types of indoor and outdoor air pollution (e.g., biomass fuel burned for cooking and heating in poorly ventilated buildings, outdoor air pollution). c. Advise patient to monitor public announcements regarding air quality.		
Nursing Diagnosis: Impaired gas exchange associated with ventilation–perfusion inequality **Goal:** Improvement in gas exchange		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Administer bronchodilators as prescribed. a. Inhalation is the preferred route. b. Observe for side effects: tachycardia, arrhythmias, central nervous system excitation, nausea, and vomiting.	1. Bronchodilators dilate the airways. The medication dosage is carefully adjusted for each patient, in accordance with clinical response.	• Verbalizes need for bronchodilators and for taking them as prescribed • Evidences minimal side effects; heart rate near normal, absence of arrhythmias,

c. Assess for correct technique of pressurized metered-dose inhaler (pMDI), dry-powder inhaler (DPI), or small-volume nebulizer (SVN) administration. 2. Evaluate effectiveness of pMDI, DPI, or SVN treatments. a. Assess for decreased shortness of breath, decreased wheezing or crackles, loosened secretions, and decreased anxiety. b. Ensure that treatment is given before meals to avoid nausea and to reduce fatigue that accompanies eating. 3. Instruct and encourage patient in diaphragmatic breathing and effective coughing. 4. Administer oxygen by the method prescribed. a. Explain rationale and	2. Combining medication with aerosolized bronchodilators is typically used to control bronchoconstriction in an acute exacerbation. Generally, however, the pMDI with spacer is the preferred route (less cost and time to treatment). 3. These techniques improve ventilation by opening airways to facilitate clearing the airways of sputum. Gas exchange is improved, and fatigue is minimized. 4. Oxygen will correct the hypoxemia. Careful observation of the liter flow or the percentage given and its effect on the patient is important. These patients generally require low-flow oxygen rates of 1–2 L/min. Monitor and titrate to achieve desired PaO_2. Periodic arterial blood gases and pulse oximetry help evaluate adequacy of oxygenation. Smoking may	normal mentation • Reports a decrease in dyspnea • Shows an improved expiratory flow rate • Uses and cleans respiratory therapy equipment as applicable • Demonstrates diaphragmatic breathing and coughing • Uses oxygen equipment appropriately when indicated • Evidences improved arterial blood gases or pulse oximetry • Demonstrates correct technique for use of pMDI, DPI, or SVN

	importance to patient. b. Evaluate effectiveness; observe for signs of hypoxemia. Notify primary provider if restlessness, anxiety, somnolence, cyanosis, or tachycardia is present. c. Analyze arterial blood gases and compare with baseline values. When arterial puncture is performed and a blood sample is obtained, hold puncture site for 5 minutes to prevent arterial bleeding and development of ecchymoses. d. Initiate pulse oximetry to monitor oxygen saturation. e. Explain that no smoking is permitted by patient or visitors while oxygen is in use.	render pulse oximetry inaccurate because the carbon monoxide from cigarette smoke also saturates hemoglobin.

Nursing Diagnosis: Impaired airway clearance associated with bronchoconstriction, increased mucus production, ineffective cough, bronchopulmonary infection, and other complications

Goal: Achievement of airway clearance

Nursing Interventions	Rationale	Expected Outcomes
1. Adequately hydrate the patient.	1. Systemic hydration keeps secretions moist and easier to expectorate. Fluids must be given with caution if right- or left-sided heart failure is present.	• Verbalizes need to drink fluids
2. Instruct in and encourage the use of diaphragmatic breathing and coughing techniques.	2. These techniques help to improve ventilation and mobilize secretions without causing breathlessness and fatigue.	• Demonstrates diaphragmatic breathing and coughing • Performs postural drainage correctly
3. Assist in administering pMDI, DPI, or SVN.	3. This ensures adequate delivery of medication to the airways.	• Coughing is minimized
4. If indicated, perform postural drainage with percussion and vibration in the morning and at night as prescribed.	4. This uses gravity to help raise secretions so they can be more easily expectorated or suctioned.	• Does not smoke
5. Instruct patient to avoid bronchial irritants such as cigarette smoke, aerosols, extremes of temperature, and fumes.	5. Bronchial irritants cause bronchoconstriction and increased mucus production, which then interfere with airway clearance.	• Verbalizes that pollens, fumes, gases, dusts, and extremes of temperature and humidity are irritants to be avoided
6. Educate about early signs of infection that are to be reported to the primary provider immediately: a. Increased sputum production	6. Minor respiratory infections that are of no consequence to the person with normal lungs can produce fatal disturbances in the lungs of the person with COPD. Early	• Identifies signs of early infection • Is free of infection (no fever, no change in sputum, lessening of dyspnea) • Verbalizes need to notify primary provider at the earliest sign of infection • Verbalizes need to stay away from crowds or people with

b. Change in color of sputum c. Increased thickness of sputum d. Increased shortness of breath, tightness in chest, or fatigue e. Increased coughing f. Fever or chills 7. Administer antibiotics as prescribed. 8. Encourage patient to be immunized against influenza and *Streptococcus pneumoniae.*	recognition is crucial. 7. Antibiotics may be prescribed to prevent or treat infection. 8. Patients with respiratory conditions are prone to respiratory infections and are encouraged to be immunized.	colds in flu season • Discusses flu and pneumonia vaccines with clinician to help prevent infection
Nursing Diagnosis: Impaired breathing associated with shortness of breath, mucus, bronchoconstriction, and airway irritants **Goal:** Improvement in breathing pattern		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Instruct patient in diaphragmatic and pursed-lip breathing. 2. Encourage alternating activity with rest periods. Encourage patient to make some decisions (bath, shaving) about care based on tolerance level.	1. This helps patient prolong expiration time and decreases air trapping. With these techniques, patient will breathe more efficiently and effectively. 2. Pacing activities permits patient to perform activities without excessive distress. 3. This strengthens and conditions the respiratory muscles.	• Practices pursed-lip and diaphragmatic breathing and uses them when short of breath and with activity • Shows signs of decreased respiratory effort and paces activities • Uses inspiratory

3. Encourage the use of an inspiratory muscle trainer if prescribed.		muscle trainer as prescribed

Nursing Diagnosis: Impaired ability to manage regime associated with fatigue secondary to increased work of breathing and insufficient ventilation and oxygenation

Goal: Independence in health management activities

Nursing Interventions	Rationale	Expected Outcomes
1. Educate patient to coordinate diaphragmatic breathing with activity (e.g., walking, bending). 2. Encourage patient to begin to bathe self, dress self, walk, and drink fluids. Discuss energy conservation measures. 3. Educate patient about postural drainage if appropriate.	1. This will encourage the patient to be more active and to avoid excessive fatigue or dyspnea during activity. 2. As condition resolves, patient will be able to do more but needs to be encouraged to avoid increasing dependence. 3. This encourages patient to become involved in own care and prepares patient to manage at home.	• Uses controlled breathing while bathing, bending, and walking • Paces activities of daily living to alternate with rest periods to reduce fatigue and dyspnea • Describes energy conservation strategies • Performs same self-care activities as before • Performs postural drainage correctly

Nursing Diagnosis: Activity intolerance due to fatigue, hypoxemia, and impaired breathing
Goal: Improvement in activity tolerance

Nursing Interventions	Rationale	Expected Outcomes
1. Support patient in establishing a regular regimen of exercise using treadmill and exercise bicycle, walking, or other appropriate exercises, such as mall walking. a. Assess the patient's current level of functioning, and develop exercise plan based on baseline functional status. b. Suggest consultation with a physical therapist or pulmonary rehabilitation program to determine an exercise program specific to the patient's capability. Have portable oxygen unit available if oxygen is prescribed for exercise.	1. Muscles that are deconditioned consume more oxygen and place an additional burden on the lungs. Through regular, graded exercise, these muscle groups become more conditioned, and the patient can do more without getting as short of breath. Graded exercise breaks the cycle of debilitation.	• Performs activities with less shortness of breath • Verbalizes need to exercise daily and demonstrates an exercise plan to be carried out at home • Walks and gradually increases walking time and distance to improve physical condition • Exercises both upper and lower body muscle groups

Nursing Diagnosis: Difficulty coping associated with reduced socialization, anxiety, depression, lower activity level, and the inability to work

Goal: Attainment of an optimal level of coping

Nursing Interventions	Rationale	Expected Outcomes
1. Help the patient develop realistic goals.	1. Developing realistic goals will promote a sense of hope and accomplishment rather than defeat and hopelessness.	• Expresses interest in the future • Participates in the discharge plan
2. Encourage activity to level of symptom tolerance.	2. Activity reduces tension and decreases degree of dyspnea as patient becomes conditioned.	• Discusses activities or methods that can be performed to ease shortness of breath
3. Educate the patient about relaxation techniques or provide a relaxation recording on audiotape, CD, or digital audio available on smartphones or tablets.	3. Relaxation reduces stress, anxiety, and dyspnea and helps patient to cope with disability.	• Uses relaxation techniques appropriately
4. Enroll patient in pulmonary rehabilitation program where available.	4. Pulmonary rehabilitation programs have been shown to promote a subjective improvement in a patient's status and self-esteem as well as increased exercise tolerance and decreased hospitalizations.	• Expresses interest in a pulmonary rehabilitation program

Nursing Diagnosis: Lack of knowledge about self-management to be performed at home
Goal: Adherence to therapeutic program and home care

Nursing Interventions	Rationale	Expected Outcomes
1. Help patient identify/develop short- and long-term goals. a. Educate the patient about disease, medications, procedures, and how and when to seek help. b. Refer patient to pulmonary rehabilitation. 2. Give strong message to stop smoking. Discuss smoking cessation strategies. Provide information about resource groups (e.g., SmokEnders, American Cancer Society, American Lung Association).	1. Patient needs to be a partner in developing the plan of care and needs to know what to expect. Education about COPD is one of the most important aspects of care; it will prepare the patient to live and cope with the COPD and improve quality of life. 2. Smoking causes permanent damage to the lung and diminishes the lungs' protective mechanisms. Airflow is obstructed, and lung capacity is reduced. Smoking increases morbidity and mortality and is also a risk factor for lung cancer.	• Understands disease and what affects it • Verbalizes the need to preserve existing lung function by adhering to the prescribed program • Understands purposes and proper administration of medications • Stops smoking or enrolls in a smoking cessation program • Identifies when and whom to call for assistance

Collaborative Problem: Atelectasis
Goal: Absence of atelectasis on x-ray and physical examination

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor respiratory status, including rate and pattern of respirations, breath sounds,	1. A change in respiratory status, including tachypnea, dyspnea, and diminished or absent	• Normal (baseline for patient) respiratory

signs and symptoms of respiratory distress, and pulse oximetry. 2. Instruct in and encourage diaphragmatic breathing and effective coughing techniques. 3. Promote the use of lung expansion techniques (e.g., deep breathing exercises, incentive spirometry) as prescribed.	breath sounds, may indicate atelectasis. 2. These techniques improve ventilation and lung expansion and ideally improve gas exchange. 3. Deep breathing exercises and incentive spirometry promote maximal lung expansion.	rate and pattern • Normal breath sounds for patient • Demonstrates diaphragmatic breathing and effective coughing • Performs deep breathing exercises, incentive spirometry as prescribed • Pulse oximetry ≥90%

Collaborative Problem: Pneumothorax
Goal: Absence of signs and symptoms of pneumothorax

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor respiratory status, including rate and pattern of respirations, symmetry of chest wall movement, breath sounds, signs and symptoms of respiratory distress, and pulse oximetry. 2. Assess pulse. 3. Assess for chest pain and precipitating factors.	1. Dyspnea, tachypnea, tachycardia, acute pleuritic chest pain, tracheal deviation away from the affected side, absence of breath sounds on the affected side, and decreased tactile fremitus may indicate pneumothorax. 2. Tachycardia is associated with pneumothorax and anxiety. 3. Pain may accompany pneumothorax.	• Normal respiratory rate and pattern for patient • Normal breath sounds bilaterally • Normal pulse for patient • Normal tactile fremitus • Absence of pain • Tracheal position is midline • Pulse oximetry ≥90%

4. Palpate for tracheal deviation/shift away from the affected side. 5. Monitor pulse oximetry and, if indicated, arterial blood gases. 6. Administer supplemental oxygen therapy, as indicated. 7. Administer analgesic agents, as indicated, for chest pain. 8. Assist with chest tube insertion and use pleural drainage system, as prescribed.	4. Early detection of pneumothorax and prompt intervention will prevent other serious complications. 5. Recognition of deterioration in respiratory function will prevent serious complications. 6. Oxygen will correct hypoxemia; administer it with caution. 7. Pain interferes with deep breathing, resulting in decreased lung expansion. 8. Removal of air from the pleural space will re-expand the lung.	• Maintains normal oxygen saturation and arterial blood gas measurements • Exhibits no hypoxemia and hypercapnia (or returns to baseline values) • Absence of pain • Symmetric chest wall movement • Lungs fully expanded bilaterally on chest x-ray
Collaborative Problem: Respiratory failure **Goal:** Absence of signs and symptoms of respiratory failure; no evidence of respiratory failure on laboratory tests		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Monitor respiratory status, including rate and pattern of respirations, breath sounds, and signs and symptoms of acute respiratory distress. 2. Monitor pulse oximetry and arterial blood gases.	1. Early recognition of deterioration in respiratory function will avert further complications, such as respiratory failure, severe hypoxemia, and hypercapnia. 2. Recognition of changes in oxygenation and acid–base balance will guide in correcting and	• Normal respiratory rate and pattern for patient with no acute distress • Recognizes symptoms of hypoxemia and hypercapnia • Maintains normal arterial blood

3. Administer supplemental oxygen and initiate mechanisms for mechanical ventilation, as prescribed.	preventing complications. 3. Acute respiratory failure is a medical emergency. Hypoxemia is a hallmark sign. Administration of oxygen therapy and mechanical ventilation (if indicated) are critical to survival.	gases/pulse oximetry or returns to baseline values

Collaborative Problem: Pulmonary arterial hypertension
Goal: Absence of evidence of pulmonary arterial hypertension on physical examination or laboratory tests

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor respiratory status, including rate and pattern of respirations, breath sounds, pulse oximetry, and signs and symptoms of acute respiratory distress. 2. Assess for signs and symptoms of right-sided heart failure, including peripheral edema, ascites, distended neck veins, crackles, and heart murmur. 3. Administer oxygen therapy, as prescribed.	1. Dyspnea is the primary symptom of pulmonary arterial hypertension. Other symptoms include fatigue, angina, near-syncope, edema, and palpitations. 2. Right-sided heart failure is a common clinical manifestation of pulmonary arterial hypertension due to increased right ventricular workload. 3. Continuous oxygen therapy is a major component of management of pulmonary arterial hypertension; it prevents hypoxemia, thereby reducing pulmonary vascular constriction	• Normal respiratory rate and pattern for patient • Exhibits no signs and symptoms of right-sided failure • Maintains baseline pulse oximetry values and arterial blood gases

	(resistance) secondary to hypoxemia.

Diminishing the quantity and viscosity of sputum can clear the airway and improve pulmonary ventilation and gas exchange. All pulmonary irritants should be eliminated or reduced, particularly cigarette smoke, which is the most persistent source of pulmonary irritation. The nurse instructs the patient in directed or controlled coughing, which is more effective and reduces the fatigue associated with undirected forceful coughing. Directed coughing consists of a slow, maximal inspiration followed by breath-holding for several seconds and then two or three coughs. "Huff" coughing may also be effective. The technique consists of one or two forced exhalations (huffs) from low to medium lung volumes with the glottis open.

Chest physiotherapy (CPT), increased fluid intake, and bland aerosol mists (with normal saline solution or water) may be useful for some patients with COPD. The use of these measures must be based on the response and tolerance of each patient. **Chest physiotherapy (CPT)** includes postural drainage, chest percussion and vibration, and breathing retraining. The goals of CPT are consistent with improved airway clearance as they are to remove bronchial secretions, improve ventilation, and increase the efficiency of the respiratory muscles.

Postural Drainage (Segmented Bronchial Drainage)

Postural drainage allows the force of gravity to assist in the removal of bronchial secretions. The secretions drain from the affected bronchioles into the bronchi and trachea and are removed by coughing or suctioning. Because the patient usually sits in an upright position, secretions are likely to accumulate in the lower parts of the lungs. Several other positions (Fig. 20-6) are used so that the force of gravity helps move secretions from the smaller bronchial airways to the main bronchi and trachea. Each position contributes to effective drainage of a different lobe of the lungs; lower and middle lobe bronchi drain more effectively when the head is down, whereas the upper lobe bronchi drain more effectively when the head is up. The secretions then are removed by coughing.

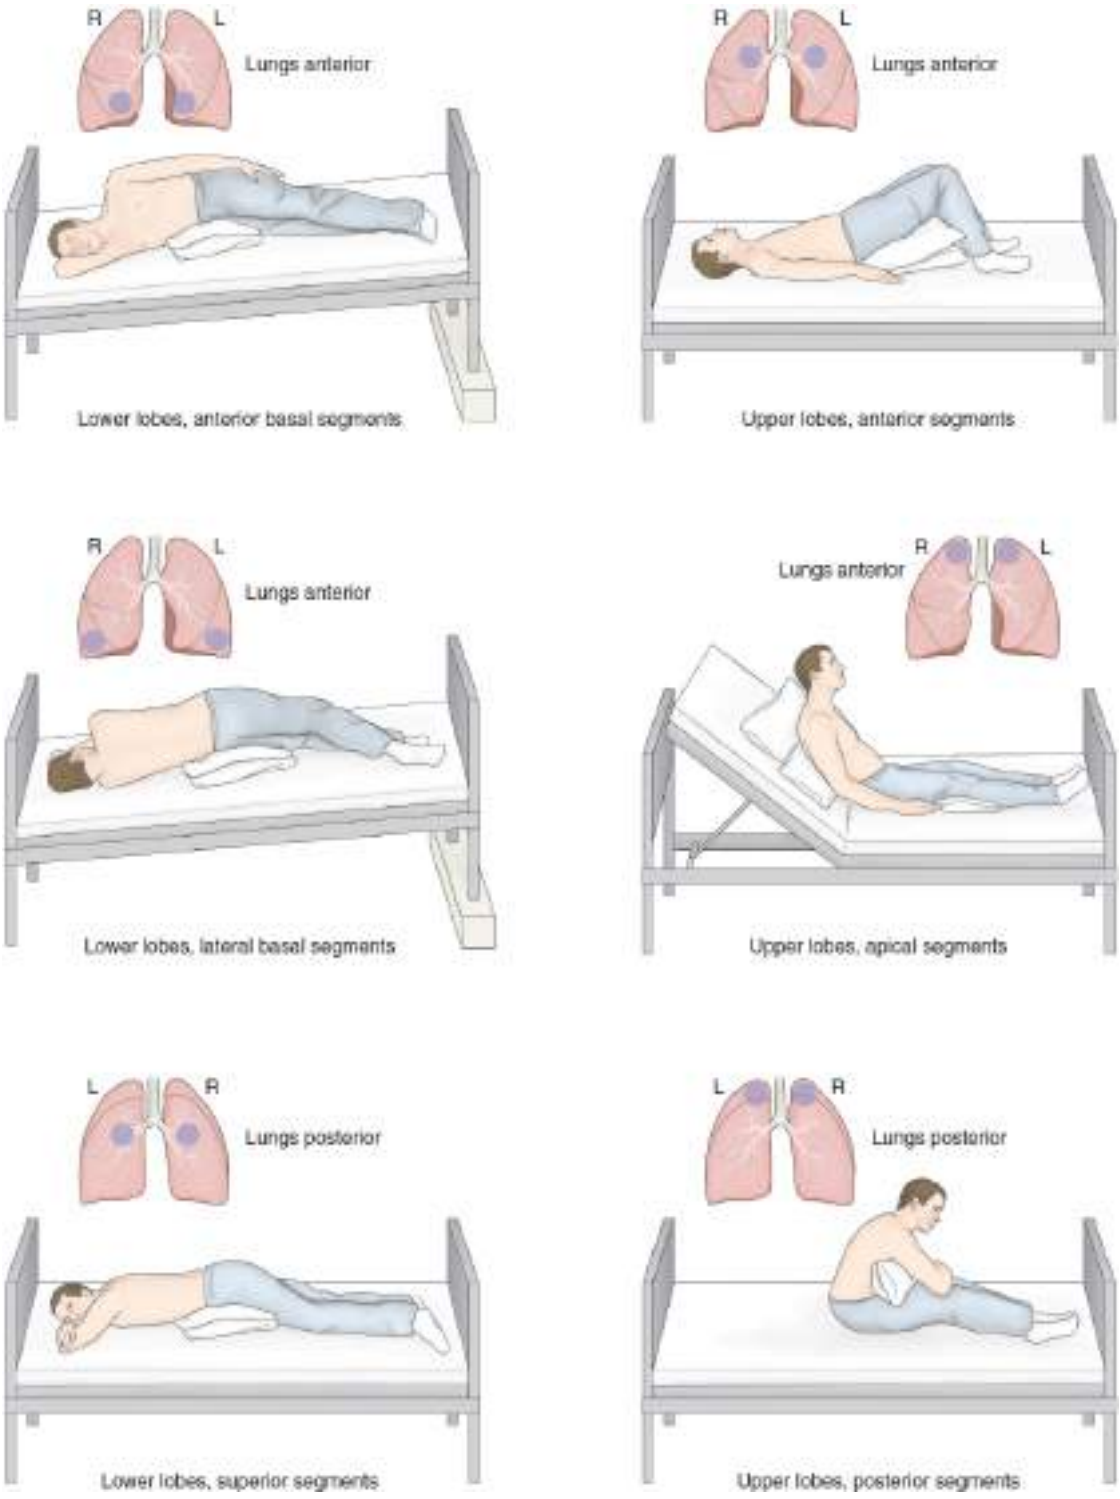


Figure 20-6 • Postural drainage positions and the areas of lung drained by each position.

The nurse should keep in mind the medical diagnosis, the lung lobes or segments involved, the cardiac status, and any structural deformities of the chest wall and spine. Auscultation of the chest before and after the procedure is used to identify the areas that need drainage and assess the effectiveness of

treatment. The nurse educates family members who will assist the patient at home to evaluate breath sounds before and after treatment. The nurse explores strategies that will enable the patient to assume the indicated positions at home. This may require the creative use of objects readily available at home, such as pillows, cushions, or cardboard boxes.

Postural drainage is usually performed two to four times daily, before meals (to prevent nausea, vomiting, and aspiration) and at bedtime. Prescribed bronchodilators, mucolytic agents, water, or saline may be nebulized and inhaled before postural drainage to dilate the bronchioles, reduce bronchospasm, decrease the thickness of mucus and sputum, and combat edema of the bronchial walls. The recommended sequence starts with positions to drain the lower lobes, followed by positions to drain the upper lobes.

The patient is made as comfortable as possible in each position and provided with an emesis basin, sputum cup, and paper tissues. The nurse instructs the patient to remain in each position for 10 to 15 minutes and to breathe in slowly through the nose and out slowly through pursed lips to help keep the airways open so that secretions can drain. If a position cannot be tolerated, the nurse helps the patient assume a modified position. When the patient changes position, instructions for how to cough and remove secretions are provided.

If the patient cannot cough, the nurse may need to suction the secretions mechanically. It also may be necessary to use chest percussion and vibration or a high-frequency chest wall oscillation (HFCWO) vest to loosen bronchial secretions and mucus plugs that adhere to the bronchioles and bronchi and to propel sputum in the direction of gravity drainage (see later discussion). If suctioning is required at home, the nurse instructs caregivers in safe suctioning technique and care of the suctioning equipment.

After the procedure, the nurse or family caregivers note the amount, color, viscosity, and character of the expelled sputum. The nurse evaluates the patient's skin color and pulse the first few times the procedure is performed. It may be necessary to administer oxygen during postural drainage.

If the sputum is foul smelling, postural drainage is performed in a room away from other patients or family members. Deodorizers may be used to counteract the odor. However, because aerosol sprays can cause bronchospasm and irritation, deodorizers should be used sparingly and with caution. After the procedure, the patient may find it refreshing to brush the teeth and use a mouthwash before resting.

Chest Percussion and Vibration

Thick secretions that are difficult to cough up may be loosened by percussing (tapping) and vibrating the chest or through the use of an HFCWO vest. Chest percussion and vibration help dislodge mucus adhering to the bronchioles and

bronchi. A scheduled program of coughing and clearing sputum, together with hydration, reduces the amount of sputum in most patients.

Chest percussion is carried out by cupping the hands and lightly striking the chest wall in a rhythmic fashion over the lung segment to be drained. The wrists are alternately flexed and extended so that the chest is cupped or clapped in a painless manner (Fig. 20-7). A soft cloth or towel may be placed over the segment of the chest that is being cupped to prevent skin irritation and redness from direct contact. Percussion, alternating with vibration, is performed for 3 to 5 minutes for each position. The patient uses diaphragmatic breathing during this procedure to promote relaxation (see later discussion on Breathing Retraining). As a precaution, percussion over chest drainage tubes and the sternum, spine, liver, kidneys, spleen, or breasts (in women) is avoided. Percussion is performed cautiously in older adult patients because of their increased incidence of osteoporosis and risk of rib fracture.

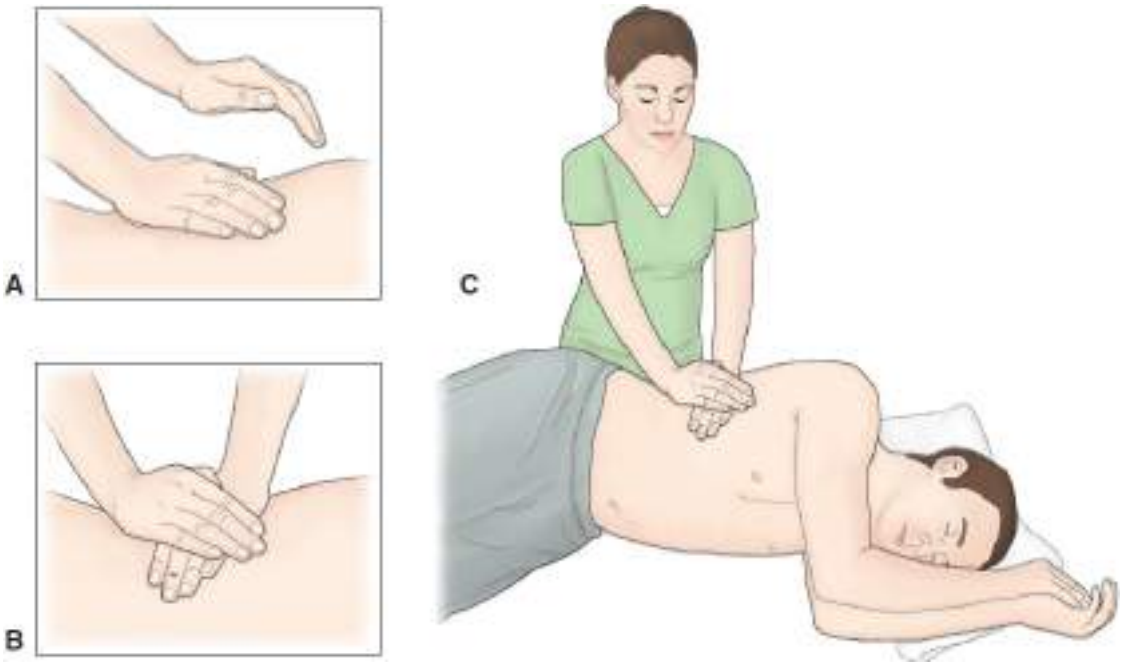

Figure 20-7 • Percussion and vibration. **A.** Proper hand position for percussion. **B.** Proper hand position for vibration. **C.** Proper technique for vibration. The wrists and elbows remain stiff; the vibrating motion is produced by the shoulder muscles.

Figure 20-8 • High-frequency chest wall oscillation (HFCWO) vest. © 2013 Hill-Rom Services, Inc. Reprinted with permission—all rights reserved.

Vibration is the technique of applying manual compression and tremor to the chest wall during the exhalation phase of respiration (see Fig. 20-7). This helps increase the velocity of the air expired from the small airways, thus freeing mucus. After three or four vibrations, the patient is encouraged to cough, contracting the abdominal muscles to increase the effectiveness of the cough.

The number of times the percussion and coughing cycle is repeated depends on the patient's tolerance and clinical response. The nurse evaluates breath sounds before and after application of these techniques.

An inflatable HFCWO vest (Fig. 20-8) may be used to provide chest therapy. The vest uses air pulses to compress the chest wall 8 to 18 times/sec, causing secretions to detach from the airway wall and enabling the patient to expel them by coughing. Patients prescribed vest therapy are generally more satisfied with this mode of treatment delivery than patients who receive manual CPT. Furthermore, research suggests that the vest is equally effective to manual CPT; however, the mode of therapy selected should consider the patient's specific needs and preferences (Hanlon, 2015; Powner, Nesmith, Kirkpatrick, et al., 2019). Technologic advances to the HFCWO vest include portable versions, the AffloVest® and Monarch®, which allow users to move about freely during therapy, thus improving patient adherence and satisfaction. In addition, CPT may also be delivered using specialized beds. These beds

feature programmable mattresses that deliver vibropercussion and may rotate the upper torso up to 45 degrees to help mobilize pulmonary secretions.

To increase the effectiveness of coughing, a flutter valve may be used, which is especially useful for patients who have CF (see later discussion). The **flutter valve** looks like a pipe but has a cap covering the bowl, which contains a steel ball. When the patient exhales actively into the device, movement of the ball causes pressure oscillations, thereby decreasing viscosity of the mucus, facilitating mucous clearance (Fig. 20-9).

When performing CPT, the nurse ensures that the patient is comfortable, is not wearing restrictive clothing, and has not just eaten. The nurse gives medication for pain, as prescribed, before applying the techniques of percussion and vibration, splints any incision, and provides pillows for support as needed. The positions are varied, but focus is placed on the affected areas. On completion of the treatment, the nurse assists the patient to assume a comfortable position.

If an HFCWO vest is being used, the patient may assume whatever position is most comfortable and may even continue to perform light activity during therapy, such as household chores (e.g., folding laundry) or engaging in hobbies (e.g., playing the guitar). The patient does not need to assume specific positions for the vest to be effective.

Treatment should be stopped if any of the following occur: increased pain, increased shortness of breath, weakness, lightheadedness, or hemoptysis. Therapy is indicated until the patient has normal respirations, can mobilize secretions, and has normal breath sounds, and until the chest x-ray findings are normal.

Nursing management of the patient using flutter valve therapy includes ensuring that the patient assumes the proper position, educating the patient on the technique for using the flutter valve, and setting realistic goals for the patient.

Improving Breathing Patterns

The breathing pattern of most people with COPD is shallow, rapid, and inefficient; the more severe the disease, the more inefficient the breathing pattern. Impaired breathing patterns and shortness of breath are due to the modified respiratory mechanics of the chest wall and lung resulting from **air trapping** (i.e., incomplete emptying of alveoli during expiration), ineffective diaphragmatic movement, airway obstruction, the metabolic cost of breathing, and stress. Breathing retraining may help improve breathing patterns. Training in diaphragmatic breathing reduces the respiratory rate, increases alveolar ventilation, and sometimes helps expel as much air as possible during expiration. Pursed-lip breathing helps slow expiration, prevent collapse of small airways, and control the rate and depth of respiration. It also promotes

relaxation, which allows patients to gain control of dyspnea and reduce feelings of panic.

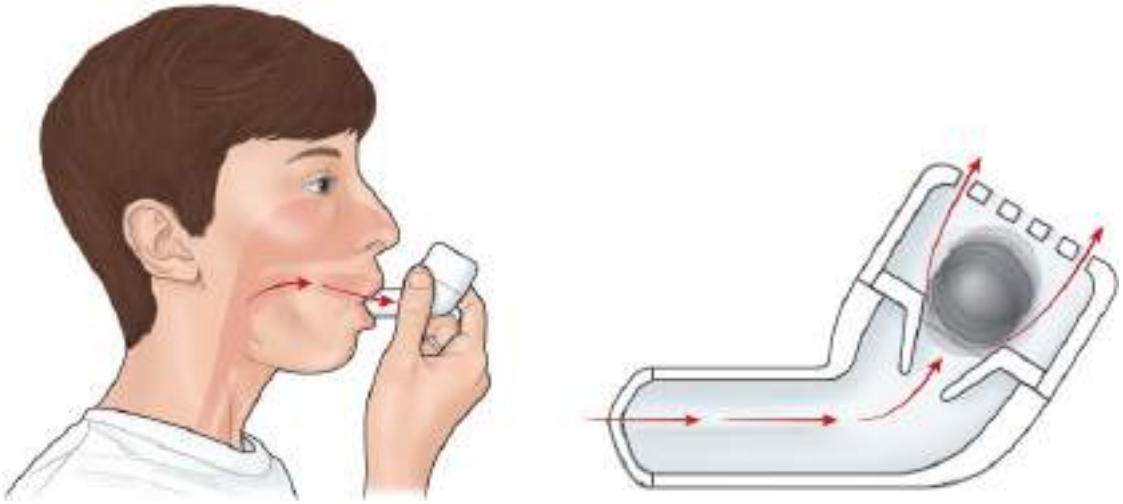

Figure 20-9 • The flutter valve is a handheld pipe-shaped device with a mouthpiece on one end, a perforated cover on the other end, and a steel ball on the inside. When the patient expires through this device, positive end pressure is enhanced, thus helping to clear respiratory secretions.

Chart 20-5 PATIENT EDUCATION

General Instructions

The nurse instructs the patient to:

- Breathe slowly and rhythmically to exhale completely and empty the lungs completely.
- Inhale through the nose to filter, humidify, and warm the air before it enters the lungs.
- Breathe more slowly by prolonging the exhalation time when feeling out of breath.
- Keep the air moist with a humidifier.

Diaphragmatic Breathing

Goal: To use and strengthen the diaphragm during breathing

The nurse instructs the patient to:

- Place one hand on the abdomen (just below the ribs) and the other hand on the middle of the chest to increase the awareness of the position of the diaphragm and its function in breathing.
- Breathe in slowly and deeply through the nose, letting the abdomen protrude as far as possible.
- Breathe out through pursed lips while tightening (contracting) the abdominal muscles.
- Press firmly inward and upward on the abdomen while breathing out.
- Repeat for 1 min; follow with a rest period of 2 min.
- Gradually increase duration up to 5 min, several times a day (before meals and at bedtime).

Pursed-Lip Breathing

Goal: To prolong exhalation and increase airway pressure during expiration, thus reducing the amount of trapped air and the amount of airway resistance

The nurse instructs the patient to:

- Inhale through the nose while slowly counting to 3—the amount of time needed to say “Smell a rose.”
- Exhale slowly and evenly against pursed lips while tightening the abdominal muscles. (Pursing the lips increases intratracheal pressure; exhaling through the mouth offers less resistance to expired air.)
- Count to 7 slowly while prolonging expiration through pursed lips—the length of time to say “Blow out the candle.”
- While sitting in a chair:
  Fold arms over the abdomen.
  Inhale through the nose while counting to 3 slowly.
  Bend forward and exhale slowly through pursed lips while counting to 7 slowly.

- While walking:
  Inhale while walking two steps.
  Exhale through pursed lips while walking four or five steps.

Breathing Retraining

Breathing retraining consists of exercises and breathing practices that are designed to achieve more efficient and controlled ventilation and to decrease the work of breathing. These exercises promote maximal alveolar inflation and muscle relaxation; relieve anxiety; eliminate ineffective, uncoordinated patterns of respiratory muscle activity; and slow the respiratory rate (Kacmarek et al., 2017). Slow, relaxed, rhythmic breathing also helps to control the anxiety that occurs with dyspnea. Specific breathing exercises include diaphragmatic and pursed-lip breathing (Chart 20-5).

Diaphragmatic breathing can become automatic with sufficient practice and concentration. Pursed-lip breathing, which improves oxygen transport, helps induce a slow, deep breathing pattern and assists the patient to control breathing, even during periods of stress. Breathing exercises should be practiced in several positions because air distribution and pulmonary circulation vary with the position of the chest.

Promoting Self-Care

As gas exchange, airway clearance, and the breathing pattern improve, the patient is encouraged to assume increasing participation in self-care activities. The patient is taught to coordinate diaphragmatic breathing with activities such as walking, bathing, bending, or climbing stairs. The patient should bathe, dress, and take short walks, resting as needed to avoid fatigue and excessive dyspnea. Fluids should always be readily available for the patient to promote adequate hydration. Patient education should address self-regulation of fluid intake. This could include the use of fluid diaries and using premeasured water containers to help patients become more cognizant of their fluid intake.

If management of secretions is a problem and some type of postural drainage or airway clearance maneuver is to be performed at home, the nurse or respiratory therapist instructs and supervises the patient before discharge or in an outpatient setting.

Improving Activity Tolerance

People with COPD have decreased exercise tolerance during specific periods of the day, especially in the morning on arising, because bronchial secretions have collected in the lungs during the night while the patient was lying down. The patient may have difficulty bathing or dressing and may become fatigued. Activities that require the arms to be supported above the level of the thorax may produce fatigue or respiratory distress but may be tolerated better after the

patient has been up and moving around for an hour or more. The nurse can help the patient reduce these limitations by planning self-care activities and determining the best times for bathing, dressing, and other daily activities.

Patients with COPD of all grades may benefit from exercise training programs. These benefits may include increased exercise tolerance and decreased dyspnea and fatigue (GOLD, 2019). Physical conditioning techniques include breathing exercises and general exercises intended to conserve energy and increase pulmonary ventilation. Graded exercises and physical conditioning programs using treadmills, stationary bicycles, and measured level walks can improve symptoms and increase work capacity and exercise tolerance. Any physical activity that can be performed regularly is helpful. Walking aids may be beneficial (GOLD, 2019). Lightweight portable oxygen systems are available for ambulatory patients who require oxygen therapy during physical activity. Education is focused on rehabilitative therapies to promote independence in executing activities of daily living. These may include pacing activities throughout the day or using supportive devices to decrease energy expenditure. The nurse evaluates the patient's activity tolerance and limitations and uses education strategies to promote independent activities of daily living. Other health care professionals (rehabilitation therapist, occupational therapist, physical therapist) may be consulted as additional resources.

Encouraging Effective Coping

Any factor that interferes with normal breathing quite naturally induces anxiety, depression, and changes in behavior. Constant shortness of breath and fatigue may make the patient irritable and apprehensive to the point of panic. Restricted activity (and reversal of family roles due to loss of employment), the frustration of having to work to breathe, and the realization that the disease is prolonged and unrelenting may cause the patient to become angry, depressed, and anxious. Sexual function may be compromised, which also diminishes self-esteem. The nurse should provide education and support to spouses or significant others and families, because the caregiver role in end-stage COPD can be challenging.

Monitoring and Managing Potential Complications

The nurse must assess for various complications of COPD, such as life-threatening respiratory insufficiency and failure, as well as respiratory infection and chronic atelectasis, which may increase the risk of respiratory failure. The nurse monitors for cognitive changes (personality and behavioral changes, memory impairment), increasing dyspnea, tachypnea, and tachycardia, which may indicate increasing hypoxemia and impending respiratory failure.

The nurse monitors pulse oximetry values to assess the patient's need for oxygen and administers supplemental oxygen as prescribed. The nurse also instructs the patient about signs and symptoms of respiratory infection that may worsen hypoxemia and reports changes in the patient's physical and cognitive status to the primary provider.

Bronchopulmonary infections must be controlled to diminish inflammatory edema and to permit recovery of normal ciliary action. Minor respiratory infections that are of no consequence to people with normal lungs can be life-threatening to people with COPD. Infection compromises lung function and is a common cause of respiratory failure in people with COPD. In COPD, infection may be accompanied by subtle changes. The nurse instructs the patient to report any signs of infection, such as a fever or change in sputum color, character, consistency, or amount. Any worsening of symptoms (increased tightness of the chest, increased dyspnea, fatigue) also suggests pneumonia and must be reported. Viral infections are hazardous to the patient because they are often followed by pneumonia caused by bacterial organisms, such as *Streptococcus pneumoniae, Moraxella catarrhalis,* and *Haemophilus influenzae* (Bartlett & Sethi, 2018).

To prevent pneumonia, the nurse encourages the patient with COPD to be immunized against influenza and pneumococcal pneumonia, because the patient is prone to respiratory infection. In addition, because each patient reacts differently to external exposures (significant air pollution, high or low temperatures, high humidity, strong smells), the nurse must assess the patient's actual and potential triggers that cause bronchospasm so that avoidance or a treatment plan can be established.

Pneumothorax is a potential complication of COPD and can be life-threatening in patients with COPD who have minimal pulmonary reserve. Patients with severe emphysematous changes can develop large bullae, which may rupture and cause a pneumothorax. Development of a pneumothorax may be spontaneous or related to an activity such as severe coughing or large intrathoracic pressure changes. If a rapid onset of shortness of breath occurs, the nurse should quickly evaluate the patient for potential pneumothorax by assessing the symmetry of chest movement, differences in breath sounds, and a decrease in pulse oximetry.

Over time, pulmonary hypertension may occur as a result of chronic hypoxemia, which causes the pulmonary arteries to constrict and leads to this complication. Pulmonary hypertension may be prevented by maintaining adequate oxygenation through an adequate hemoglobin level, improved ventilation–perfusion of the lungs, or continuous administration of supplemental oxygen (if needed).

Promoting Home, Community-Based, and Transitional Care

Referral for home, community-based, or transitional care is important. These referrals assess the patient's home environment in relation to their physical and psychological status and the patient's ability to adhere to a prescribed therapeutic regimen. These assessments include evaluating the patient's ability to cope with changes in lifestyle and physical status so that their medical management can be tailored to their specific needs. Once home care is set up, the visits provide an opportunity to reinforce the information and activities learned in the inpatient or outpatient pulmonary rehabilitation program and to have the patient and family demonstrate correct administration of medications and oxygen, if indicated, and performance of exercises. If the patient does not have access to a formal pulmonary rehabilitation program, the nurse provides the education and breathing retraining necessary to optimize the patient's functional status.

Educating Patients About Self-Care

When providing education about self-management, the nurse must assess the knowledge of patients and family members about self-care and the therapeutic regimen. The nurse should also consider whether they are comfortable with this knowledge. Familiarity with potential side effects of prescribed medications is essential. In addition, patients and family members need to learn the early signs and symptoms of infection and other complications so that they seek appropriate health care promptly. Nurses are key in promoting smoking cessation and educating patients about its importance. Patients diagnosed with COPD who continue to smoke must be encouraged and assisted to quit.

A major area of patient education involves setting and accepting realistic short-term and long-range goals. If the COPD is mild (e.g., grade I), the objectives of treatment are to increase exercise tolerance and prevent further loss of pulmonary function. If the COPD is severe (e.g., grade III), the objectives are to preserve current pulmonary function and relieve symptoms as much as possible. It is important to plan and share the goals and expectations of treatment with the patient. Both the patient and the care provider need patience to achieve these goals.

Chart 20-6 **PATIENT EDUCATION**

Use of Pressurized Metered-Dose Inhaler (pMDI)

The nurse instructs the patient to:

- Remove the cap and hold the inhaler upright.
- Shake the inhaler.
- Sit upright or stand upright. Breathe out slowly and all the way.
- Use one of two techniques: open- or closed-mouth technique.
  - *Open-mouth technique*
  - Place the pMDI 2 finger widths away from lips.
  - With mouth open and tongue flat, tilt outlet of the pMDI so that it is pointed toward the upper back of the mouth.
  - Actuate the pMDI and begin to breathe in slowly. Breathe slowly and deeply through the mouth and try to hold breath for 10 s.
  - *Closed-mouth technique*
  - Place the pMDI between the teeth and make sure the tongue is flat under the mouthpiece and does not block pMDI.
  - Seal lips around mouthpiece and actuate the pMDI. Breathe in slowly through the mouth and try to hold breath for 10 s.
- Repeat puffs as directed, allowing 1 min between puffs. There is no need to wait for other medications.
- Apply the cap to the pMDI for storage.
- After inhalation, rinse mouth with water when using a corticosteroid-containing pMDI.

The pMDI mouthpiece should be cleaned on a regular basis as should the nozzle of the canister based on the manufacturer's recommendations. As there are many types of inhalers, it is important to follow the manufacturer's instructions for use and care of the inhaler.

Adapted from Cairo, J. M. (2018). *Mosby's respiratory care equipment* (10th ed.). St. Louis, MO: Elsevier Mosby.

The nurse instructs the patient to avoid extremes of heat and cold. Heat increases the body temperature, thereby raising oxygen requirements, and cold tends to promote bronchospasm. Air pollutants such as fumes, smoke, dust, and even talcum, lint, and aerosol sprays may initiate bronchospasm. High altitudes aggravate hypoxemia.

A patient with COPD should adopt a lifestyle of moderate activity, ideally in a climate with minimal shifts in temperature and humidity. As much as possible, the patient should avoid emotional disturbances and stressful situations that might trigger a coughing episode. Self-management also includes getting sufficient rest and sleep. The medication regimen can be quite complex; patients receiving aerosol medications by a pMDI or other type of inhaler may be particularly challenged. The nurse must review educational

information and have the patient demonstrate correct pMDI use before discharge, during follow-up visits to a caregiver's office or clinic, and during home visits (Chart 20-6).

Smoking cessation goes hand in hand with lifestyle changes, and reinforcing the patient's efforts is a key nursing activity. Smoking cessation is the single most important therapeutic intervention for patients with COPD. There are many strategies, including prevention, cessation with or without oral or topical patch medications, and behavior modification techniques.

At times, the patient will need oxygen at home. The nurse instructs the patient or family in the methods for administering oxygen safely and informs the patient and family that oxygen is available in gas, liquid, and concentrated forms. The gas and liquid forms come in portable devices so that the patient can leave home while receiving oxygen therapy. Humidity must be provided while oxygen is used (except with portable devices) to counteract the dry, irritating effects of compressed oxygen on the airway (Chart 20-7). To help the patient adhere to the oxygen prescription, the nurse explains the proper flow rate and required number of hours for oxygen use as well as the dangers of arbitrary changes in flow rate or duration of therapy. The nurse also reassures the patient that oxygen is not "addictive" and explains the need for regular evaluations of blood oxygenation by pulse oximetry or arterial blood gas analysis.

Chart 20-7 **HOME CARE CHECKLIST**

Oxygen Therapy

At the completion of education, the patient and/or caregiver will be able to:

- State proper care of and administration of oxygen to patient.
- State primary provider's prescription for oxygen and the manner in which it is to be used.
- Indicate when a humidifier should be used.
- Identify signs and symptoms indicating the need for change in oxygen therapy.
- Describe precautions and safety measures to be used when oxygen is in use:
  - Know NOT to smoke or be around people who are smoking while using oxygen.
  - Post "No Smoking—Oxygen in Use" signs on doors.
  - Notify local fire department and electric company of oxygen use in home.
  - Never use paint thinners, cleaning fluids, gasoline, aerosol sprays, and other flammable materials while using oxygen.
  - Keep all methods of oxygen delivery at least 15 feet away from matches, candles, gas stove, or other source of flame, and 5 feet away from television, radio, and other appliances.
  - Keep oxygen tank out of direct sunlight.
  - When traveling in automobile, place oxygen tank on floor behind front seat.
  - If traveling by airplane, notify air carrier of need for oxygen at least 2 wks in advance.
- State how and when to place an order for more oxygen.
- Maintain and use equipment properly:
  - Identify when a portable oxygen delivery device should be used.
  - Demonstrate safe and appropriate use of and how to change from one oxygen delivery system to another (e.g., from oxygen concentrator to portable oxygen delivery).
  - Demonstrate correct adjustment of prescribed flow rate.
  - Describe how to clean and when to replace oxygen tubing.
  - Identify causes of malfunction of equipment and when to call for the replacement of equipment.
  - Describe the importance of determining that all electrical outlets are working properly.

Resources

See Chapter 2, Chart 2-6 for additional information related to durable medical equipment, adaptive equipment, and mobility skills.

Numerous educational materials are available to assist nurses in educating patients with COPD (see Resources at the end of the chapter).

Continuing and Transitional Care

Home visits by a nurse or respiratory therapist may be arranged based on the patient's status and needs. It is important to assess the patient's home environment, the patient's physical and psychological status, and the need for further education. The nurse reinforces educational points on how to use oxygen safely and effectively, including fire safety tips. To maintain a consistent quality of care and to maximize the patient's financial reimbursement for home oxygen therapy, the nurse ensures that the prescription given by the primary provider includes the diagnosis, the prescribed oxygen flow, and conditions for use (e.g., continuous use, nighttime use only). Because oxygen is a medication, the nurse reminds the patient receiving long-term oxygen therapy and the family about the importance of keeping follow-up appointments with the patient's primary provider. The patient is instructed to see the primary provider every 6 months or more often, if indicated. Arterial blood gas measurements and laboratory tests are repeated annually or more often if the patient's condition changes.

The nurse directs patients to community resources, such as pulmonary rehabilitation programs and smoking cessation programs, to help improve patients' ability to cope with their chronic condition and the therapeutic regimen and to provide a sense of worth, hope, and well-being. In addition, the nurse reminds the patient and family about the importance of participating in general health promotion activities and health screening.

Patients with COPD have indicated that information about their end-of-life needs is limited. Areas to discuss regarding end-of-life care may include symptom management, quality of life, satisfaction with care, information/communication, use of care professionals, use of differing care facilities, hospital admission, and place of death. It is crucial that patients know what to expect as the disease progresses. In addition, they should have information about their role in decisions regarding aggressiveness of care near the end of life and access to specialists who may help them and their families. As the disease course progresses, a holistic assessment of physical and psychological needs should be undertaken at each hospitalization, clinic visit, or home visit. This helps gauge the patient's assessment of the progression of the disease and its impact on quality of life and guides planning for future interventions and management (see Chapter 13 for additional information).

Bronchiectasis

Bronchiectasis is a chronic, irreversible dilation of the bronchi and bronchioles that results from destruction of muscles and elastic connective tissue. Numerous factors can induce or contribute to the development of bronchiectasis. Some of these include recurrent respiratory infections, CF, rheumatic and other systemic diseases, primary ciliary dysfunction, tuberculosis, or immune deficiency disorders (Barker, King, & Hollingsworth, 2019). Between 340,000 and 522,000 adults were living with non-CF bronchiectasis in 2013, estimates show (Weycker, Hansen, & Seifer, 2017). The increased prevalence of bronchiectasis, with an annual growth rate of 8% since 2001, may be attributed to advances in the technology for diagnosing the disease (GOLD, 2019). Bronchiectasis, a disease process separate from COPD, is often a comorbidity with COPD (GOLD, 2019). Bronchiectasis and sinusitis are the major respiratory manifestations of CF (discussed later in this chapter) (Barker et al., 2019).

Pathophysiology

The inflammatory process associated with pulmonary infections damages the bronchial wall, causing a loss of its supporting structure and resulting in thick sputum that ultimately obstructs the bronchi. The walls become permanently distended and distorted, impairing mucociliary clearance. In saccular bronchiectasis, each dilated peribronchial tube amounts to a lung abscess, the exudate of which drains freely through the bronchus. Bronchiectasis is usually localized, affecting a segment or lobe of a lung, most frequently the lower lobes.

The retention of secretions and subsequent obstruction ultimately cause the alveoli distal to the obstruction to collapse (atelectasis). Inflammatory scarring or fibrosis replaces functioning lung tissue. In time, the patient develops respiratory insufficiency with reduced vital capacity, decreased ventilation, and an increased ratio of residual volume to total lung capacity. There is impairment in the match of ventilation to perfusion (ventilation–perfusion imbalance) and hypoxemia.

Clinical Manifestations

Characteristic symptoms of bronchiectasis include chronic cough and the production of purulent sputum in copious amounts. Many patients with this disease have hemoptysis. Clubbing of the fingers is also common because of respiratory insufficiency. Patients usually have repeated episodes of pulmonary infection.

Assessment and Diagnostic Findings

Bronchiectasis is not readily diagnosed because the symptoms can be mistaken for those of chronic bronchitis. A definite sign is a prolonged history of productive, chronic cough, with sputum consistently negative for tubercle bacilli. The diagnosis is established by a CT scan, which reveals bronchial dilation. The advent of high-resolution CT scanning makes it possible to diagnose this disease during its earlier stages.

Medical Management

Treatment objectives are to promote bronchial drainage, to clear excessive secretions from the affected portion of the lungs, and to prevent or control infection and inflammation. Chest physiotherapy (CPT; see previous discussion) is essential for promoting airway drainage. Sometimes, mucopurulent sputum must be removed by bronchoscopy. Smoking cessation is important, because smoking impairs bronchial drainage by paralyzing ciliary action, increasing bronchial secretions, and causing inflammation of the mucous membranes, resulting in hyperplasia of the mucous glands.

Antibiotics are the cornerstone therapy for management of a bronchiectatic exacerbation. Antimicrobial therapy choice is based on the results of sensitivity studies on organisms cultured from sputum; however, empiric coverage (i.e., broad-spectrum antibiotics that are effective in treating commonly implicated pathogens) is often prescribed initially, pending results of sputum cultures. The most commonly implicated pathogens include *H. influenzae, M. catarrhalis, Staphylococcus aureus,* and *Pseudomonas aeruginosa* (Barker, Stoller, King, et al., 2018). Because infection with *P. aeruginosa* is associated with a greater rate of lung function deterioration, more aggressive oral or IV antibiotic therapy may be used for a longer duration. For patients with recurrent exacerbations (usually two or more during the past year), a low dose macrolide antibiotic may be used as preventative, ongoing therapy (Barker et al., 2018). In addition, patients should be vaccinated against influenza and pneumococcal pneumonia.

Secretion management is an issue for patients with bronchiectasis. Nebulized mucolytics may help to clear airway secretions. These drugs promote expectoration by breaking down the mucus blocking the airways. The administration of nebulized hypertonic saline also improves airway clearance by decreasing the viscosity of the mucus and improving the ability of secretions to move out of the airways. Bronchodilators might be prescribed to help open up the airways, thus enhancing the ability of the other medications (e.g., mucolytics, hypertonic saline) to mobilize secretions. These agents also allow a better passageway for the secretions to move through. Bronchodilators are typically administered at the beginning of each pulmonary treatment. Ensuring adequate hydration and employing CPT may also be of help in loosening and thinning secretions (Barker et al., 2018).

Surgical intervention, although used infrequently, may be indicated for patients who continue to expectorate large amounts of sputum and have repeated bouts of pneumonia and hemoptysis despite adherence to treatment regimens. The disease must involve only one or two areas of the lung that can be removed without producing respiratory insufficiency. The goals of surgical treatment are to conserve normal pulmonary tissue and to avoid infectious complications. Diseased tissue is removed, provided that postoperative lung function will be adequate. It may be necessary to remove a segment of a lobe (segmental resection), a lobe (lobectomy), or, rarely, an entire lung (pneumonectomy). Segmental resection is the removal of an anatomic subdivision of a pulmonary lobe. In select cases, video-assisted surgery (VATS) segmentectomy or lobectomy may be performed, which is associated with fewer complications and decreased length of stay. The chief advantage is that only diseased tissue is removed, and healthy lung tissue is conserved.

The surgery is preceded by a period of careful preparation. The objective is to obtain a dry (free of infection) tracheobronchial tree to prevent complications (atelectasis, pneumonia, bronchopleural fistula, and empyema). This is accomplished by postural drainage or, depending on the location, by direct suction through a bronchoscope. A course of antibacterial therapy may be prescribed. After surgery, care is the same as for any patient who has undergone chest surgery.

Nursing Management

Nursing management focuses on alleviating symptoms and helping patients clear pulmonary secretions. Patient education targets eliminating smoking and other factors that increase the production of mucus and hamper its removal. Patients and families are taught to perform postural drainage and to avoid exposure to people with upper respiratory or other infections. If the patient experiences fatigue and dyspnea, they are informed about strategies to conserve energy while maintaining as active a lifestyle as possible. The patient is educated about the early signs of respiratory infection and the progression of the disorder so that appropriate treatment can be implemented promptly. The presence of a large amount of mucus may decrease the patient's appetite and result in an inadequate dietary intake; therefore, the patient's nutritional status is assessed and strategies are implemented to ensure an adequate diet.

Asthma

Asthma is a heterogeneous disease, usually characterized by chronic airway inflammation (Global Initiative for Asthma [GINA], 2019a). This chronic inflammatory disease of the airways causes airway hyperresponsiveness,

mucosal edema, and mucus production. This inflammation ultimately leads to recurrent episodes of asthma symptoms: cough, chest tightness, wheezing, and dyspnea (Fig. 20-10). In the United States, asthma affects approximately 19 million adults and accounted for approximately 3564 deaths in 2017 (CDC, 2017b; Kochanek, Murphy, Xu, et al., 2019). Of these adults, 35.2% have intermittent severity and 64.8% have persistent severity of asthma symptoms (CDC, 2015). Nearly 10% of all ED visits are related to asthma (CDC, 2018c). Although asthma is the most common chronic disease of childhood, it can occur at any age. For most patients, asthma is a disruptive disease, affecting school and work attendance, occupational choices, physical activity, and general quality of life.

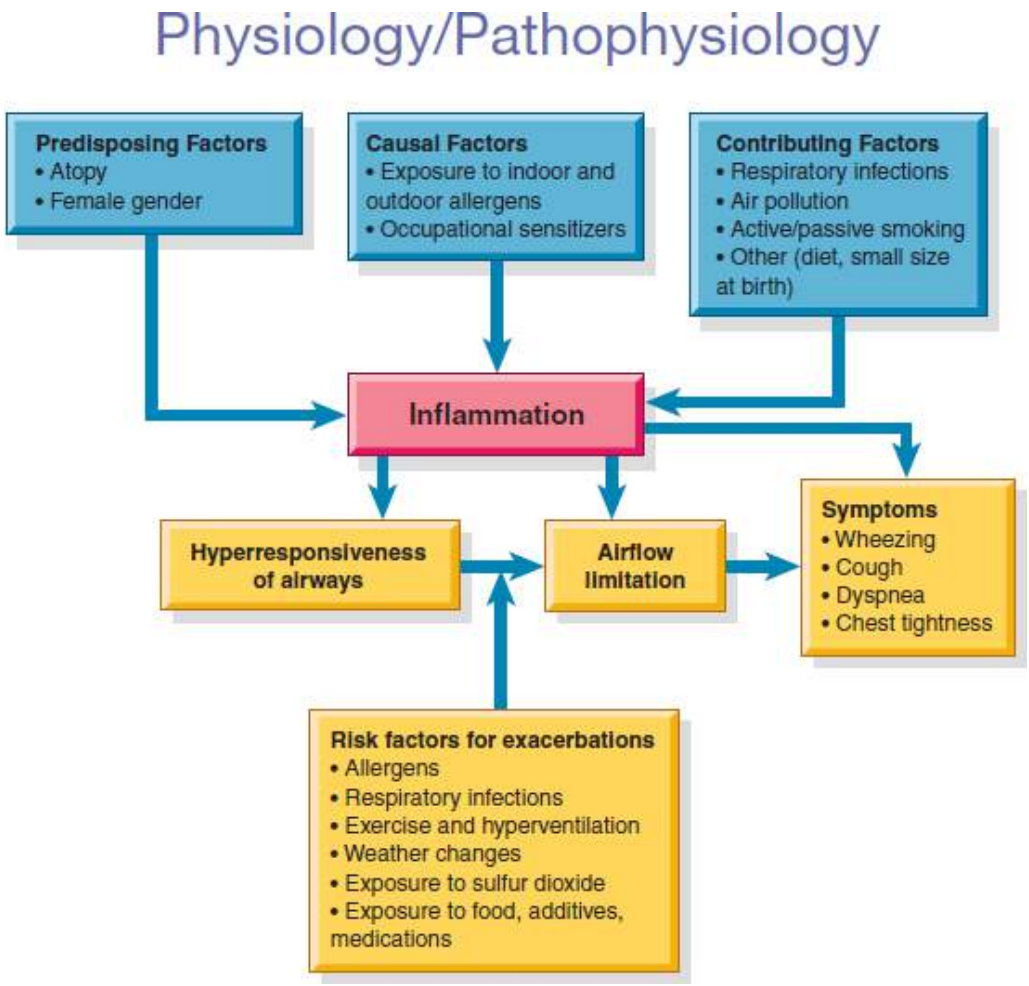

Figure 20-10 • Pathophysiology of asthma. Adapted from materials developed for the Global Initiative for Asthma (2019). Global strategy for asthma management and prevention. Available at: www.ginasthma.org

Twenty-one percent of patients with asthma smoke, even though cigarette smoke is known to trigger an attack, while nearly 17% of people without asthma smoke (CDC, 2015). Asthma–COPD overlap refers to patients who

have clinical presentations of both conditions (Papi, Brightling, Pedersen, et al., 2018). Smokers are at higher risk for having asthma–COPD overlap (Papi et al., 2018).

Despite increased knowledge regarding the pathology of asthma and the development of improved medications and management plans, the death rate from the disease continues to rise. Ethnic and racial disparities affect morbidity and mortality in asthma, particularly for African American and Hispanic/Latino American urban populations (Sullivan, Ghushchyan, Kavati, et al., 2019). Contributing to these disparities are epidemiologic considerations and risk factors that include genetic and molecular aspects; inner-city environments; limited community assets; health care access/delivery/and quality; and insufficient health insurance coverage.

Unlike other obstructive lung diseases, asthma is largely reversible, either spontaneously or with treatment. Patients with asthma may experience symptom-free periods alternating with acute exacerbations that last from minutes to hours or days.

Allergy is the strongest predisposing factor for asthma. Chronic exposure to airway irritants or allergens also increases the risk of asthma. Common allergens can be seasonal (e.g., grass, tree, weed pollens) or perennial (e.g., mold, dust, roaches, animal dander). Common triggers for asthma symptoms and exacerbations include airway irritants (e.g., air pollutants, cold, heat, weather changes, strong odors or perfumes, smoke, occupational exposure), foods (e.g., shellfish, nuts), exercise, stress, hormonal factors, medications, viral respiratory tract infections, and gastroesophageal reflux. Most people who have asthma are sensitive to a variety of triggers.

Pathophysiology

The underlying pathology in asthma is reversible diffuse airway inflammation that leads to long-term airway narrowing. This narrowing, which is exacerbated by various changes in the airway, includes bronchoconstriction, airway edema, airway hyperresponsiveness, and airway remodeling (Papi et al., 2018). The interaction of these factors determines the clinical manifestations and severity of asthma (GINA, 2019a). Over the course of a lifetime, the impact of increasing pathophysiologic changes and environmental susceptibility lead to an irreversible disease process.

Asthma is a complex disease process that involves numerous inflammatory and structural cells as well as mediators that lead to the disorder's effects. Mast cells, macrophages, T lymphocytes, neutrophils, and eosinophils all play a key role in the inflammation of asthma. When activated, mast cells release several chemicals called *mediators*. These chemicals, which include histamine, bradykinin, prostanoids, cytokines, leukotrienes, and other mediators, perpetuate the inflammatory response, causing increased blood flow,

vasoconstriction, fluid leak from the vasculature, attraction of white blood cells to the area, mucus secretion, and bronchoconstriction (Kacmarek et al., 2017; McCance & Huether, 2019).

During acute exacerbations of asthma, bronchial smooth muscle contraction or bronchoconstriction occurs quickly to narrow the airway in response to an exposure. Acute bronchoconstriction due to allergens results from an immunoglobulin E (IgE)-dependent release of mediators from mast cells; these mediators include histamine, tryptase, leukotrienes, and prostaglandins that directly contract the airway. In addition, alpha- and beta-2–adrenergic receptors of the sympathetic nervous system located in the bronchi play a role. When the alpha-adrenergic receptors are stimulated, bronchoconstriction occurs. The balance between alpha- and beta-2–adrenergic receptors is controlled primarily by cyclic 3′,5′-adenosine monophosphate (cyclic AMP). Beta-2–adrenergic stimulation results in increased levels of cyclic AMP, which inhibits the release of chemical mediators and causes bronchodilation.

As asthma becomes more persistent, the inflammation progresses and other factors may be involved in airflow limitation. These include airway edema, mucus hypersecretion, and the formation of mucus plugs. In addition, airway "remodeling" (i.e., structural changes) may occur in response to chronic inflammation, causing further airway narrowing.

Clinical Manifestations

The three most common symptoms of asthma are cough, dyspnea, and wheezing. In some instances, cough may be the only symptom. An asthma attack often occurs at night or early in the morning, possibly because of circadian variations that influence airway receptor thresholds.

An asthma exacerbation may begin abruptly but most frequently is preceded by increasing symptoms over the previous few days. There is cough, with or without mucus production. At times, the mucus is so tightly wedged in the narrowed airway that the patient cannot cough it up. There may be generalized wheezing (the sound of airflow through narrowed airways), first on expiration and then possibly during inspiration as well. Generalized chest tightness and dyspnea occur. Expiration requires effort and becomes prolonged. As the exacerbation progresses, diaphoresis, tachycardia, and a widened pulse pressure may occur along with hypoxemia and central cyanosis (a late sign of poor oxygenation). Severe, life-threatening hypoxemia can occur in asthma but is relatively uncommon. The hypoxemia is secondary to a ventilation–perfusion mismatch and readily responds to supplemental oxygenation.

Symptoms of exercise-induced asthma include maximal symptoms during exercise, absence of nocturnal symptoms, and sometimes only a description of a "choking" sensation during exercise.

Assessment and Diagnostic Findings

To establish the diagnosis, the clinician must determine that episodic symptoms of airflow obstruction are present, airflow is at least partially reversible, and other causes have been excluded. A positive family history and environmental factors, including seasonal changes, high pollen counts, mold, pet dander, climate changes (particularly cold air), and air pollution, are primarily associated with asthma. In addition, asthma is associated with a variety of foods, compounds, and occupation-related chemicals. Comorbid conditions that may accompany asthma include viral infections, gastroesophageal reflux disease, drug-induced asthma, and allergic bronchopulmonary aspergillosis. Other possible allergic reactions that may accompany asthma include eczema, rashes, and temporary edema. Questions in the assessment that may help to evaluate the patient's asthma control include:

- Have your symptoms awakened you at night or in the early morning?
- Have you needed your quick-acting relief medication more than usual?
- Have you needed unscheduled care for your asthma—a call to the primary provider's office, office visit, ED?
- Have your symptoms impacted your normal activities at school/work/sports?

During acute episodes, sputum and blood tests may disclose eosinophilia (elevated levels of eosinophils). Serum levels of IgE may be elevated if allergy is present. Arterial blood gas analysis and pulse oximetry reveal hypoxemia during acute attacks. Initially, hypocapnia and respiratory alkalosis are present. As the patient's condition worsens and they become more fatigued, the $PaCO_2$ may increase. Because carbon dioxide is 20 times more diffusible than oxygen, it is rare for $PaCO_2$ to be normal or elevated in a person who is breathing very rapidly.

Quality and Safety Nursing Alert

Normal $PaCO_2$ during an asthma attack may be a signal of impending respiratory failure.

During an exacerbation, the FEV_1 and FVC are markedly decreased but improve with bronchodilator administration (demonstrating reversibility). Pulmonary function is usually normal between exacerbations. The occurrence of a severe, continuous reaction is referred to as status asthmaticus and is considered life-threatening (see later discussion).

Asthma severity is considered in the selection of the initial type, amount, and schedule of treatments (GINA, 2019a). Disease severity is classified by current impairment and future risk of adverse events. Impairment is defined by the following factors: nighttime awakenings, the need for short-acting bronchodilators for symptom relief, work/school days missed, ability to engage in normal activities, and quality of life. Lung function is evaluated by spirometry. Assessment of risk of future adverse events is evaluated by numbers of exacerbations, the need for ED care or hospitalizations in the past year, demographic data (gender, ethnicity, nonuse of prescribed ICS therapy, existing smoking), psychosocial factors and attitudes, and beliefs about taking medication (GINA, 2019a).

Prevention

Patients with recurrent asthma should undergo testing to identify the substances that precipitate the symptoms. Possible causes are dust, dust mites, roaches, certain types of cloth, pets, horses, detergents, soaps, certain foods, molds, and pollens. If the attacks are seasonal, pollens can be strongly suspected. Patients are instructed to avoid the causative agents whenever possible. Knowledge is the key to quality asthma care. Evaluation of impairment and risk are primary methods that help ensure control.

Occupational asthma refers to asthma induced by exposure in the work environment to dusts, vapors, or fumes, with or without a preexisting diagnosis of asthma. An estimated 5% to 20% of new asthma cases in the United States are related to workplace exposures (GINA, 2019a). Work-related asthma should be part of the differential diagnosis of every case of adult-onset asthma. A detailed work history evaluation is key to identifying occupational asthma. Immediate treatment is aimed at removing or decreasing the exposure in the patient's environment and following the patient on an ongoing basis. Standard asthma medications may be prescribed to minimize bronchoconstriction and airway inflammation. In certain cases, patients may be impaired or disabled from the disease. Compensation systems are in place to protect a worker; however, these systems are often slow and complex to navigate.

Complications

Complications of asthma may include status asthmaticus, respiratory failure, pneumonia, and atelectasis. Airway obstruction, particularly during acute asthmatic episodes, often results in hypoxemia, requiring the administration of oxygen and the monitoring of pulse oximetry and arterial blood gases. Fluids are given because people with asthma are frequently dehydrated from diaphoresis and insensible fluid loss with hyperventilation.

Medical Management

Primary treatment focuses on preventing impairment of lung function, minimizing symptoms, and preventing exacerbations (Papi et al., 2018). GINA (2019a) recommendations are based on the concept of severity and control of asthma along with the domains of reducing impairment and reducing risk as keys to improving care. Asthma control is assessed by symptom management and future risk of adverse outcomes (GOLD, 2019). In an acute situation, symptom control includes using immediate intervention to diminish bronchoconstriction, which prevents increased anxiety resulting from progressive dyspnea. Uncontrolled anxiety could aggravate the situation and ultimately worsen dyspnea. Poor symptom control increases the risk of exacerbations (GINA, 2019a).

Pharmacologic Therapy

There are two general classes of asthma medications: quick-relief medications for immediate treatment of asthma symptoms and exacerbations and long-acting medications to achieve and maintain control of persistent asthma (Tables 20-5 and 20-6). Because the underlying pathology of asthma is inflammation, control of persistent asthma is accomplished primarily with regular use of anti-inflammatory medications. The route of choice for administration of these medications is a pMDI or other type of inhaler, because it allows for localized administration within the lungs (see Chart 20-6 and Table 20-3).

Quick-Relief Medications

Short-acting beta-2–adrenergic agonists (SABAs) (e.g., albuterol, levalbuterol, pirbuterol) are the medications of choice for relief of acute symptoms and prevention of exercise-induced asthma. They are used to relax smooth muscle.

Anticholinergics (e.g., ipratropium) inhibit muscarinic cholinergic receptors and reduce intrinsic vagal tone of the airway. These may be used in patients who do not tolerate short-acting beta-2–adrenergic agonists.

TABLE 20-5 Quick-Relief Medications for Treatment of Asthma

Medication	Indications/Mechanisms	Potential Adverse Effects	Nursing Considerations
Inhaled Short-Acting Beta-2 Adrenergic Agonists			
albuterol levalbuterol HFA metaproterenol sulfate	*Indications* Relief of acute symptoms; quick-relief medication Preventive treatment for exercise-induced bronchospasm *Mechanisms* Bronchodilation; binds to the beta-2 adrenergic receptor, producing smooth muscle relaxation and decreased bronchoconstriction	Tachycardia, muscle tremor, hypokalemia, increased lactic acid, headache, and hyperglycemia. Inhaled route causes few systematic adverse effects. Patients with preexisting cardiovascular disease, especially older adults, may have adverse cardiovascular reactions with inhaled therapy Lack of effect or need for regular use indicates inadequate asthma control	Instruct patient in correct use of inhaled agents and how to evaluate amount of remaining medication in pressurized metered-dose inhaler. Recommend periodic cleaning of device. Inform patient about possible adverse effects and need to inform primary provider about increased use of medication to control symptoms.
Anticholinergics			
ipratropium	*Indications* Relief of acute bronchospasm *Mechanisms* Bronchodilation; inhibition of muscarinic cholinergic receptors Reduction in vagal tone of airways May decrease mucous gland secretion	Dryness of mouth and respiratory secretions; may cause increased wheezing in some patients Does not block exercise-induced bronchospasm Is not effective in long-term control of asthma	Instruct patient in correct use of inhaled agents. Ensure adequate fluid intake. Assess patient for hypersensitivity to atropine, soybeans, peanuts; glaucoma; prostatic hypertrophy.
Corticosteroids			
Systemic methylprednisolone prednisolone	*Indications* For short-term (3–10 d) "burst;" to gain prompt	Blood glucose abnormalities, increased	Explain to patient that action is often rapid in

prednisone	control of inadequately controlled persistent asthma For moderate or severe exacerbations to prevent progression of exacerbation, reverse inflammation, speed recovery, and reduce rate of relapse *Mechanisms* Anti-inflammatory; block reaction to allergen and reduce hyperresponsiveness; inhibit cytokine production, adhesion protein activation, and inflammatory cell migration and activation; reverses beta-2 receptor downregulation	appetite, fluid retention, weight gain, mood alteration, hypertension, peptic ulcer, insomnia Consideration must be given to comorbidities that may be worsened by systemic corticosteroids	onset, although resolution of symptoms may take 3–10 d. Instruct patient about possible side effects and the importance of taking the medication as prescribed. If the patient is taking multiple doses a day, administering the last dose prior to 2 PM (when possible) may help to prevent sleep disturbances.

HFA, hydrofluoroalkane.

Adapted from Global Initiative for Asthma (GINA) (2019b). Pocket guide for asthma management. Retrieved on 7/01/2019 at: www.ginasthma.org/wp-content/uploads/2019/04/GINA-2019-main-Pocket-Guide-wms.pdf

TABLE 20-6 Long-Term Medications for Treatment of Asthma (Controller Medications)

Medication	Dosage Information	Indications/Mechanism	Potential Adverse Effects	Nursing Considerations
Inhaled Corticosteroids beclomethasone dipropionate budesonide ciclesonide flunisolide fluticasone mometasone furoate		Indication Long-term prevention of symptoms suppression, control, and reversal of inflammation Reduce need for oral corticosteroid Mechanism Anti-inflammatory; block late reaction to allergen and reduce airway hyperresponsiveness Inhibit cytokine production, adhesion protein activation, and inflammatory cell migration and activation; reverse beta-2 receptor downregulation; inhibit microvascular leakage	Cough, dysphonia, oral thrush (candidiasis), headache In high doses, systemic effects may occur (e.g., adrenal suppression, osteoporosis, skin thinning, easy bruising)	Instruct patient in correct use of pMDI and use of spacer/holding chamber devices Instruct patient to rinse mouth after inhalation to reduce local side effects.

Systemic Corticosteroids methylprednisolone prednisolone prednisone	*Indications* For prevention of symptoms in severe persistent asthma; suppression, control, and reversal of inflammation *Mechanism* Same as inhaled corticosteroids	*Long-Term Use:* adrenal axis suppression, growth suppression, dermal thinning, hypertension, diabetes, Cushing's syndrome, cataracts, muscle weakness, and, in rare instances, impaired immune function, insomnia Consideration should be given to comorbidities that could be worsened by systemic corticosteroids	Instruct patient about possible side effects and the importance of taking the medication as prescribed (usually a single dose in the morning daily or on an alternate-day schedule, which may produce less adrenal suppression). If the patient is taking multiple doses a day, administering the last dose prior to 2 PM (when possible) may help to prevent sleep disturbances.
Long-Acting Beta-2 Adrenergic Agonists Inhaled salmeterol formoterol	*Indications* Long-term prevention of symptoms, added to ICS Prevention of exercise-induced bronchospasm *Mechanism* Bronchodilation; smooth muscle relaxation following adenylate cyclase activation and increase in cAMP, producing functional antagonism of bronchoconstriction Compared to SABA, salmeterol (but not formoterol) has slower onset of action (15–30 min). Both salmeterol and formoterol have longer duration (>12 h) compared to SABA	Should not be used to treat acute symptoms or exacerbations Decreased protection against exercise-induced bronchospasm may occur with regular use Tachycardia, muscle tremor, hypokalemia, ECG changes with overdose. A diminished bronchoprotective effect may occur within 1 wk of chronic therapy. Potential risk of uncommon, severe, life-threatening, or fatal exacerbation	Reinforce to patient that these medications should not be used to treat acute asthma symptoms or exacerbations. Instruct patient about correct use of pMDI or inhaler inhaler.
Oral albuterol sustained release		Inhaled route is preferred to oral route because LABAs are longer acting and have fewer side effects than oral sustained-release agents	
Phosphodiesterase Inhibitors theophylline sustained-release tablets and capsules	*Indications* Long-term control and prevention of symptoms in mild persistent asthma or as adjunctive with ICS, in moderate or persistent asthma *Mechanism* Bronchodilation; smooth muscle relaxation from phosphodiesterase inhibition and possibly adenosine antagonism May affect eosinophilic infiltration into bronchial mucosa as well as decreased T-lymphocyte numbers in epithelium Increases diaphragm contractility and mucociliary clearance	Dose-related acute toxicities include tachycardia, nausea and vomiting, tachyarrhythmias (SVT), central nervous system stimulation, headache, seizures, hematemesis, hyperglycemia, and hypokalemia Adverse effects at usual therapeutic doses include insomnia, gastric upset, aggravation of ulcer or reflux, and difficulty in urination in older males who have prostatism Not generally recommended for exacerbations. There is minimal evidence for added benefit to optimal dose of SABA	Maintain steady-state serum concentrations between 5 and 15 mcg/mL. Be aware that absorption and metabolism may be affected by numerous factors that can produce significant changes in steady-state serum theophylline concentrations. Instruct patient to discontinue if toxicity occurs. Serum concentration monitoring is mandatory. Inform patient about the importance of blood tests to monitor serum concentration. Instruct patient to check with primary provider before taking any new medications.

Combined Medication (Corticosteroid/Long-Acting Beta-2 Adrenergic Agonist)				
fluticasone/ salmeterol	Lowest dose of DPI or HFA used for patients whose asthma is not controlled on low- to medium-dose ICS Higher dose of DPI or HFA used for patients whose asthma is not controlled on medium- to high-dose ICS	DPI 100 mcg/50 mcg 250 mcg/50 mcg 500 mcg/50 mcg HFA 45 mcg/21 mcg 115 mcg/21 mcg 230 mcg/21 mcg		
budesonide/ formoterol fluticasone furoate/vilanterol mometasone/ formoterol	Lower dose used for patients who have asthma not controlled on low- to medium-dose ICS Higher dose used for patients who have asthma not controlled on medium- to high-dose ICS Used if asthma not controlled on long-term asthma control medication.	HFA pMDI 80 mcg/4.5 mcg 160 mcg/4.5 mcg 100 mcg/25 mcg 200 mcg/25 mcg 100 mcg/5 mcg 200 mcg/5 mcg	Do not use with other long-acting beta-agonist drugs	
Leukotriene Modifiers				
Leukotriene Receptor Antagonists montelukast Available in tablets and granules		Mechanism Selective competitive inhibitor of CysLT1 receptor Indications Long-term control and prevention of symptoms in mild persistent asthma for patients ≥1 year of age May also be used with ICS as combination therapy in moderate persistent asthma	May attenuate EIB in some patients, but less effective than ICS therapy LTRA + LABA should not be used as a substitute for ICS + LABA. Headache, dizziness, upper respiratory infections, pharyngitis, sinusitis	Instruct patient to take at least 1 h before meals or 2 h after meals.
zafirlukast Available in tablets		Long-term control and prevention of symptoms in mild persistent asthma may also be used with ICS as combination therapy in moderate persistent asthma	Cases of reversible hepatitis have been reported along with rare cases of irreversible hepatic failure resulting in death and liver transplantation	Inform patient that zafirlukast can inhibit the metabolism of warfarin. INRs should be monitored if patient is taking both zafirlukast and montelukast. Instruct patients to discontinue use if they experience signs and symptoms of liver dysfunction (right upper quadrant pain, pruritus, lethargy, jaundice, nausea), and to notify their primary provider.
5-Lipoxygenase Inhibitor zileuton		Mechanism Inhibits the production of leukotrienes from arachidonic acid, both LTB and the cysteinyl leukotrienes Indications Long-term control and prevention of symptoms in mild persistent asthma for patients May be used with ICS as combination therapy in moderate persistent asthma in patients	Elevation of liver enzymes has been reported. Limited case reports of reversible hepatitis and hyperbilirubinemia	Inform patient that zileuton can inhibit the metabolism of warfarin and theophylline. Therefore, the doses of these medications should be monitored accordingly. Educate patient about the importance of monitoring medication levels and tests of liver function.

Immunomodulators				
IgE-Inhibiting IgG monoclonal antibody omalizumab Given by subcutaneous injection	Dose is given either every 2 or 4 wks and depends on the patient's body weight and IgE level before therapy A maximum of 150 mg can be given as 1 injection Medication needs to be stored under refrigeration at 2°–8°C (35.6°–46.4°F)	*Indications* Long-term control and prevention of symptoms with moderate or severe persistent allergic asthma inadequately controlled with ICS *Mechanism* Monoclonal antibody that binds to circulating IgE, preventing it from binding to the high-affinity receptors on basophils and mast cells Decreases mast cell mediator release from allergen exposure	Anaphylaxis has been reported in 0.2% of treated patients Pain, bruising, and skin reactions (itching, redness, stinging) at injection sites It is unknown if patients will develop significant antibody titers to the drug with long-term administration	Monitor patients for allergic reactions or anaphylaxis following administration. Be prepared to initiate emergency treatment if anaphylaxis occurs. Instruct patient about signs and symptoms that indicate allergic reaction and immediate action to take. Remind patient to continue to take other medications prescribed for treatment of asthma.
Interleukin-5 Receptor (IL-5R) Antagonists mepolizumab reslizumab benralizumab Mepolizumab and benralizumab are given by subcutaneous injection. Reslizumab is given by intravenous infusion.		*Indications* Long-term control and prevention of symptoms in patients with severe persistent asthma of eosinophilic phenotype. Mepolizumab and benralizumab are approved for adolescents and adults ≥12 years of age, and reslizumab is approved for adults ≥18 years of age *Mechanism* Monoclonal antibodies that decrease production and survival of eosinophils by binding to and inhibiting IL-5R. However, the specific mechanism in which these agents exert their effects in asthma has not been definitively established		Ensure the patient understands appropriate administration technique to minimize administration and dosing errors and to optimize patient safety. Note that dose and frequency of administration of biologics may be influenced by various factors such as weight, blood work, or the need for titration. Education is key to adherence and it is important to confirm patient knowledge and understanding.
Interleukin-4 Receptor Alpha (IL-4Rα) Antagonist dupilumab Given by subcutaneous injection		*Indications* Long-term control and prevention of symptoms in adolescents and adults ≥12 years of age with moderate or severe asthma of eosinophilic phenotype or oral corticosteroid dependent asthma *Mechanism* Monoclonal antibody that binds to IL-4Rα, a receptor present on various cell types and mediators involved in the inflammatory response, that inhibits IL-4 and IL-13 cytokine-induced inflammatory responses. However, the specific mechanism in which dupilumab exerts its effects in asthma has not been definitively established		

cyclic AMP; cyclic 3′,5′-adenosine monophosphate; CysLT1, cysteinyl leukotriene receptor 1; DPI, dry-powder inhaler; ECG, electrocardiogram; EIB, exercise-induced bronchospasm; HFA, hydrofluoroalkane; ICS, inhaled corticosteroid; IgE, immunoglobulin E; IgG, immunoglobulin G; INR, international normalized ratio; LABA, long-acting beta-2 adrenergic agonist; LTB, leukotriene B; LTRA, leukotriene receptor antagonist; pMDI, pressurized metered-dose inhaler; SABA, short-acting beta-2 adrenergic agonist; SVT, supraventricular tachycardia.

The combination medication ipratropium bromide and albuterol sulfate is used for quick relief of asthma symptoms and acute exacerbations. This medication is administered using a small-volume nebulizer (SVN; discussed previously).

Long-Acting Control Medications

Corticosteroids are the most potent and effective anti-inflammatory medications currently available. They are broadly effective in alleviating symptoms, improving airway function, and decreasing peak flow variability.

Initially, an inhaled form is used. All patients should rinse their mouth with water (and should not swallow the rinse) after administration of ICSs to prevent thrush, a common complication associated with the use of these drugs. However, those who lack the coordination to ensure proper administration technique should use a spacer. This will reduce medication deposition within the mouth and further reduce the risk of thrush. A systemic preparation may be used to gain rapid control of the disease; to manage severe, persistent asthma; to treat moderate to severe exacerbations; to accelerate recovery; and to prevent recurrence.

Long-acting beta-2 adrenergic agonists (LABAs) are used with anti-inflammatory medications to control asthma symptoms, particularly those that occur during the night. These agents are also effective in the prevention of exercise-induced asthma. LABAs are not indicated for immediate relief of symptoms. Salmeterol and formoterol have duration of bronchodilation of at least 12 hours. They are used with other medications in long-term control of asthma.

Leukotriene modifiers (inhibitors), or *antileukotrienes,* are a class of medications that include montelukast, zafirlukast, and zileuton. Leukotrienes, which are synthesized from membrane phospholipids through a cascade of enzymes, are potent bronchoconstrictors that also dilate blood vessels and alter permeability. Leukotriene inhibitors act either by interfering with leukotriene synthesis or by blocking the receptors where leukotrienes exert their action. They may provide an alternative to ICSs for mild persistent asthma, or they may be added to a regimen of ICSs in more severe asthma to attain further control.

Phosphodiesterase inhibitors cause bronchodilation and act as mild anti-inflammatory agents by influencing epinephrine release. Theophylline is used as an add-on agent and in conjunction with inhaled steroids; however, it is not as effective in treating asthma as the medications previously discussed. Theophylline should be used with reservation because it has the potential to cause many drug interactions and its higher risk of side effects (GOLD, 2019).

Immunomodulators prevent binding of IgE to the high-affinity receptors of basophils and mast cells. The U.S. Food and Drug Administration (FDA) approved five biologic immunomodulators for the treatment of asthma (omalizumab, mepolizumab, reslizumab, benralizumab, and dupilumab) and several others are in development. Medications in this class are add-on treatments used when patients experience poor symptom control on high-dose inhaled corticosteroids with a LABA (ICS-LABA). These immunomodulators are monoclonal antibodies that are derived from biologic sources and are therefore sometimes referred to as biologics. They help with symptom control by interfering with the inflammatory response that is associated with acute asthmatic episodes (Krings, McGregor, Bacharier, et al., 2019). Cost and patient preference for route of administration must be considered when adding

on this treatment (GOLD, 2019). Biologics are either administered subcutaneously or intravenously.

Management of Exacerbations

Asthma exacerbations are best managed by early treatment and education, including the use of written action plans as part of any overall effort to educate patients about self-management techniques, especially those with moderate or severe persistent asthma or with a history of severe exacerbations (GINA, 2019a). GINA (2019a) recommends using an ICS treatment for the prevention of exacerbations in adults. Short-acting beta-2–adrenergic agonist medications are used at the time of the exacerbation for prompt relief of airflow obstruction. Systemic corticosteroids may be necessary to decrease airway inflammation in patients who fail to respond to inhaled beta-adrenergic medications. In some patients, oxygen supplementation may be required to relieve hypoxemia associated with moderate to severe exacerbations. In addition, response to treatment may be monitored by serial measurements of lung function. Patients with persistent symptoms and/or exacerbations may benefit from routinely using ICS-LABA to improve symptom management and prevent the occurrence of exacerbations.

Evidence from clinical trials suggests that antibiotic therapy, whether given routinely or when suspicion of bacterial infection is low, is not beneficial for asthma exacerbations (GINA, 2019a). Antibiotics may be appropriate in the treatment of acute asthma exacerbations in patients who have symptoms of a respiratory infection (e.g., fever and purulent sputum, evidence of pneumonia, suspected bacterial sinusitis).

Despite insufficient data supporting or refuting the benefits of using a written asthma action plan as compared to medical management alone, it is recommended to use a written asthma action plan to educate patients about self-management (Fig. 20-11). Plans can be based on either symptoms or peak flow measurements. They should focus on daily management as well as the recognition and handling of worsening symptoms. Patient self-management and early recognition of problems lead to more efficient communication with health care providers about asthma exacerbations (GINA, 2019a).

Peak Flow Monitoring

Peak flow meters measure the highest airflow during a forced expiration (Fig. 20-12). Daily peak flow monitoring is recommended for patients who meet one or more of the following criteria: have moderate or severe persistent asthma, have poor perception of changes in airflow or worsening symptoms, have unexplained response to environmental or occupational exposures, or at the discretion of the clinician and patient (GINA, 2019a). Peak flow

monitoring helps measure asthma severity and, when added to symptom monitoring, indicates the current degree of asthma control.

The patient is instructed in the proper technique (Chart 20-8), particularly about using maximal effort; peak flows are monitored for 2 or 3 weeks after receipt of optimal asthma therapy. Then, the patient's "personal best" value is measured. The green (80% to 100% of personal best), yellow (60% to 80%), and red (less than 60%) zones are determined, and specific actions are delineated for each zone, enabling the patient to monitor and manipulate their own therapy after careful instruction (GINA, 2019a).

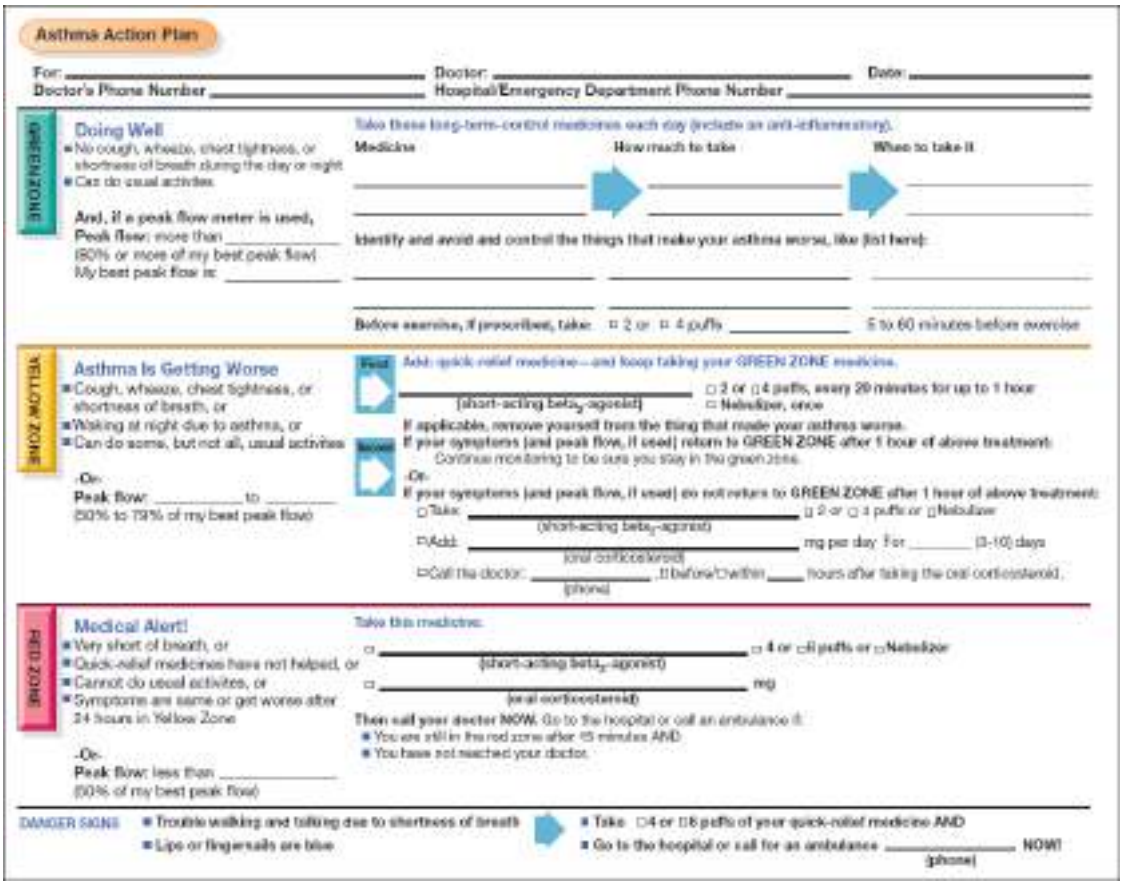

Figure 20-11 • Asthma action plan. Adapted from National Heart, Lung, and Blood Institute (NHLBI). (2012). Asthma care quick reference: Diagnosing and managing asthma. NIH Publication No. 12–5075. Revised September 2012.

Figure 20-12 • Peak flow meters measure the highest volume of airflow during a forced expiration. The patient takes a deep breath and places lips around the mouthpiece (**A**), and then exhales hard and fast (**B**). Volume may be measured in color-coded zones: the green zone signifies 80% to 100% of personal best; yellow, 60% to 80%; and red, less than 60%. If peak flow falls below the red zone, the patient should take the appropriate actions prescribed by the patient's primary provider.

Chart 20-8 HOME CARE CHECKLIST

Use of Peak Flow Meter in Asthma Management

At the completion of education, the patient and/or caregiver will be able to:

- Describe the rationale for using a peak flow meter in asthma management.
- Explain how peak flow monitoring is used along with symptoms to determine severity of asthma.
- Demonstrate steps for using the peak flow meter correctly.
  1. Move the indicator to the bottom of the numbered scale.
  2. Stand up.
  3. Take a deep breath, and fill the lungs completely.
  4. Place mouthpiece in mouth, and close lips around mouthpiece. (Do not put tongue inside opening.)
  5. Blow out hard and fast with a single blow.
  6. Record the number achieved on the indicator. If patient coughs or a mistake is made in the process, do it again.
  7. Repeat steps 1–5 two more times, and write the highest number in the asthma diary.
- Explain how to determine the "personal best" peak flow reading.
- Describe the significance of the color zones for peak flow monitoring.
- Demonstrate how to clean the peak flow meter.
- Discuss how and when to contact the primary provider about changes or decreases in peak flow values.

GINA (2019a) recommends that peak flow monitoring be considered an adjunct to asthma management for patients with moderate to severe persistent asthma. Peak flow monitoring plans may enhance communication between the patient and health care providers and may increase the patient's awareness of disease status and control.

Nursing Management

The immediate nursing care of patients with asthma depends on the severity of symptoms. The patient may be treated successfully as an outpatient if asthma symptoms are relatively mild or may require hospitalization and intensive care if symptoms are acute and severe. The patient and family are often frightened and anxious because of the patient's dyspnea. Therefore, a calm approach is an important aspect of care. The nurse assesses the patient's respiratory status by monitoring the severity of symptoms, breath sounds, peak flow, pulse oximetry, and vital signs.

The nurse generally performs the following interventions:

- Obtains a history of allergic reactions to medications before administering medications.
- Identifies medications the patient is taking.
- Administers medications as prescribed and monitors the patient's responses to those medications. These medications may include an antibiotic if the patient has an underlying respiratory infection.
- Administers fluids if the patient is dehydrated.

If the patient requires intubation because of acute respiratory failure, the nurse assists with the intubation procedure, continues close monitoring of the patient, and keeps the patient and family informed about procedures. (See Chapter 19 for discussion of intubation and mechanical ventilation.)

Promoting Home, Community-Based, and Transitional Care

Implementation of basic asthma management principles at the community level is a major challenge. Strategies include education of health care providers, establishment of programs for asthma education (for patients and providers), the use of outpatient follow-up care for patients, and a focus on chronic management versus acute episodic care. Nurses are pivotal to achievement of these objectives.

Educating Patients About Self-Care

Patient education is a critical component of care for patients with asthma. Multiple inhalers, different types of inhalers, antiallergy therapy, antireflux medications, and avoidance measures are essential for long-term control. This complex therapy requires a partnership between the patient and the health care providers to determine the desired outcomes and to formulate a plan to achieve those outcomes. The patient then carries out daily therapy as part of self-care management, with input and guidance by their health care providers. Before a partnership can be established, the patient must understand the following:

- Nature of asthma as a chronic inflammatory disease
- Definitions of inflammation and bronchoconstriction
- Purpose and action of each medication
- Triggers to avoid and how to avoid them
- Proper inhalation technique
- How to perform peak flow monitoring (see Chart 20-8)
- How to implement an asthma action plan (see Fig. 20-11)
- When to seek assistance, and how to do so

An assortment of excellent educational materials is available from the National Heart, Lung, and Blood Institute and other sources (see Resources section at the end of the chapter). The nurse should obtain current educational materials for the patient based on the patient's diagnosis, causative factors, educational level, and cultural background. If a patient has a coexisting sensory impairment (i.e., vision loss or hearing impairment), materials should be provided in an alternative format.

Continuing and Transitional Care

Nurses who have contact with patients with asthma in any setting use the opportunity to assess the patient's respiratory status and ability to manage self-care to prevent serious exacerbations. Nurses emphasize adherence to the prescribed therapy, preventive measures, and the need to keep follow-up appointments with health care providers. Home visits to assess the home environment for allergens may be indicated for patients with recurrent exacerbations. Nurses refer patients to community support groups. In addition, nurses remind patients and families about the importance of health promotion strategies and recommended health screening.

Unfolding Patient Stories: Jennifer Hoffman • Part 1

Jennifer Hoffman is a 33-year-old woman diagnosed with asthma in childhood. She has come to the clinic multiple times over the last 2 mo complaining of continued symptoms. Her asthma action plan was adjusted by her primary provider last month. What measures can the nurse take to determine areas needing education reinforcement? How can the nurse ensure that Jennifer is accurately following the prescribed asthma regimen and monitoring medication effectiveness? (Jennifer Hoffman's story continues in Chapter 33.)

Care for Jennifer and other patients in a realistic virtual environment: vSim (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Status Asthmaticus

An asthma exacerbation can range from mild to severe with potential respiratory arrest (GINA, 2019a). The term *status asthmaticus* is sometimes used to describe rapid onset, severe, and persistent asthma that does not

respond to conventional therapy. The attacks can occur with little or no warning and can progress rapidly to asphyxiation. Infection, anxiety, inhaler abuse, dehydration, increased adrenergic blockage, and nonspecific irritants may contribute to these episodes. An acute episode may be precipitated by hypersensitivity to medications, such as aspirin, beta-blockers, and nonsteroidal anti-inflammatory drugs (NSAIDs) (American Academy of Allergy, Asthma & Immunology [AAAAI], 2019; GOLD, 2019).

Pathophysiology

The basic characteristics of asthma (inflammation of bronchial mucosa, constriction of the bronchiolar smooth muscle, and thickened secretions) decrease the diameter of the bronchi and occur in status asthmaticus. The most common scenario is severe bronchospasm, with mucus plugging leading to asphyxia. A ventilation–perfusion abnormality results in hypoxemia. There is a reduced PaO_2 and initial respiratory alkalosis, with a decreased $PaCO_2$ and an increased pH. As status asthmaticus worsens, the $PaCO_2$ increases and the pH decreases, reflecting respiratory acidosis.

Clinical Manifestations

The clinical manifestations are the same as those seen in severe asthma; signs and symptoms include labored breathing, prolonged exhalation, distended neck veins, and wheezing. However, the extent of wheezing does not indicate the severity of the attack. As the obstruction worsens, the wheezing may disappear; this is frequently a sign of impending respiratory failure.

Assessment and Diagnostic Findings

The severity of an exacerbation may be evaluated by a general assessment of the patient (degree of breathlessness, ability to talk, positioning of patient, level of alertness or cognitive function), physical assessment (respiratory rate, the use of accessory muscles, presence of central cyanosis, auscultatory findings, pulse, and pulsus paradoxus), and laboratory evaluation (peak expiratory flow after a bronchodilator, PaO_2 and $PaCO_2$, and pulse oximetry). Pulmonary function studies are the most accurate means of assessing an acute, severe airway obstruction, though not practical to obtain during this type of an emergent situation. Arterial blood gas measurement and/or pulse oximetry are obtained if the patient cannot perform pulmonary function maneuvers because of severe obstruction or fatigue, or if the patient does not respond to treatment. Respiratory alkalosis (low $PaCO_2$) is the most common early finding in patients with an ongoing asthma exacerbation and is due to hyperventilation. At this early stage, relatively fewer acinar units (i.e., pulmonary alveolar units

where gas exchange occurs) are obstructed/constricted compared to those that are functional, and hyperventilation occurs as part of the sympathetic response.

Quality and Safety Nursing Alert

In status asthmaticus, increasing PaCO2 (to normal levels or levels indicating respiratory acidosis) is a danger sign signifying impending respiratory failure.

Medical Management

Close monitoring of the patient and objective reevaluation for response to therapy are key in status asthmaticus. In the emergency setting, the patient is treated initially with a short-acting beta-2–adrenergic agonist and subsequently a short course of systemic corticosteroids, especially if the patient does not respond to the short-acting beta-2–adrenergic agonist. Corticosteroids are critical in the therapy of status asthmaticus and are used to decrease the intense airway inflammation and swelling. Inhaled short-acting beta-2–adrenergic agonists provide the most rapid relief from bronchospasm. A pMDI, with or without a spacer, may be used for administering the medications. However, more commonly, short-acting bronchodilators will be given via an SVN. A mouthpiece or facemask can be used and the bronchodilator is continuously given to the patient. The patient does not have to work to coordinate the breathing pattern, which can otherwise cause additional anxiety in this acute situation. The patient requires supplemental oxygen and IV fluids for hydration. Oxygen therapy is initiated to treat dyspnea, central cyanosis, and hypoxemia. High-flow supplemental oxygen is best delivered using a partial or complete non-rebreathing mask. Sedatives are contraindicated. Magnesium sulfate, a calcium antagonist, may be given to induce smooth muscle relaxation; the magnesium can relax smooth muscle and hence cause bronchodilation by competing with calcium at calcium-mediated smooth muscle–binding sites. IV magnesium sulfate is not recommended for routine use in asthma exacerbations; however, when given as a single 2-g infusion over 20 minutes, it may be helpful in treating patients who present with severely compromised pulmonary function, who have not responded to initial therapy, and with persistent hypoxemia (GINA, 2019a). Adverse effects of magnesium sulfate may include facial warmth, flushing, tingling, nausea, central nervous system depression, respiratory depression, and hypotension.

If there is no response to repeated treatments, hospitalization is required. Other criteria for hospitalization include poor pulmonary function test results and deteriorating blood gas levels (respiratory acidosis), which may indicate that the patient is tiring and will require mechanical ventilation. Most patients

do not need mechanical ventilation, but it is used for patients in respiratory failure, for those who tire and are too fatigued by the attempt to breathe, and for those whose condition does not respond to initial treatment.

For a very select group of patients with uncontrolled severe asthma, bronchial thermoplasty may be considered. Bronchial thermoplasty is the first nondrug therapy for the treatment of severe, uncontrolled asthma. It consists of controlled radiofrequency heating of the central airways through a bronchoscope. The thermal energy reduces the amount of smooth muscle involved in bronchospasm and potentially decreases the severity and frequency of symptoms. This therapy is invasive and relatively new; therefore, only select centers have the ability to perform this procedure, and it should only be considered in a select group of patients (GINA, 2019a).

Death from asthma is associated with several risk factors, including the following (GINA, 2019a):

- Past history of severe exacerbation (e.g., intubation or intensive care unit admission)
- Hospitalizations or emergency care visits for asthma within the past year
- Currently or having recently stopped using oral corticosteroids
- Not using ICSs
- Overuse of SABAs
- Concurrent psychiatric disease or psychosocial problems
- Poor adherence to written asthma action plan
- Poor adherence to medication regimen
- Presence of a food allergy

Nursing Management

The main focus of nursing management is to actively assess the airway and the patient's response to treatment. The nurse should be prepared for the next intervention if the patient does not respond to treatment.

The nurse vigilantly monitors the patient for the first 12 to 24 hours, or until the severe exacerbation resolves. The nurse also assesses the patient's skin turgor for signs of dehydration. Fluid intake is essential to combat dehydration, to loosen secretions, and to facilitate expectoration. Nurses administer IV fluids as prescribed, up to 3 to 4 L/day, unless contraindicated. Blood pressure and cardiac rhythm should be monitored continuously during the acute phase and until the patient stabilizes and responds to therapy. The patient's energy needs to be conserved, and his or her room should be quiet and free of respiratory irritants, including flowers, tobacco smoke, perfumes, or odors of cleaning agents. Nonallergenic pillows should be used. An asthma attack may also be precipitated or aggravated by exposure to latex if the patient has a latex

allergy; therefore, this type of hypersensitivity must be identified and latex-free products used, as warranted. Once the exacerbation is resolved, the factors that precipitated the exacerbation should be identified and strategies for their future avoidance implemented. In addition, the patient's medication plan should be reviewed.

Cystic Fibrosis

CF is the most common fatal autosomal recessive disease among Caucasians. It is less frequently found among Hispanic, Asian, and African Americans. A person must inherit a defective copy of the CF gene (one from each parent) to have CF. Each year, 1000 new cases of CF are diagnosed, and more than 75% of patients are diagnosed by 2 years of age (Cystic Fibrosis Foundation [CFF], 2019a). In 2010, over 50% of people with CF in the United States were diagnosed with newborn screening (Heltshe, Cogen, Ramos, et al., 2017). Approximately 30,000 children and adults in the United States have CF and half are over the age of 18. CF was once a fatal childhood disease; however, the median expected survival age is now 37 (National Institutes of Health, 2018). Furthermore, survival age is projected to rise to 57 years if the survival rate continues to improve 1.8% per year (Heltshe et al., 2017). The improved survival rate is due to advances in medical management and procedures such as lung transplantation. Now that the median survival age has increased to 37 years for patients with CF, issues that were not present in past generations have arisen. These issues include antibiotic resistance and the desire for patients with CF to have their own biologic children.

Although most patients are diagnosed by 2 years of age, this disease may not be diagnosed until later in life (CFF, 2019b). Respiratory symptoms are frequently the major manifestation of CF when it is diagnosed later in life. These patients will not demonstrate the classic symptoms of CF, which may potentially cause a diagnostic dilemma.

Pathophysiology

CF is caused by mutations or dysfunction in the protein cystic fibrosis transmembrane conductance regulator (CFTR), which normally transports chloride ions across epithelial cell membranes. Gene mutations affect transport of these ions, leading to CF, which is characterized by thick, viscous secretions in the lungs, pancreas, liver, intestine, and reproductive tract as well as increased salt content in sweat gland secretions. The most common mutation is ΔF508; however, researchers have identified more than 1700 mutations of the disease (CFF, 2019a). The numerous mutations of the CFTR gene create multiple variations in the presentation and progression of the disease.

The ability to detect the common mutations of this gene allows for routine screening for CF and the detection of carriers of the disease. Genetic counseling is an important part of health care for couples at risk (see Chapter 6). People who are heterozygous for CF (i.e., have one defective gene and one normal gene) do not have the disease but can be carriers and pass the defective gene on to their children. If both parents are carriers, their risk of having a child with CF is one in four (25%) with each pregnancy. Any biologic offspring of a patient with CF will have CF. Genetic testing should be offered to adults with a positive family history of CF and to partners of people with CF who are planning a pregnancy or seeking prenatal counseling. The hallmark pathology of CF is bronchial mucus plugging, inflammation, and eventual bronchiectasis. Commonly, the bronchiectasis begins in the upper lobes and progresses to involve all lobes.

Clinical Manifestations

The pulmonary manifestations of CF include a productive cough, wheezing, hyperinflation of the lung fields on chest x-ray, and pulmonary function test results consistent with obstructive disease of the airways. Chronic respiratory inflammation and infection are caused by impaired mucus clearance. Colonization of the airways with pathogenic bacteria usually occurs early in life. *S. aureus* and *H. influenzae* are common organisms during early childhood. As the disease progresses, *P. aeruginosa* is ultimately isolated from the sputum of most patients (Simon, Mallory, & Hoppin, 2019b). Upper respiratory manifestations of the disease include sinusitis and nasal polyps. Pulmonary complications of CF are the primary cause of morbidity and mortality in the United States (Simon, Mallory, & Hoppin, 2019a).

Nonpulmonary manifestations include gastrointestinal problems (e.g., pancreatic insufficiency, recurrent abdominal pain, biliary cirrhosis, vitamin deficiencies, recurrent pancreatitis, weight loss), CF-related diabetes, and genitourinary problems (male and female infertility). (See Chapter 44 for a discussion of pancreatitis.)

Assessment and Diagnostic Findings

The diagnosis of CF requires a clinical picture consistent with the CF phenotype and laboratory evidence of CFTR dysfunction. Key assessment findings in adults include (Katkin, Mallory, & Hoppin, 2019):

- Chronic sinopulmonary disease as manifested by chronic cough and sputum production, persistent infection consistent with typical CF pathogens, and x-ray evidence of bronchiectasis and chronic sinusitis, often with nasal polyps

- Gastrointestinal tract and nutritional abnormalities (pancreatic insufficiency, recurrent pancreatitis, biliary cirrhosis and portal hypertension, CF-related diabetes)
- Male urogenital problems as manifested by congenital bilateral absence of the vas deferens; reduced female fertility

Medical Management

CF requires both acute and chronic therapy. Cornerstones of treatment include multimodal antibiotic regimens, airway clearance measures, bronchodilators, CFTR modulators, nutritional support, and exercise (Simon et al., 2019a). Multimodal antibiotic regimens use different types of antibiotics and routes (oral, inhaled, and IV) to help control, suppress, and treat exacerbation of bacterial infections. Airway clearance measures entail the use of the mucolytics (e.g., dornase alfa; see later discussion), inhaled hypertonic saline, and various pulmonary techniques that promote mucus expectoration.

Because chronic infection (viral and bacterial) of the airways occurs in CF, control of infections is essential to treatment. It is best to prevent viral infections. Administering viral influenza vaccinations is essential for CF patients. Due to the increased risk of viral influenza, some CF patients may benefit from prophylactic treatment with a neuraminidase inhibitor (e.g., zanamivir, oseltamivir) (Simon et al., 2019a).

Bacterial infection requires aggressive therapy to improve airway clearance and the use of antibiotics based on results of sputum cultures. The majority of patients are colonized with *P. aeruginosa;* however, *S. aureus,* methicillin-resistant *Staphylococcus aureus,* and *Burkholderia cepacia* complex are examples of other commonly found pathogens (Simon et al., 2019b).

Chronic infection with *P. aeruginosa* is an independent risk factor for accelerated loss of lung function and decreased survival (Simon et al., 2019b). *P. aeruginosa* is also common in CF exacerbations and new strains may develop with recurring infections leading to different antibiotic-resistance profiles (Simon et al., 2019b). As CF patients are living longer and experiencing more exacerbations, antibiotic resistance is becoming a serious concern and can affect life expectancy.

B. cepacia complex consists of different species of bacteria. Infection with *B. cepacia* complex, in general, is associated with poor outcomes in CF patients as a result of the bacteria's inherent antibiotic resistance. Infection with this complex may prevent a CF patient from becoming a lung transplant candidate (Hachem, 2019).

Routine cultures of respiratory secretions are used to identify organisms and guide antibiotic selection. Two IV antibiotics have been typically prescribed to treat a severe exacerbation of *P. aeruginosa.* Tobramycin, along with piperacillin-tazobactam, a third-generation cephalosporin (e.g., ceftizoxime,

ceftazidime), a carbapenem (e.g., meropenem, aztreonam) may be prescribed (Simon et al., 2019b). Three newer combination medications, ceftazidime and avibactam, meropenem and vaborbactam, and ceftolozane and tazobactam, unite commonly known antibiotics with a beta-lactamase inhibitor to counteract bacterial resistance. Dosing of antibiotics is determined on a case-by-case basis; some patients may require higher doses or an extended IV infusion. When methicillin-resistant *S. aureus* accompanies *P. aeruginosa*, vancomycin is administered in addition to dual IV antibiotic therapy (Simon et al., 2019b). Careful monitoring is always required to minimize any side effects of the antibiotics.

Maintenance oral antibiotic therapies are sometimes employed to help suppress infections caused by other common bacteria such as methicillin-sensitive *S. aureus*. These infections vary across patients and require individualized patient care. The antibiotic regimens used vary depending on the specific organism grown and severity of infection.

Inhaled antibiotics are mainly used to treat *P. aeruginosa*. Tobramycin is the first-line inhaled antibiotic choice but aztreonam can be used as an alternative treatment. Typically, these antibiotics are used on a 28-day on and 28-day off regimen. Patients with deteriorating lung function or recurrent exacerbations may use these antibiotics by rotating courses of inhaled tobramycin and aztreonam without implementing a 28-day off period (Simon, Mallory, & Hoppin, 2019c). Although there is no general consensus on the use of inhaled colistimethate sodium, this drug can be used with patients who do not respond well with the other inhaled antibiotics (Simon et al., 2019c).

Various pulmonary techniques are used to promote airway clearance through the expectoration of secretions. Examples include CPT with manual postural drainage; HFCWO; autogenic drainage (a combination of breathing techniques at different lung volume levels to move the secretions to where they can be huff-coughed out); and other devices that assist in airway clearance, such as masks that generate positive expiratory pressure (PEP masks) and flutter valves (devices that provide an oscillatory expiratory pressure pattern with PEP and assist with expectoration of secretions). It is important to assure that the patient is properly positioned when using the flutter valve and that the patient uses proper technique with this treatment.

Dornase alfa is a nebulized medication given to degrade the large amount of deoxyribonucleic acid (DNA) that accumulates within CF mucus. This agent helps decrease the viscosity of the sputum and promotes expectoration of secretions. It is recommended for patients with moderate to severe disease (severity of lung disease classification is based on predicted FEV_1 percentage). In addition, inhaled hypertonic saline may be used in the chronic treatment of CF. Inhalations increase hydration of the airway surface liquid in patients with CF and improve airway clearance.

Nebulized and IV antibiotics or a combination may be used to treat chronic colonization of the lung. Nebulization provides high intrapulmonary drug concentrations and minimal systemic absorption. Inhaled tobramycin or aztreonam have been shown to decrease the frequency of pulmonary exacerbations. Acute infections are treated with a variety of IV antibiotics. Such infections remain a major cause of mortality related to pulmonary exacerbations in adults with CF.

Other therapeutic measures may be necessary as well. Anti-inflammatory agents may be used to treat inflammatory response in the airways. There is insufficient evidence for the use of routine inhaled or oral corticosteroids (Simon et al., 2019b). IV corticosteroids are used during acute exacerbations and only for those patients with asthmalike symptoms (Simon et al., 2019b). Inhaled bronchodilators (e.g., salmeterol, tiotropium bromide) may be used in patients who have a significant bronchoconstrictive component; this is confirmed by spirometry before and after therapy is instituted (Simon et al., 2019c).

Pancreatic exocrine insufficiency occurs frequently in people with CF and requires oral pancreatic enzyme supplementation with meals (Katkin, Baker, & Baker, 2019). Given the fat malabsorption in CF and increased caloric needs due to the work of breathing, nutritional counseling and weight monitoring are extremely important. Supplements of fat-soluble vitamins A, D, E, and K are also used.

CFTR modulators are a class of drugs that help prevent the progression of CF (Simon et al., 2019c). These agents are novel in that they aim to address the cause of CF as opposed to treating symptoms. There are two classes of modulators used in treating CF: potentiators (help salt and water flow through the CFTR protein channel at the cell surface) and correctors (help the CFTR protein to form the right 3D shape so that it is able to move to the cell surface). The selection of the CFTR modulator depends on the patient's specific CFTR mutation and the patient's age (Simon et al., 2019a).

Ivacaftor, a potentiator, improves salt and water movement across the membrane (thus improving hydration and clearing of mucus from the airways). The drug does not correct the gene mutation; it only helps in the movement of salt and water across the membrane. Monotherapy of ivacaftor is approved for patients with CF who are 6 months of age and older (Simon et al., 2019c).

Although corrector drugs (e.g., lumacaftor, tezacaftor) help the CFTR protein reach the cell surface, they do not diminish CF symptoms because the proteins that do reach the cell surface are unable to improve the flow of salt and water across the cell membrane. This is why lumacaftor and tezacaftor are used in combination with ivacaftor. Combined, these drugs can modestly improve lung function and reduce CF exacerbations (Simon et al., 2019c). Lumacaftor-ivacaftor is approved for patients 2 years of age and older, but is only recommended for treating patients age 2 to 5. Tezacaftor-ivacaftor is the

preferred treatment for patients 6 years of age and older because it produces fewer side effects and drug–drug interactions than lumacaftor-ivacaftor (Simon et al., 2019c).

Currently, a triple combination of tezacaftor-ivacaftor with an additional CFTR corrector is being investigated for treating various CFTR mutations. One such medication, elexacaftor-tezacaftor-ivacaftor, completed phase 3 clinical trials and is being reviewed by the FDA to treat patients with CF age 12 years and older. This drug improves ΔF508 CFTR protein processing, trafficking, and function (Simon et al., 2019c). The goal of these new modulators is to improve the functionality of the CFTR and restore chloride transport at the cellular level, thus decreasing symptoms and complications related to the disease. These positive effects include less viscous mucus production, decreased exacerbation frequency, and improved nutrient absorption.

As the pulmonary deterioration advances, supplemental oxygen is used to treat the progressive hypoxemia that occurs with CF. It helps correct the hypoxemia and may minimize the complications seen with chronic hypoxemia (pulmonary hypertension). Lung transplantation is an option for a small, select population of patients with CF. A double-lung transplantation technique is used because of chronic infection of both lungs in end-stage CF. Because there is a long waiting list for lung transplants, many patients die while waiting for suitable lungs for transplantation.

Nursing Management

Nursing management is crucial to the interdisciplinary approach required for care of adults with CF. Nursing care includes helping patients manage pulmonary symptoms and prevent complications. Specific measures include strategies that promote removal of pulmonary secretions, CPT (including postural drainage, chest percussion, and vibration), and breathing exercises (which are implemented and taught to the patient and family when the patient is very young). The patient is reminded of the need to reduce risk factors associated with respiratory infections (e.g., exposure to crowds or to people with known infections). In addition, the patient is taught the early signs and symptoms of respiratory infection and disease progression that indicate the need to notify a primary provider.

The nurse emphasizes the importance of an adequate fluid and dietary intake to promote removal of secretions and to ensure an adequate nutritional status. Because CF is a lifelong disorder, patients often have learned to modify their daily activities to accommodate their symptoms and treatment modalities. As the disease progresses, periodic reassessment of the home environment may be warranted to identify modifications required to address changes in the patient's needs, increasing dyspnea and fatigue, and nonpulmonary symptoms.

As with any chronic disease, palliative care and end-of-life issues and concerns need to be addressed with the patient when warranted. For the patient whose disease is progressing and who is developing increasing hypoxemia, preferences for end-of-life care should be discussed, documented, and honored (see Chapter 13). Patients and family members require support as they face a shortened lifespan and an uncertain future (Tomaszek, Debska, Cepuch, et al., 2019).

CRITICAL THINKING EXERCISES

1 ipc A 55-year-old man presented to the ED with complaints of acute shortness of breath and difficulty breathing. SpO_2 on admission to the ED was 85% on room air. His admitting diagnosis was acute exacerbation of COPD. He was admitted to a general medicine unit, and arrived to his room on 4 L of O_2 via nasal cannula. During his admission assessment, the patient tells you that he works in the coal mines and his shift supervisor had to bring him to the hospital. He also states that he has a long history of smoking 1 to 2 packs of cigarettes per day and his attempts to quit have been unsuccessful. While conducting the assessment, you note that the patient has a productive cough and is becoming confused to time. What is your priority as you admit this patient? What information would you provide the primary provider? What tests might be ordered to help further evaluate the patient's condition? What information would you need to ask the patient to plan for a home discharge? What health care team members would you consult to plan for a home discharge?

2 pq A 20-year-old male with a history of asthma presents to the ED with severe shortness of breath and dyspnea at rest. He said he had a cold last week and was coughing up clear sputum. This morning he began expectorating yellow sputum and became increasingly short of breath. He used his rescue inhaler with little relief. Before he came to the ED, he used his rescue inhaler every half hour. Upon presentation to ED triage, his SpO_2 was 90% on room air, but is now 84% on room air. Physical examination reveals tachycardia at 136 bpm, cyanotic lips, and tachypnea at 30 breaths/min with signs of accessory muscle use. When asked about his asthma medications, he admits he only uses his prescribed daily inhaler once a day because it is too expensive. He also stated his primary provider gave him a breathing machine for medicine but he did not know how to use it. What is your priority of care? What evidence-based medical and nursing interventions would improve the patient's respiratory status? What educational needs does this patient have?

3 ebp A 25-year-old woman is hospitalized for CF. She was admitted for elevated temperature and weight loss. At the time of admission, she was not using oxygen therapy at home. She was working full-time in a department store prior to this exacerbation. She told the social worker yesterday that she is afraid she will have to quit her job and will lose her health insurance. Her husband, who is unemployed, is also dependent on her for health insurance. Today, she is unable to eat due to the severe dyspnea. Physical assessment reveals SpO_2 of 87% on 2 L of O_2 via nasal cannula, bilateral crackles with severely diminished breath sounds on the right, and expectoration of thick yellow sputum. What evidence-based

interventions might be used to alleviate her CF symptoms? Identify the criteria used to evaluate the strength of the evidence for these practices.

UNIT 5

Cardiovascular and Circulatory Function

Case Study

USING TECHNOLOGY TO PREVENT MEDICATION ERRORS

An 85-year-old male presents to the emergency department with complaints of substernal chest pressure rated 9 on a 0–10 pain scale with pain radiating to his left arm. Other signs and symptoms include nausea, dizziness, shortness of breath (SOB), diaphoresis, and a feeling of "something bad is happening to me." He is emergently sent for cardiac catheterization; a 90% distal and 85% proximal stenosis of the right coronary artery was detected. He subsequently underwent a percutaneous coronary intervention with balloon angioplasty and placement of stents. Once recovered from anesthesia he is admitted to the cardiac step-down unit where you work. When receiving report you notice in the electronic health record (EHR) that the patient should have received the first dose of two medications in the cardiac catheterization lab following the procedure. However, these medications were not administered as prescribed and you notify the interventional cardiologist about this error.

QSEN Competency Focus: **Informatics**

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include *patient-centered care*, *interdisciplinary teamwork and collaboration*, *evidence-based practice*, *quality improvement*, *safety*, and *informatics.*

Informatics Definition: Use information and technology to communicate, manage knowledge, mitigate error, and support decision-making.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Explain why information and technology skills are essential for safe patient care	Describe how the use of the EHR and other technology can relay information to the nurse to prevent medication errors.
Skills	
Apply technology and information management tools to support safe processes of care	Describe the type of training needed to navigate the EHR efficiently. Identify how you can utilize technology to ensure effective communication, manage medication administration, and prevent errors.
Attitudes	
Value technologies that support clinical decision-making, error prevention, and care coordination	Reflect on how you value technologies that support clinical decision-making, error prevention, and care coordination. Do these values have the potential to create barriers to effective use of technology to prevent errors in your workplace?

21 Assessment of Cardiovascular Function

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the structure and function of the cardiovascular system as well as associated cardiac risk factors.
2. Explain and demonstrate the proper techniques to perform a comprehensive cardiovascular assessment.
3. Discriminate between normal and abnormal assessment findings identified by inspection, palpation, percussion, and auscultation of the cardiovascular system.
4. Recognize and evaluate the major manifestations of cardiovascular dysfunction by applying information from the patient's health history and physical assessment findings.
5. Identify diagnostic tests and methods of hemodynamic monitoring (e.g., central venous pressure, pulmonary artery pressure, arterial pressure monitoring) of the cardiovascular system and related nursing implications.

NURSING CONCEPTS

Perfusion

GLOSSARY

acute coronary syndrome: a constellation of signs and symptoms due to the rupture of atherosclerotic plaque and resultant partial or complete thrombosis within a diseased coronary artery

afterload: the amount of resistance to ejection of blood from the ventricle

apical impulse: impulse normally palpated at the fifth intercostal space, left midclavicular line; caused by contraction of the left ventricle (*synonym*: point of maximal impulse)

atrioventricular (AV) node: secondary pacemaker of the heart, located in the right atrial wall near the tricuspid valve

baroreceptors: nerve fibers located in the aortic arch and carotid arteries that are responsible for control of the blood pressure

cardiac catheterization: an invasive procedure used to measure cardiac chamber pressures and assess patency of the coronary arteries

cardiac conduction system: specialized heart cells strategically located throughout the heart that are responsible for methodically generating and coordinating the transmission of electrical impulses to the myocardial cells

cardiac output: amount of blood pumped by each ventricle in liters per minute

cardiac stress test: a test used to evaluate the functioning of the heart during a period of increased oxygen demand; test may be initiated by exercise or medications

contractility: ability of the cardiac muscle to shorten in response to an electrical impulse

depolarization: electrical activation of a cell caused by the influx of sodium into the cell while potassium exits the cell

diastole: period of ventricular relaxation resulting in ventricular filling

ejection fraction: percentage of the end-diastolic blood volume ejected from the ventricle with each heartbeat

hemodynamic monitoring: the use of pressure monitoring devices to directly measure cardiovascular function

hypertension: blood pressure that is persistently greater than 130/80 mm Hg

hypotension: a decrease in blood pressure to less than 90/60 mm Hg that compromises systemic perfusion

murmurs: sounds created by abnormal, turbulent flow of blood in the heart

myocardial ischemia: condition in which heart muscle cells receive less oxygen than needed

myocardium: muscle layer of the heart responsible for the pumping action of the heart

normal heart sounds: sounds produced when the valves close; normal heart sounds are S_1 (atrioventricular valves) and S_2 (semilunar valves)

opening snaps: abnormal diastolic sounds generated during opening of rigid atrioventricular valve leaflets

orthostatic hypotension: a significant drop in blood pressure (20 mm Hg systolic or more or 10 mm Hg diastolic or more) after an upright posture is assumed

preload: degree of stretch of the cardiac muscle fibers at the end of diastole

pulmonary vascular resistance: resistance to blood flow out of the right ventricle created by the pulmonary circulatory system

pulse deficit: the difference between the apical and radial pulse rates

radioisotopes: unstable atoms that give off small amounts of energy in the form of gamma rays as they decay; used in cardiac nuclear medicine studies

repolarization: return of the cell to resting state, caused by reentry of potassium into the cell while sodium exits the cell

S_1: the first heart sound produced by closure of the atrioventricular (mitral and tricuspid) valves

S_2: the second heart sound produced by closure of the semilunar (aortic and pulmonic) valves

S_3: an abnormal heart sound detected early in diastole as resistance is met to blood entering either ventricle; most often due to volume overload associated with heart failure

S_4: an abnormal heart sound detected late in diastole as resistance is met to blood entering either ventricle during atrial contraction; most often caused by hypertrophy of the ventricle

sinoatrial (SA) node: primary pacemaker of the heart, located in the right atrium

stroke volume: amount of blood ejected from one of the ventricles per heartbeat

summation gallop: abnormal sounds created by the presence of an S_3 and S_4 during periods of tachycardia

systemic vascular resistance: resistance to blood flow out of the left ventricle created by the systemic circulatory system

systole: period of ventricular contraction resulting in ejection of blood from the ventricles into the pulmonary artery and aorta

systolic click: abnormal systolic sound created by the opening of a calcified aortic or pulmonic valve during ventricular contraction

telemetry: the process of continuous electrocardiographic monitoring by the transmission of radio waves from a battery-operated transmitter worn by the patient

Nearly half, or 121.5 million, of American adults have one or more types of cardiovascular disease (CVD), including hypertension, coronary artery disease (CAD), heart failure (HF), and stroke (American Heart Association [AHA], 2019). Because of the increased prevalence of CVD, nurses practicing in any setting across the continuum of care, whether in the home, office, hospital, long-term care facility, or rehabilitation facility, must be able to assess the cardiovascular system. Key components of assessment include a health history, physical assessment, and monitoring of a variety of laboratory and diagnostic test results. This assessment provides the information necessary to identify nursing diagnoses, formulate an individualized plan of care, evaluate the response of the patient to the care provided, and revise the plan as needed.

Anatomic and Physiologic Overview

An understanding of the structure and function of the heart in health and in disease is essential to develop cardiovascular assessment skills.

Anatomy of the Heart

The heart is a hollow, muscular organ located in the center of the thorax, where it occupies the space between the lungs (mediastinum) and rests on the diaphragm. It weighs approximately 300 g (10.6 oz); the weight and size of the heart are influenced by age, gender, body weight, extent of physical exercise and conditioning, and heart disease. The heart pumps blood to the tissues, supplying them with oxygen and other nutrients.

The heart is composed of three layers (Fig. 21-1). The inner layer, or endocardium, consists of endothelial tissue and lines the inside of the heart and valves. The middle layer, or **myocardium**, is made up of muscle fibers and is responsible for the pumping action. The exterior layer of the heart is called the *epicardium.*

The heart is encased in a thin, fibrous sac called the *pericardium,* which is composed of two layers. Adhering to the epicardium is the visceral pericardium. Enveloping the visceral pericardium is the parietal pericardium, a tough fibrous tissue that attaches to the great vessels, diaphragm, sternum, and vertebral column and supports the heart in the mediastinum. The space between these two layers (pericardial space) is normally filled with about 20 mL of fluid, which lubricates the surface of the heart and reduces friction during systole.

Heart Chambers

The pumping action of the heart is accomplished by the rhythmic relaxation and contraction of the muscular walls of its two top chambers (atria) and two bottom chambers (ventricles). During the relaxation phase, called **diastole**, all four chambers relax simultaneously, which allows the ventricles to fill in preparation for contraction. Diastole is commonly referred to as the period of ventricular filling. **Systole** refers to the events in the heart during contraction of the atria and the ventricles. Unlike diastole, atrial and ventricular systoles are not simultaneous events. Atrial systole occurs first, just at the end of diastole, followed by ventricular systole. This synchronization allows the ventricles to fill completely prior to ejection of blood from these chambers.

The right side of the heart, made up of the right atrium and right ventricle, distributes venous blood (deoxygenated blood) to the lungs via the pulmonary artery (pulmonary circulation) for oxygenation. The pulmonary artery is the only artery in the body that carries deoxygenated blood. The right atrium receives venous blood returning to the heart from the superior vena cava (head, neck, and upper extremities), inferior vena cava (trunk and lower extremities), and coronary sinus (coronary circulation). The left side of the heart, composed of the left atrium and left ventricle, distributes oxygenated blood to the remainder of the body via the aorta (systemic circulation). The left atrium receives oxygenated blood from the pulmonary circulation via four pulmonary veins. The flow of blood through the four heart chambers is shown in Figure 21-1.

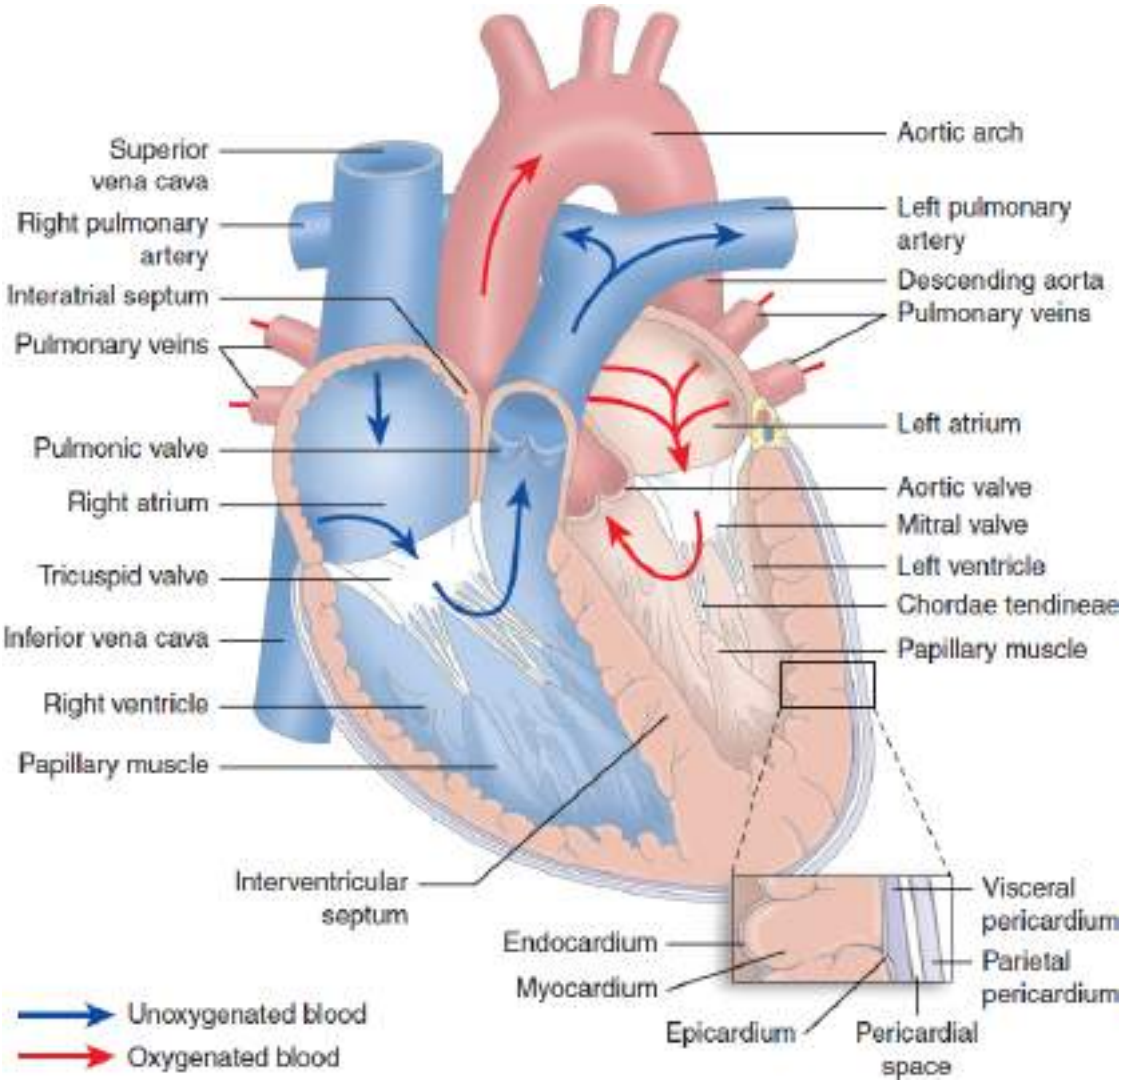

Figure 21-1 • Structure of the heart. *Arrows* show course of blood flow through the heart chambers.

The varying thicknesses of the atrial and ventricular walls are due to the workload required by each chamber. The myocardial layer of both atria is much thinner than that of the ventricles because there is little resistance as blood flows out of the atria and into the ventricles during diastole. In contrast, the ventricular walls are much thicker than the atrial walls. During ventricular systole, the right and left ventricles must overcome resistance to blood flow from the pulmonary and systemic circulatory systems, respectively. The left ventricle is two to three times more muscular than the right ventricle. It must overcome high aortic and arterial pressures, whereas the right ventricle contracts against a low-pressure system within the pulmonary arteries and capillaries (Pappano & Weir, 2019). Figure 21-2 identifies the pressures in each of these areas.

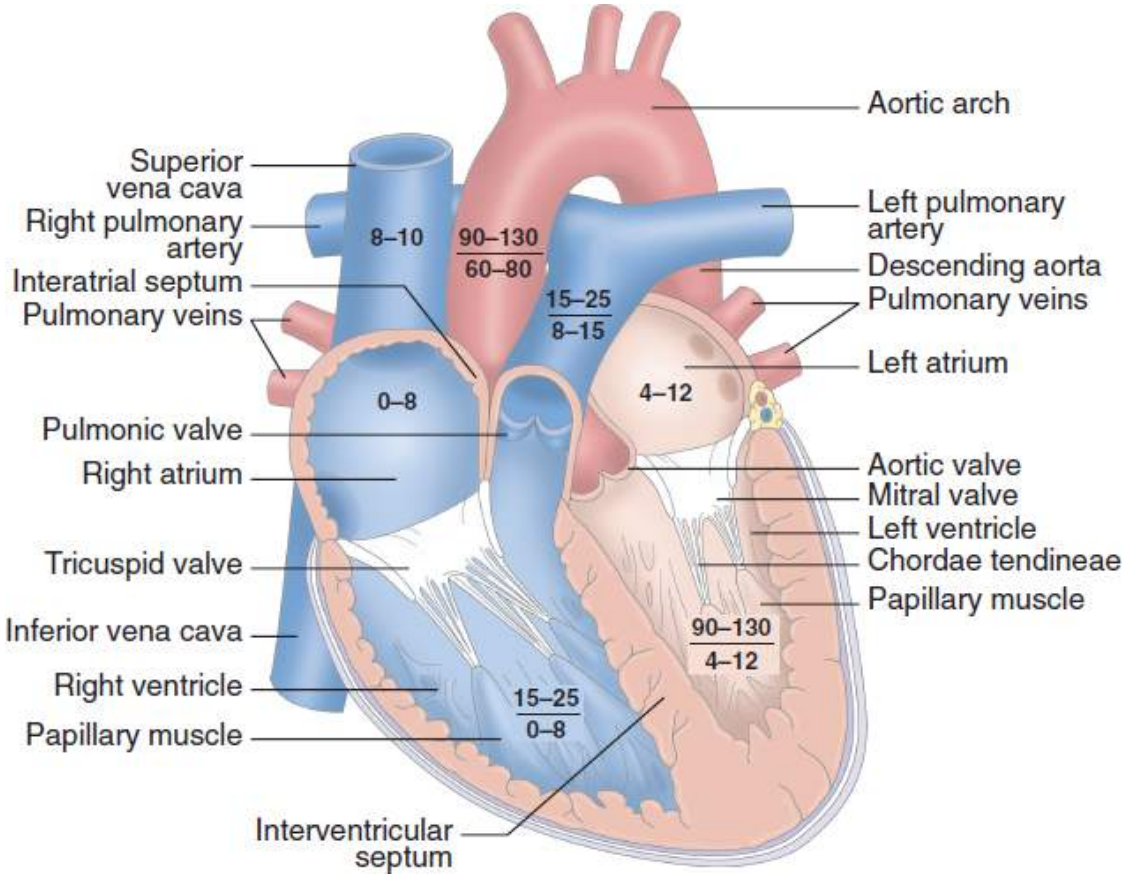

Figure 21-2 • Great vessel and chamber pressures. Pressures are identified in millimeters of mercury (mm Hg) as mean pressure or systolic over diastolic pressure.

The heart lies in a rotated position within the chest cavity. The right ventricle lies anteriorly (just beneath the sternum), and the left ventricle is situated posteriorly. As a result of this close proximity to the chest wall, the pulsation created during normal ventricular contraction, called the **apical impulse** (also called the *point of maximal impulse* [PMI]), is easily detected. In the normal heart, the PMI is located at the intersection of the midclavicular line of the left chest wall and the fifth intercostal space (Bickley, 2017).

Heart Valves

The four valves in the heart permit blood to flow in only one direction. The valves, which are composed of thin leaflets of fibrous tissue, open and close in response to the movement of blood and pressure changes within the chambers. There are two types of valves: atrioventricular (AV) and semilunar.

Atrioventricular Valves

The AV valves separate the atria from the ventricles. The tricuspid valve, so named because it is composed of three cusps or leaflets, separates the right

atrium from the right ventricle. The mitral or bicuspid (two cusps) valve lies between the left atrium and the left ventricle (see Fig. 21-1).

During diastole, the tricuspid and mitral valves are open, allowing the blood in the atria to flow freely into the relaxed ventricles. As ventricular systole begins, the ventricles contract and blood flows upward into the cusps of the tricuspid and mitral valves, causing them to close. As the pressure against these valves increases, two additional structures, the papillary muscles and the chordae tendineae, maintain valve closure. The papillary muscles, located on the sides of the ventricular walls, are connected to the valve leaflets by the chordae tendineae, which are thin fibrous bands. During ventricular systole, contraction of the papillary muscles causes the chordae tendineae to become taut, keeping the valve leaflets approximated and closed. This action prevents backflow of blood into the atria (regurgitation) as blood is ejected out into the pulmonary artery and aorta.

Semilunar Valves

The two semilunar valves are composed of three leaflets, which are shaped like half-moons. The valve between the right ventricle and the pulmonary artery is called the *pulmonic valve.* The valve between the left ventricle and the aorta is called the *aortic valve.* The semilunar valves are closed during diastole. At this point, the pressure in the pulmonary artery and aorta decreases, causing blood to flow back toward the semilunar valves. This action fills the cusps with blood and closes the valves. The semilunar valves are forced open during ventricular systole as blood is ejected from the right and left ventricles into the pulmonary artery and aorta, respectively.

Coronary Arteries

The left and right coronary arteries and their branches supply arterial blood to the heart. These arteries originate from the aorta just above the aortic valve leaflets. Unlike other arteries, the coronary arteries are perfused during diastole. With a normal heart rate of 60 to 80 bpm, there is ample time during diastole for myocardial perfusion. However, as heart rate increases, diastolic time is shortened, which may not allow adequate time for myocardial perfusion. As a result, patients are at risk for **myocardial ischemia** (inadequate oxygen supply) during tachycardia (heart rate greater than 100 bpm), especially patients with CAD.

The left coronary artery has three branches. The artery from the point of origin to the first major branch is called the *left main coronary artery.* Two branches arise from the left main coronary artery: the left anterior descending artery, which courses down the anterior wall of the heart, and the circumflex artery, which circles around to the lateral left wall of the heart.

The right side of the heart is supplied by the *right coronary artery,* which travels to the inferior wall of the heart. The posterior wall of the heart receives its blood supply by an additional branch from the right coronary artery called the *posterior descending artery* (see Chapter 23, Fig. 23-2).

Superficial to the coronary arteries are the coronary veins. Venous blood from these veins returns to the heart primarily through the coronary sinus, which is located posteriorly in the right atrium.

Myocardium

The myocardium is the middle, muscular layer of the atrial and ventricular walls. It is composed of specialized cells called *myocytes,* which form an interconnected network of muscle fibers. These fibers encircle the heart in a figure-of-eight pattern, forming a spiral from the base (top) of the heart to the apex (bottom). During contraction, this muscular configuration facilitates a twisting and compressive movement of the heart that begins in the atria and moves to the ventricles. The sequential and rhythmic pattern of contraction, followed by relaxation of the muscle fibers, maximizes the volume of blood ejected with each contraction. This cyclical pattern of myocardial contraction is controlled by the conduction system.

Function of the Heart

Cardiac Electrophysiology

The **cardiac conduction system** generates and transmits electrical impulses that stimulate contraction of the myocardium. Under normal circumstances, the conduction system first stimulates contraction of the atria and then the ventricles. The synchronization of the atrial and ventricular events allows the ventricles to fill completely before ventricular ejection, thereby maximizing cardiac output. Three physiologic characteristics of two types of specialized electrical cells, the nodal cells and the Purkinje cells, provide this synchronization:

- *Automaticity:* ability to initiate an electrical impulse
- *Excitability:* ability to respond to an electrical impulse
- *Conductivity:* ability to transmit an electrical impulse from one cell to another

Both the **sinoatrial (SA) node** (the primary pacemaker of the heart) and the **atrioventricular (AV) node** (the secondary pacemaker of the heart) are composed of nodal cells. The SA node is located at the junction of the superior vena cava and the right atrium (Fig. 21-3). The SA node in a normal resting adult heart has an inherent firing rate of 60 to 100 impulses per minute; however, the rate changes in response to the metabolic demands of the body (Weber & Kelley, 2018).

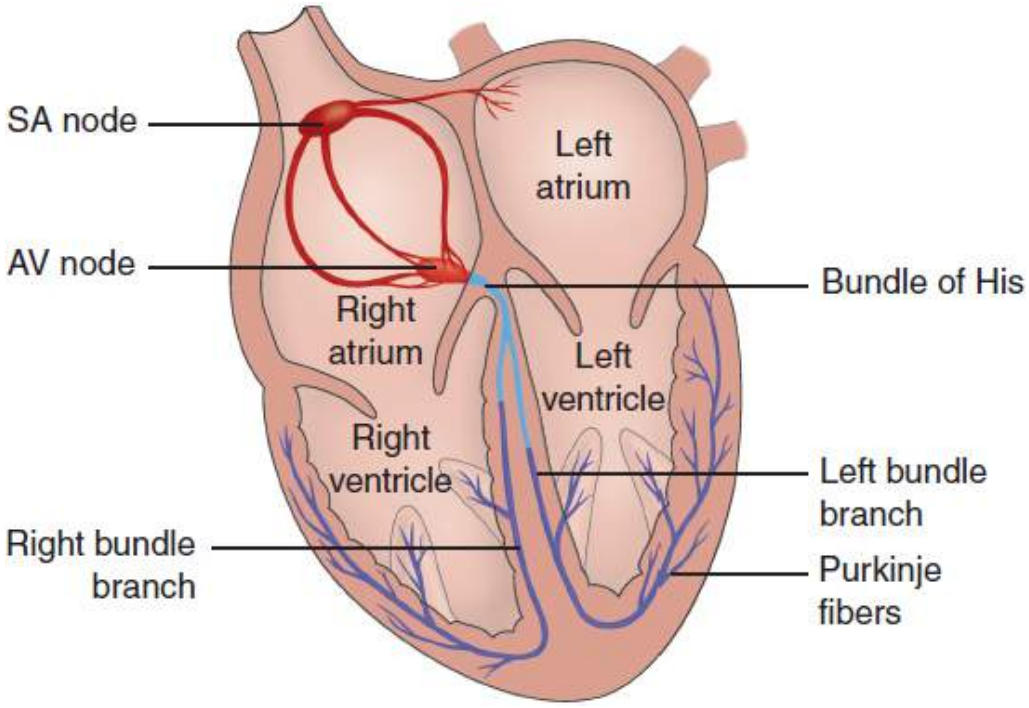

Figure 21-3 • Cardiac conduction system. AV, atrioventricular; SA, sinoatrial.

The electrical impulses initiated by the SA node are conducted along the myocardial cells of the atria via specialized tracts called *internodal pathways.* The impulses cause electrical stimulation and subsequent contraction of the atria. The impulses are then conducted to the AV node, which is located in the right atrial wall near the tricuspid valve (see Fig. 21-3). The AV node coordinates the incoming electrical impulses from the atria and after a slight delay (allowing the atria time to contract and complete ventricular filling) relays the impulse to the ventricles.

Initially, the impulse is conducted through a bundle of specialized conducting tissue, referred to as the bundle of His, which then divides into the right bundle branch (conducting impulses to the right ventricle) and the left bundle branch (conducting impulses to the left ventricle). To transmit impulses to the left ventricle—the largest chamber of the heart—the left bundle branch divides into the left anterior and left posterior bundle branches. Impulses travel through the bundle branches to reach the terminal point in the conduction system, called the *Purkinje fibers.* These fibers are composed of Purkinje cells that rapidly conduct impulses throughout the thick walls of the ventricles. This action stimulates the ventricular myocardial cells to contract (Weber & Kelley, 2018).

The heart rate is determined by the myocardial cells with the fastest inherent firing rate. Under normal circumstances, the SA node has the highest inherent rate (60 to 100 impulses per minute), the AV node has the second-highest inherent rate (40 to 60 impulses per minute), and the ventricular

pacemaker sites have the lowest inherent rate (30 to 40 impulses per minute) (Wesley, 2017). If the SA node malfunctions, the AV node generally takes over the pacemaker function of the heart at its inherently lower rate. Should both the SA and the AV nodes fail in their pacemaker function, a pacemaker site in the ventricle will fire at its inherent bradycardic rate of 30 to 40 impulses per minute.

Cardiac Action Potential

The nodal and Purkinje cells (electrical cells) generate and transmit impulses across the heart, stimulating the cardiac myocytes (working cells) to contract. Stimulation of the myocytes occurs due to the exchange of electrically charged particles, called *ions,* across channels located in the cell membrane. The channels regulate the movement and speed of specific ions—namely, sodium, potassium, and calcium—as they enter and exit the cell. Sodium rapidly enters into the cell through sodium-fast channels, in contrast to calcium, which enters the cell through calcium-slow channels. In the resting or polarized state, sodium is the primary extracellular ion, whereas potassium is the primary intracellular ion. This difference in ion concentration means that the inside of the cell has a negative charge compared with the positive charge on the outside. The relationship changes during cellular stimulation, when sodium or calcium crosses the cell membrane into the cell and potassium ions exit into the extracellular space. This exchange of ions creates a positively charged intracellular space and a negatively charged extracellular space that characterizes the period known as **depolarization**. Once depolarization is complete, the exchange of ions reverts to its resting state; this period is known as **repolarization**. The repeated cycle of depolarization and repolarization is called the *cardiac action potential.*

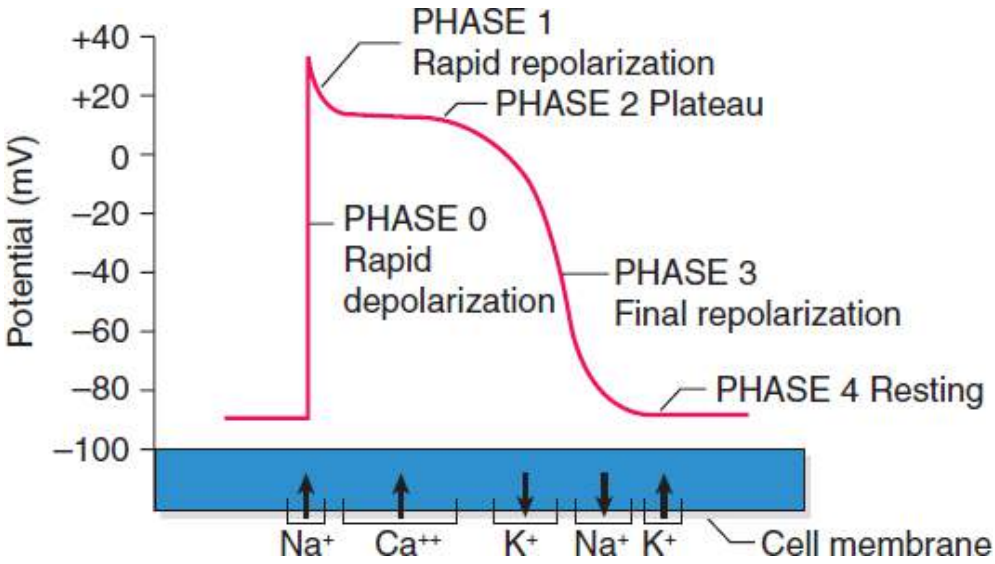

Figure 21-4 • Cardiac action potential of a fast-response Purkinje fiber. The *arrows* indicate the approximate time and direction of movement of each ion influencing membrane potential. Ca^{++} movement out of the cell is not well defined but is thought to occur during phase 4.

As shown in Figure 21-4, the cardiac action potential has five phases:

- *Phase 0:* Cellular depolarization is initiated as positive ions influx into the cell. During this phase, the atrial and ventricular myocytes rapidly depolarize as sodium moves into the cells through sodium-fast channels. The myocytes have a fast-response action potential. In contrast, the cells of the SA and AV node depolarize when calcium enters these cells through calcium-slow channels. These cells have a slow-response action potential.
- *Phase 1:* Early cellular repolarization begins during this phase as potassium exits the intracellular space.
- *Phase 2:* This phase is called the *plateau phase* because the rate of repolarization slows. Calcium ions enter the intracellular space.
- *Phase 3:* This phase marks the completion of repolarization and return of the cell to its resting state.
- *Phase 4:* This phase is considered the resting phase before the next depolarization.

Refractory Periods

Myocardial cells must completely repolarize before they can depolarize again. During the repolarization process, the cells are in a refractory period. There are two phases of the refractory period: the effective (or absolute) refractory period and the relative refractory period. During the effective refractory period, the cell is completely unresponsive to any electrical stimulus; it is

incapable of initiating an early depolarization. The effective refractory period corresponds with the time in phase 0 to the middle of phase 3 of the action potential. The relative refractory period corresponds with the short time at the end of phase 3. During the relative refractory period, if an electrical stimulus is stronger than normal, the cell may depolarize prematurely. Early depolarizations of the atrium or ventricle cause premature contractions, placing the patient at risk for arrhythmias. Premature ventricular contractions in certain situations, such as the presence of myocardial ischemia, are of concern because these early ventricular depolarizations can trigger life-threatening arrhythmias, including ventricular tachycardia or ventricular fibrillation. Several circumstances make the heart more susceptible to early depolarization during the relative refractory period, thus increasing the risk for serious arrhythmias. (These arrhythmias and others are discussed in detail in Chapter 22.)

Cardiac Hemodynamics

An important determinant of blood flow in the cardiovascular system is the principle that fluid flows from a region of higher pressure to one of lower pressure (see Fig. 21-2). The pressures responsible for blood flow in the normal circulation are generated during systole and diastole.

Cardiac Cycle

The cardiac cycle refers to the events that occur in the heart from the beginning of one heartbeat to the next. The number of cardiac cycles completed in a minute depends on the heart rate. Each cardiac cycle has three major sequential events: diastole, atrial systole, and ventricular systole. These events cause blood to flow through the heart due to changes in chamber pressures and valvular function during diastole and systole. During diastole, all four heart chambers are relaxed. As a result, the AV valves are open and the semilunar valves are closed. Pressures in all of the chambers are the lowest during diastole, which facilitates ventricular filling. Venous blood returns to the right atrium from the superior and inferior vena cava, then into the right ventricle. On the left side, oxygenated blood returns from the lungs via the four pulmonary veins into the left atrium and ventricle.

Toward the end of this diastolic period, atrial systole occurs as the atrial muscles contract in response to an electrical impulse initiated by the SA node. Atrial systole increases the pressure inside the atria, ejecting the remaining blood into the ventricles. Atrial systole augments ventricular blood volume by 15% to 25% and is sometimes referred to as the atrial kick (Wesley, 2017). At this point, ventricular systole begins in response to propagation of the electrical impulse that began in the SA node some milliseconds earlier.

Beginning with ventricular systole, the pressure inside the ventricles rapidly increases, forcing the AV valves to close. As a result, blood ceases to flow from the atria into the ventricles, and regurgitation (backflow) of blood into the atria is prevented. The rapid increase in pressure inside the right and left ventricles forces the pulmonic and aortic valves to open, and blood is ejected into the pulmonary artery and aorta, respectively. The exit of blood is at first rapid; then, as the pressure in each ventricle and its corresponding artery equalizes, the flow of blood gradually decreases. At the end of systole, pressure within the right and left ventricles rapidly decreases. As a result, pulmonary arterial and aortic pressures decrease, causing closure of the semilunar valves. These events mark the onset of diastole, and the cardiac cycle is repeated.

Chamber pressures can be measured with the use of special monitoring catheters and equipment. This technique is called **hemodynamic monitoring.** Methods of hemodynamic monitoring are covered in more detail at the end of this chapter.

Cardiac Output

Cardiac output refers to the total amount of blood ejected by one of the ventricles in liters per minute. The cardiac output in a resting adult is 4 to 6 L/min but varies greatly depending on the metabolic needs of the body. Cardiac output is computed by multiplying the stroke volume by the heart rate. **Stroke volume** is the amount of blood ejected from one of the ventricles per heartbeat. The average resting stroke volume is about 60 to 130 mL (Wiegand, 2017).

Effect of Heart Rate on Cardiac Output

The cardiac output responds to changes in the metabolic demands of the tissues associated with stress, physical exercise, and illness. To compensate for these added demands, the cardiac output is enhanced by increases in both stroke volume and heart rate. Changes in heart rate are due to inhibition or stimulation of the SA node mediated by the parasympathetic and sympathetic divisions of the autonomic nervous system. The balance between these two reflex control systems normally determines the heart rate. Branches of the parasympathetic nervous system travel to the SA node by the vagus nerve. Stimulation of the vagus nerve slows the heart rate. The sympathetic nervous system increases heart rate by innervation of the beta-1 receptor sites located within the SA node. The heart rate is increased by the sympathetic nervous system through an increased level of circulating catecholamines (secreted by the adrenal gland) and by excess thyroid hormone, which produces a catecholamine-like effect.

In addition, the heart rate is affected by central nervous system and baroreceptor activity. **Baroreceptors** are specialized nerve cells located in the

aortic arch and in both right and left internal carotid arteries (at the point of bifurcation from the common carotid arteries). The baroreceptors are sensitive to changes in blood pressure (BP). During hypertension (significant elevations in BP), these cells increase their rate of discharge, transmitting impulses to the cerebral medulla. This action initiates parasympathetic activity and inhibits sympathetic response, lowering the heart rate and the BP. The opposite is true during hypotension (low BP). Decreased baroreceptor stimulation during periods of hypotension prompts a decrease in parasympathetic activity and enhances sympathetic responses. These compensatory mechanisms attempt to elevate the BP through vasoconstriction and increased heart rate.

Effect of Stroke Volume on Cardiac Output

Stroke volume is primarily determined by three factors: preload, afterload, and contractility.

Preload refers to the degree of stretch of the ventricular cardiac muscle fibers at the end of diastole. The end of diastole is the period when filling volume in the ventricles is the highest and the degree of stretch on the muscle fibers is the greatest. The volume of blood within the ventricle at the end of diastole determines preload, which directly affects stroke volume. Therefore, preload is commonly referred to as left ventricular end-diastolic pressure. As the volume of blood returning to the heart increases, muscle fiber stretch also increases (increased preload), resulting in stronger contraction and a greater stroke volume. This relationship, referred to as the Frank–Starling (or Starling) law of the heart, is maintained until the physiologic limit of the muscle is reached.

The Frank–Starling law is based on the fact that, within limits, the greater the initial length or stretch of the sarcomeres (cardiac muscle cells), the greater the degree of shortening that occurs. This result is caused by increased interaction between the thick and thin filaments within the cardiac muscle cells. Preload is decreased by a reduction in the volume of blood returning to the ventricles. Diuresis, venodilating agents (e.g., nitrates), excessive loss of blood, or dehydration (excessive loss of body fluids from vomiting, diarrhea, or diaphoresis) reduce preload. Preload is increased by increasing the return of circulating blood volume to the ventricles. Controlling the loss of blood or body fluids and replacing fluids (i.e., blood transfusions and intravenous [IV] fluid administration) are examples of ways to increase preload.

Afterload, or resistance to ejection of blood from the ventricle, is the second determinant of stroke volume. The resistance of the systemic BP to left ventricular ejection is called **systemic vascular resistance.** The resistance of the pulmonary BP to right ventricular ejection is called **pulmonary vascular resistance.** There is an inverse relationship between afterload and stroke volume. For example, afterload is increased by arterial vasoconstriction, which leads to decreased stroke volume. The opposite is true with arterial

vasodilation, in which case afterload is reduced because there is less resistance to ejection, and stroke volume increases.

Contractility refers to the force generated by the contracting myocardium. Contractility is enhanced by circulating catecholamines, sympathetic neuronal activity, and certain medications (e.g., digoxin, dopamine, or dobutamine). Increased contractility results in increased stroke volume. Contractility is depressed by hypoxemia, acidosis, and certain medications (e.g., beta-adrenergic–blocking agents such as metoprolol).

The heart can achieve an increase in stroke volume (e.g., during exercise) if preload is increased (through increased venous return), if contractility is increased (through sympathetic nervous system discharge), and if afterload is decreased (through peripheral vasodilation with decreased aortic pressure).

The percentage of the end-diastolic blood volume that is ejected with each heartbeat is called the **ejection fraction.** The ejection fraction of the normal left ventricle is 55% to 65% (Wiegand, 2017). The right ventricular ejection fraction is rarely measured. The ejection fraction is used as a measure of myocardial contractility. An ejection fraction of less than 40% indicates that the patient has decreased left ventricular function and likely requires treatment of HF (refer to Chapter 25 for further discussion).

Gerontologic Considerations

Changes in cardiac structure and function occur with age. A loss of function of the cells throughout the conduction system leads to a slower heart rate. The size of the heart increases due to hypertrophy (thickening of the heart walls), which reduces the volume of blood that the chambers can hold. Hypertrophy also changes the structure of the myocardium, reducing the strength of contraction. Both of these changes negatively affect cardiac output. The valves, due to stiffening, no longer close properly. The resulting backflow of blood creates heart murmurs, a common finding in older adults (Bickley, 2017; Pappano & Weir, 2019).

As a result of these age-related changes, the cardiovascular system takes longer to compensate from increased metabolic demands due to stress, exercise, or illness. In these situations, older adults may become symptomatic with fatigue, shortness of breath, or palpitations and present with new physical examination findings (Bickley, 2017; Zipes, Libby, Bonow, et al., 2019). The structural and functional changes with aging and associated history and physical examination findings are summarized in Table 21-1.

Gender Considerations

Structural differences between the hearts of men and women have significant implications. The heart of a woman tends to be smaller than that of a man. The coronary arteries of a woman are also narrower in diameter than a man's arteries. When atherosclerosis occurs, these differences make procedures such as cardiac catheterization and angioplasty technically more difficult.

Women typically develop CAD 10 years later than men, as women have the benefit of the cardioprotective effects of the female hormone estrogen. The three major effects of estrogen are (1) an increase in high-density lipoprotein (HDL) that transports cholesterol out of arteries; (2) a reduction in low-density lipoprotein (LDL) that deposits cholesterol in the artery; and (3) dilation of the blood vessels, which enhance blood flow to the heart. As testosterone increases and estrogen decreases, women who are postmenopausal have a greater risk of CAD, CVD, and HF (Zhao, Guallar, Ouyang, et al., 2018). Hormone therapy (HT) is not recommended for routine prevention of CAD in women who are postmenopausal, although there are possible benefits to cardiovascular health if HT is initiated soon after the initiation of menopause (Keck & Taylor, 2018).

Assessment of the Cardiovascular System

The frequency and extent of the nursing assessment of cardiovascular function are based on several factors, including the severity of the patient's symptoms, the presence of risk factors, the practice setting, and the purpose of the assessment. Although the key components of the cardiovascular assessment remain the same, the assessment priorities vary according to patient needs. For example, an emergency department (ED) nurse performs a rapid and focused assessment of a patient in which **acute coronary syndrome** (ACS), signs and symptoms caused by ruptured atheromatous plaque in a diseased coronary artery, is suspected. Diagnosis and treatment must be started immediately, which includes an electrocardiogram (ECG) within 10 minutes of arrival to the ED (Yiadom, Baugh, McWade, et al., 2017). The physical assessment is ongoing and concentrates on evaluating the patient for ACS complications, such as a myocardial infarction (MI), arrhythmias, and HF, and determining the effectiveness of medical treatment.

TABLE 21-1 Age-Related Changes of the Cardiac System

Cardiovascular Structure	Structural Changes	Functional Changes	History and Physical Findings
Atria	↑ Size of left atrium Thickening of the endocardium	↑ Atrial irritability	Irregular heart rhythm from atrial arrhythmias
Left ventricle	Endocardial fibrosis Myocardial hypertrophy (thickening) Infiltration of fat into myocardium	Left ventricle stiff and less compliant Progressive decline in cardiac output ↑ Risk for ventricular arrhythmias Prolonged systole	Fatigue ↓ Exercise tolerance Signs and symptoms of heart failure or ventricular arrhythmias Point of maximal impulse palpated lateral to the midclavicular line ↓ Intensity S_1, S_2; split S_2 S_4 may be present
Valves	Thickening and rigidity of AV valves Calcification of aortic valve	Abnormal blood flow across valves during cardiac cycle	Murmurs may be present Thrill may be palpated if significant murmur is present
Conduction system	Connective tissue collects in SA node, AV node, and bundle branches ↓ Number of SA node cells ↓ Number of AV, bundle of His, and right and left bundle branch cells	Slower SA node rate of impulse discharge Slowed conduction across AV node and ventricular conduction system	Bradycardia Heart block ECG changes consistent with slowed conduction (↑ PR interval, widened QRS complex)
Sympathetic nervous system	↓ Response to beta-adrenergic stimulation	↓ Adaptive response to exercise: contractility and heart rate slower to respond to exercise demands Heart rate takes more time to return to baseline	Fatigue Diminished exercise tolerance ↓ Ability to respond to stress
Aorta and arteries	Stiffening of vasculature	Left ventricular hypertrophy	Progressive increase in systolic BP;

	↓ Elasticity and widening of aorta Elongation of aorta, displacing the brachiocephalic artery upward		slight ↑ in diastolic BP Widening pulse pressure Pulsation visible above right clavicle
Baroreceptor response	↓ Sensitivity of baroreceptors in the carotid artery and aorta to transient episodes of hypertension and hypotension	Baroreceptors unable to regulate heart rate and vascular tone, causing slow response to postural changes in body position	Postural BP changes and reports of feeling dizzy, fainting when moving from lying to sitting or standing position

AV, atrioventricular; BP, blood pressure; ECG, electrocardiographic; SA, sinoatrial.

Health History

The patient's ability to recognize cardiac symptoms and to know what to do when they occur is essential for effective self-care management. All too often, a patient's new symptoms or those of progressing cardiac dysfunction go unrecognized, resulting in lifesaving treatment delays. Research findings suggest that ethnic and socioeconomic factors can lead to patient-related delays (Iacoe, Ratner, Wong, et al., 2018). Women, African Americans, and older patients are reported to delay seeking treatment when they have had MIs (Zipes et al., 2019). Socioeconomic factors such as poverty, high health care costs, lack of insurance, transportation, and proximity to a health care provider or hospital can also lead to delays in care. Patients may also lack knowledge about ACS symptoms, or experience denial, fear, or uncertainty about what to do when having chest pain. Some women have the misperception that the risk for cardiac disease is only linked to weight. A female patient who is embarrassed from the social stigma of being overweight may not see a health care provider, or could be reluctant to disclose important cardiac symptoms (Merz, Andersen, Sprague, et al., 2017). Therefore, during the health history, the nurse determines if the patient and involved family members are able to recognize symptoms of an acute cardiac problem, such as ACS or HF, and seek timely treatment of these symptoms. Responses to this level of inquiry will help the nurse individualize the plan for patient and family education.

Common Symptoms

The signs and symptoms experienced by people with CVD are related to arrhythmias and conduction problems (see Chapter 22); CAD (see Chapter

23); structural, infectious, and inflammatory disorders of the heart (see Chapter 24); and complications of CAD such as HF and cardiogenic shock (see Chapters 11 and 25). These disorders have many signs and symptoms in common; therefore, the nurse must be skillful at recognizing these signs and symptoms so that patients are given timely and often lifesaving care.

The following are the most common signs and symptoms of CVD, with related medical diagnoses in parentheses:

- Chest pain or discomfort (angina pectoris, ACS, arrhythmias, valvular heart disease)
- Pain or discomfort in other areas of upper body, including one or both arms, back, neck, jaw, or stomach (ACS)
- Shortness of breath or dyspnea (ACS, cardiogenic shock, HF, valvular heart disease)
- Peripheral edema, weight gain, abdominal distention due to enlarged spleen and liver or ascites (HF)
- Palpitations (tachycardia from a variety of causes, including ACS, caffeine or other stimulants, electrolyte imbalances, stress, valvular heart disease, ventricular aneurysms)
- Unusual fatigue, sometimes referred to as vital exhaustion (an early warning symptom of ACS, HF, or valvular heart disease, characterized by feeling unusually tired or fatigued, irritable, and dejected)
- Dizziness, syncope, or changes in level of consciousness (cardiogenic shock, cerebrovascular disorders, arrhythmias, hypotension, orthostatic hypotension, vasovagal episode)

Symptoms of ACS can differ between men and women. Chest pain and discomfort related to ACS can occur in both men and women. However, women may experience more atypical or nonspecific symptoms such as chest pain at rest; pain in the jaw, arm, neck, shoulder, middle back, or epigastrium; nausea; vomiting; syncope; sweating; anxiety; and fatigue (Lichtman, Leifheit, Safdar, et al., 2018; Merz et al., 2017).

Chest Pain

Chest pain and chest discomfort are common symptoms that may be caused by a number of cardiac and noncardiac problems. Table 21-2 summarizes the characteristics and patterns of common causes of chest pain or discomfort. To differentiate among these causes of pain, the nurse asks the patient to identify the quantity (0 = no pain to 10 = worst pain), location, and quality of pain. The nurse assesses for radiation of the pain to other areas of the body and determines if associated signs and symptoms are present, such as diaphoresis or nausea. It is important to identify the events that precipitate the onset of

symptoms, the duration of the symptoms, and measures that aggravate or relieve the symptoms.

The nurse keeps the following important points in mind when assessing patients reporting chest pain or discomfort:

- The location of chest symptoms is not well correlated with the cause of the pain. For example, substernal chest pain can result from a number of causes as outlined in Table 21-2.
- The severity or duration of chest pain or discomfort does not predict the seriousness of its cause. For example, when asked to rate pain using a 0 to 10 scale, patients experiencing esophageal spasm may rate their chest pain as a 10. In contrast, patients having an acute MI, which is a potentially life-threatening event, may report having moderate pain rated as a 4 to 6 on the pain scale.
- More than one clinical cardiac condition may occur simultaneously. During an MI, patients may report chest pain from myocardial ischemia, shortness of breath from HF, and palpitations from arrhythmias. Both HF and arrhythmias can be complications of an acute MI. (See Chapter 23 for discussion of clinical manifestations of ACS, including MI.)

Past Health, Family, and Social History

The health history provides an opportunity for the nurse to assess patients' understanding of their personal risk factors for peripheral vascular, cerebrovascular, and CAD and any measures that they are taking to modify these risks. Some risk factors, such as increasing age, male gender, and heredity, including race are not modifiable. However, there are a number of risk factors, such as smoking, hypertension, high cholesterol, diabetes, obesity, and physical inactivity that can be modified by lifestyle changes or medications (Arnett, Blumenthal, Albert, et al., 2019). Online tools from the AHA and the American College of Cardiology (ACC) can be used to screen a person's risk for CVD, including risk for having an MI or stroke (ACC, 2019; AHA, 2018; see Resources at the end of this chapter for a link to these tools).

In an effort to determine how patients perceive their current health status, the nurse asks the following questions:

- How is your health? Have you noticed any changes from last year? From 5 years ago?
- Do you have a cardiologist or primary provider? How often do you go for checkups?
- What health concerns do you have?
- Do you have a family history of genetic disorders that place you at risk for CVD (Chart 21-1)?
- What are your risk factors for CAD (see Chapter 23, Chart 23-1)?

- What do you do to stay healthy and take care of your heart?

Patients who do not understand the connection between risk factors and CAD may be unwilling to make recommended lifestyle changes or manage their illness effectively. In contrast, patients who have this understanding may be more motivated to alter their lifestyle to avoid the risk of future cardiac events. The AHA published lifestyle management guidelines that identify interventions and treatment goals for each of these risk factors (Arnett et al., 2019). Chapter 23 provides an overview of this information.

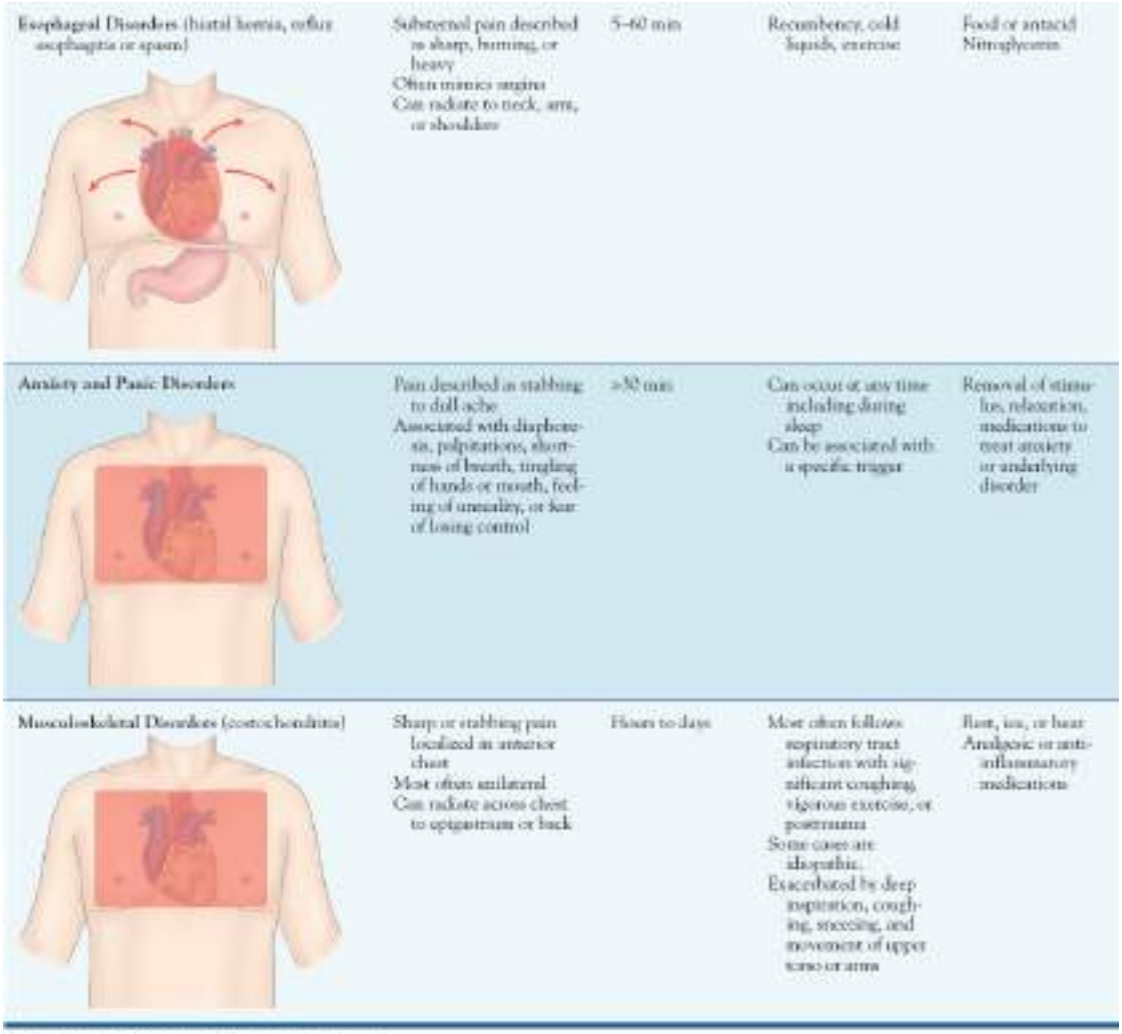
Medications

Nurses collaborate with other health care providers, including pharmacists, to obtain a complete list of the patient's medications, including dose and frequency. Vitamins, herbals, and other over-the-counter medications are included on this list. During this aspect of the health assessment, the nurse asks the following questions to ensure that the patient is safely and effectively taking the prescribed medications.

- What are the names and doses of your medications?
- What is the purpose of each of these medications?
- How and when are these medications taken? Do you ever skip a dose or forget to take them?
- Are there any special precautions associated with any of these medications?
- What symptoms or problems do you need to report to your primary provider?

TABLE 21-2 Assessing Chest Pain

Location	Character	Duration	Precipitating Events and Aggravating Factors	Alleviating Factors
Angina Pectoris, ACS (unstable angina, MI)  Less common sites of pain with myocardial ischemia	Angina: Uncomfortable pressure, squeezing, or fullness in substernal chest area Can radiate across chest to the medial aspect of one or both arms and hands, jaw, shoulders, upper back, or epigastrium Radiation to arms and hands, described as numbness, tingling, or aching	Angina: 5–15 min	Angina: Physical exertion, emotional upset, eating large meal, or exposure to extremes in temperature	Angina: Rest, nitroglycerin, oxygen
	ACS: Same as angina pectoris Pain or discomfort ranges from mild to severe Associated with shortness of breath, diaphoresis, palpitations, unusual fatigue, and nausea or vomiting	ACS: >15 min	ACS: Emotional upset or unusual physical exertion occurring within 24 h of symptom onset Can occur at rest or while asleep	ACS: Morphine, reperfusion of coronary artery with thrombolytic (fibrinolytic) agent or percutaneous coronary intervention
Pericarditis 	Sharp, severe substernal or epigastric pain Can radiate to neck, arms, and back Associated symptoms include fever, malaise, dyspnea, cough, nausea, dizziness, and palpitations	Intermittent	Sudden onset Pain increases with inspiration, swallowing, coughing, and rotation of trunk	Sitting upright, analgesia, anti-inflammatory medications
Pulmonary Disorders (pneumonia, pulmonary embolism) 	Sharp, severe substernal or epigastric pain arising from inferior portion of pleura (referred to as pleuritic pain) Patient may be able to localize the pain	≥30 min	Follows an infectious or noninfectious process (MI, cardiac surgery, cancer, immune disorders, uremia) Pleuritic pain increases with inspiration, coughing, movement, and supine positioning Occurs in conjunction with community- or hospital-acquired lung infections (pneumonia) or venous thromboembolism (pulmonary embolism)	Treatment of underlying cause



ACS, acute coronary syndrome; MI, myocardial infarction.
Adapted from Bickley, L. S. (2013). Bates' guide to physical examination and history taking (11th ed.). Philadelphia, PA: Lippincott Williams & Wilkins; Radeva, S., & Cannon, M. J. (2018). Chest pain. If it is not the heart, what is it? Nursing Clinics of North America, 53(3), 421–431; Zipes, D. P., Libby, P., Bonow, R. O., et al. (2019). Braunwald's heart disease: A textbook of cardiovascular medicine (11th ed.). Philadelphia, PA: Elsevier.

Patients recovering from ACS, including coronary stent placement or coronary artery bypass graft (CABG), are commonly prescribed dual antiplatelet therapy (DAPT). DAPT means that two antiplatelet drugs are prescribed for the patient. Aspirin, an OTC antiplatelet medication, is often prescribed for life. In addition, a second antiplatelet P2Y12 inhibitor medication (clopidogrel, prasugrel, or ticagrelor) is prescribed for 1 to 12 months, depending upon a variety of factors, including the patient's diagnosis and the type of procedure done (see Chapter 23 for further discussion of ACS treatment and pharmacologic management) (Levine, Bates, Bittl, et al., 2016). During a careful medication history, the nurse reinforces the necessity for adherence to the medication regimen.

Nutrition

Dietary modifications, exercise, weight loss, and careful monitoring are important strategies for managing three major cardiovascular risk factors: hyperlipidemia, hypertension, and diabetes. Diets that are restricted in sodium,

fat, cholesterol, or calories are commonly prescribed. The nurse obtains the following information:

- The patient's current height and weight (to determine body mass index [BMI]); waist measurement; BP; and any laboratory test results such as blood glucose, glycosylated hemoglobin (diabetes), total blood cholesterol, HDL and LDL levels, and triglyceride levels (hyperlipidemia)
- How often the patient self-monitors BP, blood glucose, and weight as appropriate to the medical diagnoses
- The patient's level of awareness regarding their target goals for each of the risk factors and any problems achieving or maintaining these goals
- What the patient normally eats and drinks in a typical day and any food preferences (including cultural or ethnic preferences)
- Eating habits (canned or commercially prepared foods vs. fresh foods, restaurant meals vs. home cooking, assessing for high-sodium foods, dietary intake of fats)
- Who shops for groceries and prepares meals

Chart 21-1 **GENETICS IN NURSING PRACTICE**

Cardiovascular Disorders

Several cardiovascular disorders are associated with genetic abnormalities. Some examples are:

- Arrhythmogenic right ventricular dysplasia (ARVD)
- Brugada syndrome
- Familial hypercholesterolemia
- Hypertrophic cardiomyopathy
- Long QT syndrome
    - Jervell and Lange-Nielsen syndrome (autosomal recessive form)
    - Romano–Ward syndrome (autosomal dominant form)
    - Genetic connective tissue disorders that impact the cardiovascular system:
- Ehlers–Danlos syndrome
- Loeys–Dietz syndrome
- Marfan syndrome

Genetic blood disorders that can impair the function of the cardiovascular system:

- Factor V Leiden
- Hemochromatosis
- Sickle cell disease

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Cardiovascular Disorders

- Assess all patients with cardiovascular symptoms for coronary artery disease, regardless of age.
- Inquire about a family history of sudden death or unexplained death.
- Ask about other family members with biochemical or neuromuscular conditions (e.g., hemochromatosis or muscular dystrophy).

Patient Assessment Specific to Cardiovascular Disorders

- Assess for signs and symptoms of hyperlipidemias (xanthomas, corneal arcus, or abdominal pain of unexplained

origin).
- Obtain an electrocardiogram and an echocardiogram.
- Assess for muscular weakness.
- Assess for episodes of shortness of breath, dizziness, or palpitations.
- Review laboratory data for abnormal values.
- Gather dietary history.
- Assess for secondary risk factors (e.g., diet, smoking, overweight, high stress, alcohol use).

Elimination

Typical bowel and bladder habits need to be identified. Nocturia (awakening at night to urinate) is common in patients with HF. Fluid collected in gravity-dependent tissues (extremities) during the day (i.e., edema) redistributes into the circulatory system once the patient is recumbent at night. The increased circulatory volume is excreted by the kidneys (increased urine production).

When straining during defecation, the patient bears down (the Valsalva maneuver), which momentarily increases pressure on the baroreceptors. This triggers a vagal response, causing the heart rate to slow and resulting in syncope in some patients. Straining during urination can produce the same response.

Because many cardiac medications can cause gastrointestinal side effects or bleeding, the nurse asks about bloating, diarrhea, constipation, stomach upset, heartburn, loss of appetite, nausea, and vomiting. Screening for bloody urine or stools should be done for patients taking antiplatelet medications (aspirin, clopidogrel, prasugrel, ticagrelor), platelet aggregation inhibitors (abciximab, eptifibatide, tirofiban), or anticoagulants (low-molecular-weight heparins such as dalteparin or enoxaparin; heparin; or oral anticoagulants such as warfarin, rivaroxaban, or apixaban).

Activity and Exercise

Changes in the patient's activity tolerance are often gradual and may go unnoticed. The nurse determines if there are recent changes by comparing the patient's current activity level with that performed in the past 6 to 12 months. New symptoms or a change in the usual symptoms during activity is a significant finding. Activity-induced angina or shortness of breath may indicate CAD. These CAD-related symptoms occur when myocardial ischemia is present, due to an inadequate arterial blood supply to the myocardium, in the setting of increased demand (e.g., exercise, stress, or anemia). Patients experiencing these kinds of symptoms need to seek medical attention. Fatigue, associated with a low left ventricular ejection fraction (less than 40%) and

certain medications (e.g., beta-adrenergic–blocking agents), can result in activity intolerance. Patients with fatigue may benefit from having their medications adjusted and learning energy conservation techniques.

Additional areas to explore include the presence of architectural barriers in the home (stairs, multilevel home); the patient's participation in cardiac rehabilitation; and his or her current exercise pattern including intensity, duration, and frequency.

Sleep and Rest

Clues to worsening cardiac disease, especially HF, can be revealed by sleep-related events. Patients with worsening HF often experience *orthopnea,* a term used to indicate the need to sit upright or stand to avoid feeling short of breath. Patients experiencing orthopnea will report that they need to sleep upright in a chair or add extra pillows to their bed. Sudden awakening with shortness of breath, called *paroxysmal nocturnal dyspnea,* is an additional symptom of worsening HF. This nighttime symptom is caused by the reabsorption of fluid from dependent areas of the body (arms and legs) back into the circulatory system within hours of lying in bed. This sudden fluid shift increases preload and places increased demand on the heart of patients with HF, causing sudden pulmonary congestion.

Sleep-disordered breathing (SDB) is an abnormal respiratory pattern due to intermittent episodes of upper airway obstruction causing apnea and hypopnea (shallow respirations) during sleep. These abnormal sleep events cause intermittent hypoxemia, sympathetic nervous system activation, and increased intrathoracic pressure that puts mechanical stress on the heart and large artery walls. SDB impacts the length and quality of sleep. Short sleep duration (less than 7 hours per night) and poor sleep quality (interrupted sleep) are associated with the cardiovascular risks of hypertension, atherosclerosis, CAD, and stroke (Domínguez, Fuster, Fernández-Alvira, et al., 2019). Untreated SDB is also linked to HF and arrhythmias. Obstructive sleep apnea (OSA) is a type of SDB that is treated by the use of continuous positive airway pressure (CPAP), although many patients have difficulty with CPAP adherance. Other treatment options include weight loss, positional therapy, mandibular advancement devices (MADs), oral appliances, or surgery (Won, Mohsenin, & Kryger, 2018; see Chapter 18 for further discussion of OSA, including risks).

During the health history, the nurse assesses for SDB by asking patients at risk if they snore loudly, have frequent bouts of awaking from sleep, awaken with a headache, or experience hypersomnolence (severe daytime sleepiness). For patients with a diagnosis of SDB or OSA, the nurse determines if the patient has been prescribed a CPAP, MAD, or oral appliance, and the frequency of its use. Patients who are being admitted to the hospital or going for an ambulatory surgical procedure should be instructed to bring their sleep aid devices with them.

Self-Perception and Self-Concept

Self-perception and self-concept are both related to the cognitive and emotional processes that people use to formulate their beliefs and feelings about themselves. Having a chronic cardiac illness, such as HF, or experiencing an acute cardiac event, such as an MI, can alter a person's self-perception and self-concept. Patients' beliefs and feelings about their health are key determinants of adherence to self-care recommendations and recovery after an acute cardiac event. To reduce the risk of future cardiovascular-related health problems, patients are asked to make difficult lifestyle changes, such as quitting smoking. Patients who have misperceptions about the health consequences of their illness are at risk for nonadherence to these recommended lifestyle changes. The health history is used to discover how patients perceive their health by asking questions that may include the following:

- What is your cardiac condition?
- How has this illness changed your feelings about your health?
- What do you think caused this illness?
- What consequences do you think this illness will have on your physical activity, work, social relationships, and role in your family?
- How much of an influence do you think you have on controlling this illness?

The patient's responses to these questions can guide the nurse in planning interventions to ensure that the patient is prepared to manage the illness and that adequate services are in place to support the patient's recovery and self-care needs.

Roles and Relationships

Patients with CVD are being managed with complex medical regimens and sophisticated technology, such as implantable cardioverter defibrillators (ICDs) and left ventricular assist devices. Hospital stays for cardiac disorders have shortened. Many invasive diagnostic cardiac procedures, such as cardiac catheterization, are being performed in the ambulatory setting. Support from family members helps to lessen the patient's burden of managing self-care for cardiac illnesses. Social support is closely linked to patient depression and CVD outcomes. Patients who are depressed and who have poor social support have an increased risk of poor cardiac outcomes (Kim, Kang, Bae, et al., 2019).

To assess patients' roles in their families and their relationships, both components of social support, the nurse asks each patient: Who do you live with? Who is your primary caregiver at home? Who helps you manage your health? The nurse also assesses for any significant effects that the cardiac illness has had on the patient's role in the family. Are there adequate finances

and health insurance? The answers to these questions help the nurse determine if consultation with social services or others is necessary to tailor the plan of care to meet the patient's self-care needs.

Sexuality and Reproduction

Sexual dysfunction affects twice as many people with CVD compared with the general population. Depression, anxiety, erectile dysfunction, and major cardiac events such as an MI are common reasons that patients report decreased sexual activity. Patients and their partners are concerned about the effects of physical exertion on the heart and if the activity may cause another heart attack, sudden death, or untoward symptoms such as angina, dyspnea, or palpitations. Couples often lack adequate information about the physical demands related to sexual activity, which is considered a low-intensity exercise. The nurse can help patients by initiating discussions about sexuality and encouraging them to discuss problems with their primary provider or cardiologist. The exercise and counseling provided in cardiac rehabilitation programs may also improve sexual activity (Boothby, Dada, Rabi, et al., 2018).

Chart 21-2 **NURSING RESEARCH PROFILE**

Depression, Self-Efficacy, and Physical Activity among Patients with Coronary Artery Disease

Siow, E., Leung, D. Y., Wong, E. M., et al. (2018). Do depressive symptoms moderate the effects of exercise self-efficacy on physical activity among patients with coronary heart disease? *Journal of Cardiovascular Nursing*, *33*(4), e26–e34.

Purpose

Physical activity and exercise can reduce cardiac complications in patients with coronary artery disease (CAD). Patients with higher levels of self-efficacy are more likely to start and maintain an exercise program. Patients with CAD are also at risk for developing depression, which can lead to isolation and low activity levels. Therefore, the purpose of this study was to examine the relationship between the symptoms of depression, exercise self-efficacy, and physical activity among patients with CAD. The nurse researchers also explored if depression could impact the relationship between exercise self-efficacy and physical activity in this population.

Design

A cross-sectional, exploratory study was conducted with adult participants with CAD who were hospitalized in an emergency medicine or general medical unit. This study was performed at two hospitals in Hong Kong. The nurse researchers conducted a survey interview with 149 participants before discharge from the hospital. Participants completed a survey with questions about their socioeconomic status, current level of physical activity, self-efficacy about exercise, and symptoms of depression. Participants were then asked about their physical activity using the Godin–Shephard Leisure-Time Physical Activity questionnaire, about exercise self-efficacy using the Self-Efficacy for Exercise scale, and about depression using the Centre for Epidemiological Studies-Depression tool. Other information such as body mass index (BMI), medical diagnosis, and how many times participants were admitted to the hospital was obtained from the hospital records.

Findings

Most participants in this study were older adults with a mean age of 73 ±13 years, were male, married, living with family, and had a lower socioeconomic status. Approximately 50% of this sample had a normal BMI, and over half did some level of exercise. Participants with greater exercise self-efficacy were more likely to engage in physical activity. However, this relationship was stronger among participants with symptoms of depression. Participants who were depressed reported lower levels of self-efficacy and engaging in less physical activity.

Nursing Implications

The results of this study demonstrate the importance of assessing self-efficacy, physical activity, and depression among patients with CAD. It is

important to intervene and educate patients about lifestyle changes that improve exercise self-efficacy. Improving this level of confidence can help patients who are depressed start or increase their level of physical activity, which may improve cardiovascular health.

A reproductive history is necessary for women of childbearing age, particularly those with seriously compromised cardiac function. The reproductive history includes information about previous pregnancies, plans for future pregnancies, oral contraceptive use (especially in women older than 35 years who smoke), menopausal status, and the use of HT. Women who have a history of preeclampsia during pregnancy, preterm labor, or giving birth to an infant that was small for gestational age have a higher risk for developing CVD (Lane-Cordova, Khan, Grobman, et al., 2019).

Coping and Stress Tolerance

Anxiety, depression, and stress are known to influence both the development of and recovery from CAD and HF. Depression is twice as prevalent in women compared to men and has a negative impact on quality of life and overall prognosis. Patients who are depressed are more likely to be readmitted to the hospital after having a heart attack. The risk of depression is lower if the patient has relationship and work stability, a higher educational level, a healthy lifestyle, and the absence of comorbidities such as diabetes. Although the association between depression and CAD is not completely understood, biologic factors (e.g., platelet abnormalities, inflammatory responses, insulin resistance), lifestyle factors (e.g., diet, exercise, smoking), and behavioral factors (e.g., substance abuse, unemployment, social isolation) contribute to this link. Patients who are depressed are less motivated to adhere to follow-up appointments, take prescribed medications, or make recommended lifestyle changes such as smoking cessation, losing weight, exercising, or participating in cardiac rehabilitation (Jha, Qamar, Vaduganathan, et al., 2019; Vaccarino, Badimon, Bremner, et al., 2019; Yuan, Fang, Liu, et al., 2019). See Chart 21-2 for a Nursing Research Profile on depression, self-efficacy, and physical activity.

Patients with CAD or HF should be assessed for depression. Patients who have depression exhibit common signs and symptoms, such as feelings of worthlessness or guilt, problems falling asleep or staying asleep, having little interest or pleasure in doing things that they usually enjoy, having difficulty concentrating, restlessness, and recent changes in appetite or weight. The Patient Health Questionnaire (PHQ-2) is a two-question self-reported patient assessment tool recommended by the AHA. The nurse asks the patient:

- *Do you have little interest or pleasure in doing things over the last 2 weeks?*
- *Are you feeling down, depressed or hopeless over the last 2 weeks?*

The nurse scores the patient's responses to each question by assigning 0 for "not at all," 1 for "several days," 2 for "more than half the days," or 3 for "nearly every day." The PHQ-2 score ranges from 0 to 6. Patients with a positive score greater than or equal to 3 complete a focused screening called the PHQ-9 and are referred to their primary providers for further evaluation (Jha et al., 2019).

Stress initiates a variety of responses, including increased levels of catecholamines and cortisol, and has been strongly linked to cardiovascular events, such as an MI. Therefore, patients need to be assessed for sources of stress; the nurse asks about recent or ongoing stressors, previous coping styles and effectiveness, and the patient's perception of their current mood and coping ability. A widely used tool used to measure life stress is the Social Readjustment Rating Scale (Homes & Rahe, 1967). Examples of items on this scale include death of a spouse, divorce, and change in responsibilities at work. Each item is assigned a score of 11 to 100. Patients identify the items that happened to them in the previous year. Patients with a score less than 150 have a slight risk for future illness, whereas a score of 150 to 299 indicates a moderate risk. A score of 300 or higher indicates a high risk for future illness. Consultation with a psychiatric advanced practice nurse, psychologist, psychiatrist, or social worker is indicated for patients who are anxious or depressed or for patients who are having difficulty coping with their cardiac illness.

Physical Assessment

Physical assessment is conducted to confirm information obtained from the health history, to establish the patient's current or baseline condition, and, in subsequent assessments, to evaluate the patient's response to treatment. Once the initial physical assessment is completed, the frequency of future assessments is determined by the purpose of the encounter and the patient's condition. For example, a focused cardiac assessment may be performed each time the patient is seen in the outpatient setting, whereas patients in the acute care setting may require a more extensive assessment at least every 8 hours. During the physical assessment, the nurse evaluates the cardiovascular system for any deviations from normal with regard to the following (examples of abnormalities are in parentheses):

- The heart as a pump (reduced pulse pressure, displaced PMI from fifth intercostal space midclavicular line, gallop sounds, murmurs)
- Atrial and ventricular filling volumes and pressures (elevated jugular venous distention, peripheral edema, ascites, crackles, postural changes in BP)

- Cardiac output (reduced pulse pressure, hypotension, tachycardia, reduced urine output, lethargy, or disorientation)
- Compensatory mechanisms (peripheral vasoconstriction, tachycardia)

General Appearance

This part of the assessment evaluates the patient's level of consciousness (alert, lethargic, stuporous, comatose) and mental status (oriented to person, place, time; coherence). Changes in level of consciousness and mental status may be attributed to inadequate perfusion of the brain from a compromised cardiac output or thromboembolic event (stroke). Patients are observed for signs of distress, which include pain or discomfort, shortness of breath, or anxiety.

The nurse notes the size of the patient (normal, overweight, underweight, or cachectic). The patient's height and weight are measured to calculate BMI, as well as the waist circumference (see Chapter 4). These measures are used to determine if obesity (BMI greater than 30 kg/m^2) and abdominal fat (males: waist greater than 40 inches; females: waist greater than 35 inches) are placing the patient at risk for CAD.

Assessment of the Skin and Extremities

Examination of the skin includes all body surfaces, starting with the head and finishing with the lower extremities. Skin color, temperature, and texture are assessed for acute and chronic problems with arterial or venous circulation. Table 21-3 summarizes common skin and extremity assessment findings in patients with CVD. The most noteworthy changes include the following:

- Signs and symptoms of acute obstruction of arterial blood flow in the extremities, referred to as the six *P*s, are *p*ain, *p*allor, *p*ulselessness, *p*aresthesia, *p*oikilothermia (coldness), and *p*aralysis. During the first few hours after invasive cardiac procedures (e.g., cardiac catheterization, percutaneous coronary intervention [PCI], or cardiac electrophysiology testing), affected extremities should be assessed frequently for these acute vascular changes.
- Major blood vessels of the arms and legs may be used for catheter insertion. During these procedures, systemic anticoagulation with heparin is necessary, and bruising or small hematomas may occur at the catheter access site. However, large hematomas are a serious complication that can compromise circulating blood volume and cardiac output. Patients who have undergone these procedures must have catheter access sites frequently observed until hemostasis is adequately achieved.
- Edema of the feet, ankles, or legs is called *peripheral edema.* Edema can be observed in the sacral area of patients on bed rest. The nurse assesses the patient for edema by using the thumb to place firm

pressure over the dorsum of each foot, behind each medial malleolus, over the shins or sacral area for 5 seconds. *Pitting edema* is the term used to describe an indentation in the skin created by this pressure (see Chapter 25, Fig. 25-2). The degree of pitting edema relies on the clinician's judgment of depth of edema and time the indentation remains after release of pressure. Pitting edema is graded as absent (0) or as present on a scale from trace (1+ ≤0.25 inch) to severe (4+ ≥1 inch) (Urden, Stacy, & Lough, 2017). It is important that clinicians use a consistent scale in order to ensure reliable clinical measurements and management. Peripheral edema is a common finding in patients with HF and peripheral vascular diseases, such as deep vein thrombosis or chronic venous insufficiency.

  - Prolonged capillary refill time indicates inadequate arterial perfusion to the extremities. To test capillary refill time, the nurse compresses the nail bed briefly to occlude perfusion and the nail bed blanches. Then, the nurse releases pressure and determines the time it takes to restore perfusion. Normally, reperfusion occurs within 2 seconds, as evidenced by the return of color to the nail bed. Prolonged capillary refill time indicates compromised arterial perfusion, a problem associated with cardiogenic shock and HF.
  - Clubbing of the fingers and toes indicates chronic hemoglobin desaturation and is associated with congenital heart disease.

- Hair loss, brittle nails, dry or scaling skin, atrophy of the skin, skin color changes, and ulcerations are indicative of chronically reduced oxygen and nutrient supply to the skin observed in patients with arterial or venous insufficiency (see Chapter 26 for a complete description of these conditions) (Weber & Kelley, 2018).

TABLE 21-3 Common Assessment Findings Associated with Cardiovascular Disease

Assessment Findings	Associated Causes and Conditions
Clubbing of the fingers or toes (thickening of the skin under the fingers or toes)	Chronic hemoglobin desaturation most often due to congenital heart disease, advanced pulmonary diseases
Cool/cold skin and diaphoresis	Low cardiac output (e.g., cardiogenic shock, acute myocardial infarction) causing sympathetic nervous system stimulation with resultant vasoconstriction
Cold, pain, pallor of the fingertips or toes	Intermittent arteriolar vasoconstriction (Raynaud disease). Skin may change in color from white, blue, and red accompanied by numbness, tingling, and burning pain
Cyanosis, central (a bluish tinge observed in the tongue and buccal mucosa)	Serious cardiac disorders (pulmonary edema, cardiogenic shock, congenital heart disease) result in venous blood passing through the pulmonary circulation without being oxygenated
Cyanosis, peripheral (a bluish tinge, most often of the nails and skin of the nose, lips, earlobes, and extremities)	Peripheral vasoconstriction, allowing more time for the hemoglobin molecules to become desaturated. It can be caused by exposure to cold environment, anxiety, or ↓ cardiac output
Ecchymosis or bruising (a purplish-blue color fading to green, yellow, or brown)	Blood leaking outside of the blood vessels Excessive bruising is a risk for patients on anticoagulants or platelet-inhibiting medications
Edema, lower extremities (collection of fluid in the interstitial spaces of the tissues)	Heart failure and vascular problems (PAD, chronic venous insufficiency, deep vein thrombosis, thrombophlebitis)
Hematoma (localized collection of clotted blood in the tissue)	Bleeding after catheter removal/tissue injury in patients on anticoagulant/antithrombotic agents
Pallor (↓ skin color in fingernails, lips, oral mucosa, and lower extremities)	Anemia or ↓ arterial perfusion. Suspect PAD if feet develop pallor after elevating legs 60 degrees from a supine position
Rubor (a reddish-blue discoloration of the legs, seen within 20 s to 2 min after placing in a dependent position)	Filling of dilated capillaries with deoxygenated blood, indicative of PAD
Ulcers, feet and ankles: Superficial, irregular ulcers at medial malleolus. Red to yellow granulation tissue	Rupture of small skin capillaries from chronic venous insufficiency
Ulcers, feet and ankles: Painful, deep, round ulcers on feet or from exposure to pressure. Pale to black wound base	Prolonged ischemia to tissues due to PAD. Can lead to gangrene
Thinning of skin around a cardiac implantable electronic device	Erosion of the device through the skin

Xanthelasma (yellowish, raised plaques observed along nasal portion of eyelids)	Elevated cholesterol levels (hypercholesterolemia)

PAD, peripheral arterial disease.

Blood Pressure

Systemic arterial BP is the pressure exerted on the walls of the arteries during ventricular systole and diastole. It is affected by factors such as cardiac output; distention of the arteries; and the volume, velocity, and viscosity of the blood. A normal adult BP is considered a systolic BP less than 120 mm Hg over a diastolic BP less than 80 mm Hg. High BP, called **hypertension,** is defined in two stages and is based upon BP taken on at least two instances. Stage 1 hypertension is a systolic BP between 130 and 139 mm Hg or a diastolic BP between 80 and 89 mm Hg. Stage 2 hypertension is a systolic BP over 140 mm Hg or a diastolic over 90 mm Hg (Whelton, Carey, Aronow, et al., 2018). **Hypotension** refers to an abnormally low systolic and diastolic BP that can result in lightheadedness or fainting. (See Chapter 27 for additional definitions, measurement, and management.)

Pulse Pressure

The difference between the systolic and the diastolic pressures is called the *pulse pressure.* A normal pulse pressure is 40 mm Hg. A narrow pulse pressure (e.g., BP of 92/74 mm Hg and pulse pressure of 18 mm Hg) occurs when there is vasoconstriction that is compensating for a low stroke volume and ejection velocity (shock, HF, hypovolemia, mitral regurgitation) or obstruction to blood flow during systole (mitral or aortic stenosis). This compensation allows for adequate organ perfusion. A wide pulse pressure (e.g., BP of 88/38 mm Hg and pulse pressure of 50 mm Hg) is associated with conditions that elevate the stroke volume (anxiety, exercise, bradycardia), or cause vasodilation (fever, septic shock). Abnormal pulse pressures require further cardiovascular assessment (Urden et al., 2017).

Orthostatic (Postural) Blood Pressure Changes

There is a gravitational redistribution of approximately 500 mL of blood into the lower extremities immediately upon standing. This venous pooling reduces blood return to the heart, compromising preload that ultimately reduces stroke volume and cardiac output. As a consequence, the autonomic nervous system is activated. The sympathetic nervous system increases heart rate and enhances peripheral vasoconstriction, whereas parasympathetic activity of the heart via the vagus nerve is decreased. This stabilization occurs within 1 minute (Ricci, De Caterina, & Fedorowski, 2015).

Normal postural responses that occur when a person moves from a lying to a standing position include (1) a heart rate increase of 5 to 20 bpm above the resting rate; (2) an unchanged systolic pressure, or a slight decrease of up to 10 mm Hg; and (3) a slight increase of 5 mm Hg in diastolic pressure.

Orthostatic (postural) hypotension is a sustained decrease of at least 20 mm Hg in systolic BP or 10 mm Hg in diastolic BP within 3 minutes of moving from a lying or sitting to a standing position. It is usually accompanied by dizziness, lightheadedness, or syncope. The risk of orthostatic hypotension increases with age and is associated with fall risk (Ricci et al., 2015).

Orthostatic hypotension in patients with CVD is most often due to a significant reduction in preload, which compromises cardiac output. Reduced preload, which is reflective of intravascular volume depletion, is caused by dehydration from overdiuresis, bleeding (due to antiplatelet or anticoagulant medications or post intravascular procedures), or medications that dilate the blood vessels (e.g., nitrates and antispasmodic agents). In these situations, the usual mechanisms needed to maintain cardiac output (increased heart rate and peripheral vasoconstriction) cannot compensate for the significant loss in intravascular volume. As a result, the BP drops and heart rate increases with changes from lying or sitting to upright positions (Chart 21-3).

The following is an example of BP and heart rate measurements in a patient with orthostatic hypotension:

Supine: BP 120/70 mm Hg, heart rate 70 bpm
Sitting: BP 100/55 mm Hg, heart rate 90 bpm
Standing: BP 98/52 mm Hg, heart rate 94 bpm

Arterial Pulses

The arteries are palpated to evaluate the pulse rate, rhythm, amplitude, contour, and obstruction to blood flow.

Pulse Rate

The normal pulse rate varies from a low of 50 bpm in healthy, athletic young adults to rates well in excess of 100 bpm after exercise or during times of excitement. Anxiety can raise the pulse rate during the physical examination. If the rate is higher than expected, the nurse should reassess the pulse near the end of the physical examination, when the patient may be more relaxed.

Chart 21-3 **ASSESSMENT**

Assessing Patients for Orthostatic Hypotension

The following steps are recommended when assessing patients for orthostatic hypotension:

- Position the patient supine for 10 minutes before taking the initial blood pressure (BP) and heart rate measurements.
- Reposition the patient to a sitting position with legs in the dependent position, wait 2 minutes, then reassess both BP and heart rate measurements.
- If the patient is symptom free or has no significant decreases in systolic or diastolic BP, assist the patient into a standing position, obtain measurements immediately, and recheck in 2 minutes; continue measurements every 2 minutes for a total of 10 minutes to rule out orthostatic hypotension.
- Return the patient to a supine position if orthostatic hypotension is detected or if the patient becomes symptomatic.
- Document heart rate and BP measured in each position (e.g., supine, sitting, standing) and any signs or symptoms that accompany the postural changes.

Adapted from Momeyer, M. A., & Mion, L. C. (2018). Orthostatic hypotension: An often overlooked risk factor for falls. *Geriatric Nursing*, *39*(4), 483–486; Urden, L. D., Stacy, K. M., & Lough, M. E. (2017). *Critical care nursing: Diagnosis and management* (8th ed.). St. Louis, MO: Elsevier Mosby.

Pulse Rhythm

The rhythm of the pulse is normally regular. Minor variations in regularity of the pulse may occur with respirations. The pulse rate may increase during inhalation and slow during exhalation due to changes in blood flow to the heart during the respiratory cycle. This phenomenon, called *sinus arrhythmia,* occurs most commonly in children and young adults.

For the initial cardiac examination, or if the pulse rhythm is irregular, the heart rate should be counted by auscultating the apical pulse, located at the PMI, for a full minute while simultaneously palpating the radial pulse. Any discrepancy between contractions heard and pulses felt is noted. Disturbances of rhythm (arrhythmias) often result in a **pulse deficit,** which is a difference between the apical and radial pulse rates. Pulse deficits commonly occur with atrial fibrillation, atrial flutter, and premature ventricular contractions. These arrhythmias stimulate the ventricles to contact prematurely, before diastole is finished. As a result, these early ventricular contractions produce a smaller stroke volume, which can be heard during auscultation but do not produce a palpable pulse (see Chapter 22 for a detailed discussion of these arrhythmias).

Pulse Amplitude

The pulse amplitude, indicative of the BP in the artery, is used to assess peripheral arterial circulation. The nurse assesses pulse amplitude bilaterally and describes and records the amplitude of each artery. The simplest method characterizes the pulse as absent, diminished, normal, or bounding. Scales are also used to rate the strength of the pulse. The following is an example of a 0 to 4 scale:

0: Not palpable or absent
+1: Diminished—weak, thready pulse; difficult to palpate; obliterated with pressure
+2: Normal—cannot be obliterated
+3: Moderately increased—easy to palpate, full pulse; cannot be obliterated
+4: Markedly increased—strong, bounding pulse; may be abnormal

The numerical classification is subjective; therefore, when documenting the pulse amplitude, specify location of the artery and scale range (e.g., "left radial +3/+4") (Weber & Kelley, 2018).

If the pulse is absent or difficult to palpate, the nurse can use a continuous wave Doppler. This portable ultrasound device has a transducer that is placed over the artery. The transducer emits and receives ultrasound beams. Rhythmic changes are heard as blood cells flow through patent arteries, whereas obstruction to blood flow is evidenced by no changes in sound. (Ultrasound techniques are discussed in more detail in Chapter 26.)

Pulse Contour

The contour of the pulse conveys important information. In patients with stenosis of the aortic valve, the valve opening is narrowed, reducing the amount of blood ejected into the aorta. The pulse pressure is narrow, and the pulse feels feeble. In aortic insufficiency, the aortic valve does not close completely, allowing blood to flow back from the aorta into the left ventricle. The rise of the pulse wave is abrupt and strong, and its fall is precipitous—a "collapsing" or "water hammer" pulse. The true contour of the pulse is best appreciated by palpating over the carotid artery rather than the distal radial artery, because the dramatic characteristics of the pulse wave may be distorted when the pulse is transmitted to smaller vessels.

Palpation of Arterial Pulses

To assess peripheral circulation, the nurse locates and evaluates all arterial pulses. Arterial pulses are palpated at points where the arteries are near the skin surface and are easily compressed against bones or firm musculature. Pulses are detected over the right and left temporal, common carotid, brachial, radial, femoral, popliteal, dorsalis pedis, and posterior tibial arteries (see Chapter 26, Fig. 26-2). A reliable assessment of the pulses depends on accurate identification of the location of the artery and careful palpation of the

area. Light palpation is essential; firm finger pressure can obliterate the temporal, dorsalis pedis, and posterior tibial pulses and confuse the examiner. In approximately 10% of patients, the dorsalis pedis pulses are not palpable (Sidawy & Perler, 2019). In such circumstances, both are usually absent and the posterior tibial arteries alone provide adequate blood supply to the feet. Arteries in the extremities are often palpated simultaneously to facilitate comparison of quality.

Quality and Safety Nursing Alert

Do not simultaneously palpate both the temporal and carotid arteries, because it is possible to decrease the blood flow to the brain.

Jugular Venous Pulsations

Right-sided heart function can be estimated by observing the pulsations of the jugular veins of the neck, which reflects central venous pressure (CVP). CVP is the pressure in the right atria or the right ventricle at the end of diastole. If the internal jugular pulsations are difficult to see, pulsations of the external jugular veins may be noted. These veins are more superficial and are visible just above the clavicles, adjacent to the sternocleidomastoid muscles.

In patients with euvolemia (normal blood volume), the jugular veins are normally visible in the supine position with the head of the bed elevated to 30 degrees (Bickley, 2017). Obvious distention of the veins with the patient's head elevated 45 to 90 degrees indicates an abnormal increase in CVP. This abnormality is observed in patients with right-sided HF, due to hypervolemia, pulmonary hypertension, and pulmonary stenosis; less commonly with obstruction of blood flow in the superior vena cava; and rarely with acute massive pulmonary embolism.

Heart Inspection and Palpation

The heart is examined by inspection, palpation, and auscultation of the precordium or anterior chest wall that covers the heart and lower thorax. A systematic approach is used to examine the precordium in the following six areas. Figure 21-5 identifies these important landmarks:

1. *Aortic area*—second intercostal space to the right of the sternum. To determine the correct intercostal space, the nurse first finds the angle of Louis by locating the bony ridge near the top of the sternum, at the junction of the sternum and the manubrium. From this angle, the second intercostal space is located by sliding one finger to the left or right of the

sternum. Subsequent intercostal spaces are located from this reference point by palpating down the rib cage.

2. *Pulmonic area*—second intercostal space to the left of the sternum
3. *Erb point*—third intercostal space to the left of the sternum
4. *Tricuspid area*—fourth and fifth intercostal spaces to the left of the sternum
5. *Mitral (apical) area*—left fifth intercostal space at the midclavicular line
6. *Epigastric area*—below the xiphoid process

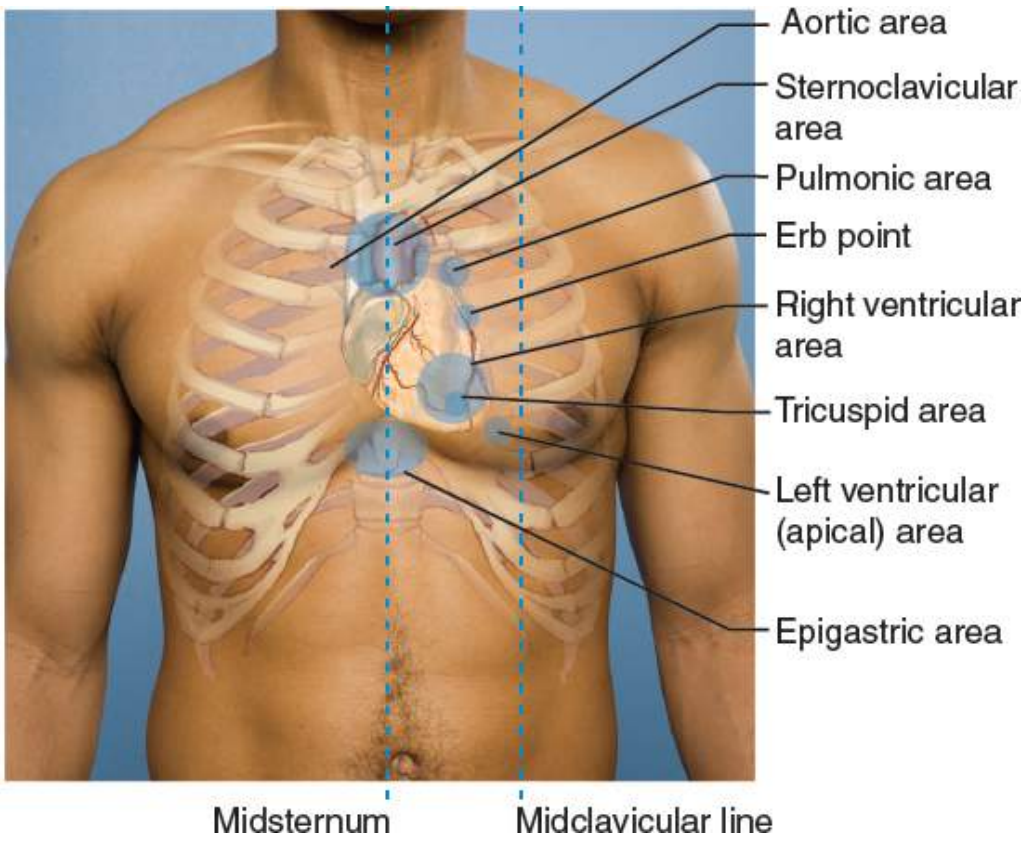

Figure 21-5 • Areas of the precordium to be assessed when evaluating heart function.

Figure 21-6 • Palpating the apical impulse. **A.** Remain on the patient's right side, and ask the patient to remain supine. Use the finger pads to palpate the apical impulse in the mitral area (fifth intercostal space at the midclavicular line). **B.** You may ask the patient to roll to the left side to better feel the impulse using the palmar surfaces of your hand. Photos used with permission from Weber, J. R., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

For most of the examination, the patient lies supine, with the head of the bed or the examination table slightly elevated. A right-handed examiner stands at the right side of the patient, a left-handed examiner at the left side.

Each area of the precordium is inspected for pulsations and is then palpated. An apical impulse is a normal finding observed in young patients and adults who have thin chest walls.

The apical impulse may be felt as a light pulsation, 1 to 2 cm in diameter. It is felt at the onset of the first heart sound and lasts for only half of ventricular systole (see the next section for a discussion of heart sounds). The nurse uses the palm of the hand to locate the apical impulse initially and the finger pads to assess its size and quality. Palpation of the apical pulse may be facilitated by repositioning the patient to the left lateral position, which puts the heart in closer contact with the chest wall (Fig. 21-6).

There are several abnormalities that the nurse may find during palpation of the precordium. Normally, the apical impulse is palpable in only one intercostal space; palpability in two or more adjacent intercostal spaces indicates left ventricular enlargement. An apical impulse below the fifth intercostal space or lateral to the midclavicular line usually denotes left ventricular enlargement from left ventricular HF. If the apical impulse can be palpated in two distinctly separate areas and the pulsation movements are paradoxical (not simultaneous), a ventricular aneurysm may be suspected. A broad and forceful apical impulse is known as a left ventricular heave or lift because it appears to lift the hand from the chest wall during palpation.

A vibration or purring sensation may be felt over areas where abnormal, turbulent blood flow is present. It is best detected by using the palm of the

hand. This vibration is called a *thrill* and is associated with a loud murmur. Depending on the location of the thrill, it may be indicative of serious valvular heart disease; an atrial or ventricular septal defect (abnormal opening); or stenosis of a large artery, such as the carotid artery.

Heart Auscultation

A stethoscope is used to auscultate each of the locations identified in Figure 21-5, with the exception of the epigastric area. The purpose of cardiac auscultation is to determine heart rate and rhythm and evaluate heart sounds. The apical area is auscultated for 1 minute to determine the apical pulse rate and the regularity of the heartbeat. Normal and abnormal heart sounds detected during auscultation are described next.

Normal Heart Sounds

Normal heart sounds, referred to as **S_1** and **S_2**, are produced by closure of the AV valves and the semilunar valves, respectively. The period between S_1 and S_2 corresponds with ventricular systole (Fig. 21-7). When the heart rate is within the normal range, systole is much shorter than the period between S_2 and S_1 (diastole). However, as the heart rate increases, diastole shortens.

Normally, S_1 and S_2 are the only sounds heard during the cardiac cycle (Bickley, 2017).

S_1—First Heart Sound

Tricuspid and mitral valve closure creates the first heart sound (S_1). The word "lub" is used to replicate its sound. S_1 is usually heard the loudest at the apical area. S_1 is easily identifiable and serves as the point of reference for the remainder of the cardiac cycle.

The intensity of S_1 increases during tachycardias or with mitral stenosis. In these circumstances, the AV valves are wide open during ventricular contraction. The accentuated S_1 occurs as the AV valves close with greater force than normal. Similarly, arrhythmias can vary the intensity of S_1 from beat to beat due to lack of synchronized atrial and ventricular contraction.

S_2—Second Heart Sound

Closure of the pulmonic and aortic valves produces the second heart sound (S_2), commonly referred to as the "dub" sound. The aortic component of S_2 is heard the loudest over the aortic and pulmonic areas. However, the pulmonic component of S_2 is a softer sound and is heard best over the pulmonic area.

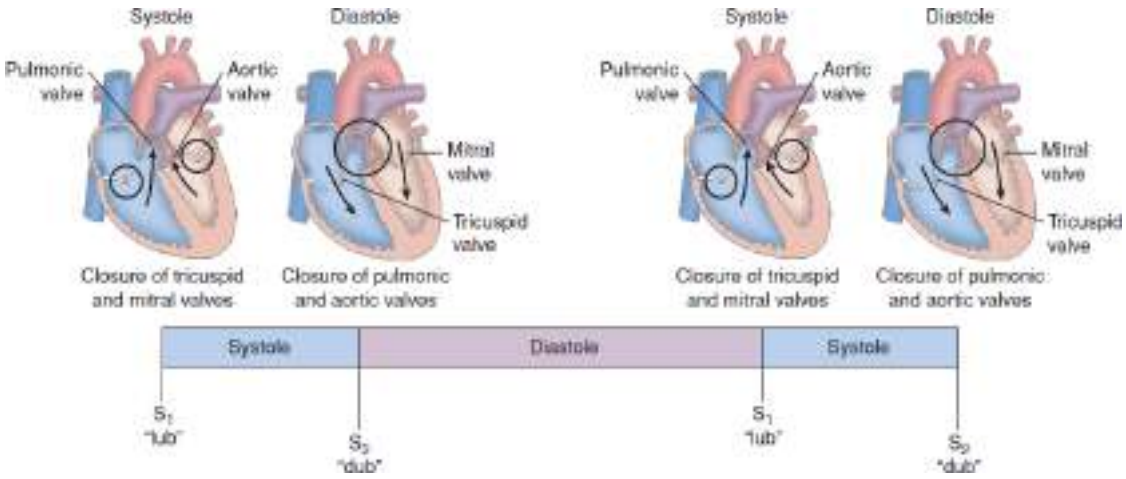

Figure 21-7 • Normal heart sounds. The first heart sound (S_1) is produced by closure of the mitral and tricuspid valves ("lub"). The second heart sound (S_2) is produced by closure of the aortic and pulmonic valves ("dub"). *Arrows* represent the direction of blood flow.

Although these valves close almost simultaneously, the pulmonic valve lags slightly behind the aortic valve. In some individuals, it is possible to distinguish between the closure of the aortic and pulmonic valves. When this situation occurs, the patient is said to have a split S_2. Normal physiologic splitting of S_2 is accentuated on inspiration and disappears on expiration. During inspiration, there is a decrease in intrathoracic pressure and subsequent increase in venous return to the right atrium and ventricle. The right ventricle takes a little longer to eject this extra volume, which causes the pulmonic valve to close a little later than normal. Splitting of S_2 that remains constant during inspiration and expiration is an abnormal finding. Abnormal splitting of the second heart sound can be caused by a variety of disease states (valvular heart disease, septal defects, bundle branch blocks). Splitting of S_2 is best heard over the pulmonic area.

Abnormal Heart Sounds

Abnormal sounds develop during systole or diastole when structural or functional heart problems are present. These sounds are called **S_3** or **S_4** gallops, opening snaps, systolic clicks, and murmurs. S_3 and S_4 gallop sounds are heard during diastole. These sounds are created by the vibration of the ventricle and surrounding structures as blood meets resistance during ventricular filling. The term *gallop* evolved from the cadence that is produced by the addition of a third or fourth heart sound, similar to the sound of a galloping horse. Gallop sounds are very low-frequency sounds and are heard with the bell of the stethoscope placed very lightly against the chest.

S_3—Third Heart Sound

An S_3 ("DUB") is heard early in diastole during the period of rapid ventricular filling as blood flows from the atrium into a noncompliant ventricle. It is heard immediately after S_2. "Lub-dub-DUB" is used to imitate the abnormal sound of a beating heart when an S_3 is present. It represents a normal finding in children and adults up to 35 or 40 years of age. In these cases, it is referred to as a physiologic S_3 (Fig. 21-8). In older adults, an S_3 is a significant finding, suggesting HF. It is best heard with the bell of the stethoscope. If the right ventricle is involved, a right-sided S_3 is heard over the tricuspid area with the patient in a supine position. A left-sided S_3 is best heard over the apical area with the patient in the left lateral position.

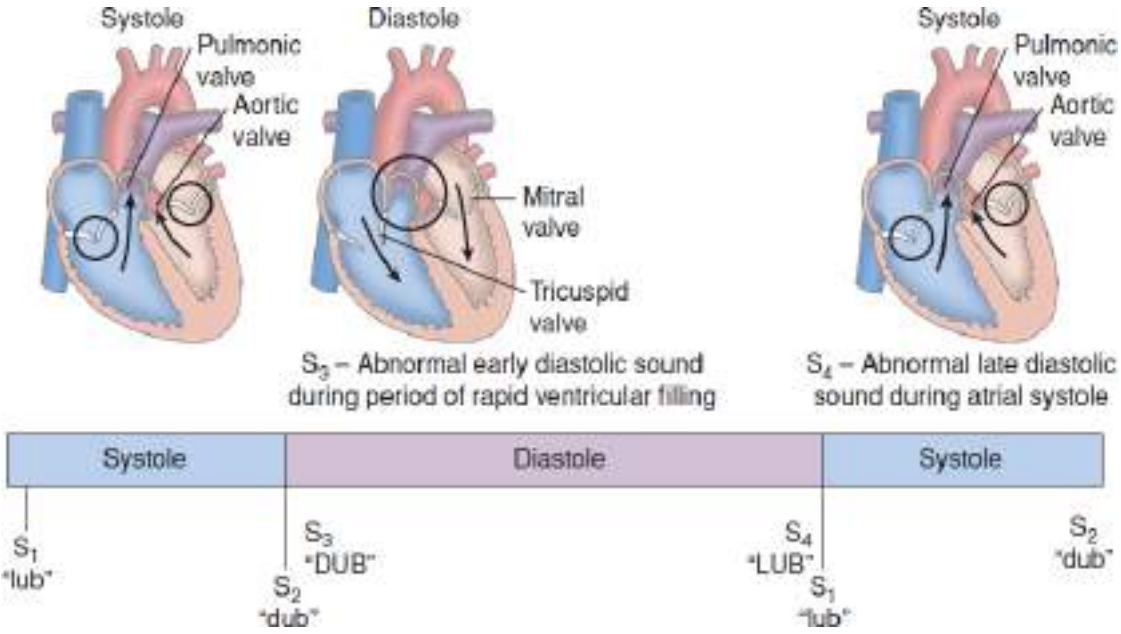

Figure 21-8 • Gallop sounds. An S_3 ("DUB") is an abnormal sound heard immediately following S_2 (closure of semilunar valves). This sound is generated very early in diastole as blood flowing into the right or left ventricle is met with resistance. S_4 ("LUB") is an abnormal sound created during atrial systole as blood flowing into the right or left ventricle is met with resistance. *Arrows* represent the direction of blood flow.

S_4—Fourth Heart Sound

S_4 ("LUB") occurs late in diastole (see Fig. 21-8). S_4 heard just before S_1 is generated during atrial contraction as blood forcefully enters a noncompliant ventricle. This resistance to blood flow is due to ventricular hypertrophy caused by hypertension, CAD, cardiomyopathies, aortic stenosis, and numerous other conditions. "LUB lub-dub" is the mnemonic used to imitate

this gallop sound. S_4, produced in the left ventricle, is auscultated using the bell of the stethoscope over the apical area with the patient in the left lateral position. A right-sided S_4, although less common, is heard best over the tricuspid area with the patient in supine position. There are times when both S_3 and S_4 are present, creating a quadruple rhythm, which sounds like "LUB lub-dub DUB." During tachycardia, all four sounds combine into a loud sound, referred to as a **summation gallop**.

Opening Snaps and Systolic Clicks

Normally, no sound is produced when valves open. However, diseased valve leaflets create abnormal sounds as they open during diastole or systole. **Opening snaps** are abnormal diastolic sounds heard during opening of an AV valve. For example, mitral stenosis can cause an opening snap, which is an unusually high-pitched sound very early in diastole. This sound is caused by high pressure in the left atrium that abruptly displaces or "snaps" open a rigid valve leaflet. Timing helps to distinguish an opening snap from the other gallop sounds. It occurs too long after S_2 to be mistaken for a split S_2 and too early in diastole to be mistaken for an S_3. The high-pitched, snapping quality of the sound is another way to differentiate an opening snap from an S_3. Hearing a murmur or the sound of turbulent blood flow is expected following the opening snap. An opening snap is heard best using the diaphragm of the stethoscope placed medial to the apical area and along the lower left sternal border.

In a similar manner, stenosis of one of the semilunar valves creates a short, high-pitched sound in early systole, immediately after S_1. This sound, called a **systolic click**, is the result of the opening of a rigid and calcified aortic or pulmonic valve during ventricular contraction. Mid to late systolic clicks may be heard in patients with mitral or tricuspid valve prolapse as the malfunctioning valve leaflet is displaced into the atrium during ventricular systole. Murmurs are expected to be heard following these abnormal systolic sounds. These sounds are the loudest in the areas directly over the malfunctioning valve.

Murmurs

Murmurs are created by turbulent flow of blood in the heart. The causes of the turbulence may be a critically narrowed valve, a malfunctioning valve that allows regurgitant blood flow, a congenital defect of the ventricular wall, a defect between the aorta and the pulmonary artery, or an increased flow of blood through a normal structure (e.g., with fever, pregnancy, hyperthyroidism). Murmurs are characterized and consequently described by several characteristics, including their timing in the cardiac cycle, location on the chest wall, intensity, pitch, quality, and pattern of radiation (Chart 21-4).

Friction Rub

A harsh, grating sound that can be heard in both systole and diastole is called a *friction rub*. It is caused by abrasion of the inflamed pericardial surfaces from pericarditis. Because a friction rub may be confused with a murmur, care should be taken to identify the sound and to distinguish it from murmurs that may be heard in both systole and diastole. A pericardial friction rub can be heard best using the diaphragm of the stethoscope, with the patient sitting up and leaning forward.

Auscultation Procedure

During auscultation, the patient remains supine and the examining room is as quiet as possible. A stethoscope with both diaphragm and bell functions is necessary for accurate auscultation of the heart.

Using the diaphragm of the stethoscope, the examiner starts at the apical area and progresses upward along the left sternal border to the pulmonic and aortic areas. Alternatively, the examiner may begin the examination at the aortic and pulmonic areas and progress downward to the apex of the heart. Initially, S_1 is identified and evaluated with respect to its intensity and splitting. Next, S_2 is identified, and its intensity and any splitting are noted. After concentrating on S_1 and S_2, the examiner listens for extra sounds in systole and then in diastole.

Sometimes it helps to ask the following questions: Do I hear snapping or clicking sounds? Do I hear any high-pitched blowing sounds? Is this sound in systole, or diastole, or both? The examiner again proceeds to move the stethoscope to all of the designated areas of the precordium, listening carefully for these sounds. Finally, the patient is turned on the left side and the stethoscope is placed on the apical area, where an S_3, an S_4, and a mitral murmur are more readily detected.

Once an abnormality is heard, the entire chest surface is reexamined to determine the exact location of the sound and its radiation. The patient may be concerned about the prolonged examination and must be supported and reassured. The auscultatory findings, particularly murmurs, are documented by identifying the following characteristics (see Chart 21-4): location on chest wall, timing, intensity, pitch, quality, and radiation.

Interpretation of Heart Sounds

Interpreting heart sounds requires detailed knowledge of cardiac physiology and pathophysiology. However, all nurses should have adequate knowledge and skill to recognize normal heart sounds (S_1, S_2) and the presence of abnormal sounds. When assessment is at this very basic level of practice, abnormal findings are reported for further evaluation and treatment. More advanced skills are required of nurses caring for critically ill patients with

CVD or those nurses functioning in advanced practice roles. Nurses in these roles readily identify abnormal heart sounds, recognize the diagnostic significance of their findings, and use their assessment skills to evaluate patients' responses to medical interventions. For example, these highly skilled nurses monitor heart sounds in patients with HF to detect the resolution of an S_3 after treatment with a diuretic.

Chart 21-4

Characteristics of Heart Murmurs

Heart murmurs are described in terms of location, timing, intensity, pitch, quality, and radiation. These characteristics provide information needed to determine the cause of the murmur and its clinical significance.

Location

Pinpointing the location of the murmur helps to determine the underlying structures that are involved in generating the abnormal sounds. The locations described in Figure 21-5 are used to identify where the loudest sounds are detected. The description should include the exact location from which the sound emanates, such as the location of the intercostal space and other important landmarks (right or left sternal border; midsternal, midclavicular, anterior axillary, or midaxillary lines). For example, a ventricular septal defect can be located at the left sternal border in the third and fourth intercostal spaces.

Timing

A murmur is described in terms of when it occurs during the cardiac cycle (systole or diastole). Murmurs are further differentiated by identifying exactly when during systole or diastole they are heard. A skilled clinician can detect that the murmur is occurring during early, mid, or late systole or diastole. Some murmurs have sounds that occur in both systole and diastole.

Intensity

A grading system is used to describe the intensity or loudness of a murmur.

Grade 1: Very faint and difficult for the inexperienced clinician to hear
Grade 2: Quiet but readily perceived by the experienced primary provider
Grade 3: Moderately loud
Grade 4: Loud and may be associated with a thrill
Grade 5: Very loud; heard when stethoscope is partially off the chest; associated with a thrill
Grade 6: Extremely loud; detected with the stethoscope off the chest; associated with a thrill

Pitch

Pitch describes the sound frequency, identified as high, medium, or low pitched. High-pitched murmurs are heard best with the stethoscope's diaphragm, whereas low-pitched sounds are detected using the bell of the stethoscope placed lightly on the chest wall.

Quality

Quality describes the sound that the murmur resembles. Murmurs can produce a rumbling, blowing, whistling, harsh, or musical sound. For

example, murmurs caused by mitral or tricuspid regurgitation have a blowing quality, whereas mitral stenosis generates a rumbling sound.

Radiation

Radiation refers to the transmission of the murmur from the point of maximal intensity to other areas in the upper chest. The examiner determines if radiation is present by listening carefully to areas of the heart adjacent to the point where the murmur is the loudest. If radiation is present, the exact location is described. A murmur associated with aortic stenosis, for example, can radiate into the neck, down the left sternal border, and into the apical area.

Assessment of Other Systems

Lungs

The details of respiratory assessment are described in Chapter 17. Findings frequently exhibited by patients with cardiac disorders include the following:

Hemoptysis: Pink, frothy sputum is indicative of acute pulmonary edema.

Cough: A dry, hacking cough from irritation of small airways is common in patients with pulmonary congestion from HF.

Crackles: HF or atelectasis associated with bed rest, splinting from ischemic pain, or the effects of analgesic, sedative, or anesthetic agents often results in the development of crackles. Typically, crackles are first noted at the bases (because of gravity's effect on fluid accumulation and decreased ventilation of basilar tissue), but they may progress to all portions of the lung fields.

Wheezes: Compression of the small airways by interstitial pulmonary edema may cause wheezing. Beta-adrenergic–blocking agents (beta-blockers), particularly noncardioselective beta-adrenergic–blocking agents such as propranolol, may cause airway narrowing, especially in patients with underlying pulmonary disease.

Abdomen

For the patient with CVD, several components of the abdominal examination are relevant:

Abdominal distention: A protuberant abdomen with bulging flanks indicates ascites. Ascites develops in patients with right ventricular or biventricular HF (both right- and left-sided HF). In the failing right heart, abnormally high chamber pressures impede the return of venous blood. As a result, the liver and spleen become engorged with excessive venous blood (hepatosplenomegaly). As pressure in the portal system rises, fluid shifts

from the vascular bed into the abdominal cavity. Ascitic fluid, found in the dependent or lowest points in the abdomen, will shift with position changes.

Hepatojugular reflux: This test is performed when right ventricular or biventricular HF is suspected. The patient is positioned so that the jugular venous pulse is visible in the lower part of the neck. While observing the jugular venous pulse, firm pressure is applied over the right upper quadrant of the abdomen for 30 to 60 seconds. An increase of 1 cm or more in jugular venous pressure is indicative of a positive hepatojugular reflux. This positive test aids in confirming the diagnosis of HF.

Bladder distention: Urine output is an important indicator of cardiac function. Reduced urine output may indicate inadequate renal perfusion or a less serious problem such as one caused by urinary retention. When urine output is decreased, the patient must be assessed for a distended bladder or difficulty voiding. The bladder may be assessed with an ultrasound scanner (see Chapter 47, Fig. 47-8) or the suprapubic area palpated for an oval mass and percussed for dullness, indicative of a full bladder.

Gerontologic Considerations

When performing a cardiovascular examination on an older patient, the nurse may note such differences as more readily palpable peripheral pulses because of decreased elasticity of the arteries and a loss of adjacent connective tissue. Palpation of the precordium in older adults is affected by the changes in the shape of the chest. For example, a cardiac impulse may not be palpable in patients with chronic obstructive pulmonary disease, because these patients usually have an increased anterior–posterior chest diameter. Kyphoscoliosis, a spinal deformity that occurs in many older adult patients, may move the cardiac apex downward so that palpation of the apical impulse is obscured.

Hypertension affects 46% of adults. The prevalence increases with age and is also impacted by race and ethnicity. The risk of a middle-age adult developing hypertension is over 90% for African Americans and Hispanic/Latino Americans. Untreated hypertension is associated with significant cardiovascular morbidity and mortality, including stroke (Whelton et al., 2018). Isolated systolic hypertension is of concern in adults over 55 year of age, and occurs because of stiffening of the vasculature and a decrease in vascular elasticity due to the aging process (Zipes et al., 2019). Another common BP problem in the older adult is orthostatic hypotension, which is a result of impaired baroreceptor function necessary to regulate BP. Other factors that heighten the risk for orthostatic hypotension include prolonged bed rest, dehydration, and many cardiovascular medications (e.g., beta-blockers,

angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, diuretics, nitrates).

An S_4 that is associated with hypertension is common in older adults. It is thought to be due to a decrease in compliance of the left ventricle. The S_2 is usually split. At least 60% of older patients have murmurs, the most common being a soft systolic ejection murmur resulting from sclerotic changes of the aortic leaflets (Bickley, 2017) (see Table 21-1).

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in patients with cardiovascular conditions. The nurse should educate the patient on the purpose, what to expect, and any possible side effects related to these examinations prior to testing. The nurse should note trends in results because they provide information about disease progression as well as the patient's response to therapy.

Laboratory Tests

Samples of the patient's blood are sent to the laboratory for the following reasons:

- To screen for risk factors associated with CAD
- To establish baseline values before initiating other diagnostic tests, procedures, or therapeutic interventions
- To monitor response to therapeutic interventions
- To assess for abnormalities in the blood that affect prognosis

Normal values for laboratory tests may vary depending on the laboratory and the health care institution. This variation is due to the differences in equipment and methods of measurement across organizations.

Cardiac Biomarker Analysis

The diagnosis of MI is made by evaluating the history and physical examination, the 12-lead ECG, and the results of laboratory tests that measure serum cardiac biomarkers. Myocardial cells that become necrotic from prolonged ischemia or trauma release specific enzymes (creatine kinase [CK]), CK isoenzymes (CK-MB), and proteins (myoglobin, troponin T, and troponin I). These substances leak into the interstitial spaces of the myocardium and are carried by the lymphatic system into general circulation. As a result, abnormally high levels of these substances can be detected in serum blood samples. (See Chapter 23 for further discussion of cardiac biomarker analysis.)

Blood Chemistry, Hematology, and Coagulation Studies

Table 21-4 provides information about some common serum laboratory tests and the implications for patients with CVD. Discussion of lipid, brain (B-type) natriuretic peptide (BNP), C-reactive protein (CRP), and homocysteine measurements follows.

Lipid Profile

Cholesterol, triglycerides, and lipoproteins are measured to evaluate a person's risk of developing CAD, especially if there is a family history of premature heart disease, or to diagnose a specific lipoprotein abnormality. Cholesterol and triglycerides are transported in the blood by combining with plasma proteins to form lipoproteins called LDL and HDL. Although cholesterol levels remain relatively constant over 24 hours, the blood specimen for the lipid profile should be obtained after a 12-hour fast.

Cholesterol Levels

Cholesterol is a lipid required for hormone synthesis and cell membrane formation. It is found in large quantities in brain and nerve tissue. Two major sources of cholesterol are diet (animal products) and the liver, where cholesterol is synthesized. Factors that contribute to variations in cholesterol levels include age, gender, diet, exercise patterns, genetics, menopause, tobacco use, and stress levels. Total cholesterol level is calculated by adding the HDL, LDL, and 20% of the triglyceride level.

High cholesterol levels increase the risk of CVD regardless of the patient's age. Lifestyle changes are recommended to lower cholesterol levels. After determining a person's 10-year risk for atherosclerotic vascular disease, medication is prescribed if necessary. Statins, a class of cholesterol-lowering medications, are often prescribed. Other nonstatins may be added to medication management to further reduce cholesterol; these include ezetimibe, bile acid sequestrants, and PCSK9 inhibitors (Grundy, Stone, Bailey, et al., 2019) (see Chapter 23 for more details).

TABLE 21-4 Common Serum Laboratory Tests and Implications for Patients with Cardiovascular Disease

Laboratory Test Reference Range	Implications
Blood Chemistries	
Blood urea nitrogen (BUN): 8–20 mg/dL	BUN and creatinine are end products of protein metabolism excreted by the kidneys. Elevated BUN reflects reduced renal perfusion from decreased cardiac output or intravascular fluid volume deficit as a result of diuretic therapy or dehydration.
Calcium (Ca^{++}): 8.8–10.4 mg/dL	Calcium is necessary for blood coagulability, neuromuscular activity, and automaticity of the nodal cells (sinus and atrioventricular nodes). *Hypocalcemia:* Decreased calcium levels slow nodal function and impair myocardial contractility. The latter effect increases the risk for heart failure. *Hypercalcemia:* Increased calcium levels can occur with the administration of thiazide diuretics because these medications reduce renal excretion of calcium. Hypercalcemia potentiates digitalis toxicity, causes increased myocardial contractility, and increases the risk for varying degrees of heart block and sudden death from ventricular fibrillation.
Creatinine *Male:* 0.6–1.2 mg/dL *Female:* 0.4–1.0 mg/dL	Both BUN and creatinine are used to assess renal function, although creatinine is a more sensitive measure. Renal impairment is detected by an increase in both BUN and creatinine. A normal creatinine level and an elevated BUN suggest an intravascular fluid volume deficit.
Magnesium (Mg^{++}): 1.8–2.6 mg/dL	Magnesium is necessary for the absorption of calcium, maintenance of potassium stores, and metabolism of adenosine triphosphate. It plays a major role in protein and carbohydrate synthesis and muscular contraction. *Hypomagnesemia:* Decreased magnesium levels are due to enhanced renal excretion of magnesium from the use of diuretic or digitalis therapy. Low magnesium levels predispose patients to atrial or ventricular tachycardias. *Hypermagnesemia:* Increased magnesium levels are commonly caused by the use of cathartics or antacids containing magnesium. Increased magnesium levels depress contractility and excitability of the myocardium, causing heart block and, if severe, asystole.
Potassium (K^{+}): 3.5–5 mEq/L	Potassium has a major role in cardiac electrophysiologic function. *Hypokalemia:* Decreased potassium levels due to administration of potassium-excreting diuretics can cause many forms of arrhythmias, including life-threatening ventricular tachycardia or ventricular fibrillation, and predispose patients taking digitalis preparations to digitalis toxicity.

	Hyperkalemia: Increased potassium levels can result from an increased intake of potassium (e.g., foods high in potassium or potassium supplements), decreased renal excretion of potassium, the use of potassium-sparing diuretics (e.g., spironolactone), or the use of angiotensin-converting enzyme inhibitors that inhibit aldosterone function. Serious consequences of hyperkalemia include heart block, asystole, and life-threatening ventricular arrhythmias.
Sodium (Na^+): 135–145 mEq/L	Low or high serum sodium levels do not directly affect cardiac function. *Hyponatremia:* Decreased sodium levels indicate fluid excess and can be caused by heart failure or administration of thiazide diuretics. *Hypernatremia:* Increased sodium levels indicate fluid deficits and can result from decreased water intake or loss of water through excessive sweating or diarrhea.
Coagulation Studies	Injury to a vessel wall or tissue initiates the formation of a thrombus. This injury activates the coagulation cascade, the complex interactions among phospholipids, calcium, and clotting factors that convert prothrombin to thrombin. The coagulation cascade has two pathways: the intrinsic and extrinsic pathways. Coagulation studies are routinely performed before invasive procedures, such as cardiac catheterization, electrophysiology testing, and cardiac surgery.
Activated partial thromboplastin time (aPTT) *Lower limit of normal:* 21–35 s	aPTT measures the activity of the intrinsic pathway and is used to assess the effects of unfractionated heparin. A therapeutic range is 1.5–2.5 times baseline values. Adjustment of heparin dose is required for aPTT <50 s (↑ dose) or >100 s (↓ dose).
Prothrombin time (PT) *Lower limit of normal:* 11–13 s	PT measures the extrinsic pathway activity and is used to monitor the level of anticoagulation with warfarin.
International normalized ratio (INR): 0.8–1.2	The INR, reported with the PT, provides a standard method for reporting PT levels and eliminates the variation of PT results from different laboratories. The INR, rather than the PT alone, is used to monitor the effectiveness of warfarin. The therapeutic range for INR is 2–3.5, although specific ranges vary based on diagnosis.
Hematologic Studies	
Complete blood count (CBC)	The CBC identifies the total number of white and red blood cells and platelets, and measures hemoglobin and hematocrit. The CBC is carefully monitored in patients with cardiovascular disease.
Hematocrit *Male:* 42–52% *Female:* 36–48%	The hematocrit represents the percentage of red blood cells found in 100 mL of whole blood. The red blood cells contain hemoglobin, which transports oxygen to the cells.

Hemoglobin *Male:* 14–17.4 g/dL *Female:* 12–16 g/dL	Low hemoglobin and hematocrit levels have serious consequences for patients with cardiovascular disease, such as more frequent angina episodes or acute myocardial infarction.
Platelets: 140,000–400,000/mm^3	Platelets are the first line of protection against bleeding. Once activated by blood vessel wall injury or rupture of atherosclerotic plaque, platelets undergo chemical changes that form a thrombus. Several medications inhibit platelet function, including aspirin, clopidogrel, and intravenous glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatide, and tirofiban). When these medications are given, it is essential to monitor for thrombocytopenia (low platelet counts).
White blood cell (WBC) count: 4500–11,000/mm^3	WBC counts are monitored in patients who are immunocompromised, including patients with heart transplants or in situations where there is concern for infection (e.g., after invasive procedures or surgery).

LDL is the primary transporter of cholesterol and triglycerides into the cell. One harmful effect of LDL is the deposition of these substances in the walls of arterial vessels. HDL has a protective action because it transports cholesterol away from the tissue and cells of the arterial wall to the liver for excretion (Grundy et al., 2019).

Triglycerides

Triglycerides, composed of free fatty acids and glycerol, are stored in the adipose tissue and are a source of energy. Triglyceride levels increase after meals and are affected by stress. Diabetes, alcohol use, and obesity can elevate triglyceride levels. These levels have a direct correlation with LDL and an inverse one with HDL.

Brain (B-Type) Natriuretic Peptide

BNP is a neurohormone that helps regulate BP and fluid volume. It is primarily secreted from the ventricles in response to increased preload with resulting elevated ventricular pressure. The level of BNP in the blood increases as the ventricular walls expand from increased pressure, making it a helpful diagnostic, monitoring, and prognostic tool in the setting of HF. Because this serum laboratory test can be quickly obtained, BNP levels are useful for prompt diagnosis of HF in settings such as the ED. Elevations in BNP can occur from a number of other conditions such as pulmonary embolus, MI, and ventricular hypertrophy. Therefore, the primary provider correlates BNP levels with abnormal physical assessment findings and other diagnostic tests before

making a definitive diagnosis of HF. A BNP level greater than 100 pg/mL is suggestive of HF.

C-Reactive Protein

CRP is a protein produced by the liver in response to systemic inflammation. Inflammation is thought to play a role in the development and progression of atherosclerosis. The high-sensitivity CRP (hs-CRP) test is used as an adjunct to other tests to predict CVD risk. People with high hs-CRP levels (3 mg/L or greater) may be at greatest risk for CVD compared to people with moderate (1 to 3 mg/L) or low (less than 1 mg/L) hs-CRP levels (Sidawy & Perler, 2019).

Homocysteine

Homocysteine, an amino acid, is linked to the development of atherosclerosis because it can damage the endothelial lining of arteries and promote thrombus formation. Therefore, an elevated blood level of homocysteine is thought to indicate a high risk for CAD, stroke, and peripheral vascular disease, although it is not an independent predictor of CAD. Genetic factors and a diet low in folate, vitamin B_6, and vitamin B_{12} are associated with elevated homocysteine levels. A 12-hour fast is necessary before drawing a blood sample for an accurate serum measurement. Test results are interpreted as optimal (less than 12 mcmol/L), borderline (12 to 15 mcmol/L), and high risk (greater than 15 mcmol/L) (Zipes et al., 2019).

Chest X-Ray and Fluoroscopy

A chest x-ray is obtained to determine the size, contour, and position of the heart. It reveals cardiac and pericardial calcifications and demonstrates physiologic alterations in the pulmonary circulation. Although it does not help diagnose acute MI, it can help diagnose some complications (e.g., HF). Correct placement of pacemakers and pulmonary artery catheters is also confirmed by chest x-ray.

Fluoroscopy is an x-ray imaging technique that allows visualization of the heart on a screen. It shows cardiac and vascular pulsations and unusual cardiac contours. This technique uses a movable x-ray source, which makes it a useful aid for positioning transvenous pacing electrodes and for guiding the insertion of arterial and venous catheters during cardiac catheterization and other cardiac procedures.

Electrocardiography

The ECG is a graphic representation of the electrical currents of the heart. The ECG is obtained by placing disposable electrodes in standard positions on the skin of the chest wall and extremities. Recordings of the electrical current

flowing between two electrodes are made on graph paper or displayed on a monitor. Several different recordings can be obtained by using a variety of electrode combinations, called *leads*. Simply stated, a lead is a specific view of the electrical activity of heart. The standard ECG is composed of 12 leads or 12 different views, although it is possible to record 15 or 18 leads.

The 12-lead ECG is used to diagnose arrhythmias, conduction abnormalities, and chamber enlargement, as well as myocardial ischemia, injury, or infarction. It can also suggest cardiac effects of electrolyte disturbances (high or low calcium and potassium levels) and the effects of antiarrhythmic medications. A 15-lead ECG adds three additional chest leads across the right precordium and is used for early diagnosis of right ventricular and left posterior (ventricular) infarction. The 18-lead ECG adds three posterior leads to the 15-lead ECG and is useful for early detection of myocardial ischemia and injury. To enhance interpretation of the ECG, the patient's age, gender, BP, height, weight, symptoms, and medications (especially digitalis and antiarrhythmic agents) are noted on the ECG requisition. (See Chapter 22 for a more detailed discussion of ECG.)

Continuous Electrocardiographic Monitoring

Continuous ECG monitoring is the standard of care for patients who are at high risk for arrhythmias. This form of cardiac monitoring detects abnormalities in heart rate and rhythm. Many systems have the capacity to monitor for changes in ST segments, which are used to identify the presence of myocardial ischemia or injury (see Chapter 23). Two types of continuous ECG monitoring techniques are used in health care settings: hardwire cardiac monitoring, found in EDs, critical care units, and progressive care units; and telemetry, found in general nursing care units or outpatient cardiac rehabilitation programs. Hardwire cardiac monitoring and telemetry systems vary in sophistication; however, most systems have the following features in common:

- Monitor more than one ECG lead simultaneously.
- Monitor ST segments (ST-segment depression is a marker of myocardial ischemia; ST-segment elevation provides evidence of an evolving MI).
- Provide graded visual and audible alarms (based on priority, asystole merits the highest grade of alarm).
- Interpret and store alarms.
- Trend data over time.
- Print a copy of rhythms from one or more specific ECG leads over a set time (called a *rhythm strip*).
- Save electronic copies of cardiac rhythms into the electronic health record (EHR).

Quality and Safety Nursing Alert

Patients placed on continuous ECG monitoring must be informed of its purpose and cautioned that it does not detect shortness of breath, chest pain, or other ACS symptoms. Thus, patients are instructed to report new or worsening symptoms immediately.

Hardwire Cardiac Monitoring

Hardwire cardiac monitoring is used to continuously observe the heart for arrhythmias and conduction disorders using one or two ECG leads. A real-time ECG is displayed on a bedside monitor and at a central monitoring station. In critical care units, additional components can be added to the bedside monitor to continuously monitor hemodynamic parameters (noninvasive BP, arterial pressures, pulmonary artery pressures), respiratory parameters (respiratory rate, oxygen saturation), and ST segments for myocardial ischemia. The nurse must know the specific indication for each patient's ECG monitoring.

Telemetry

In addition to hardwire cardiac monitoring, the ECG can be continuously observed by **telemetry**—the transmission of radio waves from a battery-operated transmitter to a central bank of monitors. The primary benefit of using telemetry is that the system is wireless, which allows patients to ambulate while one or two ECG leads are monitored. The patient has electrodes placed on the chest with a lead cable that connects to the transmitter. The transmitter can be placed in a disposable pouch and worn around the neck, or simply secured to the patient's clothing. Most transmitter batteries are changed every 24 to 48 hours.

Lead Systems

The number of electrodes needed for hardwire cardiac monitoring and telemetry is dictated by the lead system used in the clinical setting. Electrodes need to be securely and correctly placed on the chest wall to accurately capture arrhythmias (Sandau, Funk, Auerbach, et al., 2017). Chart 21-5 provides helpful hints on how to apply these electrodes. There are three-, four-, or five-lead systems available for ECG monitoring. The type of lead system used determines the number of lead options for monitoring. For example, the five-lead system provides up to seven different lead selections. Unlike the other two systems, the five-lead system can monitor the activity of the anterior wall of the left ventricle. Figure 21-9 presents diagrams of electrode placement.

The two ECG leads most often selected for continuous ECG monitoring are leads II and V_1. Lead II provides the best visualization of atrial depolarization (represented by the P wave). Lead V_1 best records ventricular depolarization and is most helpful when monitoring for certain arrhythmias (e.g., premature ventricular contractions, tachycardias, bundle branch blocks) (see Chapter 22). In addition to proper lead and electrode placement, it is important for the nurse to review and customize alarm settings for each patient to reduce false alarms and alarm fatigue (Jepsen, Sendelbach, Ruppel, et al., 2018).

Chart 21-5

Applying Electrodes

The monitoring system requires an adequate electrical signal to analyze the patient's cardiac rhythm. Proper use of this technology includes the correct application of electrodes to reduce false alarms on the cardiac monitor. When applying electrodes, the recommendations below should be followed to optimize skin adherence and conduction of the heart's electrical current:

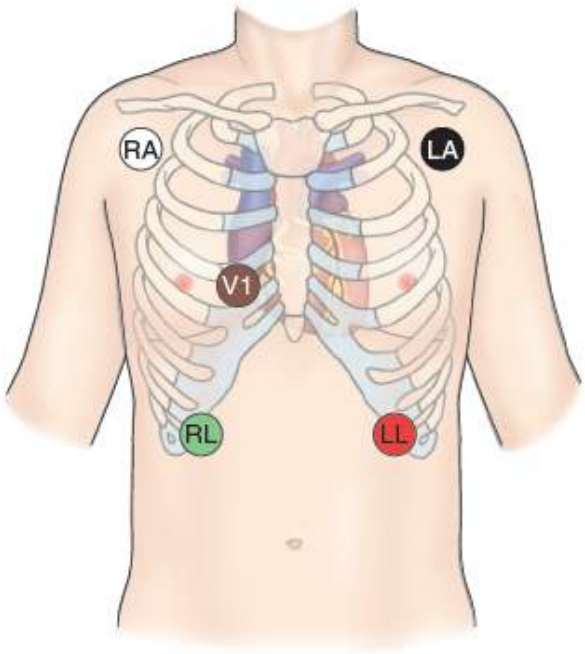
- Débride the skin surface of dead cells with soap and water; dry well using a wash cloth or gauze.
- Clip (do not shave) hair from around the electrode site, if needed.
- Connect the electrodes to the lead wires prior to placing them on the chest (connecting lead wires when electrodes are in place may be uncomfortable for some patients).
- Peel the backing off the electrode, and check to make sure the center is moist with electrode gel.
- Locate the appropriate lead placement, and apply the electrode to the skin, securing it in place with light pressure.
- Change the electrodes every 24 hours, examine the skin for irritation, and apply the electrodes to different locations.
- If the patient is sensitive to the electrodes, use hypoallergenic electrodes.

Adapted from Jepsen, S., Sendelbach, S., Ruppel, H., et al. (2018). AACN Practice Alert: Managing alarms in acute care across the life span: Electrocardiography and pulse oximetry. *Critical Care Nurse*, *38*(2), e16–e20.

Ambulatory Electrocardiography

Ambulatory electrocardiography is a form of continuous or intermittent ECG home monitoring. It is used for longer-term monitoring, since some arrhythmias occur intermittently and are difficult to capture with a 12-lead ECG in the office setting. This monitoring can help to identify the etiology of chest pain, syncope or palpitation caused by arrhythmias, detect episodes of

myocardial ischemia, evaluate effectiveness of treatment of HF and arrhythmias, and evaluate the functioning of ICDs and pacemakers. Several types of devices are available and are worn either externally or implanted under the skin. The ECG is transmitted to a centralized monitoring station via telephone or wireless technology to a secure Web site (Sampson, 2019).



RA – Right arm (white)
LA – Left arm (black)
RL – Right leg (green)
LL – Left leg (red)
V_1 – Chest or precordium (brown)

Figure 21-9 • Electrode placement used in continuous electrocardiographic monitoring for three-lead system, placement on RA, LA, and LL; four-lead system, placement on RA, LA, RL, and LL; five-lead system, placement on RA, LA, RL, LL, and V_1.

Continuous Monitors

Commonly called Holter monitors, these small portable recorders are connected to chest electrodes (number varies based on model used) that record all ECG activity using two or more leads onto a digital memory device. The patient usually wears the recorder for 24 to 48 hours. The patient is also asked to keep a diary to note the date and time of symptoms and activities. The diary is used by the primary provider to correlate symptoms with detected arrhythmias. Once monitoring is completed, the patient returns the device and diary to the primary provider's office. Data from the digital memory device are then uploaded into a computer for analysis, and rhythms that need further

evaluation by the primary provider are identified. Therefore, Holter monitors do not provide real-time ECG recordings or analysis. The effectiveness of this form of monitoring is dependent upon the patient's adherence with wearing the monitor, keeping an accurate diary, and if an arrhythmia occurred during the monitoring period (Sampson, 2019; Urden et al., 2017).

A novel alternative to the use of the Holter monitor is ECG patch monitoring, which uses Bluetooth technology. An ECG patch with adhesive backing is placed over the left pectoral area, eliminating the need for multiple ECG electrodes, wires, and recorders. The patch is single use, waterproof, and easily concealed under clothing. The patient wears the patch for 7 to 14 days and then returns it to the manufacturer for analysis. This device can detect more arrhythmias compared to the Holter monitor since it is worn by the patient for a longer period of time (Sampson, 2019).

Intermittent Monitors

Intermittent cardiac event monitors are devices that can capture arrhythmias when the patient experiences symptoms such as palpitations, dizziness, or lightheadedness. Patients may need to record events for several days to a month. The recorded ECGs are transmitted to the primary provider by telephone or a wireless transmission. The symptom event monitor and external loop recorder are two common forms of external intermittent cardiac event monitors.

The symptom event monitor is used to record and store the ECG during only during times when the patient is experiencing symptoms. Patients activate the symptom event monitor by pressing a button for devices that are worn on the wrist or by placing a small handheld device over the chest.

The loop recorder, a small battery-operated device, can record and store short periods of ECG activity. The monitor is inserted under the skin or worn on a wrist band. Some loop recorders are programmed to detect bradycardia, tachycardia, and irregular rhythms and do not require patient interaction. Other loop recorders require the patient to activate ECG recordings by pushing a button. The device records the patient's ECG for a predetermined time before and after the device activation. This is a preferred method over the symptom event monitor because it has more monitoring capabilities.

Real-time smart phone monitoring is a novel approach to cardiac event recording. The KardiaMobile® is a small device that connects to a smart phone app. The patient places two fingers on the device which generates a PDF file that can be sent electronically to the provider. Similarly, a patient can place a finger on the digital section of the Apple watch® to generate a rhythm strip. This rhythm is displayed on the watch face and a PDF file is sent to an app on the Apple iPhone® (Sampson, 2019).

Cardiac Implantable Electronic Devices

Cardiac implantable electronic devices include pacemakers and ICDs. These lifesaving devices are used to manage patients with serious cardiac illnesses. The technology available today allows for remote wireless monitoring of these devices to determine battery life, pacing parameters and therapies, and occurrence of serious atrial and ventricular arrhythmias. A transmitter, which is placed in the patient's home, sends device data to a secure data repository on a secure Web portal. A unique feature of these implantable devices is that they have programmable alerts that automatically detect and transmit arrhythmias without the need for patient interaction (see Chapter 22 for further discussion).

An implantable cardiac monitor such as the Reveal LINQ™ is another type of electronic device. This small device is implanted subcutaneously under the skin and has a battery life of 3 years. Recordings are triggered when an arrhythmia is detected by the device. Recordings are sent wirelessly via a home monitoring device for expert evaluation. Compared with event recorders described previously, this device offers advantages such as eliminating the patient's need to change electrodes and wear or carry the monitoring device. This type of monitoring is recommended for patients who have infrequent symptoms or require longer-term ECG monitoring (Sampson, 2019).

Nursing Interventions for Inpatient Cardiac Monitoring

A body of evidence indicates that most alarms occurring during inpatient ECG monitoring are false alarms. Nurses dealing with excessive alarms become desensitized to these sounds and develop alarm fatigue. Alarm fatigue delays response time or results in missed alarms. Several nursing interventions facilitate acquisition of accurate data, reduce risk of alarm fatigue, and ensure patient safety when using cardiac monitoring (Jepsen et al., 2018; Sandau et al., 2017).

To minimize false alarms, the ECG recordings must be free of artifact, which is an abnormal ECG pattern caused by muscular activity, patient movement, electrical interference, or lead cable or electrode malfunction. Artifact can mimic arrhythmias and cause unnecessary false alarms. Key to the elimination of artifact is using proper skin preparation before applying electrodes and changing the electrodes every 24 hours. During electrode changes, the skin should be assessed for allergic responses (itchy, reddened skin) to the adhesive or electrode gel. If present, the electrodes are replaced with hypoallergenic electrodes. Rotation of electrode placement on the skin will reduce the risk for skin breakdown (see Fig. 21-9).

Electrodes and lead connections need to be positioned correctly. Improper positioning can result in artifact that mimics ischemia or arrhythmias. Two leads should be selected that provide the best tracing for arrhythmia monitoring, which are usually lead II and the chest lead V_1. Electrical equipment in use around the patient should be inspected to be certain that it is functioning properly and has been recently checked by the medical

engineering department per organization policy, because improperly functioning equipment may cause false alarms from artifact.

An effort should be made to individualize the ECG alarm parameters to meet the patient's monitoring needs. For example, if the patient has atrial fibrillation, it is appropriate to turn off the irregular heart rate alarm. Keeping it on will create unnecessary alarms, contributing to alarm fatigue. Similarly, the bradycardia and tachycardia alarms should be adjusted, slightly below or above the patient's underlying heart rate (Jepsen et al., 2018; Sandau et al., 2017).

The nurse's role is to respond to and correct all monitor alarms immediately. Inoperative (inop) monitoring alarms—used to communicate that electrodes have fallen off, that leads are loose, or that the system's battery power is low (e.g., telemetry)—are just as significant as arrhythmia alarms indicating that the patient is tachycardic, bradycardic, or experiencing another potentially life-threatening arrhythmia. Timely responses to all alarms can prevent serious consequences, including death.

Hospital-acquired infections can be transmitted through lead wire cables. This may be prevented by using disposable lead wire cables, or by keeping reusable cables and transmitter equipment clean, per organizational policy. A patient should never be connected to monitoring equipment that has not been thoroughly cleaned between patients. If a patient is scheduled for a device implant, such as a pacemaker, electrodes should not be placed over the planned incision site. Likewise, electrodes should never be placed over an incision, implanted device, open wounds, or inflamed skin.

Electrodes should be removed once monitoring is discontinued and skin cleansed to remove excess electrode gel and adhesive. Metal-containing electrodes must be removed before sending a patient for any magnetic resonance scan, including magnetic resonance angiography (MRA).

Telemetry transmitters and other monitoring equipment should be maintained according to the manufacturer's recommendations. Monitoring devices of any type should not be submerged in water. A monitoring device may break if dropped; therefore, it should be secured to the patient's gown or clothing.

Cardiac Stress Testing

Normally, the coronary arteries dilate to four times their usual diameter in response to increased metabolic demands for oxygen and nutrients. However, coronary arteries affected by atherosclerosis dilate less, compromising blood flow to the myocardium and causing ischemia. Therefore, abnormalities in cardiovascular function are more likely to be detected during times of increased oxygen demand, or "stress." The **cardiac stress test** procedures—the exercise stress test, pharmacologic stress test, and radionucleotide imaging

studies—are noninvasive ways to evaluate if there is myocardial ischemia and higher myocardial oxygen requirement during these tests. Cardiac imaging is performed during the resting state and immediately after stress testing. The results can identify specific coronary artery lesions and ischemic areas of the heart (King, 2017). Since complications of stress testing can be life-threatening (MI, cardiac arrest, HF, and bradycardia and tachycardia with hemodynamic compromise), testing facilities must have staff and equipment ready to provide treatment, including advanced cardiac life support.

Exercise Stress Testing

Procedure

During an exercise stress test, the patient walks or runs on a treadmill (most common) or pedals a stationary bicycle. A protocol guides exercise intensity based upon the patient's age and heart rate goal (King, 2017). During the test, the following are monitored: two or more ECG leads for heart rate, rhythm, and ischemic changes; BP; skin temperature; physical appearance; perceived exertion; and symptoms, including chest pain, dyspnea, dizziness, leg cramping, and fatigue. The test is stopped when the target heart rate is achieved or if the patient experiences signs of myocardial ischemia. Abnormal findings include chest pain, ventricular arrhythmia, ST-segment depression, and lack of heart rate or BP elevation with exercise (King, 2017).

Nursing Interventions

In preparation for the exercise stress test, the patient is instructed to fast for several hours before the test and to avoid stimulants such as tobacco and caffeine. Medications may be taken with sips of water. The primary provider may instruct the patient to hold beta-blockers, calcium channel blockers, and digitalis for up to 48 hours before the stress test. Clothes and sneakers or rubber-soled shoes suitable for exercising are to be worn. The nurse prepares the patient for the stress test by describing how the stress test is performed, the type of monitoring equipment used, the rationale for insertion of an IV catheter, and what symptoms to report. The exercise method is reviewed, and patients are asked to put forth their best exercise effort. If the test is to be performed with echocardiography or radionuclide imaging (described in the next section), this information is reviewed as well. After the test, the patient is monitored for 10 to 15 minutes until vital signs and assessment findings return to normal. Once stable, patients may resume their usual activities.

Pharmacologic Stress Testing

Procedure

Patients who are cognitively impaired and unable to follow directions or physically disabled or deconditioned will not be able to achieve their target

heart rate by exercising on a treadmill or bicycle. Vasodilating agents such as dipyridamole, adenosine, or regadenoson given as an IV infusion are used to mimic the effects of exercise by maximally dilating normal coronary arteries and identifying stenotic arteries that cannot vasodilate. The side effects of these agents are related to the vasodilating action and include chest pain, headache, flushing, nausea, heart block, and dyspnea. If necessary the effects of these drugs can be reversed with IV aminophylline. Adenosine has an extremely short half-life (less than 10 seconds), so any severe effects subside rapidly. These vasodilating medications are the agents used in conjunction with radionuclide imaging techniques. Patients undergoing pharmacologic stress tests must avoid xanthine derivatives including theophylline, aminophylline, and caffeine as they block the effects of the vasodilating agents.

Dobutamine is another option for use during a pharmacologic stress test. This medication is a synthetic sympathomimetic agent that increases heart rate, myocardial contractility, and BP, thereby increasing the metabolic demands of the heart. It is the agent of choice when echocardiography is used because of its effects on altering myocardial wall motion (due to enhanced contractility). Dobutamine is also used for patients who have bronchospasm or pulmonary disease and cannot tolerate having doses of theophylline withheld.

Nursing Interventions

In preparation for the pharmacologic stress test, the patient is instructed not to eat or drink anything for at least 3 hours before the test. The patient must also be told to refrain from eating any liquid or food that contain chocolate or caffeine for 24 hours and to avoid taking medications that contain caffeine. This restriction also includes caffeine-free coffee, tea, and carbonated beverages. If caffeine is ingested before a stress test using vasodilating agents, the test will have to be rescheduled. Patients taking aminophylline, theophylline, or dipyridamole are instructed to stop taking these medications for 24 to 48 hours before the test (if tolerated). The patient is informed about the transient sensations that may occur during infusion of the vasodilating agent, such as flushing or nausea, which will disappear quickly. The patient is instructed to report the occurrence of any other symptoms during the test to the cardiologist or nurse. The stress test may take about 1 hour, or up to 3 hours if imaging is performed.

Radionuclide Imaging

Radionuclide imaging studies are noninvasive tests that use radioisotopes to evaluate coronary artery perfusion, detect myocardial ischemia and infarction, and/or assess left ventricular function. **Radioisotopes** are unstable atoms that give off small amounts of energy in the form of gamma rays as they decay. When radioisotopes are injected into the bloodstream, the energy emitted can

be detected by a gamma scintillation camera positioned over the body. These radioisotopes are called tracers.

Myocardial Perfusion Imaging

Myocardial perfusion imaging is performed using two types of techniques: single photon emission computed tomography (SPECT) or positron emission tomography (PET). It is commonly performed after an acute MI to determine if arterial perfusion to the heart is compromised during activity and to evaluate the extent of myocardial damage. It is also used to evaluate if myocardial ischemia from CAD is the cause of chest pain or other CAD-related symptoms.

These imaging techniques are performed in combination with stress testing to compare images obtained when the heart is resting to images of the heart in a stressed state resulting from exercise or medications. An area of the myocardium that shows no perfusion or reduced perfusion is said to have a "defect" present. Comparing resting images with images taken after the stress test helps differentiate ischemic myocardium from infarct-related myocardium. A defect that does not change in size before and after stress is called a fixed defect. Fixed defects indicate that there is no perfusion in that area of the myocardium, which is the case after an MI. Defects that appear or that get larger after the stress test images are taken indicate reduced perfusion to that area of the heart. Because the defect disappears with rest, it is called a reversible defect. Reversible defects constitute positive stress test findings. Typically, cardiac catheterization is recommended after a positive test result to determine the severity of obstructions to blood flow caused by CAD.

The patient undergoing myocardial perfusion imaging with stress testing should be prepared for the type of stressor to be used (exercise or medication) and provided with details of what to expect during imaging. The imaging is performed in two stages. Usually, the resting images are taken first. An IV is inserted to administer the radioisotope, and electrodes are placed on the chest to monitor the heart rate and rhythm. Women who are nursing, pregnant or think they are pregnant should not undergo myocardial perfusion imaging. The nurse alerts the primary provider if any of these conditions are present.

Single Photon Emission Computed Tomography

SPECT is widely available and is the most common technique of myocardial perfusion imaging. In addition, the ability of SPECT to detect myocardial ischemia is between 80% and 90% (King, 2017).

Procedure

SPECT is a painless, noninvasive procedure that involves the injection of the nuclear medicine radionucleotide (technetium-99m [^{99m}Tc]; rubidium-82) and imaging. During SPECT, patients are positioned supine on the table with their

arms over their heads. The gamma camera circles around the chest area converting the signals from the traces into pictures of the heart. The procedure takes approximately 30 minutes. The second scan is repeated after an exercise or pharmacologic stress test.

Nursing Interventions

The nurse's primary role is to prepare the patient for SPECT and insert an IV catheter or assess an existing IV for patency and suitability. The IV is used to inject the tracer. The patient may be concerned about receiving a radioactive substance and needs to be reassured that these tracers are safe—the radiation exposure is similar to that of other diagnostic x-ray studies. No postprocedure radiation precautions are necessary.

Positron Emission Tomography

PET is another noninvasive procedure in which a radioactive tracer chemical is administered to the patient and images are obtained. These images generally have a higher resolution compared to SPECT. PET technology is expensive and is likely to be found at large or academic medical centers.

Procedure

During PET, tracers are given by injection; one compound is used to determine blood flow in the myocardium, and another determines the metabolic function. The PET camera provides detailed three-dimensional images of the distributed compounds. The viability of the myocardium is determined by comparing the extent of glucose metabolism in the myocardium to the degree of blood flow. For example, ischemic but viable tissue will show decreased blood flow and elevated metabolism. For a patient with this finding, revascularization through surgery or angioplasty will probably be indicated to improve heart function. Restrictions of food intake before the test vary among institutions, but because PET evaluates glucose metabolism, the patient's blood glucose level should be within the normal range before testing.

Nursing Interventions

The nurse instructs the patient to refrain from using alcohol and caffeine for 24 hours before undergoing PET because of the stimulating effects they may have on the heart. For patients with diabetes and who are taking insulin, the nurse needs to discuss insulin doses and food restrictions with the primary provider. The nurse assesses patients for fear of closed spaces or claustrophobia. Patients who have this condition are reassured that medications can be given to help them relax. The nurse also reassures patients that radiation exposure is at safe and acceptable levels, similar to those of other diagnostic x-ray studies.

To prepare the patient for PET, the nurse inserts an IV or assesses the existing IV catheter for patency and suitability, and then describes the

procedure to the patient. The patient is positioned on a table with hands above the head. The table then slides into a donut-shaped scanner. While in the scanner, the patient must lie still so that clear images of the heart can be obtained. A baseline scan is performed, which takes about 30 minutes. Then a tracer is injected into the IV and the scan is repeated. The patient's glucose level is monitored throughout the procedure. The scan takes from 1 to 3 hours to complete.

Test of Ventricular Function and Wall Motion

Equilibrium radionuclide angiocardiography (ERNA), also known as multiple-gated acquisition (MUGA) scanning, is a common noninvasive technique that uses a conventional scintillation camera interfaced with a computer to record images of the heart during several hundred heartbeats. The computer processes the data and allows for sequential viewing of the functioning heart. The sequential images are analyzed to evaluate left ventricular function, wall motion, and ejection fraction.

The patient is reassured that there is no known radiation danger and is instructed to remain motionless during the scan.

Additional Imaging

Additional cardiac imaging techniques include computed tomography (CT) and MRA.

Computed Tomography

Procedure

Cardiac CT scanning is a form of cardiac imaging that uses x-rays to provide accurate cross-sectional "virtual" slices of specific areas of the heart and surrounding structures. Complex mathematical and computer algorithms are used to analyze the slices to create three-dimensional images. Multidetector CT (MDCT) is a fast form of CT scanning that takes multiple slices at the same time. This technology produces high-resolution clear images of cardiac anatomy (Liddy, Buckley, Kok, et al., 2018). Two types of cardiac CT scanning include coronary CT angiography and electron beam CT (EBCT) (for coronary calcium scoring).

Coronary CT angiography requires the use of an IV contrast agent to enhance the x-rays and improve visualization of cardiac structures. This test is used to evaluate coronary arteries for stenosis, the aorta for aneurysms or dissections, graft patency after coronary artery bypass grafting, pulmonary veins in patients with atrial fibrillation, and cardiac structures for congenital anomalies. Patients may receive beta-blockers prior to the scan to control heart rate and rhythm and reduce artifact. Another way to minimize artifact is to

have patients hold their breath periodically throughout the scan. Coronary CT angiography is used with caution in patients with renal insufficiency. The contrast agent used during the CT scan is excreted through the kidneys; therefore, renal function should be assessed prior to the scan. It may be necessary to administer IV hydration before and after the scan to minimize the effect of the contrast on renal function. Patients will require premedication with corticosteroids and antihistamines if they experienced a reaction to a contrast agent in the past (Mervak, Cohan, Ellis, et al., 2017).

EBCT is used to calculate a coronary artery calcium score that is based on the amount of calcium deposits in the coronary arteries. This score is used to predict the likelihood of cardiac events, such as MI, or the need for a revascularization procedure in the future. Coronary artery calcium scoring is used for the evaluation of individuals without known CAD and offers limited incremental prognostic value for individuals with known CAD, such as those with stents and bypass grafts. Currently, EBCT is thought to be a reasonable test to consider in patients with low to intermediate risk for future CAD-related events. Results of the test may help to reclassify them to higher risk and thus intensify primary prevention measures (Arnett et al., 2019).

Nursing Interventions

The nurse provides details of the procedure to help prepare the patient for the test. Patients need to be prepared to hold their breath at certain times during the procedure, so it is important for the nurse to practice with the patient before going for CT scan. The patient is positioned on a table, and the scanner rotates around the table during the test. The procedure is noninvasive and painless. However, to obtain adequate images, the patient must lie completely still during the scanning process. An IV is necessary if contrast is to be used to enhance the images. The patient should be told to expect transient flushing, metallic taste, nausea, or bradycardia during the contrast infusion.

Magnetic Resonance Angiography

Procedure

MRA is a noninvasive, painless technique that is used to examine both the physiologic and anatomic properties of the heart. MRA uses a powerful magnetic field and computer-generated pictures to image the heart and great vessels. It is valuable in diagnosing diseases of the aorta, heart muscle, and pericardium, as well as congenital heart lesions. The application of this technique to the evaluation of coronary artery anatomy is limited because the quality of the images is distorted by respirations, the beating heart, and certain implanted devices (stents and surgical clips). In addition, this technique cannot adequately visualize the small distal coronary arteries as accurately as conventional angiography performed during a cardiac catheterization.

Nursing Interventions

Because of the magnetic field used during MRA, patients must be screened for contraindications for its use. Patients with any type of cardiac implantable electronic device need to be screened to see if it is safe for the patient to undergo the test (Indik, Gimbel, Abe, et al., 2017). MRA cannot be performed on patients who have metal plates, prosthetic joints, or other metallic implants that can become dislodged if exposed to MRA. Patients are instructed to remove any jewelry, watches, or other metal items (e.g., ECG leads). Transdermal patches that contain a heat-conducting aluminized layer (e.g., nitroglycerin, clonidine, fentanyl) must be removed before MRA to prevent burning of the skin.

During MRA, the patient is positioned supine on a table that is placed into an enclosed imager or tube containing the magnetic field. A patient who is claustrophobic may need to receive a mild sedative before undergoing an MRA. An intermittent clanking or thumping that can be annoying is generated by the magnetic coils, so the patient may be offered a headset to listen to music. The scanner is equipped with a microphone so that the patient can communicate with the staff. The patient is instructed to remain motionless during the scan.

Echocardiography

Transthoracic Echocardiography

Echocardiography is a noninvasive ultrasound test that is used to measure the ejection fraction and examine the size, shape, and motion of cardiac structures. It is particularly useful for diagnosing pericardial effusions; determining chamber size and the etiology of heart murmurs; evaluating the function of heart valves, including prosthetic heart valves; and evaluating ventricular wall motion.

Procedure

Echocardiography involves transmission of high-frequency sound waves into the heart through the chest wall and the recording of the return signals. With the traditional transthoracic approach, the ultrasound is generated by a handheld transducer applied to the front of the chest. The transducer picks up the echoes and converts them to electrical impulses that are recorded and displayed on a monitor. It creates sophisticated, spatially correct images of the heart. An ECG is recorded simultaneously to assist in interpretation of the echocardiogram.

With the use of Doppler techniques, an echocardiogram can also show the direction and velocity of the blood flow through the heart. These techniques are used to assess for “leaking valves,” conditions referred to as valvular

regurgitation, and will also detect abnormal blood flow between the septum of the left and right heart.

Echocardiography may be performed with an exercise or pharmacologic stress test. Images are obtained at rest and then immediately after the target heart rate is reached. Myocardial ischemia from decreased perfusion during stress causes abnormalities in ventricular wall motion and is easily detected by echocardiography. A stress test using echocardiography is considered positive if abnormalities in ventricular wall motion are detected during stress but not during rest. These findings are highly suggestive of CAD and require further evaluation, such as a cardiac catheterization.

Nursing Interventions

Before transthoracic echocardiography, the nurse informs the patient about the test, explaining that it is painless. Echocardiographic monitoring is performed while a transducer that emits sound waves is moved over the surface of the chest wall. Gel applied to the skin helps transmit the sound waves. Periodically, the patient is asked to turn onto the left side or hold a breath. The test takes about 30 to 45 minutes. If the patient is to undergo an exercise or pharmacologic stress test with echocardiography, information on stress testing is also reviewed with the patient.

Transesophageal Echocardiography

Procedure

A significant limitation of transthoracic echocardiography is the poor quality of the images produced. Ultrasound loses its clarity as it passes through tissue, lung, and bone. An alternative technique involves threading a small transducer through the mouth and into the esophagus. This technique, called *transesophageal echocardiography* (TEE), provides clearer images because ultrasound waves pass through less tissue. A topical anesthetic agent and sedation are used during TEE because of the discomfort associated with the positioning of the transducer in the esophagus (refer to Chapter 15 for further discussion of sedation for procedures). Once the patient is comfortable, the transducer is inserted into the mouth and the patient is asked to swallow several times until it is positioned in the esophagus.

The high-quality imaging obtained during TEE makes this technique an important first-line diagnostic tool for evaluating patients with many types of CVD, including HF, valvular heart disease, arrhythmias, and many other conditions that place the patient at risk for atrial or ventricular thrombi. Pharmacologic stress testing using dobutamine and TEE can also be performed. It is frequently used during cardiac surgery to continuously monitor the response of the heart to the surgical procedure (e.g., valve replacement or coronary artery bypass). Complications are uncommon during TEE; however,

if they do occur, they are serious. These complications are caused by sedation and impaired swallowing resulting from the topical anesthesia (respiratory depression and aspiration) and by insertion and manipulation of the transducer into the esophagus and stomach (vasovagal response or esophageal perforation). The patient must be assessed before TEE for a history of dysphagia or radiation therapy to the chest, which increases the likelihood of complications.

Nursing Interventions

Prior to the test, the nurse provides preprocedure education and ensures that the patient has a clear understanding of what the test entails and why it is being performed, instructs the patient not to eat or drink anything for 6 hours prior to the study, and checks to make sure that informed consent has been obtained. The nurse also inserts an IV line or assesses an existing IV for patency and suitability and asks the patient to remove full or partial dentures. During the test, the nurse provides emotional support and monitors level of consciousness, BP, ECG, respiration, and oxygen saturation (SpO_2). During the recovery period, the patient must maintain bed rest with the head of the bed elevated to 45 degrees. Following the procedural sedation policy of the agency, the nurse monitors the patient for dyspnea and assesses vital signs, SpO_2, level of consciousness, and gag reflex as recommended. Food and oral fluids are withheld until the patient is fully alert and the effects of the topical anesthetic agent are reversed, usually 2 hours after the procedure; if the gag reflex is intact, the nurse begins feeding with sips of water, then advances to the preprocedure diet. Patients are informed that a sore throat may be present for the next 24 hours; they are instructed to report the presence of a persistent sore throat, shortness of breath, or difficulty swallowing to the medical staff. If the procedure is performed in an outpatient setting, a family member or friend must be available to transport the patient home from the test site.

Cardiac Catheterization

Cardiac catheterization is a common invasive procedure used to diagnose structural and functional diseases of the heart and great vessels. The results guide treatment decisions including the need for revascularization (PCI or CABG) and other interventions to manage structural defects of the valves or septum (see Chapter 23).

This procedure involves the percutaneous insertion of radiopaque catheters into a large vein and an artery. Fluoroscopy is used to guide the advancement of the catheters through the right and left heart, referred to as right and left heart catheterizations, respectively. In most situations, patients undergo both right and left heart catheterizations. However, right heart catheterization is performed without a left heart catheterization when patients only need

myocardial biopsies or measurement of pulmonary artery pressures. Of note, left heart catheterization involves the use of a contrast agent. These agents are necessary to visualize patency of the coronary arteries and evaluate left ventricular function.

In preparation for the procedure, patients have blood tests performed to evaluate metabolic function (electrolytes and glucose) and renal function (blood urea nitrogen and creatinine level). Baseline coagulation studies (activated partial thromboplastin time [aPTT], international normalized ratio [INR], and prothrombin time [PT]) are obtained to guide dosing of anticoagulation during the procedure. Because bleeding and hematoma formation are procedural risks, a complete blood cell count (CBC; includes the hematocrit, hemoglobin, and platelets) is necessary to establish baseline values. Later these results are compared with postprocedure results to monitor for blood loss.

A health history is obtained to assess for previous reactions to a contrast agent and determine if the patient has any risk factors for contrast-induced nephropathy (CIN). This uncommon complication is a form of acute kidney injury that is usually reversible. Patients with chronic kidney disease or renal insufficiency, diabetes, HF, hypotension, dehydration, use of nephrotoxic medications, and advanced age are at risk for CIN. CIN is defined as an increase in the baseline serum creatinine by 25% or more or an absolute increase of 0.5 mg/dL within 48 to 72 hours after the administration of contrast (Urden et al., 2017). See Chapter 47, Chart 47-5 for further discussion of nursing care of patient undergoing imaging study with the use of a contrast agent.

During a cardiac catheterization, the patient has one or more IV catheters for administration of fluids, sedatives, heparin, and other medications. The patient is continuously monitored for chest pain or dyspnea and for changes in BP and ECG, which are indicative of myocardial ischemia, hemodynamic instability, or arrhythmias. Resuscitation equipment must be readily available, and staff must be prepared to provide advanced cardiac life support measures as necessary.

Postprocedure, patients remain on bed rest for 2 to 6 hours before they are permitted to ambulate. Variations in time to ambulation are related to the size of the catheters used during the procedure, the site of catheter insertion (femoral or radial artery), the patient's anticoagulation status, and other factors (e.g., advanced age, obesity, bleeding disorder). The use of a radial access site and smaller (4- or 6-Fr) arterial catheters are associated with shorter bed rest restrictions.

Cardiac catheterization may be performed in the ambulatory setting. Unless the results demonstrate the need for immediate treatment, patients are discharged home. Hospitalized patients undergoing cardiac catheterization for

diagnostic and interventional purposes (PCI, valvuloplasty) are returned to their hospital rooms for recovery (see Chapter 23).

Right Heart Catheterization

Right heart catheterization usually precedes left heart catheterization. It is performed to assess the function of the right ventricle and tricuspid and pulmonary valves. The procedure involves the passage of a catheter from a brachial, internal jugular, or femoral vein into the right atrium, right ventricle, pulmonary artery, and pulmonary arterioles. Pressures and oxygen saturations from each of these areas are obtained and recorded. The pulmonary artery pressures are used to diagnose pulmonary hypertension. A biopsy of a small piece of myocardial tissue can also be obtained during a right heart catheterization. The results of the biopsy are used to diagnose the etiology of a cardiomyopathy (abnormality of myocardium) or heart transplant rejection. At the completion of the procedure, the venous catheter is removed and hemostasis of the affected vein is achieved using manual pressure. Although right heart catheterization is considered relatively safe, potential complications include arrhythmias (from contact of the catheter with the endocardium), venous spasm, infection at the insertion site, and right heart perforation.

Left Heart Catheterization

Prior to left heart catheterization, patients who have previously experienced a reaction to a contrast agent are premedicated with antihistamines (e.g., diphenhydramine) and corticosteroids (e.g., prednisone). Patients at risk for CIN receive pre- and postprocedure preventive strategies. IV saline hydration increases vascular volume, facilitates removal of contrast from the kidneys, and reduces the risk of CIN (Liu, Hong, Wang, et al., 2019).

Left heart catheterization is performed to evaluate the aortic arch and its major branches, patency of the coronary arteries, and the function of the left ventricle and mitral and aortic valves. Left heart catheterization is performed by retrograde catheterization of the left ventricle. In this approach, the interventional cardiologist usually inserts the catheter into the right radial or a femoral artery and advances it into the aorta and left ventricle. Potential complications include arrhythmias, MI, perforation of the left heart or great vessels, and systemic embolization.

During a left heart catheterization, angiography is performed. Angiography is an imaging technique that involves the injection of the contrast agent into the arterial catheter. The contrast agent is filmed as it passes through the chambers of the left heart, aortic arch, and its major arteries. Coronary angiography is another technique used to observe the coronary artery anatomy and evaluate the degree of stenosis from atherosclerosis. To perform this test, a catheter is positioned into one of the coronary arteries. Once in position, the

contrast agent is injected directly into the artery and images are obtained. The procedure is then repeated using the opposite coronary artery. Ventriculography is also performed to evaluate the size and function of the left ventricle. For this test, a catheter is positioned in the left ventricle and a large amount of contrast agent (30 mL) is rapidly injected into the ventricle.

The manipulation of catheters in the coronary arteries and left ventricle as well as injection of the contrast agent can cause intermittent myocardial ischemia. Vigilant monitoring throughout left heart catheterization is needed to detect myocardial ischemia, which can trigger chest pain and life-threatening arrhythmias.

Once the procedure is completed, the arterial catheter is withdrawn. There are several options available to achieve arterial hemostasis, including applying manual pressure and hemostatic devices available from numerous vendors. For the radial artery, a compression device, such as the Terumo TR Band®, is positioned over the artery. It has a mechanism that is inflated with air to put pressure against the artery. It remains in place for about 2 hours. A radial approach and a compression device are both common practices and are associated with lower risks for bleeding and vascular complications, as well as a shorter time to ambulation postprocedure (Mason, Shah, Tamis-Holland, et al., 2018).

For the femoral approach, manual pressure may be used alone or in combination with mechanical compression devices such as the FemoStop™. Many types of percutaneously deployed vascular closure devices are also available. These devices are positioned at the femoral arterial puncture site after completion of the procedure. They deploy a saline-soaked gelatin sponge (QUICKSEAL), collagen (VasoSeal), sutures (Perclose ProGlide™), or a combination of both collagen and sutures (Angio-Seal). Other products that expedite arterial hemostasis include external patches (Syvek Patch, Clo-Sur P.A.D.). These products are placed over the puncture site as the catheter is removed and manual pressure is applied for 4 to 10 minutes. Once hemostasis is achieved, the patch is covered with a dressing that remains in place for 24 hours. The interventional cardiologist determines which closure device, if any, will be deployed based on the artery used to insert the catheter, patient's condition, device availability, and personal preference.

Major benefits of the vascular closure devices include reliable, immediate hemostasis and a shorter time on bed rest without a significant increase in bleeding or other complications. Rare complications associated with these devices include bleeding around the closure device, infection, and arterial obstruction.

Nursing Interventions

Nursing responsibilities before cardiac catheterization include:

- Instructing the patient to fast, usually for 8 to 12 hours, before the procedure.
- Informing the patient that if catheterization is to be performed as an outpatient procedure, a friend, family member, or other responsible person must transport the patient home.
- Informing the patient about the expected duration of the procedure and advising that it will involve lying on a hard table for less than 2 hours.
- Reassuring the patient that IV medications are given to maintain comfort.
- Informing the patient about sensations that will be experienced during the catheterization. Knowing what to expect can help the patient cope with the experience. The nurse explains that an occasional pounding sensation (palpitation) may be felt in the chest because of extra heartbeats that almost always occur, particularly when the catheter tip touches the endocardium. The patient may be asked to cough and to breathe deeply, especially after the injection of the contrast agent. Coughing may help disrupt an arrhythmia and clear the contrast agent from the arteries. Breathing deeply and holding the breath help lower the diaphragm for better visualization of heart structures. The injection of a contrast agent into either side of the heart may produce a flushed feeling throughout the body and a sensation similar to the need to void, which subsides in 1 minute or less.
- Encouraging the patient to express fears and anxieties. The nurse provides education and reassurance to reduce apprehension.

Nursing responsibilities after cardiac catheterization are guided by hospital policy and primary provider preferences and may include:

- Observing the catheter access site for bleeding or hematoma formation and assessing peripheral pulses in the affected extremity (dorsalis pedis and posterior tibial pulses in the lower extremity, radial pulse in the upper extremity) every 15 minutes for 1 hour, every 30 minutes for 1 hour, and hourly for 4 hours or until discharge. BP and heart rate are also assessed during these same time intervals.
- Evaluating temperature, color, and capillary refill of the affected extremity during these same time intervals. The patient is assessed for affected extremity pain, numbness, or tingling sensations that may indicate arterial insufficiency. The best technique to use is to compare the examination findings between the affected and unaffected extremities. Any changes are reported promptly.

- Screening carefully for arrhythmias by observing the cardiac monitor or by assessing the apical and peripheral pulses for changes in rate and rhythm. A vasovagal reaction, consisting of bradycardia, hypotension, and nausea, can be precipitated by a distended bladder or by discomfort from manual pressure that is applied during removal of an arterial or venous catheter. The vasovagal response is reversed by promptly elevating the lower extremities above the level of the heart, infusing a bolus of IV fluid, and administering IV atropine to treat the bradycardia.
- Maintaining activity restrictions for 2 to 6 hours after the procedure. The determination of bed rest, chair activity, and time to commence ambulation is dependent upon location of arterial approach, size of the catheter used during the procedure, medications administered, and method used to maintain hemostasis. If manual pressure or a mechanical device was used during a femoral artery approach, the patient remains on bed rest for up to 6 hours with the affected leg straight and the head of the bed elevated no greater than 30 degrees. For comfort, the patient may be turned from side to side with the affected extremity straight. If a percutaneous vascular closure device or patch was deployed, the nurse checks local nursing care standards and anticipates that the patient will have fewer activity restrictions. If the radial closure device was used, the patient can sit up in a chair until the effects of sedation have dissipated, and early ambulation is encouraged. After the vascular closure device removal, a dressing is applied over the catheter access site. Patients can return to normal activities the day after the procedure but must avoid strenuous wrist activities for several days (Mason et al., 2018). Analgesic medication is given as prescribed for discomfort.
- Instructing the patient to report chest pain and bleeding or sudden discomfort from the catheter insertion sites promptly.
- Monitoring the patient for CIN by observing for elevations in serum creatinine levels. IV hydration is used to increase urinary output and flush the contrast agent from the urinary tract; accurate oral and IV intake and urinary output are recorded.
- Ensuring patient safety by instructing the patient to ask for help when getting out of bed the first time after the procedure. The patient is monitored for bleeding from the catheter access site and for orthostatic hypotension, indicated by complaints of dizziness or lightheadedness.

For patients being discharged from the hospital on the same day as the procedure, additional instructions are provided (Chart 21-6).

Electrophysiologic Testing

The electrophysiology study (EPS) is an invasive procedure that plays a major role in the diagnosis and management of serious arrhythmias. EPS may be indicated for patients with syncope, palpitations, or both, and for survivors of cardiac arrest from ventricular fibrillation (sudden cardiac death) (Kusumoto, Schoenfeld, Barrett, et al., 2019). EPS is used to distinguish atrial from ventricular tachycardias when the determination cannot be made from the 12-lead ECG; to evaluate how readily a life-threatening arrhythmia (e.g., ventricular tachycardia, ventricular fibrillation) can be induced; to evaluate AV node function; to evaluate the effectiveness of antiarrhythmic medications in suppressing the arrhythmia; or to determine the need for other therapeutic interventions, such as a cardiac implantable electronic device, or radiofrequency ablation. (See Chapter 22 for a detailed discussion of EPS.)

Chart 21-6 **PATIENT EDUCATION**

Self-Management After Cardiac Catheterization

After discharge from the hospital for cardiac catheterization, patients should follow these guidelines for self-care:

- *If the artery in your wrist artery was used:* Return to normal activities tomorrow. Strenuous activities of the wrist such as manual labor, tennis, or driving may be restricted for a few days per your provider's orders.
- *If the artery in your groin was used:* For the next 24 hours, do not bend at the waist, strain, or lift heavy objects.
- Do not submerge the puncture site in water. Avoid tub baths, but shower as desired.
- Talk with your primary provider about when you may return to work, drive, or resume strenuous activities.
- If bleeding occurs, sit (arm or wrist approach) or lie down (groin approach) and apply firm pressure to the puncture site for 10 minutes. Notify your primary provider as soon as possible and follow instructions. If there is a large amount of bleeding, call 911. Do not drive to the hospital.
- Call your primary provider if any of the following occur: swelling, new bruising or pain from your procedure puncture site, temperature of 101°F or more.
- If test results show that you have coronary artery disease, talk with your primary provider about options for treatment, including cardiac rehabilitation programs in your community.
- Talk with your primary provider about lifestyle changes to reduce your risk for further or future heart problems, such as quitting smoking, lowering your cholesterol level, initiating dietary changes, beginning an exercise program, cardiac rehabilitation, or losing weight.
- Your primary provider may prescribe one or more new medications depending on your risk factors (medications to lower your blood pressure or cholesterol; aspirin or clopidogrel to prevent blood clots). Take all of your medications as instructed. If you feel that any of them are causing side effects, call your primary provider immediately. Do not stop taking any medications before talking to your primary provider.

Hemodynamic Monitoring

Critically ill patients require continuous assessment of their cardiovascular system to diagnose and manage their complex medical conditions. This type of assessment is achieved by the use of direct pressure monitoring systems, referred to as hemodynamic monitoring. Common forms include CVP, pulmonary artery pressure, and intra-arterial BP monitoring. Patients requiring hemodynamic monitoring are cared for in critical care units. Some progressive care units also admit stable patients with CVP, pulmonary artery catheters, or intra-arterial BP monitoring. To perform hemodynamic monitoring, a CVP, pulmonary artery, or arterial catheter is introduced into the appropriate blood vessel or heart chamber. It is connected to a pressure monitoring system that has several components, including:

- A disposable flush system, composed of IV normal saline solution, tubing, stopcocks, and a flush device, which provides continuous and manual flushing of the system.
- A pressure bag placed around the flush solution that is maintained at 300 mm Hg of pressure. The pressurized flush system delivers 3 to 5 mL of solution per hour through the catheter to prevent clotting and backflow of blood into the pressure monitoring system.
- A transducer to convert the pressure coming from the artery or heart chamber into an electrical signal.
- An amplifier or monitor, which increases the size of the electrical signal for display on an oscilloscope.

Nurses caring for patients who require hemodynamic monitoring receive training prior to using this sophisticated technology. The nurse helps ensure safe and effective care by adhering to the following guidelines:

- Ensuring that the system is set up and maintained properly. For example, the pressure monitoring system must be kept patent and free of air bubbles.
- Checking that the stopcock of the transducer is positioned at the level of the atrium before the system is used to obtain pressure measurements. This landmark is referred to as the phlebostatic axis (Fig. 21-10). The nurse uses a marker to identify this level on the chest wall, which provides a stable reference point for subsequent pressure readings.
- Establishing the zero reference point in order to ensure that the system is properly functioning at atmospheric pressure. This process is accomplished by placing the stopcock of the transducer at the phlebostatic axis, opening the transducer to air, and activating the zero function key on the bedside monitor. Measurements of CVP, BP, and pulmonary artery pressures can be made with the head of the bed elevated up to 60 degrees;

however, the system must be repositioned to the phlebostatic axis to ensure an accurate reading (Urden et al., 2017).

Complications from the use of hemodynamic monitoring systems are uncommon and can include pneumothorax, infection, and air embolism. The nurse observes for signs of pneumothorax during the insertion of catheters using a central venous approach (CVP and pulmonary artery catheters). The longer any of these catheters are left in place (after 72 to 96 hours), the greater the risk of infection. Air emboli can be introduced into the vascular system if the stopcocks attached to the pressure transducers are mishandled during blood drawing, administration of medications, or other procedures that require opening the system to air. Therefore, nurses handling this equipment must demonstrate competence prior to caring independently for a patient requiring hemodynamic monitoring.

Catheter-related bloodstream infections are the most common preventable complication associated with hemodynamic monitoring systems. The Centers for Disease Control and Prevention (CDC) has published comprehensive guidelines for the prevention of these infections (O'Grady, Alexander, Burns, et al., 2011; Talbot, Stone, Irwin, et al., 2017). To minimize the risk of infection, a group of evidence-based interventions, called a care *bundle,* should be implemented.

The CDC and Infusion Nursing Society have additional infection control guidelines that pertain to the ongoing care of these patients, including skin care, dressing changes, and line and connector care that are outlined in Table 21-5.

Central Venous Pressure Monitoring

CVP is a measurement of the pressure in the vena cava or right atrium. The pressure in the vena cava, right atrium, and right ventricle is equal at the end of diastole; thus, the CVP also reflects the filling pressure of the right ventricle (preload). The normal CVP is 2 to 6 mm Hg. It is measured by positioning a catheter in the vena cava or right atrium and connecting it to a pressure monitoring system. The CVP is most valuable when it is monitored over time and correlated with the patient's clinical status. A CVP greater than 6 mm Hg indicates an elevated right ventricular preload. There are many problems that can cause an elevated CVP, but the most common problem is hypervolemia (excessive fluid circulating in the body) or right-sided HF. In contrast, a low CVP (less than 2 mm Hg) indicates reduced right ventricular preload, which is most often from hypovolemia. Dehydration, excessive blood loss, vomiting or diarrhea, and overdiuresis can result in hypovolemia and a low CVP. This diagnosis can be substantiated when a rapid IV infusion of fluid causes the CVP to increase.

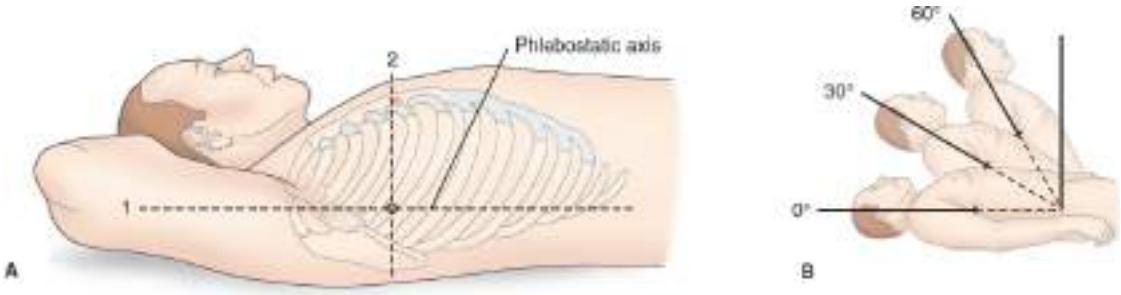

Figure 21-10 • **A.** The phlebostatic axis is the reference point for the atrium when the patient is positioned supine. It is the intersection of two lines on the chest wall: (*1*) the midaxillary line drawn between the anterior and posterior surfaces of the chest and (*2*) the line drawn through the fourth intercostal space. Its location is identified with a skin marker. The stopcock of the transducer used in hemodynamic monitoring is "leveled" at this mark prior to taking pressure measurements. **B.** Measurements can be taken with the head of the bed (HOB) elevated up to 60 degrees. Note the phlebostatic axis changes as the HOB is elevated; thus, the stopcock and transducer must be repositioned after each position change.

TABLE 21-5 Nursing Interventions to Prevent Intravascular Catheter-Related Bloodstream Infections

Topic	Intervention
Hand hygiene	• Wash hands with soap and water or use alcohol-based hand rubs before and after contact with the catheter for any reason.
Dressing	• Wear clean or sterile gloves when changing the dressing. • Cleanse the skin during dressing changes with a >0.5% chlorhexidine preparation with alcohol. • Use a chlorhexidine-impregnated dressing at the catheter insertion site. Do not use topical antibiotic ointment or creams on insertion sites. • Dress the site with sterile gauze or sterile, transparent, semipermeable dressing to cover the catheter site. If the patient is diaphoretic or if the site is bleeding or oozing, use a gauze dressing until it is resolved. • Change gauze dressings every 2 d or transparent dressings at least every 7 d and whenever dressings become damp, loosened, or visibly soiled.
Catheter site	• Assess the site regularly—visually when changing the dressing or by palpation through an intact dressing. Remove the dressing for a thorough assessment if the patient has tenderness at the insertion site, fever without obvious source, or other signs of local or bloodstream infection.
Needleless catheter systems	• Change needleless connectors, administration sets, and pressure tubing per institutional policy, usually every 96 h. • Scrub ports, connectors, and hubs with alcohol, chlorhexidine/alcohol, or povidone–iodine before and after access. • Apply alcohol-impregnated caps to needless connectors between uses.
Bathing	• Clean the skin daily with a 2% chlorhexidine wash. • Do not submerge the catheter or catheter site in water. • Showering is permitted if the catheter and related tubing are placed in an impermeable cover.

Patient education	• Ask patients to report any new discomforts from the catheter site.

P., Alexander, A., Burns, L., et al. (2011). 2017 Update of the guidelines for the prevention of intravascular catheter-related infections, 2011. Retrieved on 5/15/2019 at: www.cdc.gov/infectioncontrol/pdf/guidelines/bsi-guidelines-H.pdf; Talbot, T. R., Stone, E. C., Irwin, K., et al. (2017). 2017 Updated recommendations on the use of chlorhexidine-impregnated dressings for prevention of intravascular catheter-related infections. Retrieved on 5/15/ 2019 at: www.cdc.gov/infectioncontrol/pdf/guidelines/c-i-dressings-H.pdf

Before insertion of a CVP catheter, the site is prepared as recommended by the CDC (see Chapter 11, Chart 11-2). The preferred site is the subclavian vein; the femoral vein is generally avoided (O'Grady et al., 2011). A local anesthetic agent is used. During this sterile procedure, the physician threads a single-lumen or multilumen catheter through the vein into the vena cava just above or within the right atrium. Once the CVP catheter is inserted, it is secured and a dry sterile dressing is applied. Position of the catheter is confirmed by a chest x-ray.

Nursing Interventions

The frequency of CVP measurements is dictated by the patient's condition and the treatment plan. In addition to obtaining pressure readings, the CVP catheter is used for infusing IV fluids, administering IV medications, and drawing blood specimens. Nursing care of the patient with a CVP catheter follows central line and pressure tubing guidelines (see Table 21-5).

Pulmonary Artery Pressure Monitoring

Pulmonary artery pressure monitoring is used in critical care for assessing left ventricular function, diagnosing the etiology of shock, and evaluating the patient's response to medical interventions (e.g., fluid administration, vasoactive medications). A pulmonary artery catheter and a pressure monitoring system are used. A variety of catheters are available for cardiac pacing, oximetry, cardiac output measurement, or a combination of functions. Pulmonary artery catheters are balloon-tipped, flow-directed catheters that have distal and proximal lumens (Fig. 21-11). The distal lumen has a port that opens into the pulmonary artery. Once connected by its hub to the pressure monitoring system, it is used only to continuously measure pulmonary artery pressures. The proximal lumen has a port that opens into the right atrium. It is used to administer IV medications and fluids or to monitor right atrial pressures (i.e., CVP). Each catheter has a balloon inflation hub and valve. A syringe is connected to the hub, which is used to inflate or deflate the balloon

with air (maximum 1.5-mL capacity). The valve opens and closes the balloon inflation lumen.

A pulmonary artery catheter with specialized capabilities has additional components. For example, the thermodilution catheter has three additional features that enable it to measure cardiac output: a thermistor connector attached to the cardiac output computer of the bedside monitor, a proximal injectate port used for injecting fluids when obtaining the cardiac output, and a thermistor (positioned near the distal port) (see Fig. 21-11).

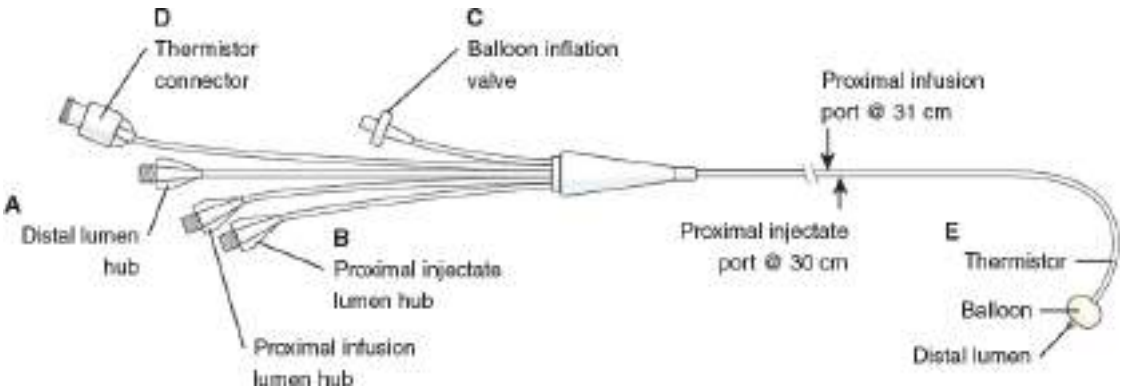

Figure 21-11 • The pulmonary artery catheter used for obtaining pressure measurements and cardiac output. **A.** The pressure monitoring system is connected to the distal lumen hub. **B.** Intravenous solutions are infused through the proximal infusion and injectate lumen hubs. **C.** An air-filled syringe connected to the balloon inflation valve is used for balloon inflation during catheter insertion and pulmonary artery wedge pressure measurements. **D.** To obtain cardiac output, the thermistor connector is inserted into the cardiac output component of the bedside cardiac monitor, and 5 to 10 mL of normal saline is injected in 4 seconds into the proximal injectate port. **E.** The thermistor located near the balloon is used to calculate the cardiac output. Redrawn courtesy of Baxter Healthcare Corporation, Edwards Critical Care Division, Santa Ana, California.

The pulmonary artery catheter, covered with a sterile sleeve, is inserted into a large vein, preferably the subclavian, through a sheath. As noted previously, the femoral vein is avoided; insertion techniques and protocols mirror those used for inserting a CVP catheter (see previous discussion) (O'Grady et al., 2011). The sheath is equipped with a side port for infusing IV fluids and medications. The catheter is then passed into the vena cava and right atrium. In the right atrium, the balloon tip is inflated, and the catheter is carried rapidly by the flow of blood through the tricuspid valve into the right ventricle, through the pulmonic valve, and into a branch of the pulmonary artery. When the catheter reaches the pulmonary artery, the balloon is deflated and the catheter is secured with sutures (Fig. 21-12). Fluoroscopy may be used during

insertion to visualize the progression of the catheter through the right heart chambers to the pulmonary artery. This procedure can be performed in the operating room, in the cardiac catheterization laboratory, or at the bedside in the critical care unit. During insertion of the pulmonary artery catheter, the bedside monitor is observed for pressure and waveform changes, as well as arrhythmias, as the catheter progresses through the right heart to the pulmonary artery.

Once the catheter is in position, the following are measured: right atrial, pulmonary artery systolic, pulmonary artery diastolic, mean pulmonary artery, and pulmonary artery wedge pressures (see Fig. 21-2 for normal chamber pressures). Monitoring of the pulmonary artery diastolic and pulmonary artery wedge pressures is particularly important in critically ill patients because they are used to evaluate left ventricular filling pressures (i.e., left ventricular preload).

It is important to note that the pulmonary artery wedge pressure is achieved by inflating the balloon tip for a maximum of 15 seconds, which causes it to float more distally into a smaller portion of the pulmonary artery until it is wedged into position. This is an occlusive maneuver that impedes blood flow through that segment of the pulmonary artery. Therefore, the wedge pressure is measured immediately and the balloon deflated promptly to restore blood flow.

Quality and Safety Nursing Alert

After measuring the pulmonary artery wedge pressure, the nurse ensures that the balloon is deflated and that the catheter has returned to its normal position. This important intervention is verified by evaluating the return of the pulmonary artery systolic and diastolic waveform displayed on the bedside monitor.

Nursing Interventions

Catheter site care is essentially the same as for a CVP catheter. Similar to CVP measurement, the transducer must be positioned at the phlebostatic axis to ensure accurate readings (see Fig. 21-10). Serious complications include pulmonary artery rupture, pulmonary thromboembolism, pulmonary infarction, catheter kinking, arrhythmias, and air embolism.

Intra-Arterial Blood Pressure Monitoring

Intra-arterial BP monitoring is used to obtain direct and continuous BP measurements in critically ill patients who have severe hypertension or hypotension. Arterial catheters are also useful when arterial blood gas measurements and blood samples need to be obtained frequently.

The radial artery is the usual site selected. However, placement of a catheter into the radial artery can further impede perfusion to an area that has poor circulation. As a result, the tissue distal to the cannulated artery can become ischemic or necrotic. Patients with diabetes, peripheral vascular disease, or hypotension, receiving IV vasopressors, or having had previous surgery are at highest risk for this complication. Before arterial line insertion, two tests may be considered to assess circulation; namely, a Doppler ultrasound or a modified Allen's test. A Doppler ultrasound assesses blood flow of the artery. The modified Allen's test assesses collateral circulation. To perform the Allen's test, the patient's hand is elevated and the patient is asked to make a fist. The nurse compresses the radial and ulnar arteries simultaneously, causing the hand to blanch. After the patient opens the fist, the nurse releases the pressure on the ulnar artery. If blood flow is restored (hand turns pink) within 7 seconds, the circulation to the hand may be adequate enough to tolerate placement of a radial artery catheter (Wiegand, 2017).

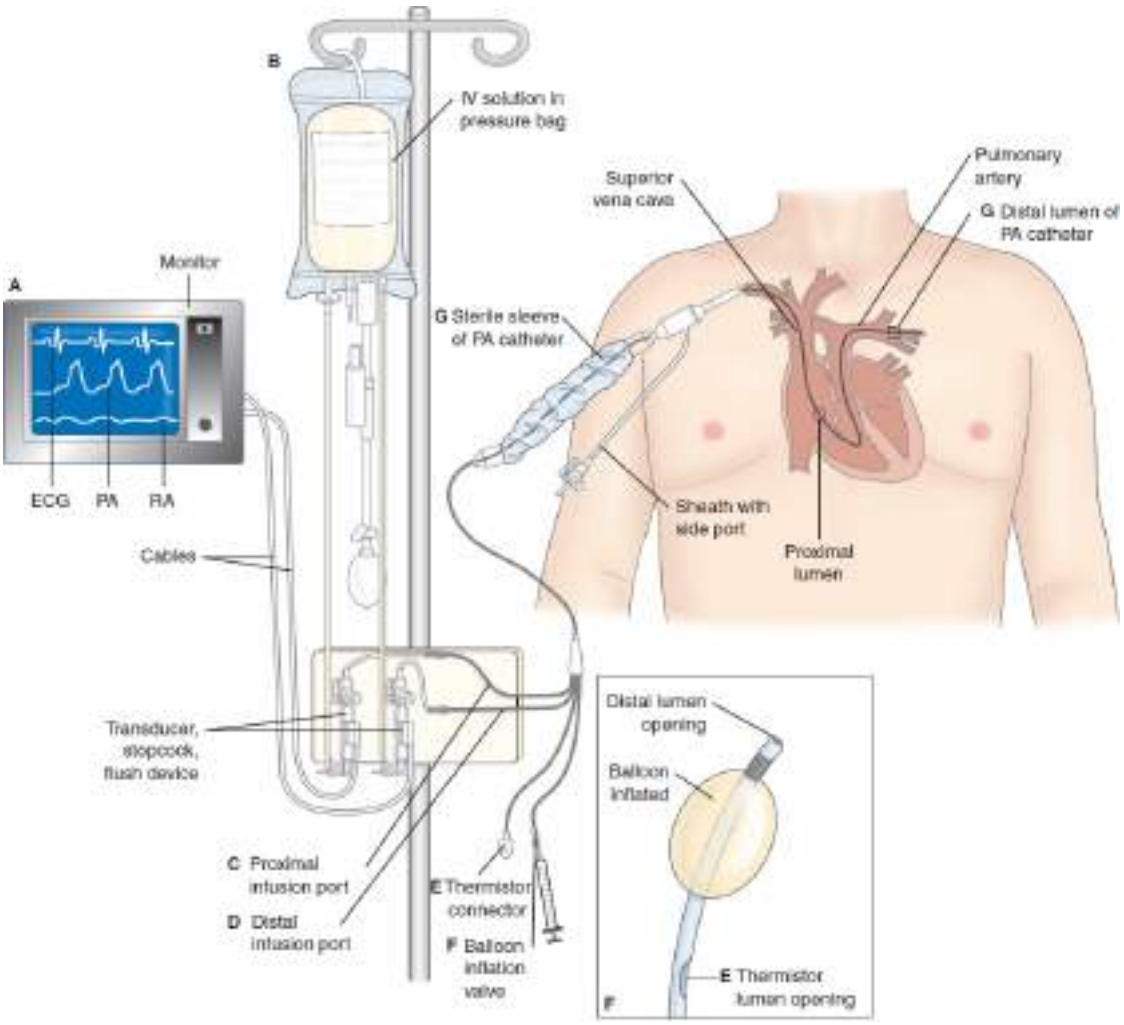

Figure 21-12 • Pulmonary artery (PA) catheter and pressure monitoring systems. Bedside monitor that connects with cables (**A**) to the pressure monitoring systems (includes intravenous [IV] solution in a pressure bag, IV tubing, and two transducers with stopcocks and flush devices) (**B**). This system connects to the proximal infusion port that opens in the right atria (**C**) and is used to infuse fluids or medications and monitor central venous pressures and the distal infusion port (**D**). This port opens in the PA and is used to monitor PA pressures. **E.** The thermistor connector is attached to the bedside cardiac monitor to obtain cardiac output. **F.** An air-filled syringe is attached to the balloon inflation valve during catheter insertion and measurement of PA wedge pressure. **G.** PA catheter positioned in the pulmonary artery. Note the sterile sleeve over the PA catheter. The PA catheter is threaded through the sheath until it reaches the desired position in the PA. The side port on the sheath is used to infuse medications or fluids. ECG, electrocardiogram; RA, right atrium.

Nursing Interventions

Site preparation and care are the same as for CVP catheters. The catheter flush solution is normal saline, which is the same as for CVP and pulmonary artery catheters. A transducer is attached, and pressures are measured in millimeters of mercury (mm Hg). The nurse monitors the patient for complications, which include local obstruction with distal ischemia, external hemorrhage, massive ecchymosis, dissection, air embolism, blood loss, pain, arteriospasm, and infection.

Minimally Invasive Cardiac Output Monitoring Devices

Monitoring cardiac output using the pulmonary artery catheter has been the standard of practice in critical care since its inception over 50 years ago. Its use has diminished recently with the availability of new, less invasive devices. Several types of devices are commercially available. Selection of a specific device for clinical use is determined by availability, provider preferences, and the patient's clinical condition (Urden et al., 2017).

Pulse pressure analysis uses an arterial pressure waveform to continuously estimate the patient's stroke volume. One such device, the Edwards Lifesciences Vigileo monitoring system, is connected to an existing radial or femoral arterial line via its FloTrac transducer. Using age, gender, body surface area, and BP of the patient, this device calculates continuous cardiac output and other parameters used in the management of critically ill patients. The major drawback to this device is that in order for it to capture accurate data, it must first capture optimal arterial waveforms. Therefore, this type of device has limited usefulness in patients with poor waveform signals, some arrhythmias, hemodynamic instability, and those who may be concomitantly using an intra-aortic balloon pump (see Chapter 11).

Esophageal Doppler probes are used to noninvasively estimate cardiac output. The esophageal probe measures blood flow velocity within a cross-sectional area of the descending aorta to calculate cardiac output. The use of this device in the perioperative setting has been shown to improve patient outcomes, including decreased lengths of hospital stay and an overall decrease in rates of complications (Urden et al., 2017).

The Fick method, which uses carbon dioxide (CO_2) measures, is an additional method used to estimate cardiac output. To obtain cardiac output using this method, a rebreathing loop is attached to the ventilator along with an infrared CO_2 sensor, an airflow sensor, and pulse oximeter. Continuous readings of cardiac output may be updated every 3 minutes with the use of this device. As an alternative, a Fick calculation may be done that uses the patient's body surface area and oxygen consumption (arterial and venous saturations and hemoglobin) to determine cardiac output.

CRITICAL THINKING EXERCISES

1 pq You receive report on a 65-year-old male patient being transferred to the cardiac ICU from the cardiac catheterization lab. The nurse reports that the patient has a history of chest pain, ACS, MI, hypertension, and diabetes. An elective right and left heart catheterization was performed and three stents were placed in the coronary arteries. The patient received normal saline IV 250 mL, heparin 4500 units, fentanyl 100 mg, and midazolam 2 mg. A TR Band is in place over the right radial artery which must stay in place for 2 hours. The patient tolerated the procedure well. What are your top nursing priorities when the patient arrives to the unit? Discuss key nursing interventions after cardiac catheterization. Describe how the nursing care of a patient with radial access differs from a patient with femoral access. What education will you provide the patient concerning postprocedure care?

2 ebp You are assigned to care for a 48-year-old female patient with a pulmonary artery (PA) catheter. She has advanced heart failure and is on the transplant waiting list. What cardiac assessment findings do you expect to find? The charge nurse rounds and asks you if a care bundle has been implemented. What is a care bundle? How will you care for the pulmonary artery catheter to reduce the risk of catheter-related bloodstream infections? What is the strength of the evidence that guides these interventions?

22 Management of Patients with Arrhythmias and Conduction Problems

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Correlate the components of the normal electrocardiogram with physiologic events of the heart.
2. Define the electrocardiogram as a waveform that represents the cardiac electrical event in relation to the lead (placement of electrodes).
3. Analyze elements of an electrocardiographic rhythm strip: ventricular and atrial rate, ventricular and atrial rhythm, QRS complex and shape, QRS duration, P wave and shape, PR interval, and P:QRS ratio.
4. Identify the electrocardiographic criteria, causes and management of arrhythmias, and use the nursing process as a framework for care of the patient with an arrhythmia, including conduction disturbances.
5. Compare the different types of pacemakers, their uses, possible complications, and nursing implications.
6. Describe the key points of using a defibrillator; identify the purpose of an implantable cardioverter defibrillator, the types available, and the nursing implications.
7. Describe the nursing management of patients with implantable cardiac devices.

NURSING CONCEPTS

Perfusion

GLOSSARY

ablation: purposeful destruction of heart muscle cells, usually in an attempt to correct or eliminate an arrhythmia

arrhythmia: disorder of the formation or conduction (or both) of the electrical impulse within the heart, altering the heart rate, heart rhythm, or both and potentially causing altered blood flow (also referred to as dysrhythmia)

artifact: distorted, irrelevant, and extraneous electrocardiographic (ECG) waveforms

automaticity: ability of the cardiac cells to initiate an electrical impulse

cardiac resynchronization therapy (CRT): biventricular pacing used to correct interventricular, intraventricular, and atrioventricular conduction disturbances that occur in patients with heart failure

cardioversion: electrical current given in synchrony with the patient's own QRS complex to stop an arrhythmia

chronotropy: rate of impulse formation

conduction: transmission of electrical impulses from one cell to another

defibrillation: electrical current given to stop an arrhythmia, not synchronized with the patient's QRS complex

depolarization: process by which cardiac muscle cells change from a more negatively charged to a more positively charged intracellular state

dromotropy: conduction velocity

electrocardiogram (ECG): a record of a test that graphically measures the electrical activity of the heart, including each phase of the cardiac cycle

implantable cardioverter defibrillator (ICD): a device implanted into the chest wall to treat arrhythmias

inotropy: force of myocardial contraction

P wave: the part of an ECG that reflects conduction of an electrical impulse through the atrium; atrial depolarization

paroxysmal: arrhythmia that has a sudden onset and terminates spontaneously; usually of short duration, but may recur

PP interval: the duration between the beginning of one P wave and the beginning of the next P wave; used to calculate atrial rate and rhythm

PR interval: the part of an ECG that reflects conduction of an electrical impulse from the sinoatrial node through the atrioventricular node

QRS complex: the part of an ECG that reflects conduction of an electrical impulse through the ventricles; ventricular depolarization

QT interval: the part of an ECG that reflects the time from ventricular depolarization through repolarization

repolarization: process by which cardiac muscle cells return to a more negatively charged intracellular condition, their resting state

RR interval: the duration between the beginning of one QRS complex and the beginning of the next QRS complex; used to calculate ventricular rate and rhythm
